Universal presence of fungi

man has been indirectly aware of their activities since the first loaf of leavened bread was baked and the first tub of grape must was turned into wine. Yet, even now, few people realize that they are almost constantly either benefitted or harmed by these organisms. Fungi are everywhere—in the soil and the air; in lakes, rivers, and seas; on and within plants and animals; in food and clothing, and in the human body as well—and in very large numbers; it is this that makes them so important in the human environment. Together with bacteria, fungi are responsible for the disintegration of organic matter and the release, into the soil or atmosphere, of the carbon, oxygen, nitrogen, and phosphorus that otherwise would be forever locked up in the dead bodies of plants and animals. They are essential to many household and industrial processes, notably the making of bread, wines, beer, and certain cheeses. They are used in the production of a number of organic acids, enzymes (biological catalysts), and vitamins, and are the sources of a number of antibiotics besides penicillin. Fungi are also used as food: mushrooms, morels, and truffles are epicurean delicacies.

Fungi have had a significant role in the accumulation of biological knowledge. In 1927 the properties that make the red bread mold, *Neurospora*, an ideal organism for the study of the laws of heredity were pointed out. Geneticists and biochemists, using *Neurospora* as an experimental tool, have discovered a great deal about the manner in which genes control enzymes and about the biochemical pathways that operate in living organisms.

Although man has benefitted from the activities of certain fungi, he has also learned to look for villains among them. Numerous instances of destruction, disease, and death are directly traceable to fungi. The chestnut forests of the United States, for example, have been destroyed by the chestnut-blight fungus, and the elms in both the U.S. and Europe have been devastated by the fungus that causes Dutch-elm disease. Blights, rusts, wilts, and smuts destroy crops as man cultivates land more intensively (see DISEASES OF PLANTS)—though increasingly effective

control measures have been developed (see PEST CONTROL). Fungi cause various diseases in man—*e.g.*, athlete's foot and ringworm, candidiasis and aspergillosis, histoplasmosis and coccidioidomycosis. Mildews, molds, and rots ruin clothing and foods.

Ancient peoples were familiar with the ravages of fungi in agriculture but attributed these diseases to the wrath of the gods. The Romans even designated a particular deity, Robigus, as the god of rust and, in an effort to propitiate him, organized an annual festival, the Robigalia, in his honour.

The mushrooms, because of their size, are easily seen in the fields and forests and consequently were the only fungi known before the discovery of the microscope in the 17th century. With that discovery came the beginnings of scientific knowledge of many kinds of fungi, previously unseen, and of the obscure life processes of fungi, large and small, that had been hidden from man's eye, if not entirely from his awareness.

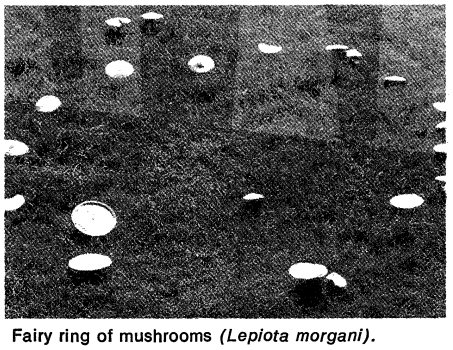
GENERAL FEATURES

Basic structure of fungi

A typical fungus consists of a mass of branched, tubular filaments that bear spores, or reproductive bodies, in various ways. The filaments, called hyphae (singular hypha), are collectively known as the mycelium, which makes up the thallus, or undifferentiated body, of the typical fungus. The mycelium grows by utilizing food materials from the environment and, upon reaching a certain stage of maturity, forms—either directly or in special fruiting bodies—spores that become detached and start new individuals. A spore thus serves the same purpose as a seed but is much simpler in structure, often consisting of a single cell. When a fungal spore germinates, it soon develops into a hypha, which grows, branches, and becomes the mycelium of the new individual.

All fungal structures are, therefore, made of hyphae or portions of hyphae; for example, a mushroom—visibly consisting of a stem supporting a cap with gills on the underside—is constructed entirely of microscopic filaments intricately associated and interwoven into specialized tissues. The mushroom is the fruiting body that bears the spores; the main body of the fungus is underground and consists of a tremendous network of hyphae—the mycelium—spread over a very large area, often several metres (yards) in diameter. This mycelium obtains food from organic matter in the soil and grows outward, just below the surface, in a circular fashion. In certain species the hyphal branches at the edge of the mycelium become organized at intervals into elaborate tissues that develop above ground into mushrooms. Such a circle of mushrooms is known as a fairy ring because, in the Middle Ages, it was believed to represent the path of dancing fairies. The ring marks the periphery of an enormous fungus colony, which, if undisturbed, continues to produce ever wider fairy rings year after year.

Walter Dawn



Fairy ring of mushrooms (*Lepiota morgani*).

Size range and diversity of structure. The part of a fungus that is generally visible is the fruiting body or sporophore. Sporophores vary greatly in size, shape, colour, and longevity. Some are microscopic and completely invisible to the unaided eye; others are no larger than a pin head; still others are gigantic structures. Among the largest sporophores are those of the mushrooms, bracket fungi, and puffballs. Some mushrooms reach a diameter of eight to ten inches and a height of ten to 12. Bracket fungi 15 inches (40 centimetres) or more in diameter are not uncommon, and puffballs often exceed that size. The largest puffballs on record measured 60 inches (150 centimetres) in diameter. The number of spores within such giants reaches several trillion.

Distribution and abundance. Fungi are found in all temperate and tropical regions of the world where there is sufficient moisture to enable them to grow. They have also been reported from the Arctic and Antarctic regions but are much more rare there, being replaced by lichens, which have a fungal component (see below *Lichen*). In general, fungi are abundant in moist habitats where organic matter is plentiful and less abundant in drier areas or in habitats with little or no organic matter. About 50,000 species of fungi have been described, but it has been estimated that there may be as many as 100,000 to 250,000 total species. Previously undescribed species are constantly being discovered and, as the tropics become more thoroughly explored, many more will undoubtedly be found.

Number of fungus species

NATURAL HISTORY

Reproduction, as contrasted with growth, is the production of new individuals resembling their parents. Characteristically, fungi reproduce by the production and dissemination of spores, a reproductive body capable of growing into a new individual. Spores may be produced either directly by asexual methods or indirectly through sexual reproduction. Sexual reproduction in fungi, as in other living organisms, involves the fusion of two nuclei that are brought together when two sex cells (gametes) unite. Asexual reproduction is simpler and more direct.

Asexual reproduction. Perhaps the simplest method of reproduction of fungi is by direct fragmentation of the thallus, the body of a fungus, which may consist of one cell or a network of filaments called a mycelium. Some yeasts, which are single-celled fungi, reproduce by simple cell division, in which one cell undergoes nuclear division and splits into two daughter cells; after some growth, these cells divide, and, eventually, a population of cells forms. In filamentous fungi the mycelium may fragment into a number of segments, each of which is capable of growing into a new individual. In the laboratory, a fragment of the mycelium is generally used to propagate a fungus. In nature, fragmentation occurs when various natural forces cause the breaking up of the mycelium in the soil or other substrata. Budding, another method of asexual reproduction, occurs in most yeasts and in some filamentous fungi. In this process, a bud develops on the surface of either the yeast cell or the hypha, its cytoplasm being continuous with that of the parent cell. The nucleus of the parent cell then divides; one of the daughter nuclei migrates into the bud, and the other remains in the parent cell. The latter is capable of producing many buds over its surface by continuous synthesis of cytoplasm and repeated nuclear divisions. After a bud develops to a certain point and even before it is severed from the parent cell, it is itself capable of budding by the same process. Thus a chain of cells may be produced. Eventually, the individual buds pinch off the parent cell and become individual yeast cells. Buds that are pinched off a hypha of a filamentous fungus behave as spores; *i.e.*, they germinate, each giving rise to a structure called a germ tube, which develops into a new hypha.

Budding

Although fragmentation, fission, and budding are methods of reproduction in a number of fungi, the majority reproduce asexually by the formation of bodies called spores. Spores produced asexually are often termed mitospores, and such spores are produced in a variety of ways. For a discussion of spores see below *Form and Function*.

Sexual reproduction. As in other living organisms, sexual reproduction in the fungi consists of three sequential stages: plasmogamy, karyogamy, and meiosis. Plasmogamy, the fusion of two protoplasts (the contents of two cells), brings together two compatible nuclei, each containing a single (haploid) set of chromosomes, in

preparation for nuclear fusion (karyogamy). In the lower fungi, karyogamy usually follows plasmogamy almost immediately. In the more evolved fungi, however, karyogamy is separated from plasmogamy. Karyogamy results in the formation of a diploid nucleus (*i.e.*, a nucleus containing two sets of chromosomes, one from each parent). The cell in which karyogamy occurs is called the zygote. In most fungi, the zygote is the only cell in the entire life cycle that is diploid. Once karyogamy has occurred, meiosis (cell division resulting in reduction of the chromosome number to one set per cell) generally follows immediately and restores the haploid phase. Either the haploid nuclei that result from meiosis or their immediate progeny are generally incorporated in spores termed meiospores.

Fungi employ a variety of methods to accomplish plasmogamy. Some produce specialized sex cells (gametes) that are released from differentiated sex organs called gametangia. In other fungi, the gametangia come in contact, and nuclei pass from the male gametangium into the female, thus assuming the function of gametes. In still other fungi, the gametangia themselves may fuse in order to bring their nuclei together. Finally, some of the most advanced fungi produce no gametangia at all; the somatic (vegetative) hyphae take over the sexual function, come in contact, fuse, and exchange nuclei.

Fungi in which a single individual bears both male and female gametangia are hermaphroditic fungi. Rarely, gametangia of different sexes are produced by separate individuals, one a male, the other a female. Such species are termed dioecious. Dioecious species usually produce sex organs only in the presence of an individual of the opposite sex.

Incompatibility. Many fungi produce clearly differentiated male and female organs on the same thallus, but the individual thalli, originating from single uninucleate spores, are sexually self-sterile because their sex organs are incompatible. Such fungi require the presence of thalli of different mating types in order for sexual fusion to take place. The simplest form of this mechanism occurs in fungi in which there are two mating types, often designated + and − (or *A* and *a*). Gametes produced by one type of thallus are compatible only with gametes produced by the other type. Such fungi are said to be heterothallic. Many fungi, however, are homothallic; *i.e.*, sex organs produced by a single thallus are self-compatible, and a second thallus is unnecessary for sexual reproduction. Some of the most complex fungi (*e.g.*, mushrooms) do not develop differentiated sex organs; rather, the sexual function is carried out by their somatic hyphae, which unite and bring together compatible nuclei in preparation for fusion. Homothallism and heterothallism are encountered in these fungi, as well as in those in which sex organs are easily distinguishable. Compatibility, therefore, refers to a physiological differentiation and sex to a morphological (structural) one; the two phenomena, although related, are not synonymous.

Sexual hormones. Various mechanisms involving organic substances called hormones induce formation of sex organs or bring together gametes for sexual union. In *Allomyces* (Chytridiomycetes) a hormone named sirenin, secreted by the female gametes, attracts the male gametes, which swim toward the former and fuse with them. In *Achlya* (Oomycetes) one or more sex hormones induce the formation of gametangia and attract the male to the female. In the Zygomycetes, in which the gametangia are usually not differentiated structurally, a hormonal mechanism brings together hyphal tips of opposite mating types. In *Ascobolus* (Ascomycetes) the receptive branch (trichogyne) of the female gametangium actively turns toward the nonmotile male gamete (spermatium), which secretes an attractant.

Attraction of sex cells to each other by hormones

Life cycle. In the life cycle of a sexually reproducing fungus, a haploid phase alternates with a diploid phase. The haploid phase ends with nuclear fusion, and the diploid phase begins with the formation of the zygote (the cell resulting from fusion of two sex cells). A special kind of nuclear division, termed meiosis or reduction division, restores the haploid number of chromosomes and initiates the haploid phase, which produces the gametes. In the majority of fungi, all structures are haploid except the zygote. Nuclear fusion takes place at the time of zygote formation, and meiosis follows immediately. Only in the water mold *Allomyces* and a few related genera, and in some yeasts is alternation of a haploid thallus with a diploid thallus definitely known. In the class Oomycetes the place of meiosis in the life cycle is in doubt. If, as is probable, the thallus in this class is diploid and meiosis takes place just before the formation of the gametes, then the gametes would be the only haploid structures in the entire life cycle, and the Oomycetes would be unique among the fungi in this respect.

In the higher fungi, a third condition is interspersed between the haploid and diploid phases of the life cycle. In these fungi, plasmogamy (fusion of the cellular contents of two hyphae) results in dikaryotic hyphae in which each cell contains two nuclei, one from each parent. Eventually, a nuclear pair fuses to form the zygote nucleus. In the Basidiomycetes, the most advanced class of fungi, the binucleate cells divide successively and give rise to a binucleate mycelium, which is the main assimilative phase of the life cycle. It is the binucleate mycelium that eventually forms the basidia in which nuclear fusion and meiosis take place prior to the formation of the basidiospores.

As stated before, fungi usually reproduce both sexually and asexually. The asexual cycle produces mitospores, and the sexual cycle produces meiospores. Even though both types of spores are produced by the same mycelium, they are very different in form and easily distinguished. The asexual phase usually precedes the sexual phase in the life cycle and may be repeated frequently before the sexual phase appears.

Some fungi differ from others in their lack of one or the

other of these stages; some reproduce only sexually (except for fragmentation, which is common in most) and many only asexually. A number of fungi exhibit the phenomenon of parasexuality in which processes comparable to plasmogamy, karyogamy, and meiosis take place but not at a specified time or at specified points in the life cycle of the organism. Parasexuality is characterized by the prevalence of heterokaryosis in a mycelium; *i.e.*, the presence, side by side, of nuclei of different genetic composition.

Parasexuality

Ecology. Fungi are either terrestrial or aquatic, the latter living in freshwater or marine environments. Freshwater species usually do not tolerate high degrees of salinity in nature, although some are found in slightly brackish water; most prefer clean, cool waters, but a few thrive in highly polluted streams. The soil furnishes an ideal habitat for a large number of species.

Saprobes. Relatively little is known of the effects of the environment on the distribution of saprobic fungi (*i.e.*, fungi utilizing dead organic material as food). The availability of elaborated, organic food is certainly one of the factors controlling such distribution. A great number of fungi appear able to utilize most types of organic materials, such as lignin, cellulose, or other polysaccharides, which have been added to soils or waters by dead vegetation. It follows that most saprobic fungi may be expected to be cosmopolitan (widely distributed), at least in habitats with a sufficient organic content to support fungal growth. Fungi with specific nutritional requirements are, of course, more localized.

Moisture and temperature are two ecological factors, in addition to organic matter, that are of prime importance in determining distribution of fungi. Laboratory studies have shown that many, perhaps the majority, of fungi are mesophilic; *i.e.*, have an optimum growth temperature of 20–30° C (68–86° F). Some species (*i.e.*, thermophilic ones) are able to grow at 50° C (122° F) or higher but are unable to grow below 30° C. Although the optimum temperature for growth of most fungi lies at or above 20° C (68° F), a large number of species are able to grow close to or below 0° C (32° F). The so-called snow molds and the fungi that cause spoilage of refrigerated foods are examples of this group. Obviously, temperature relationships influence the distribution of various species. Certain other effects of temperature are also important determining factors in the habitats of fungi. Many coprophilous (dung-inhabiting) fungi, for example, although able to grow at a temperature of 20–30° C, require a short period at 60° C (140° F) for their spores to germinate.

Whereas a great many saprobes are cosmopolitan, some are strictly tropical, others are strictly temperate-zone forms. Whether temperature is the main factor in determining such distribution is not known.

Plant parasites. The distribution of parasitic species is closely correlated with the distribution of the plant hosts with which they are associated. Fungi that parasitize a variety of plant hosts are likely to be more widely distributed than the more specialized parasites. It is of interest to note in this connection that certain fungi common in temperate regions are also found in the tropical highlands where their hosts can grow.

A fungus that occurs both in the temperate zone and in the tropical lowlands often completes its life cycle in one of the two environments but not in the other. The powdery mildews (family Erysiphaceae), as a group, for example, go through both asexual and sexual cycles in the temperate zones, producing mitospores (conidia) and meiospores (ascospores) respectively; seldom do they form sexual stages in the tropics. Whether this is a matter of temperature or some other factor is not yet known.

Human pathogens. Some fungi that cause human diseases, such as *Candida albicans*, are universally distributed; others, like *Paracoccidioides brasiliensis*, which is confined to South and Central America, have a more limited distribution. The factors that affect the distribution of the human pathogens are unknown. The great increase in international travel, migration, and troop movements in the second half of the 20th century undoubtedly were major factors in the spread of these fungi.

Symbionts. Among symbiotic fungi, those that enter into mycorrhizal relationships (see below) and the lichen fungi, are probably the best known. Among the mycorhizal fungi are the boletes (Basidiomycetes, family Boletaceae), whose mycorrhizal relationships with larch trees (*Larix*) and other conifers have long been known; others include the truffles (Ascomycetes, order Tuberales), some of which are believed to form mycorrhizae with oak (*Quercus*) or beech (*Fagus*) trees, and various species of *Rhizoctonia* (mycelial stage of certain Basidiomycetes), which form orchid mycorrhizae.

Lichens are universally distributed, abundantly in some areas, more sparsely in others. In the Arctic regions, lichens are a dominant part of the flora. The same is true in some tropical regions. Lichens are pioneering organisms in that they are among the first to colonize lava flows and can subsist on bare rock exposed to the sun in very dry areas where few other organisms can survive. On the other hand, some are also found in the tropical rain forest together with mosses and liverworts. Lichens are particularly sensitive to changes in light conditions. A lichen community can virtually disappear or certainly change in species composition if it is shaded by abundant overgrowth of shrubs or trees. Most of the lichen fungi are Ascomycetes specialized in their association with their algal hosts. A few are Basidiomycetes.

Fungus–insect associations. Another kind of symbiotic relationship between fungi and host organisms is exemplified by that of the fungal genus *Septobasidium* and certain scale insects (order Homoptera) that feed on trees. The mycelium forms elaborate structures over colonies of insects feeding on the bark. Each insect sinks its proboscis (tubular sucking organ) into the bark and remains there the rest of its life, sucking sap. The fungus sinks haustoria (special absorbing structures) into the bodies of some of the insects and feeds on them without killing them. The parasitized insects are, however, rendered sterile.

Two-stage parasitism of scale insects

The perpetuation of the insect species and the spread of the fungus are accomplished by the uninfected members of the colony, which live in fungal "houses," safe from enemies. Newly hatched scale insects crawl over the surface of the fungus, which is at that time sporulating. Fungal spores adhere to the young insects, germinate, and infect them. As the young insects settle down in a new

place on the bark to begin feeding, they establish new fungal colonies. Thus, part of the insect colony is sacrificed to the fungus as food in return for the fungal protection provided for the rest of the insects. The insect is parasitic on the tree, and the fungus is parasitic on the insect, but the tree is the ultimate victim.

Ants of the tribe Attini feed exclusively on fungi, which they cultivate in underground gardens. The leaf-cutting ants in this group bring in sections of freshly cut leaves and flowers and chew small pieces about one millimetre (1/25 inch) in diameter into pulp. Anal droppings are then placed on the bits of pulp, which are planted in the garden in the centre of the nest. Fungal mycelium from an old garden is then transferred to the newly planted material and allowed to grow. Other fungi are kept out of the garden. The entire ant colony subsists on the cultivated fungus. Four kinds of fungi, *Leucocoprinus gongylophora, Tyridomyces formicarum,* and species of *Lepiota* and *Auricularia* are known to be so cultivated—and are not known to occur naturally other than in ant gardens.

The order Laboulbeniales includes minute Ascomycetes that are anchored on the outer skeleton of insects; they seldom penetrate beyond it and do not cause disease of the host. Specialization is extreme in some instances; a particular species of fungus may grow only on individual insects of one sex and often only on a particular organ.

The sooty molds constitute another interesting ecological group of fungi associated with insects. The majority are tropical or subtropical, but some species occur in the temperate zones. All sooty molds are epiphytic (*i.e.*, they grow on the surfaces of other plants); but only in areas where scale insects are present. The fungi parasitize neither the plants nor the insects, but obtain their nourishment exclusively from the honeydew secretions of the scale insects. Growth of the dark mycelium over the plant leaves, however, is often so dense as to reduce greatly the intensity of the light that reaches the leaf surface; this in turn significantly reduces the rate of photosynthesis.

FORM AND FUNCTION

Structure of the thallus. In almost all fungi the hypha, and therefore the thallus—the undifferentiated, nutrient-absorbing body of the fungus—has cell walls. (The thalli of the true slime molds lack cell walls and are sometimes classified as protozoans rather than fungi.) A hypha is a many-branched tube lined or filled with a jellylike substance called cytoplasm. The tube itself may be either continuous throughout or divided into compartments, or cells, by cross walls called septa (singular septum). In nonseptate (*i.e.*, coenocytic) hyphae, the nuclei are scattered throughout the cytoplasm. In septate hyphae, each cell may contain one, two, or many nuclei, depending on the type of fungus or the stage of hyphal development. The cells of fungi are similar in structure to those of many other organisms. The minute nucleus, readily seen only in young portions of the hypha, is surrounded by a double membrane and typically contains one nucleolus. In addition to the nucleus, various other components are embedded in the cytoplasm.

The wall of the hypha is complex in both composition and structure. Its exact chemical composition varies in different fungal groups. In some fungi the wall contains considerable quantities of cellulose, a complex carbohydrate that is the chief constituent of the cell walls of plants; in most fungi, however, chitosan and chitin, horny carbohydrate substances similar to cellulose, are present in the walls, to the exclusion of cellulose. In at least three fungi (*Rhizidiomyces apophysatus, Apodachlya* species, and *Ceratocystis ulmi*), and probably in others, both chitin and cellulose are components of the cell wall. Among the many other chemical substances in the walls of fungi are some that may thicken or toughen the wall of some tissues, thus imparting rigidity and strength. The wall is not a passive, dead envelope; rather there is reason to believe that it may have a regulatory function in the interchange of materials between the hypha and its external environment. The chemical composition of the wall of a particular fungus may vary at different stages of the organism's growth—a possible indication that the wall plays some part in determining the form of the fungus. In some yeasts, fusion of sexually functioning cells is brought about by the interaction of specific chemical substances on the walls of two compatible mating types.

When the mycelium grows in or on a surface—the soil, a log, a culture medium—it appears as a mass of loose, cottony threads. The richer the composition of the growth medium, the more profuse the threads and the more feltlike the mass. On the sugar-rich growth substances used in scientific laboratories, the assimilative (somatic) hyphae are so interwoven as to form a thick, almost leathery colony. On the soil, inside a leaf, in the skin of animals, or in other parasitized plant or animal tissues, the hyphae are usually spread in a loose network. The mycelium of the so-called higher fungi does, however, become organized at times into compact masses of different sizes that serve various functions. Some of these masses, called sclerotia, become extremely hard and serve to carry the fungus over periods of adverse conditions of temperature and moisture. Ergot is an example. The underground sclerotia of *Poria cocos,* an edible pore fungus known in the United States under the Indian name tuckahoe, may reach a diameter of 20 to 25 centimetres (8 to 10 inches). Various other tissues are also produced by the interweaving of the assimilative hyphae of some fungi. Stromata (singular stroma) are cushion-like tissues that bear spores in various ways. Rhizomorphs are long strands of parallel hyphae cemented together. Those of the honey mushroom *Armillariella mellea,* which are black and resemble shoestrings, are intricately constructed and are differentiated to conduct water and food materials from one part of the thallus to another.

Sporophores and spores. When the mycelium of a fungus reaches a certain stage of growth, it begins to produce spores either directly on the somatic hyphae or, more often, on special sporiferous (spore-producing) hyphae, which may be loosely arranged or grouped into intricate structures, the fruiting bodies or sporophores. The type of sporophore produced is characteristic of the group to which a fungus belongs, and the classification of fungi is based almost entirely on the characters of their sporophores and spores.

Fruiting structures as determinants of classification

The lower fungi (*i.e.*, more primitive) produce spores in sporangia, which are saclike sporophores whose entire cytoplasmic contents cleave into spores, called sporangiospores. Sporangiospores are either naked and flagellated (zoospores) or walled and nonmotile (aplanospores). The more primitive aquatic and terrestrial fungi tend to produce zoospores. The zoospores of aquatic fungi swim in the surrounding water by means of one or two variously located flagella (whiplike organs of locomotion), depending on the group to which the fungus belongs. Zoospores produced by terrestrial fungi are released after a rain from the sporangia in which they are borne and swim for a time in the rainwater between soil particles or on the wet surfaces of plants, where the sporangia are formed by parasitic fungi. After some time, the zoospores lose their flagella and surround themselves with walls; each zoospore germinates by a germ tube that grows into a system of hyphae. The bread molds (Zygomycetes), which are the most advanced of the lower fungi, produce only aplanospores (nonmotile spores) in their sporangia.

The higher fungi (Ascomycetes, Deuteromycetes, and Basidiomycetes) do not produce motile spores of any kind even though some of them are aquatic in fresh or marine waters. In these fungi, asexually produced spores (usually termed conidia) are typically formed terminally or laterally on special spore-producing hyphae, the conidiophores, which are variously arranged; *i.e.*, singly on the hyphae or grouped in special asexual fruiting bodies such as flask-shaped pycnidia, mattress-like acervuli, cushion-shaped sporodochia, or sheaflike synnemata.

Sexually produced spores of the higher fungi result from meiosis and are formed either in saclike structures (asci) or on the surface of typically club-shaped structures (basidia). Asci and basidia may be borne naked, directly on the hyphae, or in various types of sporophores, termed ascocarps or basidiocarps, depending on whether they bear asci or basidia. Well-known examples of ascocarps

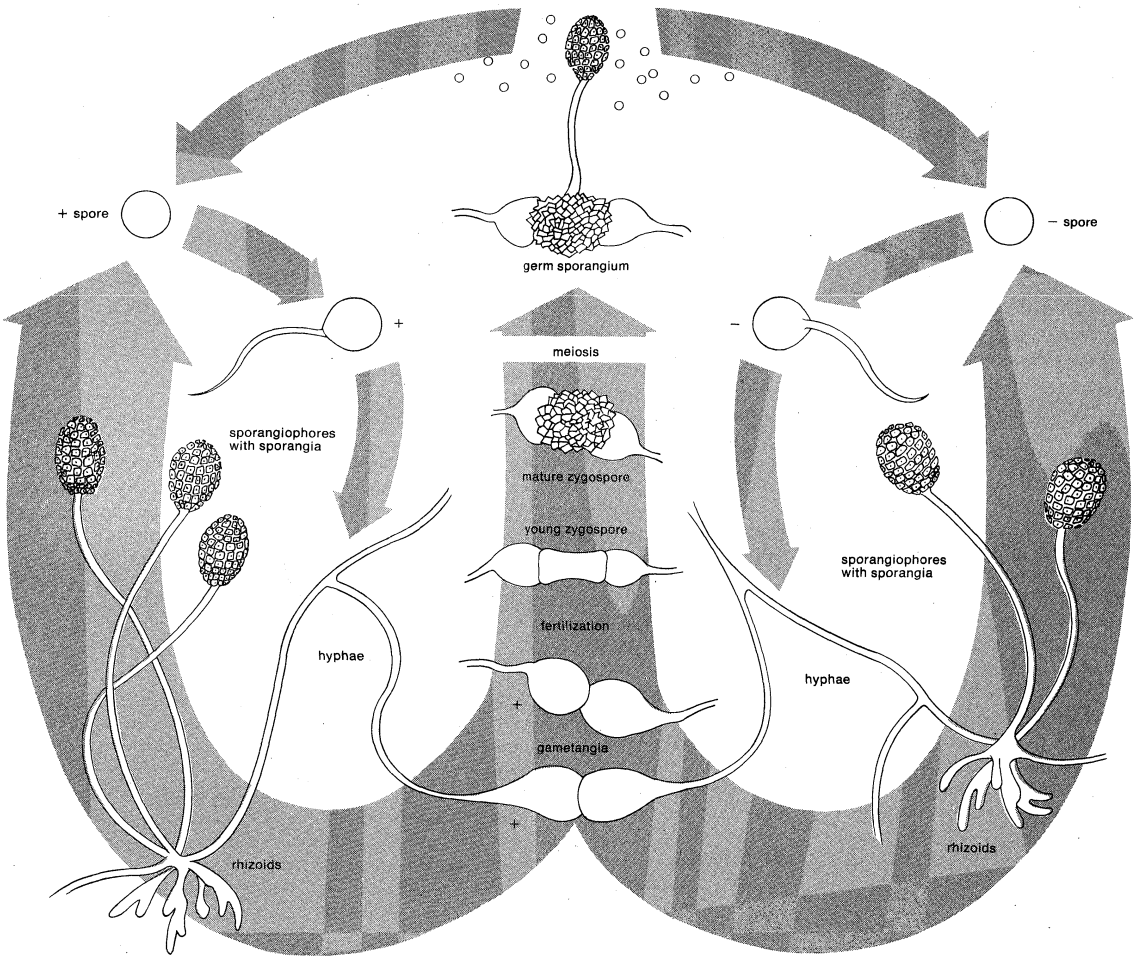

Figure 3: Life cycle of the common bread mold *Rhizopus stolonifer*, a zygomycete.
From C.J. Alexopoulos, *Introductory Mycology*, 2nd ed., copyright © (1962); John Wiley and Sons, Inc., reprinted by permission

are the morels, the cup fungi, and the truffles. Commonly encountered basidiocarps are mushrooms, puffballs, stinkhorns, and bird's-nest fungi.

Growth. Under favourable environmental conditions, fungal spores germinate and form hyphae. During this process, the spore absorbs water through its wall, the cytoplasm becomes activated, nuclear division takes place, more cytoplasm is synthesized, a break appears in the outer wall of the spore, and from the wall a germ tube bulges out, already enveloped by a wall of its own that is formed as the tube grows. The growing tip of a hypha may be roughly divided into three regions: (1) the apical zone about eight microns (.008 millimetres or .0003 inches) in length, in which all growth occurs and in which an accumulation of cytoplasmic vesicles (tiny bubbles or spheres) takes place; (2) the subapical region, extending about 40 microns back of the apical zone, which is rich in cytoplasmic components, such as dictyosomes (Golgi bodies—particulate or netlike components of the cytoplasm that function as secretory structures) and vesicles, but is devoid of vacuoles; and (3) the zone of vacuolation, which is characterized by the presence of many vacuoles and the accumulation of lipids. The growing tip eventually gives rise to a branch. This is the beginning of the branched mycelium. Growing tips that come in contact with neighbouring hyphae often fuse with them to form a hyphal net. In such a vigorously growing system, the cytoplasm is in constant motion, streaming toward the growing tips. Eventually, the older hyphae become highly vacuolated and may be stripped of most of their cytoplasm. All living portions of a thallus are potentially capable of growth. If a small piece of mycelium is placed under conditions favourable for growth, it develops into a new thallus even if no growing tips are included in the severed portion.

Regions of growth in a fungus hypha

Growth of a septate mycelium (*i.e.*, with cross walls between adjacent cells) entails the formation of new septa in the young hyphae. Septa are formed by ringlike growth from the wall of the hypha toward the centre until the septa are complete. In the higher fungi, the septum stops growing before it is complete; the result is a central pore through which the cytoplasm flows, thus establishing organic connection throughout the thallus. In the mycelium of most Basidiomycetes (*e.g.*, mushrooms, puffballs), the septa are much more elaborate, the central pore being bordered by a barrel-shaped, inflated structure that appears to function as a valve.

The individual fungus is potentially immortal, for it continues to grow at the hyphal tips as long as conditions remain favourable. It is possible that, in undisturbed places, mycelia exist that have grown continuously for many thousands of years. The older parts of the hyphae die and decompose, releasing nitrogen and other nutrients into the soil. Thus, if a fairy ring develops in a pasture, city lawn, or golf course, the grass just inside the circle of mushrooms, fertilized by dead hyphae, may be noticeably greener than the grass outside the ring.

Optimum conditions for hyphal growth vary with the species. Generally speaking, acid growth substances and temperatures near 20° to 30° C (68° to 86° F) are most favourable. Some species are thermophilic (*i.e.*, grow best in elevated temperatures) and grow little, if at all, at temperatures below 40° C (104° F). Temperatures slightly above freezing (32° F) inhibit but do not altogether prevent fungal growth, as is shown by the spoilage of foods in a refrigerator. High humidity enhances the growth of the hyphae. Light seems to have little effect on growth but is required by some fungi for sporulation.

Nutrition. Since fungi possess no chlorophyll—the pigment molecules of green plants—they are unable to

carry out photosynthesis and must obtain carbohydrates —the products of photosynthesis—from materials in which they are stored in the form of sugars, starches, celluloses, hemicelluloses, and lignins. Fungi therefore lead either a saprobic or a parasitic existence; in the former case they obtain their food from dead organic material, in the latter by feeding on living organisms (usually plants), thus causing disease.

External digestion of food

Fungi secure food through the action of enzymes (biological catalysts) secreted into the surface on which they are growing; the enzymes digest the food, which then is absorbed directly through the hyphal walls. The rotting of fruits, such as peaches and citrus fruits in storage, demonstrates this phenomenon, in which the infected parts are softened by the action of the fungal enzymes. In brown rot of peaches, the softened area is somewhat larger than the actual area invaded by the hyphae: the periphery of the brown spot has been softened by enzymes that act ahead of the invading mycelium. Food must enter the hyphae in solution, and, since most fungi have no special absorbing organs, the entire mycelial surface is capable of taking in materials dissolved in water. Some fungi, however, produce special rootlike hyphae, called rhizoids, which anchor the thallus to the growth surface and probably also absorb food. Many parasitic fungi are even more specialized in this respect, producing special absorptive organs called haustoria.

Saprobiosis. Together with the bacteria, saprobic fungi are to a large extent responsible for the decomposition of organic matter. They are also responsible for the decay and decomposition of foodstuffs. Among other destructive saprobes are fungi that destroy timber and timber products as their mycelia invade and digest the wood; many of these produce their spores in large, woody, fruiting bodies—*e.g.*, bracket or shelf fungi. Paper, textiles, and leather are often attacked and destroyed by fungi. This is particularly true in tropical regions, where temperature and humidity are often very high. Photographic film used in the tropics is specially packaged in an effort to exclude fungi. Fungal growth on lenses in binoculars, cameras, telescopes, and other optical equipment is a serious problem in regions where humidity is high.

The nutritional requirements of saprobes (and of some parasites that can be cultivated artificially) have been determined by growing fungi experimentally on various synthetic substances of known chemical composition. The fungi seem to exhibit the same morphological characteristics in these culture media as they do in nature. Carbon is supplied in the form of sugars or starch; the majority of fungi thrive on such sugars as glucose, fructose, mannose, maltose, and to a lesser extent, sucrose. Decomposition products of proteins—*e.g.*, proteoses, peptones, and amino acids—can be used by most fungi as nitrogen sources; ammonium compounds and nitrates also serve for many species. It is doubtful, however, that any fungus can combine, or fix, atmospheric nitrogen into usable compounds. Chemical elements such as phosphorus, sulfur, potassium, magnesium, and small quantities of iron, zinc, manganese, and copper are needed by most fungi for vigorous growth; elements such as calcium, molybdenum, and gallium are required by at least some species. Oxygen and hydrogen are absolute requirements; they are supplied in the form of water or are obtained from carbohydrates. Many fungi, deficient in thiamine and biotin, must obtain these vitamins from the environment; most fungi appear able to synthesize all other vitamins necessary for their growth and reproduction. As a rule, fungi are aerobic organisms; *i.e.*, they require free oxygen. Fermentations, however, take place under anaerobic conditions as well. Knowledge of the physiology of saprobic fungi has enabled industry to use several species for fermentation purposes.

Parasitism. In contrast with the saprobic fungi, parasitic fungi attack living organisms, penetrate their outer defenses, invade them, and obtain nourishment from living cytoplasm, causing disease and sometimes the death of the host. Most pathogenic (disease-causing) fungi are parasites of plants, but several are known to cause diseases of the lower animals and man. Most parasites enter the host through a natural opening, such as a stomate (microscopic air pore) in a leaf, a lenticel (small opening through bark) in a stem, a broken plant hair or a hair socket in a fruit, or a wound in the plant or animal epidermis (skin). Such wounds may be insect punctures or accidentally inflicted scratches, cuts, or bruises.

Fungus-caused diseases

Among the most common and widespread diseases of plants caused by fungi are the various downy mildews—*e.g.*, of grape, onion, tobacco; the powdery mildews—*e.g.*, of grape, cherry, apple, peach, rose, lilac; the smuts—*e.g.*, of corn, wheat, onion; the rusts—*e.g.*, of wheat, oats, beans, asparagus, snapdragon, hollyhock; apple scab; brown rot of stone fruits; and various leaf spots, blights, and wilts. These diseases cause millions of dollars' worth of damage annually all over the world.

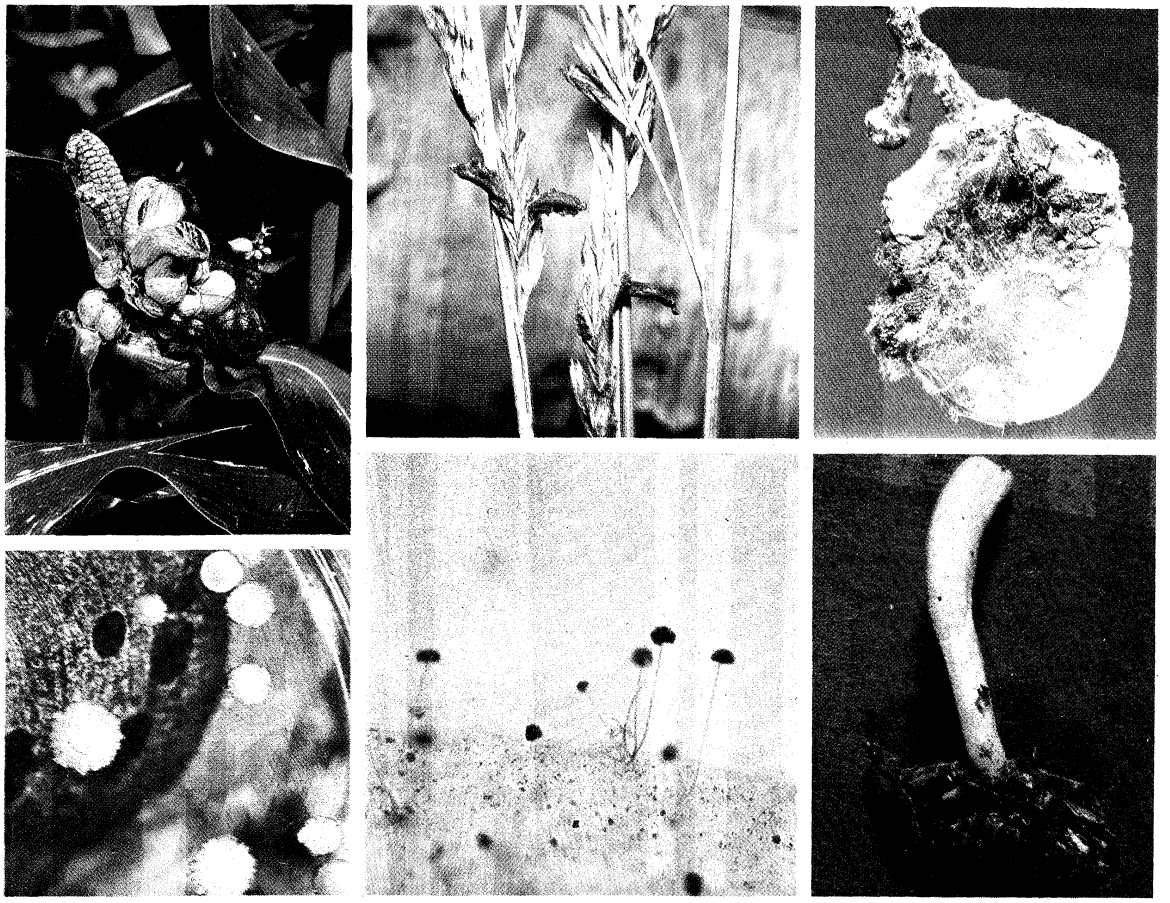
Infection of a plant takes place when the spores of a pathogenic fungus fall on the leaves or the stem of a susceptible host and germinate, each producing a germ tube. The tube grows on the surface of the host until it finds an opening; then the tube enters the host, puts out branches between the cells of the host, and forms a mycelial network within the invaded tissue. The germ tubes of some fungi produce special pressing organs called appressoria, from which a microscopic, needlelike peg presses against and punctures the epidermis of the host; after penetration, a mycelium develops in the usual manner. Many parasitic fungi absorb food from the host cells through the hyphal walls appressed against the cell walls of the host's internal tissues. Others produce haustoria (special absorbing structures) that branch off from the intercellular hyphae and penetrate the cells themselves. Haustoria, which may be short, bulbous protrusions or large branched systems filling the whole cell, are characteristically produced by obligate (*i.e.*, invariably parasitic) parasites; some facultative (*i.e.*, occasionally parasitic) parasites such as the potato blight, *Phytophthora infestans*, also produce them. Obligate parasites, which require living cytoplasm and have extremely specialized nutritional requirements, cannot be grown in artificial culture under presently known conditions; their physiology, therefore, is not yet well understood. Examples of obligate parasites are the downy mildews and the powdery mildews.

Predation. A number of fungi have developed ingenious mechanisms for trapping animals of microscopic size, such as amoebas, roundworms (nematodes), and rotifers. After an animal is captured, the fungus penetrates its body and quickly destroys it. Many of these fungi secrete adhesive substances over the surface of their hyphae, so that a passing animal that touches any portion of the mycelium adheres firmly to it. Soon a penetration tube grows out of a hypha and penetrates the host's soft body. This haustorium grows and branches, and enzymes secreted by it quickly kill the animal, whose cytoplasm serves as food for the fungus.

Animal-trapping fungi

Other fungi produce hyphal loops in which small animals become ensnared until the fungus is able to send haustoria into their bodies and kill them. Perhaps the most amazing of these fungal traps are the so-called constricting rings of some species of *Arthrobotrys*, *Dactylella*, and *Dactylaria*—soil-inhabiting fungi easily grown under laboratory conditions. In the presence of nematodes, the mycelium produces large numbers of rings through which the average nematode is barely able to pass. When a nematode rubs the inner wall of a ring, which usually consists of three cells with touch-sensitive inner surfaces, the cells of the ring swell rapidly, and the resulting constriction holds the worm tightly. All efforts of the nematode to free itself fail, and a hypha, which grows out of one of the swollen ring cells at its point of contact with the worm, penetrates the animal's body, branches therein, and kills the host, which is then used for food by the fungus. In the absence of nematodes, these fungi do not usually produce rings in appreciable quantities. A substance (nemin) of largely unknown chemical composition is secreted by the nematodes and stimulates the fungus to form the mycelial rings.

Mycorrhiza. A large number of fungi "infect" the roots of plants forming an association with them called my-



Fungi of economic or scientific interest.
(Top left) Corn smut (*Ustilago*) on *Zea mays* yearly destroys a considerable percentage of the corn (maize) crop. (Top centre) Ergot (*Claviceps purpurea*), the original source of LSD-25 as well as a drug used in obstetrics, attacks rye and other cereal grains and causes the disease ergotism when eaten. (Top right) Blue-green mold (*Penicillium*), shown on grape, attacks many fruits and is the source of the drug penicillin. (Bottom left) Brewers' yeast colonies (*Saccharomyces cerevisiae*) growing on agar medium. (Bottom centre) Bread mold (*Rhizopus stolonifer*) showing the sporangia that bear conidia (asexual spores). (Bottom right) Parasitic *Cordyceps militaris* attacking insect pupa.
(Top left) J.C. Allen and Son, (top centre, top right) Walter Dawn, (bottom left) A to Z Botanical Collection—EB Inc., (bottom centre) Grant Heilman—EB Inc., (bottom right) F.K. Anderson—EB Inc.

corrhiza or mycorhiza. This association differs markedly from ordinary root infection, which is responsible for root-rot diseases. Mycorrhizal fungi establish a mild form of parasitism that in many instances verges on mutualism; *i.e.*, it is beneficial to the plant as well as to the fungus.

Lichens. A lichen is a "composite plant" consisting of an alga and a fungus in intimate association. The fungus forms a characteristic stroma (the body of the lichen) in which the algal cells are embedded. The fungal hyphae penetrate many of the algal cells with haustoria and therefore "parasitize" them; but, as in mycorrhizae, the relationship is benign in that the algal cells are protected by the fungal mantle from too much light, in exposed situations, and perhaps also from extreme desiccation (see LICHEN).

EVOLUTION AND PHYLOGENY

The origin of the fungi is obscure, the fossil record being scanty and virtually meaningless. The older theory supposed the fungi to have originated by loss of chlorophyll from one or two groups of algae, one school favouring the development of the fungi monophyletically (*i.e.*, from a single ancestor) from the green algae, the other postulating that the lower fungi originated from the green algae but that the Ascomycetes came from the class Florideae of the red algae and later gave rise to the Basidiomycetes. Most present-day mycologists derive the fungi from ancestral flagellates (algal or protozoan organisms bearing flagella, whiplike swimming organs) but yield that the Oomycetes may have had a separate origin because of the supposed absence of chitin from, and the known presence of cellulose in, their cell walls; their probably diploid thallus; and their sexual reproduction through oogamy (production of differentiated egg cells).

As for the interrelationships among fungal groups, there is much controversy. The modern tendency is to emphasize flagellation as an important phylogenetic criterion in the lower fungi. Thus, all the posteriorly uniflagellate fungi (*i.e.*, those with a single flagellum located at the rear end of the organism) are brought together in one class, Chytridiomycetes; all the anteriorly uniflagellate in the class Hyphochytridiomycetes, and so on, as may be seen in the section on classification below. Whether the Plasmodiophoromycetes should be grouped with the Myxomycetes (slime molds) and removed from the fungi because of their plasmodial phase and their swarm cells, which bear two anterior whiplash flagella, is a moot question.

Those who favour a monophyletic development derive the Zygomycetes from the Chytridiomycetes through *Zygochytrium*, in which sexual reproduction is said to be zygomycetous (*i.e.*, of the same type as is found in the class Zygomycetes), and the Ascomycetes from the Zygomycetes), through the genus *Dipodascus*, which has a many-spored "ascosporangium." The yeasts are considered to be either primitive or advanced (hence simple by reduction), depending on how one wishes to derive them.

Virtually all mycologists agree that the Basidiomycetes have been derived from the Ascomycetes. This opinion is based on the similarity of the nuclear cycle of the ascus

and basidium, the supposed homology of the clamp connection (a structure joining two adjacent cells in the Basidiomycetes) with the crozier (a hook-shaped terminal cell found in Ascomycetes), and the similarity of the binucleate mycelium of Basidomycetes with the ascogenous (ascus-producing) hyphae of Ascomycetes. Not all, however, are agreed as to which group of Ascomycetes gave rise to the Basidiomycetes, nor indeed as to which Basidiomycetes are primitive and which are advanced. Whether the holobasidium (simple, club-shaped basidium) or the heterobasidium (septate or deeply divided basidium) came first is a highly controversial question that has a great bearing on the origin of the Basidiomycetes. Also, the fact that the dolipore (inflated) septum has not been found in the rusts or smuts or in any clearly nonbasidiomycetous group poses an interesting question on the origin of the Basidiomycetes.

CLASSIFICATION

Distinguishing taxonomic features. The fungi as a group are distinguished from other organisms by the nature of their somatic (body) and reproductive structures, and by the mode of nutrition they employ. Within the division Mycota, the classes are further distinguished by variations of these characteristics, particularly those involving reproductive stages.

Annotated classification. The following classification is adapted from G.W. Martin in Ainsworth's *Dictionary of the Fungi*, 5th ed. (1961).

DIVISION MYCOTA (fungi)

Eukaryotic (with true nuclei), achlorophyllous (without chlorophyll), acellular, unicellular, or multicellular organisms; microscopic or macroscopic in size; usually with cell walls and filaments; typically reproducing by spores produced asexually or sexually; walls containing chitin, cellulose, or both, among other substances. About 50,000 living species; fewer than 500 fossil species known.

Subdivision Myxomycotina (true slime molds)

Assimilative stage a multinucleate, free living, essentially naked, acellular, mobile plasmodium (jellylike mass), which becomes converted into one or more characteristic sporocarps; holozoic (feeding like an animal; *i.e.*, by engulfing solid food particles); sexual reproduction by fusion of compatible myxamoebae (motile amoeba-like cells) or flagellated cells; spores enveloped in definite cell walls containing cellulose.

Class Myxomycetes (slime molds)

Characters of the subdivision. Cosmopolitan, terrestrial, sporulating on any substratum on which the plasmodium settles, such as living plants, plant debris, stones, etc. (see SLIME MOLD).

Subclass Ceratiomyxomycetidae. Fructification exosporous (spores borne externally), with spores on individual stalks, each spore giving rise to a protoplast that cleaves into 8 swarm cells.

Order Ceratiomyxales. Characters of the subclass. One genus (*Ceratiomyxa*) with 3 species, 1 of which (*C. fruticulosa*) is ubiquitous, the other 2 tropical.

Subclass Myxogastromycetidae. Spores borne internally in characteristic sessile (nonstalked) or stipitate (stalked) often brilliantly coloured sporophores ranging in size from 50 microns to 6 centimetres or more, characteristically containing a capillitium (tangled mass of threadlike structures) interspersed with the spores. Spores upon germination giving rise to 1 to 4 creeping myxamoebae or flagellated swarm cells.

Order Liceales. Microscopic (*Licea*) to large (*Reticularia*) sporophores devoid of capillitium but which may contain pseudocapillitium; lime absent; typically on dead wood or on bark of dead or living trees, rarely on dead leaves; spores in mass pallid, bright-coloured, or dingy olivaceous, hyaline (transparent, but still characteristically coloured) or subhyaline by transmitted light. About 70 species.

Order Echinosteliales. Microscopic, stalked; lime never present; capillitium, when present, scanty, arising from the tip of the columella; (central internal stalk of sporophore); spores white, pale pink, pale yellow, or brown in mass, typically with conspicuous, evenly distributed thickened areas on the walls; assimilative stage a protoplasmodium. Ten species.

Order Trichiales. Stalked or sessile with persistent peridium but without columella; lime rarely present and then scanty and on the surface only; capillitium abundant, consisting of a network or of separate elaters (filaments of the capillitium); spores bright-coloured in mass. About 150 species. *Arcyria, Hemitrichia,* and *Trichia* are the largest genera.

Order Stemonitales. Usually stalked, sometimes sessile; lime rarely present and then confined to the hypothallus (a filmlike residue that remains after the formation of sporangia), stalk, and columella; spores in mass black or deep violaceous or ferruginous (rust-coloured); assimilative stage an aphanoplasmodium (*i.e.*, a nongranular, transparent, thin plasmodium showing little or no differentiation into endoplasm and ectoplasm). About 90 species. *Stemonitis, Comatricha,* and *Lamproderma* are the most common genera.

Order Physarales. Stalked or sessile; lime characteristically present on the peridium and the capillitium; spores in mass black, deep violaceous, or ferruginous; assimilative stage a phaneroplasmodium (*i.e.*, a granular, thick, opaque plasmodium whose veins have clearly differentiated endoplasm and ectoplasm). About 190 species. *Physarum* is the largest genus with *Physarella, Fuligo, Diderma,* and *Didymium.*

Subdivision Eumycotina (true fungi)

Assimilative stage walled, typically filamentous (a mycelium), sometimes unicellular, usually eucarpic (having only part of the thallus forming a fruiting structure); asexual reproduction by fission, budding, fragmentation, or, more typically, by spores; sexual reproduction by various means, usually resulting in the formation of resting structures or meiospores.

Class Chytridiomycetes

Unicellular or filamentous, holocarpic (having all of the thallus involved in the formation of the fruiting body) or eucarpic; motile cells (zoospores or planogametes) with a single, posterior, whiplash flagellum. Mostly aquatic fungi saprobic or parasitic on algae, fungi, or less often, on flowering plants.

Order Chytridiales. Mycelium lacking but rhizoids (short absorbing filaments) or rhizomycelium often present. Chiefly freshwater saprobes or parasites of algae and fungi. Some terrestrial species, such as *Olpidium brassicae* and *Synchytrium endobioticum* cause plant disease. About 550 species.

Order Blastocladiales. Water molds with a restricted thallus, characterized by the production of thick-walled, pitted, resistant sporangia; sexual reproduction by isogamous (equal in size and alike in form) or anisogamous (unequal in size but still similar in form) planogametes; *Allomyces* exhibits an alternation of two equal generations. Most are saprobes but various species of *Coelomomyces* are parasitic in mosquito larvae; uniquely, their hyphae are devoid of cell walls. More than 50 species.

Order Monoblepharidales. Water molds with an extensive, foamy mycelium; sexual reproduction by a motile male gamete (antherozoid) fertilizing a nonmotile differentiated egg, resulting in a thick-walled oospore. About 20 species.

Class Hyphochytridiomycetes

A small group of mostly marine fungi very similar to the order Chytridiales but with motile cells bearing a single tinsel flagellum (*i.e.*, a flagellum with short side branches along the central axis, comblike).

Order Hyphochytriales. Characters of the class. About 15 species.

Class Plasmodiophoromycetes

Endoparasites (internal parasites) of fungi or plants often causing hypertrophy (excessive abnormal growth). Assimilative stage an endophytic (living within plant tissue) plasmodium that becomes converted into a group of zoosporangia (structures producing motile asexual spores) or a large number of small, walled spores; motile cells with 2 unequal, anterior, whiplash flagella.

Order Plasmodiophorales. Characters of the class. *Plasmodiophora* and *Spongospora* cause serious plant diseases. About 35 species (see also SLIME MOLD).

Class Oomycetes

Aquatic, amphibious, or terrestrial fungi; saprobic, facultatively (occasionally) or obligately (invariably) parasitic on plants, a few on fish. Asexual reproduction typically by zoospores with 2 anterior or lateral flagella, 1 whiplash, 1 tinsel; sexual reproduction usually by contact of differentiated gametangia (gamete-or sex-cell-producing structures) with nuclei from the male fertilizing differentiated eggs and resulting in thick-walled oospores; thallus probably diploid with meiosis occurring in the gametangia.

Order Lagenidiales. Holocarpic, unicellular or filamentous water molds, parasitic on algae and fungi or saprobic; oogonium (egg-producing structure) typically containing a single egg. About 85 species.

Order Saprolegniales. Mostly eucarpic, filamentous water molds or soil fungi; saprobic or parasitic; hyphae without constrictions or cellulin plugs; oogonia containing 1 to many free eggs. Some species are diplanetic, *i.e.*, they produce 2 types of zoospores, primary (pear-shaped with anterior flagel-

la) and secondary (kidney-shaped with lateral flagella). Some (*Aphanomyces*) cause root rots; others (*Saprolegnia*) infect fish and fish eggs. About 200 species.

Order Leptomitales. Aquatic saprobes found often in polluted waters; eucarpic; hyphae constricted, with cellulin plugs, arising from a well-defined basal cell; oogonium typically containing a single egg, which may be free or embedded in periplasm (a peripheral layer of protoplasm). Twenty species.

Order Peronosporales. Aquatic or terrestrial; parasitic on algae or vascular plants, the latter mostly obligate parasites causing downy mildews; zoosporangia, in advanced species, borne on well-differentiated sporangiophores, deciduous and behaving as conidia (asexually produced spores). About 250 species.

Class Zygomycetes

Terrestrial saprobes or parasites of plants, animals, or humans; asexual reproduction by aplanospores (nonmotile spores) in sporangia, or by conidia; sexual reproduction by fusion of morphologically similar gametangia, sometimes differing in size, resulting in thick-walled zygospores.

Order Mucorales. Saprobic, weakly parasitic on plants, or parasitic on humans and then causing mucormycosis (a pulmonary infection); asexual reproduction by sporangiospores, one-spored sporangiola (a small deciduous sporangium), or conidia. In the genus *Pilobolus* the heavily cutinized sporangium is forcibly discharged. These fungi are often called the bread molds. About 360 species.

Order Entomophthorales. Insect parasites or saprobes, some implicated in animal or human diseases; asexual reproduction by modified sporangia functioning as conidia, forcibly bread molds. About 360 species.

Order Zoopagales. Parasitic on amoebae, rotifers, nematodes, or other small animals, which they trap by various specialized mechanisms; asexual reproduction by conidia borne singly or in chains, not forcibly discharged. About 60 species.

Class Trichomycetes

Commensals (organisms living parasitically on another organism, but conferring some benefit in return, or at least not harming the host) with a filamentous thallus attached by a holdfast or basal cell to the digestive tract or external cuticle of living arthropods; asexual reproduction by sporangiospores (a spore borne within a sporangium), trichospores (zoospores or ciliated spores), arthrospores, (a spore resulting from fragmentation of a hypha), or amoeboid cells; sexual reproduction, where known, zygomycetous.

Order Amoebidiales. Thallus coenocytic (without cross walls, with numerous freely distributed nuclei) arising from a holdfast; amoeboid cells formed. About 12 species.

Order Eccrinales. Thallus coenocytic, attached by a holdfast to the digestive tract of arthropods; aplanosporangia produced in succession. More than 50 species.

Order Asellariales. Thallus branched, septate, attached by a basal coenocytic cell; asexual reproduction by arthrospores. Six species.

Order Harpellales. Thallus simple or branched, septate. Asexual reproduction by trichospores; sexual reproduction zygomycetous. About 35 species.

Class Ascomycetes

Saprobic or parasitic on plants, animals, or humans; some are unicellular but most are filamentous, the hyphae septate with 1, rarely more, perforations in the septa; cells uninucleate or multinucleate; asexual reproduction by fission, budding, fragmentation, or, more typically, by conidia usually produced on special sporiferous (spore-producing) hyphae, the conidiophores, which are borne loosely on somatic (main-body) hyphae or variously assembled in asexual fruiting bodies; sexual reproduction by various means resulting in the production of meiosphores (ascospores) formed by free-cell formation in saclike structures (asci), which are produced naked or, more typically, are assembled in characteristic open or closed fruiting bodies (ascocarps). Among the largest and most commonly known ascomycetes are the morels, cup fungi, saddle fungi, and truffles.

Subclass Hemiascomycetidae. Asci naked, formed from single cells or on hyphae; no ascocarps or ascogenous hyphae produced; saprobic or parasitic.

Order Protomycetales. Spore-sac compound (a synascus). A poorly known small group of plant parasitic ascomycetes. Twenty or more species.

Order Endomycetales. Mostly saprobic, a few parasitic; zygote or single cell transformed directly into the ascus; mycelium sometimes lacking. This group includes the yeasts and their relatives.

Order Taphrinales. Parasites on vascular plants. Asci produced from binucleate ascogenous (ascus-producing) cells formed from the hyphae in the manner of chlamydospores (thick-walled spores). Ninety or more species.

Subclass Euascomycetidae. Asci unitunicate (ascus wall single-layered), borne in various types of ascocarps; saprobic or parasitic on plants, animals, or humans.

Order Eurotiales. Asci globose to broadly oval, typically borne at different levels in cleistothecia (completely closed ascocarp or fruiting structure). Most of the human and animal dermatophytes belong here. Also many saprobic soil or coprophilous fungi. Possibly up to 150 species.

Order Microascales. Asci evanescent (quickly deteriorating), borne at different levels in perithecia (closed ascocarps with a pore in the top) with ostioles (the opening of the perithecium), or sometimes a long necklike structure terminating in a pore. Some serious plant parasites such as *Ceratocystis ulmi* (Dutch elm disease) and *C. fagacearum* (oak wilt) belong here. About 100 species.

Order Onygenales. Asci formed in a mazaedium (a fruiting body consisting of a powdery mass of free spores interspersed with sterile threads, enclosed in a peridium or wall structure), evanescent, and liberating the ascospores as a powdery mass among sterile threads. About 25 species.

Order Erysiphales. Obligate parasites on flowering plants causing powdery mildews; mycelium white, superficial in most, feeding by means of haustoria sunken into the epidermal cells of the host; 1 to several asci in a cleistothecium, if more than 1, in a basal layer at maturity; asci globose to broadly oval; cleistothecia with appendages. About 150 species.

Order Meliolales. Mycelium dark, superficial on leaves and stems of vascular plants, typically bearing appendages (termed hyphopodia or setae); asci in basal layers in ostiolate perithecia without appendages; mostly tropical fungi. More than 1,000 species.

Order Chaetomiales. Asci in basal layers in superficial perithecia that bear conspicuous, straight or curly, simple or branched, hairs on the surface; asci evanescent. About 110 species.

Order Xylariales. Perithecia with dark, membranous or carbonous (appearing as black burned wood) walls, with or without a stroma (a compact structure on or in which fructifications are formed); asci persistent, borne in a basal layer among paraphyses (elongate structures resembling asci but sterile), which may ultimately gelatinize and disappear. A rather large group of fungi one of which, *Neurospora crassa*, has been used extensively in genetic and biochemical studies. Approximately 4,500 species.

Order Diaporthales. Perithecia immersed in plant tissue or in a stroma with their long ostioles protruding; ascal stalks gelatinizing, freeing the asci from their basal attachment; paraphyses lacking. The chestnut blight fungus (*Endothia parasitica*) belongs here. Close to 500 species.

Order Hypocreales. Perithecia and stromata when present, brightly coloured, soft, fleshy, or waxy, when fresh; asci borne in a basal layer among apical paraphyses. About 800 species.

Order Clavicipitales. Perithecia immersed in a stroma that issues from a sclerotium (a hard-resting body resistant to unfavourable environmental conditions); asci with a thick apex penetrated by a central canal through which the septate, threadlike ascospores are ejected. The ergot fungus (*Claviceps purpurea*), cause of ergotism in plants, animals and humans, and the original source of LSD, belongs to this order. Some other Clavicipitales parasitize insect larvae. About 170 species.

Order Coryneliales. Asci in ascostromata with funnel-shaped ostioles at maturity. About 20 species.

Order Coronophorales. Asci in ascostromata with irregular or round, never funnel-shaped openings. About 30 species.

Order Laboulbeniales. Ascomycetes of uncertain affinity; minute parasites of insects and arachnids with mycelium represented only by haustoria and stalks. About 1,635 species.

Order Ostropales. Ascocarp a locule-like apothecium (an open, often cuplike, ascocarp); asci inoperculate (without a terminal pore) constructed as in the Clavicipitales; ascospores septate, threadlike. About 80 species.

Order Phacidiales. Ascocarp an apothecium immersed in a black stroma, the upper covering of which splits in stellate (star-shaped) or irregular fashion when ascospores mature. About 150 species.

Order Helotiales. Ascocarp an apothecium bearing inoperculate asci exposed from an early stage. Some important plant diseases are caused by members of this group. *Monilinia fructicola* causes brown rot of stone fruits. The earth tongues (*Geoglossaceae*) also belong here. More than 1,500 species.

Order Pezizales. Ascocarp an apothecium bearing operculate (with a hinged cap) asci above the ground; apothecia often large, cup- or saucer-shaped, spongy, brainlike, saddle-shaped, etc. This group includes the morels, the false morels, and the saddle fungi among others. About 700 species.

Order Tuberales (truffles). The ascocarps, mostly closed and borne below the ground, are considered to be modified apothecia. The asci are globose, broadly oval, or club-shaped. About 230 species.

Subclass Loculoascomycetidae. Asci bitunicate, borne in ascostromata; saprobic or parasitic on plants.

Order Myriangiales. Asci borne singly in locules arranged at various levels in a more or less globose stroma. About 100 species.

Order Dothideales. Asci borne in fascicles (clusters) in a locule devoid of sterile elements. About 600 species.

Order Pleosporales. Asci borne in a basal layer among pseudoparaphyses. More than 2,000 species.

Order Microthyriales. Stroma flattened, hemispherical, opening by a pore or tear; base usually lacking; asci borne among pseudoparaphyses. Mostly tropical fungi. About 1,200 species.

Order Hysteriales. Stroma boat-shaped, opening by a longitudinal slit, which renders it apothecium-like; asci borne among pseudoparaphyses. About 110 species.

Class Basidiomycetes

Saprobic or parasitic on plants or insects; filamentous; the hyphae septate, the septa typically inflated (dolipore) and centrally perforated; mycelium of 2 types, primary of uninucleate cells, succeeded by secondary, consisting of dikaryotic cells, this often bearing bridgelike clamp connections over the septa; asexual reproduction by fragmentation, oidia (thin-walled, free, hyphal cells behaving as spores), or conidia; sexual reproduction by fusion of hyphae (somatogamy), fusion of an oidium with a hypha (oidization), or fusion of a spermatium (a nonmotile male structure that empties its contents into a receptive female structure during plasmogamy —a kind of gamete) with a specialized receptive hypha (spermatization), resulting in dikaryotic hyphae that eventually give rise to basidia, either singly on the hyphae or in variously shaped basidiocarps; meiospores (basidiospores) borne on basidia. In the rusts (Uredinales) and smuts (Ustilaginales), the dikaryotic hyphae produce teleutospores (thick-walled resting spores), which are a part of the basidial apparatus. This is a large class of fungi containing the rusts, smuts, jelly fungi, club, coral and shelf fungi, mushrooms, puffballs, stinkhorns, and bird's-nest fungi.

Subclass Heterobasidiomycetidae. Basidia septate or deeply divided, or arising from a teleutospore or cyst; basidiospores often germinating by repetition, budding, or production of conidia. The subclass includes the jelly fungi, the rusts, and the smuts.

Order Tremellales (jelly fungi). Fruiting bodies (basidiocarps) well formed, appearing as inconspicuous horny crusts when dry but usually bright-coloured to black gelatinous masses after a rain. A few are parasitic on mosses, vascular plants, or insects; most are saprobes. About 500 species.

Order Uredinales (rusts). Parasitic on vascular plants. The basidial apparatus consists of a thick-walled teleutospore (probasidium) which either gives rise to a 4-celled tube (metabasidium) on which basidiospores are borne, or which itself becomes 4-celled and produces basidiospores directly; basidiospores forcibly discharged. Many rusts are heteroecious; *i.e.*, they require 2 species of host to complete their life cycle. Rusts are among the fungi most destructive to agriculture. About 4,600 species.

Order Ustilaginales (smuts). Called smuts because the masses of spores (sori) are usually black and dusty. Basidial apparatus consisting of a thick-walled teleutospore (probasidium), which, upon germination, gives rise to a septate or nonseptate tube (metabasidium), which bears the basidiospores. Basidiospores not forcibly discharged, germinating usually by budding, or fusing and then producing a mycelial germ tube. The various cereal smuts are of great economic importance. About 700 species.

Subclass Homobasidiomycetidae. This subclass includes the great majority of the Basidiomycetes. Most produce conspicuous, large-fruiting bodies, which bear the spores on basidia. The basidia are simple, cylindrical, or club-shaped. The basidiospores, which may or may not be forcibly discharged, germinate directly into a mycelium.

Order Exobasidiales. Basidiocarps lacking; basidia produced in a layer on the surface of parasitized vascular plants. Fifteen species.

Order Polyporales. Basidiocarps present. A large and probably heterogeneous order of fungi in which the basidia are borne in various ways but rarely on gills. It includes the coral fungi, the club fungi, the chanterelles, and the pore (shelf or bracket) fungi among others. Common genera include *Stereum, Clavaria, Hydnum, Cantharellus, Polyporus, Fomes. Schizophyllum* has been used extensively for genetic research. Perhaps 2,500 species.

Order Agaricales (mushrooms and boletes). Basidia produced in layers (hymenia) on the underside of fleshy fruiting bodies (basidiocarps), in tubes (boletes) or on gills (mushrooms). Some of these fungi form mycorrhizae, some are parasitic and cause root rots. The majority are saprobic. 4,000 to 5,000 species.

Order Hymenogastrales. Basidiocarps underground or on the surface but usually buried in humus, remaining closed, the interior (gleba) disintegrating into a slimy mass containing the spores. About 225 species.

Order Lycoperdales (puffballs). Gleba dry and powdery at maturity; consisting of small, pale spores and well-developed capillitium. About 160 species.

Order Sclerodermatales. These are puffballs with a hard peridium enclosing a dry, powdery gleba consisting of large, dark spores and some capillitium. About 120 species.

Order Phallales (stinkhorns). Gleba slimy and fetid at maturity; exposed on an elongated or net-shaped receptacle. *Phallus, Mutinus, Dictyophora, Simblum, Clathrus* are temperate-zone genera. About 70 species.

Order Nidulariales (bird's-nest fungi). The gleba separates into chambers, which become thick-walled, waxy, and hard. These are the peridioles ("eggs"), which are evident within a cup-like or goblet-like basidiocarp, the whole resembling a bird's nest at maturity. *Cyathus* and *Crucibulum* are the 2 most widely distributed genera. About 60 species.

Form-class Deuteromycetes

Fungi with septate mycelium reproducing only asexually and resembling asexual stages of Ascomycetes and Basidiomycetes.

Form-order Sphaeropsidales. Conidia borne in pycnidia. About 5,500 species.

Form-order Melanconiales. Conidia borne in acervuli. About 1,000 species.

Form-order Moniliales. Conidia borne on variously assembled conidiophores but never in pycnidia or acervuli. 10,000 or more species.

Form-order Mycelia Sterilia. No conidia produced. Probably mycelial stages of Basidiomycetes. About 200 species.

Critical appraisal. Although the fungi are traditionally classified in the plant kingdom, some of their characteristics argue strongly against such affinities. Chief among them are their heterotrophy (*i.e.*, the obtaining of food from an outside source rather than producing it as do green plants), and the almost universal presence of chitin, which is also found in the skin of many invertebrate animals such as insects, in their walls. Although, with the exception of the slime molds (Myxomycetes, or Mycetozoa), the fungi have never actually been included in the animal kingdom, some taxonomists have proposed their removal from the plant kingdom and their inclusion either in the kingdom Protista or in a separate kingdom —Fungi (see CLASSIFICATION, BIOLOGICAL).

Within the division Mycota, older classification systems applied the name Phycomycetes (algal fungi) to the six classes of "lower fungi" found in present-day systems (Chytridiomycetes, Hyphochytridiomycetes, Plasmodiophoromycetes, Oomycetes, Zygomycetes, and Trichomycetes). Although no longer recognized as a formal taxonomic category, the name Phycomycetes is still used informally by many mycologists as a useful term for designating those fungi that produce their spores in sporangia and have, in most cases, coenocytic hyphae—as is true of the presently recognized six classes.

The groups that are designated as the form-class Deuteromycetes (also sometimes called "Fungi Imperfecti") consist of organisms whose sexual stages either have not been found, or do not exist, together with the asexual stages of some sexually reproducing species. It has happened that sexual stages have been found for some species in this group and whenever this occurs, the species is immediately given a name appropriate to its proper taxonomic group. Sometimes, however, it has been found advisable to maintain the form-category name even though sexual stages are known and this has led to the unusual condition of one species having been assigned two scientific names, only one of which, of course, is valid—the one applying to the sexual stage. The practice is justified mainly for the convenience of having a classification system, artificial though it is, into which conidial (asexual) forms may be grouped and studied. It has even been found useful to extend the concept of form

categories to include the conidial stages of known sexually reproducing fungi, mainly Ascomycetes. Since many of these fungi, particularly the parasitic ones, are usually encountered only in the conidial stage, they can be easily identified by making use of the form-category classification. The convenience is great and the practice so widespread that in 1950 the International Botanical Congress legalized the use of form-names for conidial stages, recognizing, of course, the name of the perfect (sexual) stage as the official name of the whole organism.

Myriapod

Myriapod is a general term applied to any member of several closely related groups of the invertebrate phylum Arthropoda—the extinct Archipolypoda; the Diplopoda, or millipedes; the Chilopoda, or centipedes; the Pauropoda; and the Symphyla. The myriapods are a little-known group, although some 11,000 living species have been recognized.

General features. *Importance.* Most myriapods are secretive and seldom seen. Some attract attention by spectacular mass migrations; others are found occasionally in dark corners of houses and other buildings. Certain tropical species inflict painful bites on man. The primary significance of myriapods, however, is the role they play in the ecological balance of forested regions. In addition, their limited ability to migrate, their dependence upon stable conditions of moisture and shelter, and their general intolerance of seawater, together with the fact that they appeared rather early in geological history and, since then, have evolved little, make the myriapods im-

portant indicators of land–water relationships; these organisms thus provide useful information for understanding evolution and geographic dispersal.

Size range, distribution, and abundance. For the most part, myriapods are relatively small. Pauropods do not exceed two millimetres (about 1/12 inch), symphylids are rarely more than four millimetres. The smallest chilopods (centipedes) are about 5 mm; the largest may reach about 27 centimetres (about 10½ inches), but the average is about 30 mm (about 1⅕ inches). Diplopods (millipedes) range in length from about 3 mm to about 28 cm; the average size for the group, however, is less than 50 mm (about two inches).

The four living myriapod classes are distributed widely throughout the tropical and temperate regions; in some areas myriapods are conspicuous in the fauna of the soil, including its organic portion (humus). Because they are largely phytosaprophagous (subsisting on dead plants), they play an important role in the breakdown of dead vegetable material. Some species are primarily carnivorous, however.

Greater numbers of individuals of tiny myriapod species occur than do those of large ones. Myriapods are most abundant and diverse in forests, although some species of diplopods and an even greater number of chilopods thrive in grassland or in semi-arid habitats; still others live in desert conditions.

Representative myriapods. Line scales indicate approximate size of each myriapod.

Natural history. *Reproduction and life cycle.* Internal fertilization occurs in all myriapods; however, the method of sperm transfer from male to female is indirect and highly variable. Paired gonads occur in both sexes, and maturation, with production of viable gametes (reproductive cells), begins at the time of the final molt (shedding of skin). In diplopods, symphylids, and pauropods, ducts from the gonads open near the anterior (front) end of the body, usually just behind the base of the second pair of legs; in chilopods the reproductive systems of both sexes open at the posterior (hind) end of the body.

Sperm transfer

Only in the diplopods does sexual contact occur. In diplopods except those of the order Polyxenida, the male produces a spermatophore, or sperm-bearing capsule, either during or prior to clasping the female. Subsequently he transfers the capsule to specialized receptacles at the openings of the oviducts (tubes that carry the eggs) by mouth or by means of modified appendages (gonopods) on the seventh body segment. There is little courtship activity, the male usually finding the female by chemical sensors and then seizing her.

In diplopods of the order Polyxenida and in other myriapod groups, sperm transfer is much less direct and usually entails deposition of a spermatophore by the male and its subsequent recovery by the female. In Pauropoda and Polyxenida, the male constructs a small web of silken threads, in which he deposits several drops of spermatic fluid; the female subsequently picks up the sperm near her oviduct openings. Sperm transfer in the symphylids is more complex. The female recovers spermatophores with her mouthparts, and the sperm remain in special receptacles inside the mouth until deposition of the eggs. Fertilization is accomplished by the female's transferring some of the stored sperm from the oral cavity to the nearby opening of the oviduct on the second body segment, by means of a chewing-like activity.

Chilopods practice a form of courtship that involves a mutual caressing of the antennae, followed by the construction of an irregular web and deposition of a spermatophore by the male. In some species the female picks up the sperm mass almost immediately; in others she may leave the area after courtship and not return to the spermatophore for several hours. A male of the order Scutigerida has been observed transferring the spermatophore from its web to the female gonopore with his mouth. Following transfer of the spermatophore, fertilization occurs after the sperm have moved along the oviduct.

The number of eggs produced varies among different groups. Usually diplopods of the orders Spirobolida and Spirostreptida produce a few relatively large eggs; those of the order Polydesmida produce as many as 2,000 relatively small ones.

Care of the eggs varies among diplopods. Spirobolids coat each egg with a layer of undigested material from the mouth, then pass it backward by the legs and place it into the rectum, where most of the moisture is removed. The completed egg capsule closely resembles a fecal pellet of the species. Members of the orders Polydesmida and Julida construct an earthen "igloo"; the female deposits her eggs through the top before sealing it. The young, after hatching inside the capsule, apparently derive some nourishment from the capsular material as they gnaw their way out. Species of the order Glomerida also build earthen capsules, enclosing only one or two eggs in each. Diplopods of the order Chordeumida enclose their eggs in a cocoon, the threads of which are produced by spinnerets, special organs at the posterior end of the body.

Chilopod females of certain members of the orders Scutigerida and Lithobiida deposit the eggs singly, roll them in dirt for camouflage, then place them in a concealed place. Chilopods of the orders Geophilida and Scolopendrida, accumulate the eggs into a cluster, which is brooded and protected by the female from desiccation, fungal infestation, and predation. Development is largely completed prior to hatching, and the newly emerged animal is similar to the adult except for its smaller size, lack of pigmentation, and sexual immaturity. The young chilopods sometimes remain with the mother for several days after hatching.

Molting and growth

In diplopods, pauropods, symphylids, and two orders of chilopods (Lithobiida and Scutigerida), segmentation of the embryo is not completed before the eggs hatch; the immature animal thus has fewer segments than the adult and must pass through anamorphosis—a sequence of growth stages during which segments and appendages are added. The young hatchlings usually begin life with three pairs of legs at the anterior end of the body. Subsequent growth is characterized by periods of active feeding alternating with quiescent phases during which the animal sheds its exoskeleton (hard external covering) and forms a new one; forms several new legless segments at the end of the body; and develops appendages for the legless segments of the preceding molt.

The number of immature stages (stadia) required to reach maturity varies among the different groups. Matur-

ation of the reproductive system usually occurs at the final molt, after which no further growth occurs. In some diplopods and chilopods, however, molting and growth may continue after the attainment of sexual maturity. During the molting period the animals are soft and defenseless, and many diplopods construct a round molting chamber consisting of mud and excrement in which to pass this time safely.

Some myriapods attain maturity within a few months after hatching; others may require a year or more, during which time the body increases in size and length. If the species typically has a short period of immaturity, adulthood also is brief. Slower growing forms, on the other hand, may live several years after completing their development.

Behaviour. Myriapods, generally secretive animals, pass much of their life hidden in the soil or in leaf mold; thus they have not developed the complex patterns of behaviour that occur in many other arthropod groups—*e.g.*, insects, spiders, and crabs. Most diplopods, symphylids, and pauropods are primarily phytosaprophagous; only rarely do they eat healthy living plants. Some diplopods accept animal tissue as food, and a few species appear to be preferentially carnivorous. All chilopods, however, are apparently predators that feed upon small organisms.

Most myriapod species are negatively phototropic; *i.e.*, they avoid light and are active at night or in conditions of shade or darkness; sudden exposure to sunlight results in either active evasive responses or, particularly in diplopods, a coiling of the body.

Defensive behaviour

Myriapods respond to human handling by vigorously writhing and twisting their bodies, by releasing a defensive secretion, and sometimes by discharging their intestinal contents. Most chilopods attempt to bite when picked up by man, particularly the large scolopendrids. Some chilopods have strong, thickened rear legs capable of inflicting a sharp pinch.

The predatory chilopods are basically solitary animals; the herbivorous pauropods and diplopods, however, often gather in large groups in a particularly favourable habitat. Under exceptionally favourable conditions, populations of diplopods may increase until a mass migration takes place. Sometimes the purpose of the migration may be to escape unfavourable conditions. "Armies" of migrating diplopods occasionally invade homes or contaminate water supplies in rural areas by falling into wells and dying there. Locomotives have been stopped by the slippery crushed bodies of great numbers of diplopods covering the rails.

Locomotion. The methods of locomotion among myriapods vary, as would be expected in a group with such diversity of body form. Some myriapods are long and cylindrical with rigid body segments, others relatively short and flexible; some are adapted to surface running, others to burrowing in the soil. The overall characteristics of each myriapod group presumably reflect adaptations of locomotory mechanisms appropriate to particular environmental niches.

A basically elongated, cylindrical body form with short legs can, in general, be associated with the need for a powerful forward (pushing or burrowing) motion. The mechanism characteristic of the rigid-bodied diplopods, however, is quite different from the burrowing mechanism of similarly elongated, short-legged chilopods of the order Geophilida. The latter have a highly flexible body capable of little direct pushing motion, but they have the ability to wedge through small crevices.

The nerves that lead to the leg muscles come from the ganglia, or nerve centres, of the ventral nerve cord; in a slowly moving diplopod, leg movement begins near the head and passes backward in a series of wavelike motions, suggesting the passage of a primary impulse along the entire ventral nerve.

Myriapods with relatively short bodies often have long legs and the ability to run rapidly. Variations in the internal musculature and the mechanism of leg attachment to the body reflect functional requirements for different gaits among the various groups.

Ecology. Small diplopods and chilopods, as well as all pauropods and symphylids, usually live in conditions of sustained coolness and moisture. Some species may be active during the day, crawling on the forest floor or climbing trees, but such activity is usually confined to the larger species capable of resisting dehydration. Only a few diplopods (order Spirostreptida) and chilopods (order Scolopendrida) have been able to adapt to arid or semidesert conditions; even these forms do not tolerate prolonged exposure to full sunlight.

Myriapods, however, are found in a wide variety of habitats, ranging from holes and crevices in the soil (including the burrows of earthworms, insects, and small mammals) to caves, leaf litter, loose bark, rotting logs, and even on plants some distance above the ground.

Many species adapt readily to human intrusion into their environment. Under such conditions they may thrive and sometimes are accidentally transported great distances (*e.g.*, on agricultural products). The common house chilopod (*Scutigera coleoptrata*) occurs widely in the Northern Hemisphere in places such as basements and has become adapted to outdoor conditions in areas far beyond its original range. Many tropical diplopods now are found in plantations and gardens throughout the warmer parts of the world, to the extent that their native distribution can no longer be ascertained.

Adaptation to environment

Although most diplopods are unable to endure being exposed to seawater, many chilopods live in the intertidal zone along seacoasts, where they hide beneath stones or among algae and prey upon worms and other small organisms.

Diplopods, pauropods, and symphylids are primary consumers in the ecological food chain, deriving their nourishment chiefly from dead and decomposing organic material. Chilopods, which are mainly predators, are secondary consumers in the food chain and thus usually occur in much smaller numbers.

Myriapods are parasitized internally by various protozoans, nematodes (a minute type of worm), and certain fungi. A few species of flies act as external parasites; mites live on the legs and in depressions of the body wall. Predators include certain insects of the order Heteroptera, the larval stages of some beetles (Coleoptera), scorpions, spiders, chilopods, salamanders and toads, various birds, and small mammals such as shrews, moles, and mice.

Form and function. Myriapods are characterized by the presence of mandibles, one pair of antennae, tracheae (respiratory tubules), and little or no tendency for modification of the body into thoracic and abdominal regions. These features, except for the last, are shared with insects, and it is the opinion of some authorities that the transition between symphylids and true winged insects has been so gradual that the insects should be considered myriapods. The five myriapod classes are sharply differentiated. Except on the basis of individual characters of questionable significance, it is not possible to arrange the four living classes into groups.

Members of the class Diplopoda (millipedes), perhaps the most specialized myriapods, are characterized by the fusion of the original body somites, or segments, into pairs, forming diplosomites, or paired somites, each equipped with two pairs of legs (except where secondarily lost) and two ganglia on the ventral nerve cord. In most millipedes the legs of the original anterior somite have migrated posteriorly, permitting each diplosomite to be telescoped into the preceding one. Diplosomites occur only in millipedes, and this character is the most significant in their taxonomic ranking as a class. At the anterior end of the body several segments may be provided either with a single pair of legs or none. This reduction is commonly associated with the ability of most species to roll the head region backward in a protective posture.

Specializations of millipedes

The mouthparts of the millipede also are distinctive, consisting of one pair of mandibles—usually massive—and a flattened platelike structure, the gnathochilarium, which forms the floor of the front part of the mouth. This structure, once thought to correspond to the two original pairs of maxillae (external mouthparts), is now regarded

as being formed by the fusion of the two appendages of the fourth head somite of the embryo. The form and arrangement of the small sclerites, or sections, of the gnathochilarium differ from group to group and are important in classification; in some millipede orders this structure is reduced to a small fragile plate with no suggestion of individual sclerites.

The body wall of most millipedes is calcified. The presence of calcium carbonate in addition to the basic chitin material (chitin is a complex carbohydrate) results in a rigid, brittle skeletal structure found in no other group. In what is presumed to be the primitive arrangement, each diplosomite consists of a dorsal surface (the tergum), two lateral surfaces (the pleura), and a ventral surface (the sternum) connected by hardened tissue. Various modifications of this arrangement occur—in some cases, the tergal and pleural sclerites are fused, and in others all four elements are fused into a ring.

Most diplopods have a nearly circular body with short legs. In a few groups, the posterior part of each segment has broad lateral extensions (paranota), which, when horizontally directed, give the effect of a broad, flat body. In most diplopod orders, some species have glands that secrete a volatile fluid capable of repelling predators and killing fungi. Comparable glands are unknown in other myriapod classes.

The class Pauropoda includes a number of extremely small myriapods, remarkable in lacking well-developed tracheal and circulatory systems. The thin flexible body wall contains setae (bristles) in regularly arranged patterns. The body consists of 12 segments, including a pygidium, or terminal segment, and there are nine pair of legs. The dorsal, or back, side is modified to form from six to ten tergal plates. The head contains a pair of mandibles and a structure formed from a pair of fused maxillae, perhaps analogous to the millipede gnathochilarium. The most characteristic pauropod structures, however, are the paired antennae, composed of a four-jointed stalk with two branches, one long and one short.

Symphylid structure

Symphylid species are small, fragile, and lacking pigmentation. The head bears a pair of simple, multisegmented moniliform (beardlike) antennae, a pair of mandibles, and two pairs of maxillae similar to those of insects. As in the insects, the second pair of maxillae are fused into a so-called labium. The long slender body is composed of 12 leg-bearing segments provided with 15 or 22 tergites and a legless terminal segment bearing a pair of large cerci—sensory structures perhaps homologous with walking legs. On the legs, close to the juncture with the body, is a small projection called a stylus and a small saclike structure—characters presumably homologous with similar structures on the abdominal appendages of certain wingless insects. No other myriapods have these structures. A tracheal system and a simple dorsal circulatory vessel are present.

The external structure of members of the class Chilopoda (centipedes) approximates the ancestral, or least specialized, myriapod. The centipedes are characterized by one pair of legs on each body segment, by modification of the appendages of the first trunk segment into a pair of forceps-like fangs, and by the presence of two pairs of maxillae behind the small mandibles. The antennae are short, simple, beadlike, unbranched, and composed of a number of short unmodified segments. The head is flattened and covered by a single plate. The centipede body is typically elongated and more or less flattened. The body wall is chitinous and flexible and lacks calcium carbonate. Each body segment corresponds to an original embryonic somite and is composed of at least a dorsal tergum and a ventral sternum, with a variable number of smaller pleural sclerites in different patterns according to the taxonomic group. The body shows no differentiation into thorax and abdomen. The hindmost legs are often elongated or otherwise modified, particularly in the male. In some groups, the segment of the leg nearest the body may have glands opening on the lower side. In other groups, the sternal, or lower, body plates may likewise be perforated with minute ducts of internal glands.

In most chilopods, the mouthparts, located ventrally and well back from the front of the head, are relatively small and often quite fragile. What often appear to be functional mouthparts are the modified legs of the first body segment, turned forward beneath the head (often extending in front of it) and provided with poison glands opening through the tip. All species of centipedes thus are poisonous, a character not found in any other myriapod class. The tracheal system opens through spiracles, or pores, usually located on the sides of the body. The spiracles may form a continuous series or be absent from specific body segments.

Poison gland in centipedes

Evolution and paleontology. Information about the evolution of myriapods is deduced largely from the characters of living species. There is no fossil record for pauropods, and that for diplopods, symphylids, and chilopods is of little value. Apparently, however, all of these groups originated in the Devonian Period (about 345,000,000–395,000,000 years ago) during the great evolutionary radiation of terrestrial arthropods. The earliest diplopod fossils are from middle Pennsylvanian beds of the United States and central Europe. Some of these fossils represent living orders but have not been identified with certainty. The next oldest fossil diplopods are of the Oligocene Epoch (about 26,000,000–38,000,000 years ago), chiefly from northern Europe. All of the recognizable species from this period belong to modern families and genera. Chilopods and symphylids are not known with certainty earlier than the Oligocene. The fossils from that period represent modern genera.

There is general agreement that myriapods and insects share a number of common features, not only of morphology but also of embryological patterns and reproductive biology. It is generally believed that these groups originated in the Early Devonian or Late Silurian Period (about 395,000,000–400,000,000 years ago) from a common ancestral type probably bearing a close resemblance to modern symphylids.

Classification. *Distinguishing taxonomic features.* Myriapods may be identified on the basis of subtle, often concealed, characteristics—mouthparts, genitalia, pore and seta distribution. Perhaps less than 20 percent of the myriapod species have been discovered and classified. New families continue to appear, and the status of several orders remains uncertain. The classes comprising the myriapods are very different, although most live in temperate or tropical regions, have separate sexes, are mostly relatively small in size, and require moisture and shelter to survive.

Annotated classification. The classification of myriapods is not settled. Many categories are involved; the scheme below represents a brief summary of one of several possible schemes. The groups indicated with a † are extinct and known only from fossils.

MYRIAPOD

Myriapod is a general term used to describe members of 5 arthropod classes, consisting of about 11,000 known extant species; size range varies from 2 to 280 mm; important in maintaining ecological balance of tropical and temperate regions; most feed on dead plants, some (centipedes) are carnivorous.

† **Class Archipolypoda**

Apparently similar to diplopods, but with segmental elements less coalesced; head larger than body segments and provided with large compound eyes; possibly aquatic in habit; some species probably several feet in length; lived during Silurian and Pennsylvanian periods (about 280,000,000–430,000,000 years ago).

Order Euphoberiida. Characteristics same as those for class.

Class Diplopoda (millipedes)

Elongated myriapods; abdomen consisting of an indefinite number of double segments (diplosomites), most with 2 pair of legs; mouthparts consisting of mandibles and maxillae fused into a platelike structure, a gnathocilarium; trachea present; thorax with gonopores in the 3rd segment (progoneate); length 3 mm–28 cm; about 8,000 known species; Pennsylvanian to Recent.

Subclass Penicillata

Minute; 11–13 distinct body segments; both wall thin, with series and tufts of specialized bristles, without carbonate impregnation; sperm transfer to female indirect, by a spermato-

phore, or sperm-bearing, web constructed by male; about 80 species known; Oligocene to Recent.

Order Polyxenida. Three families, chiefly tropical; genus *Polyxenus* in North America and Eurasia.

Subclass Pentazonia

Small to large in size; body short and robust, segments consist of arched tergum, 2 pleura, 2 paramedian sterna separated by coxae; last pair of legs of male modified into clasping organ to hold female during sperm transfer; about 200 species; Pennsylvanian to Recent.

Order Glomeridesmida. One family in Indonesia, India, West Indies.

Order Glomerida. Two suborders: Sphaeriotheridea distributed throughout southern Africa, India, and Australasia (about 100 species); Glomeridideа distributed throughout the Northern Hemisphere and in Southeast Asia (about 150 species).

†*Order Amnilyspedida.* Flourished during the Pennsylvanian Period (about 280,000,000–325,000,000 years ago) in North America and Europe.

Subclass Helminthomorpha

"Typical" diplopods, usually elongated and slender; body segments usually cylindrical; sternum never divided; most sclerites coalesced; 7th pair of legs modified into gonopods for sperm transfer; about 7,600 species; Pennsylvanian to Recent.

Order Spirobolida. Chiefly tropical; 12 families; includes some of the most common and conspicuous diplopods.

Order Stemmiulida. One family with species in Central America, the West Indies, West Africa, South India, Ceylon, and New Guinea.

Order Polyzoniida. Two families: Polyzoniidae, native to the Northern Hemisphere; Siphonotidae, native to the Southern Hemisphere; species small, poorly known.

Order Siphonophorida. One family in tropical America and Southeast Asia.

Order Julida. Mainly in Northern Hemisphere; several hundred known species in 4 families; many species common in gardens.

Order Spirostreptida. Eight families; chiefly tropical; includes the largest known diplopod species, up to 28 cm (nearly 1 ft) long; other species less than ½ in.

Order Callipodida. Small group (3–4 families) chiefly in the Mediterranean region and in North America; agile, largely predatory species found in dry, rocky places and in caves.

Order Platydesmida. Two families; in the Northern Hemisphere and Southeast Asia; often colonial in habit; males of some species brood the eggs.

Order Chordeumida (Craspedosomatida). Many species in 20–30 families; occur mainly in the Northern Hemisphere; produce a silken thread to construct egg cocoons and molting chambers.

Order Polydesmida. A large, worldwide group of 40–50 families; all species eyeless; most with 20 body segments; body length from 3 mm to 13 cm (about ⅛–5 in.); often brightly coloured.

Class Pauropoda

Very small, length up to 1.9 mm; progoneate; 2 pairs of appendages transformed into mouthparts; usually 9 pairs of walking legs; branched antennae; circulatory and tracheal systems much reduced or lacking; about 180 living species known; worldwide distribution; no fossil record.

Order Pauropodida (Tetramerocerata). Three families; worldwide distribution.

Order Millotauropodida (Hexamerocerata). One family only in Madagascar.

Class Symphyla

Small, soft-bodied; 3 pairs of mouthparts, 12 leg-bearing segments; terminal segment with a pair of cerci (sensory structures); elongated moniliform antennae; gonopore usually on 4th trunk segment; length to 8 mm; about 120 living species known; in tropical regions; Oligocene to Recent.

Order Scolopendrellida. Characteristics same as class; 3 families.

Class Chilopoda (centipedes)

Elongated with many distinct abdominal segments, each with one pair of legs; head with moniliform antennae, 3 pairs of mouthparts; limbs of first abdominal segment modified as poison claws; gonopore on last segment (opisthogoneate); length about 5 mm–26.5 cm; about 2,800 living species known worldwide; Cretaceous to Recent.

Order Scolopendrida (Scolopendromorpha). Largest known chilopods, up to 26.5 cm (about 10 in.) but others less than an inch in length; large forms capable of inflicting severe bites; 2 families.

Order Geophilida (Geophilomorpha). Slender, extremely elongated; mostly burrowers, but some occur in caves and intertidal zones; nearly 200 pairs of legs in some species; 8 families.

Order Lithobiida (Lithobiomorpha). Short-bodied, fast-running species; body with 15 segments; found in North and South Temperate zones; about 6 families.

Order Scutigerida (Scutigeromorpha). Short-bodied species with extremely long legs; mouthparts leg-like in appearance; stigmata opening middorsally; found chiefly in tropical regions; one family.

Critical appraisal. Previous classificiation of myriapods have been to a large extent, based on the writing of C. Attems, one of the great authorities on these animals; his classification was summarized in 1926 (see below *Bibliography*). Many of Attems' concepts originated from those of earlier workers; he was conservative both in defining groups and in naming them. The arrangement of diplopod groups has undergone many changes and is still being modified. A revised list of higher categories was published by Ralph Chamberlin and Richard Hoffman in 1958 and another by the latter in 1969.

Because several myriapod features are found also in insects, and because the transition between symphylids and true winged insects is so gradual, some authorities would include the insects with the other myriapod groups in a subphylum Myriapoda. Other authorities (see bibliography under Tiegs and Manton) defend the traditional viewpoint that insects should be maintained as a category with rank equivalent to the myriapod classes; the latter is the arrangement followed in the classification scheme above.

The features of the various myriapod classes are sharply differentiated. An earlier arrangement of grouping the Diplopoda, Pauropoda, and Symphyla into a category called Progoneata and of grouping the Chilopoda and Insecta into an equivalent category called Opisthogoneata has been discredited as having been based upon a character—position of the gonopore of the male—of only secondary importance.

Formerly, the millipedes and centipedes were grouped together as the class Myriapoda, but their features differ to such an extent that each is now given class status.

BIBLIOGRAPHY. CARL GRAF VON ATTEMS, "Myriopoda," in W. KUKENTHAL and T. KRUMBACH (eds.), *Handbuch der Zoologie*, vol. 4 (1926), the best general, illustrated reference (in German) to myriapods, although the classification is out of date; R.V. CHAMBERLIN and R.L. HOFFMAN, *Checklist of the Millipeds of North America* (1958), the only recent complete list of diplopods, now outdated; ALFRED KAESTNER, *Invertebrate Zoology*, vol. 2, trans. and adapted by H.W. and L.R. LEVI (1968), contains a good chapter on the myriapods; A.G. SHAROV, *Basic Arthropodan Stock* (1966), the view of an eminent Russian paleontologist, highly controversial in many areas, but with interesting insights and valuable information; R.E. SNODGRASS, *A Textbook of Arthropod Anatomy* (1952), an excellent introductory account of the morphology of all arthropod groups, beautifully illustrated; O.W. TIEGS and S.M. MANTON, "The Evolution of the Arthropoda," *Biol. Rev.*, 33:255–337 (1958), a detailed and comprehensive review of the subject, including an historical survey of earlier works.

Myrtales

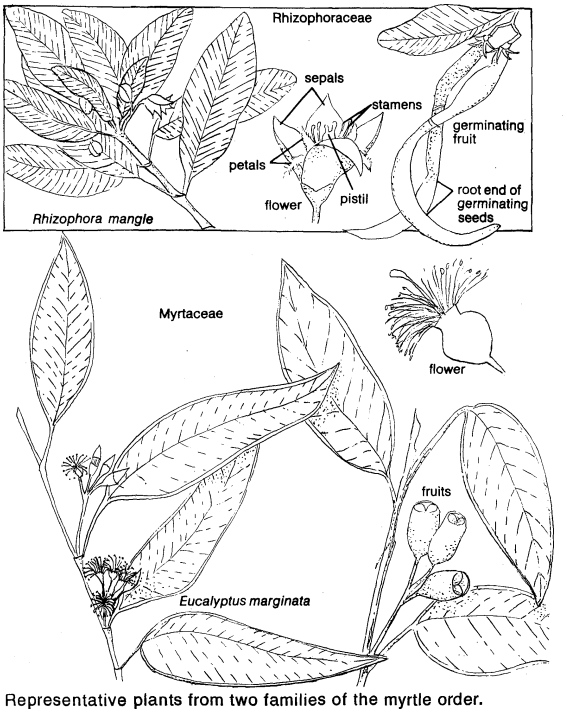
The Myrtle order (Myrtales) consists of over 400 genera and nearly 10,000 species of flowering plants, and its representatives grow in a variety of habitats throughout the world. Members of the family Melastomataceae are particularly abundant in Brazil, where they form a characteristic component of the vegetation. In many parts of Australia, Myrtaceae is the most prominent plant family, with the genus *Eucalyptus* forming large forests. These two families are the largest in the order, and together they account for approximately three-quarters of the total genera and species.

GENERAL FEATURES

Predominance of the woody habit, either as shrubs or trees, is a feature of the order, and some members of the genus *Eucalyptus* are among the world's tallest trees. *E. regnans*, the mountain ash of Victoria and Tasmania, commonly attains a height of over 300 feet (90 metres), and an exceptional specimen was once measured at 370 feet (113 metres). Some herbaceous (nonwoody) species, however, occur in the families Lythraceae, Melastomataceae, and Onagraceae, while the family Trapaceae consists entirely of herbaceous annuals (plants entirely completing a life cycle in one growing season). In the Lythraceae family, there is an association between habit and climate; in temperate regions, the species are annual or perennial herbs, whereas in warmer areas they are often woody shrubs and, sometimes, trees. In the family Penaeaceae, which is confined to rather dry areas of southwestern and southern Africa, the plants are small shrubs of heathlike habit adapted to dry-wasteland habitats. Diversity in size and habit is exhibited by members of the family Melastomataceae, which includes, as well as shrubs and trees, root climbers, epiphytes (plants that are not rooted in soil but live among the branches of trees), and herbaceous marsh and water plants. A similar range of variation is seen in the family Onagraceae which is found in the subtropics and temperate zones.

Diversity of growth forms

Drawing by R. Findahl



Representative plants from two families of the myrtle order.

Distribution and abundance. Members of this order are to be found chiefly in the tropics and subtropics, but most families have some representatives in temperate regions. Apart from the families Oliniaceae and Penaeaceae, which are restricted to the southern half of Africa, all families are widely distributed either as native plants or, as in the families Punicaceae and Myrtaceae, as introduced species through extensive cultivation. The widest natural distribution is that of the Onagraceae family, which has its chief development in the temperate zones of the Americas, particularly in the western regions. Its largest genus, *Epilobium*, is composed of some 160 species and is cosmopolitan except in the tropics. The family Lecythidaceae is found throughout the tropics, but the family Combretaceae, although mainly tropical, extends into the subtropics. The Lythraceae family has representatives in a variety of climatic zones, but it is most abundant in tropical America. The number of its species declines rapidly toward the temperate regions, and it is absent from the cold zones. *Lythrum salicaria* is one of the few plant species found in both Old and New Worlds, and its range covers Europe, through Asia to Japan, as well as North America and southeastern Australia. Melastomataceae, the largest family, is also mainly tropical, but its members extend into the subtropics and more temperate regions. About 2,000 of its species are native to the American continent. Two main centres of development of the family Myrtaceae are recognized: tropical America, for the berry-fruited members, and Australia, where the dry-fruited species predominate. The 600 species of *Eucalyptus* are distributed throughout Australia from the semi-arid regions to the coastal forests. The most widely spread genus is *Myrtus*, which grows in the warmer regions of both hemispheres; and the myrtle (*M. communis*) is either long naturalized in Europe or the only native *Myrtus* member in that continent. Mangrove species of the Sonneratiaceae and Rhizophoraceae families are found along tropical seacoasts, although the latter family is mainly Old World. *Rhizophora mangle* is the only native mangrove species in America, and it is restricted to peninsular Florida. The related family Anisophylleaceae is exclusively tropical, and the family Trapaceae is found from central and southern Europe to eastern Asia and from tropical to subtropical Africa.

Importance. Economically, the most important single genus is *Eucalyptus*, many of whose species are a valuable source of hardwoods. Because of their rapid growth rate, they are now grown widely throughout the temperate regions of the world as shade trees or in forestry plantations. In addition, oils with fever-controlling and germicidal properties, gums, and resins are extracted from their leaves and wood, while some species are of importance as a source of nectar and pollen for hive bees. Other members of the Myrtaceae family used for timber are *Metrosideros* and *Angophora*, and the pungent, medicinal cajeput oil is extracted from the paperbark tree, *Melaleuca leucadendron*. Two members of the Lythraceae family used as a source of good timber are the tulipwood tree of Brazil, *Physocalymma scaberrima*, and *Lagerstroemia flos-reginae* of eastern India, while *Terminalia* of the family Combretaceae and *Lecythis* and *Couroupita* of the Lecythidaceae family are also valuable timber trees. For underwater constructions such as piers and jetties, whole trunks of the mangrove *Rhizophora* are widely used because their tannin content inhibits attacks from marine wood-boring animals. Although the order is not of great importance as a source of food, edible fruits are produced by some members of most families. The most widely known is probably the pomegranate (*Punica granatum*), which is now cultivated in the warmer regions of the world for its fruit and also as an ornamental shrub. In the Myrtaceae family the guava (*Psidium guajava*), strawberry guava (*P. cattleianum*), and many species of *Eugenia* are of local value, such as the Brazil cherry (*E. michelii*), the Surinam cherry (*E. uniflora*), the Otaheite apple (*E. malaccensis*) and the rose apple (*E. jambos*). The dried flower buds of *Syzygium aromaticum* are the spice cloves of commerce, and the powdered unripe fruit of *Pimenta dioica* is allspice. The water chestnut (*Trapa natans*) is eaten in China, and the fruits of *T. bispinosa* are the source of the singhara flour of northwestern India. Other edible fruits are found in the genus *Maietia* of the Melastomataceae family and in some species of *Fuchsia*, while in tropical Africa a butter-like substance, chiquito, is obtained from the fruits of *Combretum butyrosum*. The family Lecythidaceae is notable for the Brazil nut (*Bertholletia excelsa*) and sapucaia nuts (*Lecythis*), for the oil extracted from the seeds of *Barringtonia*, and for the anchovy pear (*Grias cauliflora*), cultivated in the West Indies. The family Combretaceae supplies the Indian, or country, almond (*Terminalia catappa*) and the myrobalan nuts (*T. chebula*), but the only edible products of the family Anisophylleaceae are the poga nuts (*Poga oleosa*). Other products from members of this order are a red cosmetic dye from *Lawsonia inermis* and *Woodfordia floribunda* of the family Lythraceae, fibre for textiles from the soft bark of *Couratari* (family Lecythidaceae), colouring matter from some of the members of Melasto-

Edible fruits and other useful products

mataceae family, and tannins for tanning hides from the bark and foliage of *Rhizophora* and *Terminalia*. Many species of the Lythraceae family are horticulturally important as shade trees or as garden plants, such as crape myrtle (*Lagerstroemia*), mignonette or henna tree (*Lawsonia*), loosestrife (*Lythrum*), and cigar flower (*Cuphea*). Horticulturally important plants in the Myrtaceae family are *Eucalyptus*, myrtle (*Myrtus communis*), geraldton waxflower (*Chamaelaucium*), bottlebrush (*Callistemon*), and many others, including beautiful horticultural hybrids of *Leptospermum*. The family Melastomataceae provides the garden shrubs *Medinilla*, *Heterocentron*, and *Tibouchina* and the small vine *Schizocentron*, which is grown in hanging baskets. The herbaceous annuals or perennials of the Onagraceae family, such as those found in the genera *Oenothera*, *Clarkia*, and *Godetia*, as well as the shrubby *Fuchsia*, are familiar cultivated plants throughout the world.

NATURAL HISTORY

Life cycle. The flowers of most species have both male and female parts in the same flower (perfect, or bisexual, flowers), but those of the Sonneratiaceae, Anisophylleaceae, and Combretaceae families may have flowers of only one sex; structures of the opposite sex, though originally present, fail to mature in these cases. At the completion of meiosis (nuclear reduction division leading to gamete, or sex-cell, formation) in the anthers, the microspores remain joined together for a short time in tetrads, or clusters of four, before they separate as pollen grains. In the genus *Epilobium*, however, they remain together as permanent tetrads and are liberated as such when the anthers split open. In most members of the Onagraceae family, the pollen grains are connected by viscid threads that stick to a visiting insect; thus, hundreds of pollen grains are drawn out of the anther together. When mature, the pollen is usually two celled; *i.e.*, it consists of a large vegetative or pollen tube cell and a smaller generative cell. In the Lecythidaceae and Melastomataceae families, however, the generative cell has already divided to form the two male gametes, or sperm cells, when the anthers ripen and split. The pollen grains in these families are therefore three celled, while in the Combretaceae family both two- and three-celled conditions are shown by different species.

Family differences

Within the ovary are one or more future seeds, or ovules, each of which is provided with two seed coats, or integuments. In the centre of each ovule is the embryo sac, or female gametophyte, one of whose cells, the egg, develops into the embryo after it has been fertilized by a male gamete from a pollen grain.

In *Eucalyptus*, only relatively few of the ovules present in each ovary develop into seeds, and the majority are sterile because they lack embryo sacs. These are the ovulodes, which later shrivel and form the chaff that is shaken out of the mature capsule, together with the few viable seeds.

Pollination. Although normally the flowers open when mature, the opposite condition, of mature flowers remaining closed (cleistogamy), occurs in *Ammania* and *Rotala* of the family Lythraceae and in *Jussiaea acuminata*. The last mentioned plants grow near the Sahara in locales where the ground temperatures of 70°–80° C (158°–176° F) are too hot for insects, and there the mature flowers remain closed. Usually when mature flowers remain closed it implies self-pollination, but, in *Purpurella cleistoflora* of the family Melastomataceae, robber bumblebees effect cross-pollination when they force an entrance to the flowers in search of pollen. The normal condition, of mature flowers unfolding, however, does not necessarily mean that cross-pollination takes place, and the British *Epilobium* species form a series from the small-flowered, largely self-pollinated species to those with large, insect-pollinated flowers. Pollination by wind occurs in some of the fuchsias and perhaps in *Eucalyptus*, but usually the transfer of pollen is accomplished by insects, chiefly bees or moths and butterflies. In certain species of the Lecythidaceae and Melastomataceae families, however, hummingbirds are the pollinators, and honey eaters are the pollinators in the larger flowered members of the Myrtaceae family. *Metrosideros excelsa* of New Zealand relies for its pollination on a forest bird, the tui, which migrates in early summer to the coast of the North Island in search of nectar. In Brazil, flowers of the genus *Feijoa* are visited regularly by small birds that eat the sweet, fleshy petals. The most complex cross-pollination mechanism in the order is that of *Lythrum salicaria*, which produces three forms of flowers on different plants. The stamens, pollen grains, styles, and stigmas likewise are of three different shapes, and only certain crosses are effective in seed production.

Postfertilization events. Following fertilization, nuclear endosperm, a special nourishing tissue for the developing plant embryo, is formed in the embryo sac. This tissue subsequently becomes cellular, except in the Melastomataceae family, where it is digested by the growing embryo while it is still in the free-nuclear condition. In all other families it is the cellular endosperm that is digested, and the mature seeds are nonendospermic. Extrusion of the endosperm through the broad micropyle opening of the ovule to form haustoria, special absorbing organs, is a feature of the family Rhizophoraceae, and these may play a supplementary role in the nutrition of the embryo. The genus *Trapa* is unique in the Myrtales order in that the primary endosperm nucleus degenerates, and so no endosperm is formed, but the lack of this source of nourishment for the embryo is compensated for by its formation of a haustorial suspensor, which invades the tissues of the ovule outside the embryo sac.

Early development of the seed

The embryo is dicotyledonous (*i.e.*, it has two cotyledons, or "seed leaves"), but in the Penaeaceae family the cotyledons are minute, and in the Anisophylleaceae family they are either very small or absent. In the Melastomataceae and Trapaceae families, one cotyledon is much smaller than the other and is sometimes reduced to a scale. Polyembryony, the presence of several embryos in each seed, has been reported in several families of the order and is very common in *Myrtus communis* and *Eugenia*. In *E. paniculata* up to 21 embryos have been found in a seed, and it is unusual for there to be fewer than two.

The fruit varies from dry to fleshy, these extremes often occurring within the same family. In the genus *Lecythis* (the monkey pot), the tissues giving rise to the stamens in the flower persist and enlarge to form a lid, which separates when the fruit is ripe, and in *Bertholletia excelsa* the hardened persistent sepals (green, leaflike structures next to the petals in a flower) form a plug that is later dislodged during seed germination, and the seedlings escape through the opening.

Vivipary is a feature of many of the mangroves; that is, the seed germinates while the fruit is still retained on the tree, and, following growth of the seed leaves, the root end of the embryo elongates and passes through the micropyle opening in the ovule and then through the ovary wall. In some instances it may reach three feet in length before the seedling drops into the mud, where it establishes itself at once. In *Couroupita guianensis* and *Grias cauliflora* (family Lecythidaceae) and *Myrciaria* (family Myrtaceae) the flowers and, later, the fruits are borne directly on the old wood of the trunk. This is known as cauliflory, and in *Couroupita* the large, round, woody fruits attached to the trunk are responsible for the name cannonball tree.

Unusual responses to the environment. Those species of *Eucalyptus* that grow on poor soil in low-rainfall areas show a prominent development of the lignotuber, a woody rounded knot or lump surrounding the base of the tree trunk and usually partly or entirely underground. Such trees have a multistemmed type of growth and remain small, both in height and in stem diameter. A similar environmental response may be exhibited in medium- to high-rainfall localities in individuals growing on very shallow soil on the tops of ridges, while members of the same species growing on deeper soil nearby show no lignotuber development and have normal growth. In the Onagraceae family, temporary adaptation to an oxygen-deficient environment is seen in the genus *Jussiaea*. When plants grow in water, air spaces develop in the tissues of

the roots and submerged stems, and in *J. repens* some special spongy-tissued respiratory roots grow to the surface of the water. The same plants under ordinary dryland conditions do not exhibit these features.

Ecology. Certain members of the order are adapted to special ecological situations. For example, *Trapa* and some species of the Melastomataceae and Onagraceae families are aquatic or marsh plants, while the mangroves require habitats found only along tropical muddy seashores or estuaries. Both epiphytes and root climbers of the Melastomataceae family are confined to tropical forests, but the genus *Penaea*, with its low, shrubby habit, is adapted to life in dry parts of southwestern and southern Africa. The fireweed *Epilobium angustifolium* is one of the first plants to appear after fire devastation or other disturbances, such as bulldozing, and it achieved fame by its rapid colonization of bomb sites in Great Britain during World War II.

FORM AND FUNCTION

No structural characters are common to all families of this order. Vegetatively, many of the plants are woody perennials, and most bear opposite leaves, but variation both between and within the families is considerable, and the concept of the order is based on flower structures. Of these, the most important is the form of the receptacle, which forms a floral tube of varying length and degree of attachment to the wall of the ovary (female seed-bearing structure).

Growth peculiarities are apparent in some members of the order. For example, the alternate adult leaves of *Eucalyptus* assume a vertical position by twisting of the petiole (leafstalk) during development, but this feature is not exhibited by those species that bear permanently juvenile foliage, in which the leaves are opposite instead of alternate. In the family Combretaceae, two types of leaf arrangement occur in one genus, *Quisqualis*. Alternate leaves are borne on the stem, but in the flowering shoots the leaves are opposite, and, in some climbing species, the petiole bases persist as hooks after the leaves have dropped. Probably the most unusual growth form is that exhibited by the mangroves of the Sonneratiaceae and Rhizophoraceae families, in which portions of some roots grow upward through the mud until they project some inches above low-tide level. These "breathing roots" bear small openings in their bark and act as aerating organs. Aerial prop roots are also a feature of most mangroves, and these persist, forming a tangled jungle, even after the main roots and stem bases of the trees have decayed. The genus *Terminalia* also possesses breathing roots, and loose internal cell tissue containing air spaces occurs in the submerged portions of the stems and roots of marsh-inhabiting species of the family Melastomataceae. *Trapa*, a floating annual, is supported by the inflated petioles of its floating leaves, while its submerged leaves are finely divided and resemble roots. An interesting association with ants is exhibited by some members of the Melastomataceae family, such as *Maietia* and *Tococa*. In these, saclike outgrowths are formed on the upper surfaces of the leaves and sometimes on the petioles, and they serve as shelters (*dormatia*) for ants, which enter them from the lower surface. The ants protect the flowers from all but the legitimate flower pollinators by swarming out of hiding at any unusual disturbance of the branch.

The mangrove habit of growth

EVOLUTION

The fossil record has not contributed to an understanding of the origin of the Myrtales order, but its families, as now known, were probably all defined by Tertiary times (*i.e.*, by about 65,000,000 years ago). Theories advanced as to their evolution rest largely on deductions from comparative structural studies of living species and are, therefore, subjective. Most such schemes are based on details of floral structure. Accordingly, the perigyny–epigyny (*i.e.*, position of the flower petals and other flower parts relative to the ovary, being either "around" or "above" it) shown by the typical flower of the Myrtales order is seen as the expression of an evolutionary tendency initiated in the Saxifragales order. Because of its perigynous–epigynous flowers, the Saxifragaceae family of that order has been favoured by many as an ancestral family. It is considered by some authorities, on the other hand, that vegetative features are a more reliable guide to ancestry than those associated with reproduction (*i.e.*, the flower). On this basis, they recognize in flowering plants two independent but parallel lines of descent: the fundamentally woody families and the fundamentally herbaceous families. According to this concept, the families Lythraceae, Onagraceae, and Trapaceae in the Myrtales order may then be grouped into an order, the Lythrales, that can be thought to have arisen through the order Caryophyllales from the most primitive herbaceous flowering plants, and the remaining families can be traced ultimately from the most primitive woody flowering plants of the order Magnoliales.

CLASSIFICATION

Distinguishing taxonomic features. The chief botanical feature of importance in classification in the Myrtales order is the nature of the floral tube (receptacle, or hypanthium), whose form ranges from the free tubular condition of varying lengths to that of its partial or complete fusion with the ovary wall. This is the most important taxonomic character, and many taxonomists consider that its variation in expression between—and sometimes within—the component families represents an evolutionary sequence that reaches its final expression in epigynous flowers (*i.e.*, "inferior-ovary" flowers, those with flower parts appearing to arise at the top of the ovary rather than at its base). The number of component families in the Myrtales order varies in different classifications according to the authority. The form of the flower, the shape of the floral tube or receptacle, and the degree of its fusion with the ovary wall are characters of primary importance, but the number, arrangement, and points of origin of the stamens, as well as details of the female flower parts, are also taken into account. Vegetative features such as the form and arrangement of the leaves, the presence or absence of stipules (small, leaflike appendages at the bases of leaves), and the occurrence of internal phloem (an additional layer of special conducting cells inside the stem, varying from the usual presence of only one layer just beneath the bark) are of secondary taxonomic value.

Criteria used to define members of the order

Annotated classification. Although there are some differences in the families included in the Myrtales order by different authorities, the following is a good recent treatment. Because the number of genera and species of each family also varies among authorities, the numbers given below should be considered to be no more than a general guide.

ORDER MYRTALES

Flowers usually regular, bisexual, and 4- or 5-merous (lobed or parted), with a floral tube and showing various degrees of perigyny leading to epigyny (fusion of the floral tube around and above the ovary). Stamens are usually free, but the ovary is syncarpous (of fused sections), and the style (the slender upper part of the ovary) is simple. Fruits are either dry or succulent, with nonendospermic seeds. The order consists of mostly woody shrubs or trees with usually opposite, simple, entire leaves. Internal phloem is present in the stems of all except the Rhizophoraceae and Lecythidaceae families, but this information is not available for the Punicaceae, Anisophylleaceae, or Oliniaceae families.

Family Lythraceae

Sepals 4–6, petals 4–6 or none, stamens in 2 series of either 4+4 or 6+6, carpels (ovary sections) 2–6 fused. Flowers perigynous, rarely bilaterally symmetrical, with a spurred floral tube in the genera *Cuphea* and *Pleurophora*, and borne in racemes, panicles, or cymes. Appendages sometimes present between the sepals; petals crumpled in the bud, commonly red or purple. Fruit a capsule. Leaves opposite or whorled, stipules minute or none. Chiefly tropical, but found in all zones except frigid. About 25 genera, 470 species.

Family Sonneratiaceae

Sepals 4–8, petals 4–8 or none, stamens numerous, carpels 4–15 fused. Flowers sometimes unisexual, being either male or female, perigynous, solitary, or in 3-flowered cymes or corymbs. Calyx lobes persistent; petals often crumpled in the bud. Fruit a capsule or berry. Leaves opposite or whorled, without

stipules. Tropical coasts from eastern Africa to Australia, Polynesia, and Indomalaya. About 3 genera, 12 species.

Family Punicaceae
Sepals 5–8, petals 5–8, stamens numerous, carpels 3–7, fused. Flowers epigynous, solitary or in cymes. Sepals fleshy, persistent; petals crumpled in the bud, scarlet. Fruit berrylike. Leaves usually opposite or whorled and without stipules. Balkans to Himalayas; Socotra, an island off Yemen. One genus, *Punica,* with 2 species, one of which is the cultivated pomegranate, *P. granatum.*

Family Rhizophoraceae
Sepals 4–8, petals 4–8, stamens numerous, carpels 2–5 fused. Flowers slightly perigynous to epigynous, solitary or in cymes. Sepals fleshy and persistent, petals lobed or with lacerate margins, convoluted in the bud. Fruit a berry, rarely a capsule or drupe. Leaves opposite, often leathery, with early-deciduous stipules and branches swollen at the nodes. Tropical, mostly Old World, also found in Australia, Polynesia, and Florida. About 16 genera, 120 species.

Family Anisophylleaceae
Sepals 4, petals 4, stamens 8, carpels 4 fused. Flowers often unisexual, epigynous, borne in spikes. Sepals with erect lobes; petal margins entire, lobed or lacerate. Fruit dry, rarely a drupe or winged capsule. Leaves alternate, with 3–5 main veins, without stipules, often in 2 rows; alternate leaves may be small or minute. Tropical America, Asia and Africa. About 4 genera, 36 species.

Family Combretaceae
Sepals 5, petals 5 or none, stamens in two series of 5+5, carpels 1. Flowers epigynous, usually small, occasionally zygomorphic (bilaterally symmetric) in spikes or racemes. Sepals persistent; petals absent in the genus *Terminalia.* Fruit dry or drupelike, occasionally winged. Leaves alternate or sometimes opposite, without stipules. Found throughout the tropics, rare in subtropics. About 18 genera, 600 species.

Family Lecythidaceae
Sepals 4–6, petals 4–6 or none, stamens numerous and joined, carpels 2–6 fused, the ovary with as many chambers as carpels. Flowers sometimes zygomorphic, perigynous to epigynous, solitary or in racemes. Sepals persistent; petals lacking in the genus *Napoleona,* in which a corona is formed of petallike sterile stamens. Fruit a berry or capsule, sometimes very large, woody, and not splitting open at maturity. Leaves alternate with marginal glands, often very large, without stipules. Tropical America, west tropical Africa, northern Australia, Indomalaya. About 20 genera, 150 species.

Family Myrtaceae
Sepals 4–5, often small or even absent, petals 4–5, fused in *Eucalyptus* to form a cap that is shed when the flower opens, stamens numerous and often conspicuous, carpels one or many but fused. Flowers perigynous to epigynous, in cymes or rarely racemes or spikes. Sepals often persistent; petals usually nearly circular. Leaves usually opposite, leathery, gland-dotted, without stipules. Those with fruit a berry, rarely a drupe, are placed in the subfamily Myrtoideae. Those with leaves often alternate and fruit a capsule comprise the subfamily Leptospermoideae. The remainder belong to the subfamily Chamaelaucoideae, which is defined by dry fruits that are usually 1-seeded. Tropics and subtropics. About 100 genera, 3000 species.

Family Melastomataceae
Sepals 4–5, petals 4–5, stamens 8–10, carpels 4–5, fused. Flowers perigynous to epigynous, sometimes slightly zygomorphic, in cymes. Sepals may be reduced to a rim or united into a cap. The anther connective often extended into a conspicuous appendage. Fruit a capsule, but a berry in epiphytes. Leaves usually opposite, and each pair is arranged at right angles to the next pair on the stem, with one member of each pair often small and falling with age, the 3–9 longitudinal leaf veins connected by side branches, leaves without stipules. Found throughout the tropics, mainly in South America, less common in subtropics. About 200 genera, 4,000 species.

Family Oliniaceae
Sepals 4–5, petals 4–5, stamens 4–5, carpels 3–5 fused. Flowers epigynous, in cymes. Calyx teeth minute and deciduous or absent; petals alternating with small coloured scales. Fruit a drupe. Leaves opposite, with comblike or feather-like "nerves," or veins, without stipules; branches 4-angled. Southern and eastern tropical Africa. 1 genus, 10 species.

Family Penaeaceae
Sepals 4, petals absent, stamens 4, carpels 4, fused. Flowers perigynous, solitary or in pairs. Sepals persistent. Fruit a capsule. Leaves small, opposite, adjacent pairs at right angles to each other on the stem, mostly without petioles, stipules minute, glandlike, or absent. About 5 genera, 25 species.

Family Onagraceae
Sepals 4, petals 4, stamens in two series of 4, carpels 4, fused. Flowers epigynous, occasionally zygomorphic, solitary or in spikes, racemes, or panicles. Sepals bent downward or backward in the open flower; petals occasionally absent. Fruit a capsule, sometimes a berry or a nut. Leaves alternate, opposite, or whorled, rarely with stipules. Subtropics and temperate zones. About 20 genera, 650 species.

Family Trapaceae
Sepals 4, petals 4, stamens 4, carpels 2, fused. Aquatic plants with perigynous, solitary flowers. Sepals persistent, becoming hard and spinelike. Fruit a 1-seeded drupe with fleshy, early-deciduous ovary wall. Floating leaves in a rosette arrangement, each roughly diamond-shaped with toothed margins, without stipules; submerged leaves opposite, finely divided. Central and southeastern Europe, temperate and tropical Asia and Africa. One genus, *Trapa,* with either 30 species or, according to some authorities, 1 polymorphic (*i.e.,* having many forms) species.

Critical appraisal. Earlier taxonomic treatments of this order recognize 23 families in four suborders. The more recent view presented here, however, defines the order to include only 12 of the former families, and it recognizes the family Anisophylleaceae as a 13th independent, though closely related, family near the family Rhizophoraceae.

WILLIS, *The Eucalypts: Botany, Cultivation, Chemistry and Utilization* (1961), a very useful discussion of the economic products of eucalypts containing a good summary of growth habits, floral morphology, and leaf types.

(G.L.D.)

Mysore

The state of Mysore, situated on the west coast of India, is the seventh largest in area and the eighth largest in population of the 21 constituent states of the Republic of India. With an area of 74,037 square miles (191,757 square kilometres) and a population of about 29,000,000, it coincides approximately with the area in which the Kanarese, or Kannada, language is spoken. It is bounded by the territory of Goa and the state of Mahārāshtra to the north, by the state of Andhra Pradesh to the east, the state of Tamil Nadu to the southeast, the state of Kerala to the south, and the Arabian Sea to the west. The state extends for about 420 miles from north to south and for about 300 miles from east to west. It has a coastline 200 miles long. The state capital is the city of Bangalore (population about 1,600,000), near the southeastern border.

While it forms a coherent linguistic unit, Mysore—which includes a coastal region, part of the hill ranges known as the Western Ghāts, and the Mysore Plateau in the interior—does not coincide with natural physical boundaries. Before the independence of India in 1947, Mysore was a prosperous and progressive but landlocked princely state, with an area of less than 30,000 square miles and a population of about 7,000,000 situated on the plateau. The transfer of additional territories to the state

in 1953 and 1956 united the Kanarese-speaking peoples, gave the state an outlet to the sea, and greatly extended its boundaries. Mysore has abundant hydroelectric power and extensive forests. It is also India's chief source of gold, produces nearly two-thirds of its coffee, and also provides the bulk of the world's supply of sandalwood.

Economic importance

History. The name Mysore (from the Hindu word for "buffalo town") derives from the destruction of Mahiṣāsura by the goddess Cāmuṇḍā. The prehistory of Mysore is lost in legends that concern the struggles that took place in southern India between invading Aryan peoples and the original inhabitants; in legendary form this is represented as a conflict between devils and demons on the one hand and gods and goddesses on the other. The subsequent history of Mysore deals mainly with the state as it was before its expansion in 1953 and 1956, for no dynasty succeeded in ruling the whole region occupied by the Kanarese-speaking peoples, which is called the Karnatak (Kanara), sometimes referred to by Westerners as the Carnatic.

After the reign of Aśoka, the Mauryan emperor of India, in the 3rd century BC, the principal dynasties in the area of Mysore were the Kadambas of Banavasi, the Western Gaṅgas (who were in power from the 3rd to the 11th centuries AD), the Bānas, and other feudatories of the Pallava dynasty, which ruled from about the 4th to the 9th centuries. The rich lands of the upper Tungabhadra region and the land between that river and the Krishna River were taken from the Kadambas in the 6th century by a central Karnatak family, the Cālukyas. Their efforts, and those of their competitors of the Rāṣṭrakūṭa dynasty, to unite the plateau and exploit the softer lands of the coastal plains enriched Mysore but led to reprisals from the Tamils to the east and south. By the 12th century the Hoysaḷa dynasty had absorbed Gaṅgavāḍi (as the state of Mysore was then called); but after the Hoysaḷas had been obliged to submit to the sultan of Delhi, Mysore gradually came under the sway of the state of Vijayanagar, whose capital of the same name stood on the site now partly occupied by the village of Hampi on the Tungabhadra River in contemporary Mysore. In the latter part of the 16th century the Vijayanagar Empire faded, giving place to Mughal power north of the Tungabhadra River and to the rajahs of Mysore in the south. In the 17th century the *wadiyars* ("rulers") of Mysore profited from the conflict between the Mughal Empire and the Marāthās in western India, as well as from the internal power struggles that occurred in the Mughal Empire after the death of Aurangzeb, to expand their rule. In 1610 the *wadiyar* of Mysore seized Srirangapatnam (Seringapatam); later, Bangalore was also acquired and *wadiyar* power consolidated. Later, maladministration at home and interference in wars of succession in the plains led to the usurpation of power in 1761 by the military adventurer Hyder Ali. His invasions of Malabar and the Karnatak plains extended Mysore's dominion but eventually led, after the resulting Mysore Wars, to the death of his colourful and energetic son Tippu Sultan in 1799 and to the conquest of Mysore by the British, who sponsored the restoration of *wadiyar* rule. From 1831 to 1881 Mysore was governed by a British commissioner, after which administration was once again restored to the *wadiyars*. The last of the *wadiyars* became governor of the state after the territorial reorganizations of 1953 and 1956.

The Hyder Ali episode

Physical and natural landscape. Physiographically, Mysore is divided into four distinct regions—the coastal plain, the hill ranges (the Western Ghāts), the Mysore Plateau to the east, and the black cotton soil tract to the northwest. The coastal plain represents a continuation of the Malabar Coast and experiences heavy rainfall from June to September, when the southwest monsoon winds blow. Coastal sand dunes give place inland to small alluvial plains with coconut-fringed lagoons. The coast is difficult of access, except by sea. To the east the land rises sharply to the slopes of the Western Ghāts, which have an average height of about 3,500 feet above sea level. Covered with forest, the Ghāts form a region known as the *malnad*; it is also a watershed, and from its crest numerous swift streams, including the Sharavati River, which is associated with the Gersoppa Falls, flow to the plains. Other streams flow over the undulating Mysore Plateau, which slopes gently eastward. The plateau region has an average height of about 1,500 feet above sea level; its soils are generally porous and infertile. The basins of its rivers, however, which include the Cauvery and the Tungabhadra, which is a tributary of the Krishna River to the north, are loamy and of some fertility. From early times the smaller streams have been dammed to form irrigation reservoirs; in recent times much hydroelectric power development has taken place. In the northwest part of the state, underlying volcanic rock produces a soil known as regur, the humus-rich black cotton-growing soil of India.

Passing from west to east, the *malnad* gives way on the plateau to more open plain country, known as *maidan*, where rainfall is less and where monsoon forests are replaced by scrub forests and scrubland. The monsoon forests are rich in wildlife, which includes tigers, elephants, bison, and deer. In the *maidan*, wild boar, bears, panthers, and leopards may be encountered. Among the common birds is the peacock.

Population. Mysore had a population of about 29,200,000 in 1971, at which time Bangalore, the capital, had a population of about 1,650,000, and the city of Mysore 356,000. Other important towns are Hubli-Dhārwār 380,000; Mangalore 214,000; Belgaum 214,000; Gulbarga 146,000; Bellary 125,000; Dāvangere 121,000; Bijāpur 103,000; Shimoga 103,000; and Bhadravāti 101,000.

Ethnologically, the population of Mysore is predominantly Dravidian. The Dravidians were the original inhabitants of India and are related to the peoples of the Malay Peninsula, Sumatra, and Madagascar. Over the centuries, however, much intermixture with other races has occurred. In the north of the state, Aryan traits, mixed with Dravidian, occur. Some Anglo-Indians, representing a mixture of European and Dravidian, are occasionally encountered, particularly in Bangalore.

The Dravidian population

Kannada is the language spoken by more than 65 percent of the population, although Hindustani (a mixture of Hindi and Urdu) is often used in trade and business. Toward the borders of the state other languages, such as Tamil, Telugu, Marathi, and Konkani, are also spoken. Konkani is associated particularly with the city of Mangalore.

The major religion is Hinduism, but Jainism and Buddhism—once widespread—still survive. About 10 percent of the population follows Islām, and 2 or 3 percent is Christian.

While about 76 percent of the population is rural and only about 24 percent urban, the trend toward urbanization is becoming more marked as industrialization increases.

Administration. The state is divided into 19 districts, which are grouped into the four administrative divisions of Bangalore, Mysore, Belgaum, and Gulbarga. The head of state is the governor, who is appointed by the president of India. The bicameral legislature consists of a legislative council of 63 indirectly elected members and a legislative assembly of 208 directly elected members. The chief minister is assisted by a council composed of ministers of cabinet rank. The state high court is subordinate to the Supreme Court in New Delhi; it consists of 13 judges, who are appointed by the president of India. There are also district and subordinate courts. A public service commission, whose members are appointed by the governor, functions in an advisory capacity.

Social conditions. Mysore, which at the time of the 1971 census had a population that was more than 31 percent literate, is one of the educationally advanced states of India. There are about 34,000 schools and educational institutions, including the University of Mysore at Mysore, the Karnatak University of Dhārwār, and Bangalore University and the University of Agricultural Sciences, both at Bangalore. Nearly half of the schools and institutions are managed by the government, and the remainder of local boards and private bodies. Compulsory free primary education is provided in about 4,000

towns and villages out of the 25,000 towns and villages in the state.

By the early 1970s there were about 1,000 hospitals and dispensaries and a number of health centres in both urban and rural areas. The Employees State Insurance Scheme covers sickness, maternity, and employment injury risks and provides free medical treatment to 48,000 factory workers and their families in Bangalore. Welfare schemes are run by the government for tribal and other groups, such as the Harijan group (named "Harijan," or "people of God," by Gandhi, in place of the controversial term untouchable), and the beggars. (Beggary is discouraged by legislation.) The State Social Welfare Board also provides educational, cultural, and welfare facilities for women and children through more than 400 rural centres.

The economy. The economic resources of Mysore are constituted by its forests, its oils, its rivers, and its mineral wealth.

The forests of the *malnad* region in the west produce teak, sandalwood, bamboo, and such other products as tanning dyes, gums, and lac (a resinous substance used in the manufacture of varnishes). Oil processed from sandalwood at Mysore city is a leading state export.

Agriculture is the occupation of 80 percent of the population. The coastal plain is intensively cultivated, with rice being grown as a food crop and sugarcane as a cash crop. In the Western Ghāts coffee and tea plantations are established. More than 90 percent of India's coffee is produced there, especially in the southern part; tea is grown on the higher hills. In the eastern region, where irrigation makes cultivation possible, sugarcane is grown and a little rubber, as well as such fruits as bananas and oranges. The black cotton soil of the northwest is devoted to the cultivation of cotton, oilseeds, and peanuts (groundnuts).

Tea and coffee plantations

Mysore has sufficient hydroelectric power to supply surplus energy to neighbouring states. The Sharavati project near Jog is the largest of several hydroelectric plants that provide power to Mysore's industries.

In places the Precambrian rocks of Mysore, which are from 4,600,000,000 to 570,000,000 years old, are highly mineralized; manganese ore, iron ores, mica, chromite, copper ore, and bauxite are obtained in small quantities. From the region of the Kolār Gold Fields, 85 percent of India's gold is obtained. The principal gold mines, now nationalized, have workings up to 9,000 feet deep.

The mineral resources of the state provide the basis for the iron and steel industry at Bhadrāvati and heavy engineering works at Bangalore. Other industries in the state include cotton milling, sugar processing, and the manufacture of cement and paper. Both Mysore city and Bangalore have old established silk industries.

Isolation caused by physical features

Transportation. The obstacle formed by the Western Ghāts has prevented the building of railroads linking the ports to the plateau in the interior. There are 1,700 miles of track, most of which has a one-meter gauge. There are 95 miles of narrow gauge track. Bangalore in the southeast is the main focus of rail transportation. The port of Mangalore in the southwest, which is connected with the state of Kerala by tracks running parallel to the coast, is being improved.

Of the 24,000 miles of surfaced roads in the state, more than half is situated in the original state of Mysore on the plateau. The state as a whole compares favourably with the rest of India in road development, having 32 miles of surfaced road for every 100 square miles of territory, as compared with the national average of 16 miles per 100 square miles. The import and export trade relies primarily on road transport, but many roads in the western part of the state become impassable during the rainy season. Good roads run from Bangalore east to Madras, north to Hyderābād, northwest to Bombay, and westward through Mysore city and Mercāra to the west coast at Mangalore. Bangalore also has a national airport.

Cultural life. Mysore possesses a rich cultural heritage, compounded by the contributions of successive dynasties, which have fostered various religions and philosophies, which, in turn, have influenced literature, architecture, folklore, music, painting, and minor arts. Mauryan architecture is to be seen at Sravana Belgola, 56 miles from Mysore, where there is a giant stone figure of Gommateśvara, the Jain sage, believed to be 2,000 years old. Huge monolithic Jain statues are peculiar to the Kannada culture. The influence of the Cālukya and the Pallava dynasties is still apparent in temple architecture dating from the 7th century AD.

(G.K.G.)

Mystery Religions

Mystery religions were secret cults of the Greco-Roman world that offered to individuals a way to feel religious experiences not provided by the official public religions. They originated in tribal ceremonies that were performed by primitive peoples in many parts of the world. But, whereas in these tribal communities almost every member of the clan or the village was initiated, initiation in Greece became a matter of personal choice. The mystery religions reached their peak of popularity in the first three centuries of the Christian Era; at that time an individual could choose among many religions of this type. Their origin, however, goes back to the earlier centuries of Greek history.

Etymology of the word mystery

Etymologically, the word mystery is derived from the Greek verb *myein* ("to close"), referring to the lips and the eyes. Mysteries were always secret cults into which one had to be "initiated" (taken in). The initiate was called *mystēs*, the introducing person *mystagōgos* (leader of the *mystēs*). The leaders of the cults included the *hierophantēs* ("revealer of holy things") and the *dadouchos* ("torchbearer"). The constitutive features of a mystery society were common meals and common dances and ceremonies. People who had taken the same food and drink, joined in the same dance, and witnessed the same dramatic performances belonged together.

HISTORY

Hellenic roots. *Dionysiac.* In every Greek city the god Dionysus was worshipped by fraternities and sororities and also by mixed communities. Dionysus was a god of fruitfulness and vegetation but especially of wine. The Dionysiac festivals provided an opportunity for stepping outside of the daily routine. The festivals included not only drinking of wine and engaging in sexual activity but also participating in such significant features of Greek civilization as choral singing and mimes. In many cases, only the initiated could participate in the ceremonies. As almost every Greek did join in, initiation into the Dionysiac cult might be compared to tribal initiations (although the high quality of the art and literature produced within the religion of Dionysus lift these ceremonies to so different a level that the comparison with tribal initiations may be misleading). It seems that initiation into the Dionysiac Mysteries was accompanied by initiation into sexual life. The act of producing offspring, however, could never be wholly separated from the thought of death, so that the worshippers of Dionysus were aware of a mystic communion among the ancestors, the living generation, and the future members of the community.

Eleusinian. The most important sanctuary of Demeter (Ceres), the goddess of grain, and her daughter Kore (Persephone) was in the city of Eleusis in Attica, between Athens and Megara. Famous religious agricultural festivals—known as the Greater and the Lesser Eleusinian Mysteries—celebrating the sowing, sprouting, and reaping of the grain, were re-enacted in this city. The cy-

The myth of Kore

cle of the grain, pictured in the myth of Kore (Persephone), was thought to be parallel to the cycle of man. The myth, as told in the Homeric hymn to Demeter, tells how Hades (Pluto, or Pluton), god of the netherworld, wanted a wife and how he carried off Kore into the depths of the earth. Her mother, Demeter, through long days of searching, during which she came to Eleusis, refused to make the grain grow. Finally, Hades was bidden to send Kore back to earth. She came back to light as the grain maiden and gave birth to her son Plutus (Kore, "the maiden"; Pluton, "the rich one"; Plutus, "wealth," especially in grain). But, because Kore had eaten a pomegranate seed, a symbol of death and birth, she could not be completely released, and a compromise was reached by which she spent one-third of the year with her husband, the rest with her mother. Satisfied with this, Demeter caused grain to grow again and taught the Eleusinians her rites. The entire story of Demeter and Kore was elaborately re-enacted in the Eleusinian ceremony. Just as in the myth Kore was carried away to marry Hades and to give birth to Plutus, so was grain thrown into the field and buried in the earth to bring forth new life. Just as grain came up out of the ground and was reaped to yield man's bread and to be used as seed, so was a girl taken from her parents and her virginity "killed" to bring forth new offspring. And when a man died, he was buried in the earth to partake mystically in the cyclic renewal of life. This was the message of Eleusis: out of every grave new life grows—for the initiates there are "good hopes" for a glorious immortality in the afterlife.

Although there were festivals of Demeter throughout Greece, the true Eleusinian Mysteries were celebrated at Eleusis only. At first, the cult of Demeter was local and initiation was tribal rather than personal. By participating in the mysteries, a man became a full member of the civic body. This was changed when Eleusis was annexed to the Athenian territory about 600 BC. Initiation lost its importance as a means of conferring civic status; it became a purely religious ceremony. Every Athenian was admitted to the Eleusinian Mysteries, and soon the mysteries were open to every Greek, so that the ceremonies received an "international" character. Whoever wished to be initiated, however, had to go to Eleusis. It was a day's journey from Athens, a longer distance from most of the other Greek cities. The mystery rite became no longer a tribal ceremony. Each person had to decide for himself whether or not he wanted to be initiated. This development was possible only because Athens had become a large city with a differentiated culture that gave the individual ample choice of a way of life, including religion.

Meaning of the Dionysiac and Eleusinian mysteries

Both Dionysiac and Eleusinian mysteries had a wide range of meaning. Their essence was not contained in any written record but only in the festivals themselves—the holy days of the community. Many participants appreciated only the superficial level of the ceremonies and considered them as an opportunity for having a good time—good company, good food, intoxication, and sometimes (in the Dionysiac cult) sexual pleasures. The ceremonies were open to a deeper understanding, however, that was not made explicit by any theology or by any set of creeds but by the religious action itself, which contained the meaning and conveyed it to the participants without the interposition of words. Therefore, it was not possible to disclose to the noninitiated the mysteries by words, but it was treachery to reveal the secret dances.

Secular mystery communities. A society of initiates could drop its religious connections and become merely a social club. But because secrecy, common meals, and common drinking were implied, the Greeks and Romans regarded such clubs as mystery societies; they did not differentiate between religious associations and private clubs. The role of aristocratic clubs in Athenian politics was very important. In 415 BC the famous mystery scandal occurred. Several aristocratic societies conspired to overthrow the Athenian democracy. In order to pledge all members, a common crime was committed in which each member had to participate. One night the members of the social clubs took hammers and removed the genitals of the many Hermes statues in the city. Whoever would desert the common political cause would be denounced by his former friends for having committed a crime against religion, and many witnesses against him would be at hand. The people of Athens immediately understood that a conspiracy was developing. By a series of severe trials, the conspirators were traced and exiled. The speech of the orator Andocides, one of the conspirators, delivered in his defense in 399 BC, when the old affair was again taken up in a trial, still survives. The title of the oration is "About the Mysteries."

The secular mystery clubs continued throughout Greek and Roman history, and it was often difficult to distinguish them from religious associations. The Romans were especially distrustful of secret societies. This suspicion was justified in the case of Catiline, who led a conspiracy that attempted to overthrow the government in 63 BC. But Trajan, the Roman emperor from AD 98 to 117, did not allow the citizens of Nicomedia (modern İzmit, Turkey) to form a club that planned to provide a fire brigade, and he only reluctantly allowed the citizens of Amisus (modern Samsun, Turkey) to establish an association for charitable purposes.

Orphic. Besides community initiations, there were ceremonies for individual persons of deeper religious longing. Such persons were called Orphics after Orpheus, the Greek hero with superhuman musical skills who was supposedly the author of sacred writings; these writings were called the Orphic rhapsodies and they dealt with such subjects as purification and the afterlife. It is possible to reconstruct a common pattern for these initiations of individuals, although an Orphic "church" never existed, and the doctrines of the many small communities of individualists varied on a broad scale.

The Orphic sense of sin

Many Orphics seem to have had a strong feeling of sin and guilt. They believed that there was a divine part in man—his soul—but it was wrapped up in the body, and man's task was to liberate the soul from the body. This could be achieved by living an Orphic life, which included abstinence from meat, wine, and sexual intercourse. After death the soul would be judged. If a man had lived a righteous life, his soul would be sent to the meadows of the blessed in Elysium; but, if he had committed misdeeds, his soul would be punished in various ways and perhaps sent to hell. Following a period of reward or punishment, the soul would be incarnated in a new body. Only a soul that had lived a pious life three times could be liberated from the cycle.

Pythagoreans. The Orphic creeds were the basis of the Pythagorean brotherhood, which flourished in southern Italy beginning in the 6th century BC. The Pythagoreans were aristocratic fraternities that sometimes had a political scope. Their main achievements, however, lay in the fields of music, geometry, and astronomy. They discovered that these subjects could be explained by numbers and ratios. Combining Orphic eschatology (the study of the last things, especially death and afterlife) with their discoveries, they invested music, geometry, and astronomy with religious values. According to their doctrine, the original home of the soul was in the stars. From there it fell down to earth and associated with the body. Thus, man was a stranger on the earth, and he had to strive to liberate himself from the ties of the flesh and return to the soul's celestial home.

Platonists. The philosophy of Plato (*c.* 428–348 or 347 BC) by no means resulted from connections with a mystery cult. Yet Plato did take up many ideas from earlier Greek religion, especially from the Pythagorean brotherhood and from the Eleusinian communities, and often described his philosophy in terms derived from the mysteries. For example, the notion of searching and finding, so important in Eleusis, became an important notion in Plato's philosophy: the philosopher should never cease or relax in his quest for truth. A value was thus attached to the very act of searching. Later mystery religions, in their turn, borrowed freely from the rich imagery of Plato's dialogues and are thus deeply tinged with Platonism.

In the *Timaeus,* which is an exposition of his theory of

Plato's theory of the soul

the universe, Plato also developed his theory of the soul. The earth is surrounded by the spheres of the seven planets; the eighth sphere is that of the fixed stars. Beyond the eighth sphere is the realm of the divine. The sphere of the fixed stars, moved by the divine, continuously turns to the right at an even speed. This clockwise rotation affects the spheres of the planets, although they have their proper movement, which runs to the left, or counterclockwise. The sphere of mortality begins with the planets. The original home of each soul is in one of the fixed stars. As a result of the movement of the spheres, the soul falls through the planetary spheres to earth, where it is united with the body. The soul must then try to liberate itself from the body and ascend to the fixed star from which it fell. In later generations this picture was vividly worked out. The soul, in the course of its fall through the planetary spheres, was thought to acquire the qualities of the planets: sloth from Saturn, combativeness from Mars, lust for power from Jupiter, voluptuousness from Venus, greed from Mercury. After death, when the soul returned to the fixed star, it discarded these qualities, just as the *mystēs*, in certain initiations, discarded his everyday garment before entering the sacred place.

Many other traditional religious images were taken over by Plato, including the music of the spheres, the migration of the soul, the soul's remembrance of its celestial origin, and the idea of rewards for the righteous and punishment for the wicked. Later mystery associations adopted these concepts, which Plato had expressed so beautifully, and were deeply influenced by Plato's explanations.

The Hellenistic period. When Alexander the Great conquered the Asiatic kingdoms as far east as the Indus River, the Greek world was extended immensely. The religious ideas in Greece itself and the western part of the Alexandrian Empire, however, changed very slowly, because the Greeks, now masters of the world, felt no need for change.

In the Messenian town of Andania mysteries were celebrated in honour of the goddesses Demeter and Kore. A long inscription of 92 BC gives elaborate directions for the conduct of the rites, although, naturally, it gives no details of what went on during initiation. The mysteries in honour of the Cabeiri (gods of fertility) on the island of Samothrace attracted great attention in this period. These gods were thought to be helpers of the seafarers, and initiation into their mysteries was looked upon as a general safeguard against all misfortune but particularly against shipwreck. The Dionysiac Mysteries, with their revels and merriment, continued throughout the whole of Greek history. Together with most of the elements of Greek civilization, this cult was transferred to Italy. In 186 BC a scandal about the Bacchanalia—the Latin name for the Hellenistic Dionysiac Mysteries—so upset the Romans that a decree of the Senate prohibited them throughout Italy, except in certain special cases. These mysteries were celebrated in a lower middle class milieu and involved gross sex parties and violence conducted under the cover of mystery secrecy.

Hellenistic Mysteries in the Greek Orient

The important developments in the mystery rites during the Hellenistic period took place in the Greek Orient, where elements from the Greek and Oriental religions were blended. Contact with Greek civilization completely changed life in the Orient, where the knowledge of writing had been confined to a few priests and scribes. Society first disintegrated after the conquest of Alexander and then developed along new lines. Changes in religion were inevitable, and some influence of Oriental traditions upon the Greeks was bound to follow. But the process was a slow one and became manifest only a few centuries later.

With regard to the institution of kingship, however, syncretism worked quickly. Ancient Near Eastern kingship was originally sacral. The Syrian and Egyptian inhabitants of the newly created Greek kingdoms inevitably regarded the Greco-Macedonian kings as semidivine beings. The Greeks themselves soon submitted to this mixture of politics and religion. Such a mixture was perfectly natural to the Egyptians and Syrians, who did not perceive the structure of society as an abstraction, such as "the state" or "the nation," but saw the unity of the body politic in the person of the king. He was the symbol of the security and help that man derives from an orderly society. Mystery rituals, called royal mysteries, were developed especially in Egypt. According to traditional Egyptian religion, the ruling pharaoh was an incarnation of Horus (the sun-god), his mother or wife an incarnation of Isis (the heavenly queen), and his deceased father an incarnation of Osiris (the god of fertility). In Hellenistic times, Osiris was commonly known by the name Sarapis. These gods became equated with Greek gods: Isis with Demeter and Aphrodite; Horus with Apollo and Helios; Sarapis with Zeus, Dionysus, and Hades (Pluto). Both Greek and Egyptian myths were adopted for these divinities.

One of the suburbs of Alexandria, the newly constructed Greek capital of Egypt, was called Eleusis after the city of Demeter in Greece, and the Eleusinian Mysteries were instituted in a Greco-Egyptian adaptation. Dionysiac Mysteries were introduced on an even greater scale, so that the royal court was temporarily thrown into turmoil by the number of Bacchic ceremonies in which the king was considered to be a reincarnation of Dionysus. The Pythagorean concept of the migration of the soul was also taken over and was blended with the Egyptian belief in the reincarnation of the sun-god Horus in the reigning king.

The cult of rulers thus introduced ideas from the Greek Orient into Greek communities. But the mixture of religion and politics was a great obstacle for the propagation of the Greco-Oriental mysteries in the Mediterranean world. Even the numerous Greeks who lived in Egypt and Syria maintained the traditional Greek concept of the separation of god and man, and it was only after the political aspect of the mysteries was discarded that the religious elements could gain a life of their own. Inscriptions discovered on the Greek island of Delos demonstrate this well. The worship of Sarapis was introduced at Delos during the time the island was temporarily a naval base of the Greco-Egyptian kings. When the Egyptian influence on the island receded, the cult of Sarapis not only remained but reached new heights. The Romans later used Delos as a free port for the eastern part of the Mediterranean, and from there the worship of Sarapis and Isis spread to most of the harbours of the Greek world and to the cities in the Bay of Naples, whence it was brought by Italian merchants to Rome.

The combination of mystery elements with ruler worship is also evident in the kingdom of Commagene (eastern Turkey and northern Syria). Here, the kings assigned large funds to construct throughout the country gigantic sanctuaries, where festivals of the gods and the royal ancestors were celebrated annually on the kings' anniversary days. Long inscriptions discovered in the remains of these sanctuaries bear striking similarities to the language of the mysteries. The ceremonies, however, seem to have contained little true religion.

Roman imperial times. The great period of the mystery religions began when the Romans imposed peace upon the Mediterranean world. The Dionysiac, or Bacchic, societies flourished in the whole empire—in Greece proper, on the Greek islands, in Asia Minor, along the Danube River, and especially in Italy and at Rome. Hundreds of inscriptions attest to Bacchic Mysteries. In some circles, Orphic and Dionysiac ideas were blended, as in the community that met in the underground basilica near the Porta Maggiore ("Major Gate") at Rome. There was also a blend of ideas in the community for which the Orphic hymns were written. The members of this community (probably in Asia Minor) assembled at night in a clubhouse and held their services by the light of torches. Their rite consisted of a bloodless sacrifice and included the use of incense, prayer, and hymns. In addition to the mystery cults that were familiar from earlier times, the national religions of the peoples of the Greek Orient in their Hellenized versions began to spread. A faintly exotic flavour surrounded these religions and made them particularly attractive to the Greeks and Romans. The most popular of the Oriental mysteries was the cult

of Isis. It was already in vogue at Rome in the time of the emperor Augustus, at the beginning of the Christian era. The Emperor, who wanted to restore the genuine Roman religious traditions, disliked the Oriental influences. But men of reputation, such as Messalla, a general and patron of writers, were strongly inclined toward the Isis Mysteries. Isis, the goddess of love, was the patroness of many of the elegant Roman courtesans. The religion of Isis became widespread in Italy during the 1st and 2nd centuries AD. To a certain extent, the expansion of Judaism and Christianity over the Roman world coincided with the expansion of the Egyptian cults.

Mysteries from Asia Minor

Far less important was the influence of cults from Asia Minor. By 200 BC the Great Mother of the Gods (Magna Mater) and her consort Attis were introduced into the Roman pantheon and were considered as Roman gods. Their cult seems to have been encouraged especially under Emperor Claudius about AD 50. The Great Mother was characterized by her universal motherhood, especially over wild nature. The mysteries symbolized, through her relationship to Attis, the relations of Mother Earth to her children and were intended to impress upon the *mystēs* the subjective certainty of having been united in a special way with the goddess. There was a strong element of hope for an afterlife in this cult. The Persian god Mithra (Mithras), the god of light, was introduced much later, probably not before the 2nd century. The cult of Mithra was concerned with the origin of life from a sacred bull that was caught and then sacrificed by Mithra. According to Persian sources, the bull by its death gave birth to the sky, the planets, the earth, the animals, and the plants; thus Mithra became the creator of life. From Syria came the worship of several deities, of which Jupiter Heliopolitanus (the local god of Heliopolis; modern Ba'labakk, Lebanon) and Jupiter Dolichenus (the local god of Doliche in Commagene; modern Dülük, Turkey) were the most important. Adonis (a god of vegetation) of Byblos (in modern Lebanon) had long been familiar to the Greeks and was often considered to be closely related to Osiris; the myths and rituals of the two gods were similar. Adonis' female partner was Atargatis (Astarte), whom the Greeks identified with Aphrodite. At the time of Emperor Marcus Aurelius, in the latter half of the 2nd century AD, a "pseudoprophet" named Alexander of Abonouteichos (on the north coast of Turkey) devised a great mystery spectacle centred around a holy snake called Glycon and had great success during his lifetime.

The height of Syrian influence was in the 3rd century AD when Sol, the Syrian sun god, was on the verge of becoming the chief god of the Roman Empire. He was introduced into Rome by the emperor Elagabalus (Heliogabalus) in about AD 220, and by about AD 240 Pythian Games (*i.e.*, festivals of the sun god Apollo Helios) were instituted in many cities of the empire. The emperor Aurelian (270–275) elevated Sol to the highest rank among the gods. Sanctuaries of Sol and the gods of other planets (*septizonium*) were constructed. Even the emperor Constantine the Great, some 50 years later, wavered between Sol and Christ. For some time his religious policy was devised so as to allow the coexistence of both religions. Finally, Christianity was accepted as the official religion.

The different mystery religions were not exclusive of one another, but they appealed to different sociological groups. The middle class of the Greek and Roman cities preferred the Dionysiac societies, the festivals of which were a cult of beauty and merriment. Isis was worshipped by lower middle class people in the seaports and trading towns. The followers of the Great Mother in Italy were principally craftsmen. Mithra was the god of soldiers and of imperial officials and freedmen. There were no special societies for slaves; but they were usually admitted to the societies, and, during the time of the festival, all men were considered equal.

BELIEFS AND PRACTICES

Common features in Roman imperial times. For the first three centuries of the Christian Era, the different mystery religions existed side-by-side in the Roman Empire. They had all developed out of local and national cults and later became cosmopolitan and international. The mystery religions would never have developed and expanded as they did, however, without the new social conditions brought about by the unification of the Mediterranean world by the Romans. In the large cities and seaports, men from the remotest parts of the empire flocked together. Many people were removed from their accustomed surroundings and suffered from loneliness. They longed for new acquaintances and for assimilation, and they needed the assurance that only the knowledge of belonging to a community can give. Economic and political conditions in the Roman Empire also accelerated the growth of the mysteries. Members of a mystery society helped one another. For a lawyer, a craftsman, or a contractor, membership in a club could be the road to success. Furthermore, there is less opportunity for private initiative in a society ruled by a monarch than in a democratic society. The individual who felt that his initiative was frustrated by the preponderance of the imperial structure might well turn to a community that offered him the hope of a better future. The mystery societies, thus, commonly satisfied both a taste for individualism and a longing for brotherhood. At least in principle, the members of the communities were considered equal: one man was the other man's brother, irrespective of his origin, social rank, or nationality.

Mysteries fostered by new social conditions in the Roman Empire

Because membership in each of the mystery communities was a matter of personal choice, propaganda and missionary work were inevitable. In the religions of Isis and Mithra, missionary zeal was particularly obvious. The followers of Isis and Mithra considered Rome to be the centre of their worship, and the city was called *sacrosancta civitas* ("sacred city") in an Isis romance written in the 2nd century AD by the Latin author Apuleius.

Priesthood. The organization of the mystery religions was rather loose. The priests of Dionysus were wealthy laymen, as the priests in Greece always were. The Roman community of the Great Mother had a large group of priests (the Galli), headed by a chief priest (the Archigallus). They were eunuchs who wore female garb, who kept their hair long and perfumed with ointment, and who celebrated the goddess' rites with wild music and dancing until their frenzied excitement found its culmination in self-scourging, self-laceration, or exhaustion. Besides the priests there were priestesses and many minor officials. The followers were organized according to their function in the ritual procession as bearers of the tree (*dendrophori*) or bearers of the reed (*cannophori*). The men who carried the statue in the rites of Jupiter Dolichenus were called the sedan-chair men (*lecticarii*).

The higher grades of the Isis Mysteries were reserved to persons born of the priest caste of Egypt. To be born into this caste was more important than talent or skill. This limited the quality of the priests and was a serious disadvantage in the community's competition with other religions. But a second way of advancement within the religious group was devised for men of Greek or Roman origin. In Egypt, there was a group of elevated laymen—the porters of the holy shrine (*pastophori*). They were inferior in rank to everyone of the priest caste; but in Greek and Roman countries the rank of the *pastophori* became a surrogate for the native priest caste of Egypt. The *pastophori* were, in fact, the religious leaders of the communities.

Rites and festivals. A period of preparation preceded the initiation in each of the mysteries. In the Isis religion, for example, a period of 11 days of fasting, including abstinence from meat, wine, and sexual activity, was required before the ceremony. The candidates were segregated from the common folk in special apartments in the holy precinct of the community centre; they were called "the chastely living ones" (*hagneuontes*).

In all the mystery religions the candidates swore an oath of secrecy; the oath of the Isis Mysteries is preserved on papyrus. Before initiation, a confession of sins was expected. The candidate sometimes told at length the story of the faults of his life up to the point of his baptism, which was commonly a part of the initiation ceremony,

and the community of devotees listened to the confession. It was believed that the rite of baptism would wash away all the candidate's sins, and, from that point on, his life would be changed for the better, because he had enrolled himself in the service of the saviour god.

In the Mithraic ceremonies, there were seven degrees of initiations: Corax (Raven), Nymphus (Bridegroom), Miles (Soldier), Leo (Lion), Perses (Persian), Heliodromus (Courier of the Sun), and Pater (Father). Those in the lowest ranks, certainly the Corax, were the servants of the community during the sacred meal of bread and water that formed part of the rite.

Initiation ceremonies

The initiation ceremonies usually mimed death and resurrection. This was done in the most extravagant manner. In some ceremonies, candidates were buried or shut up in a sarcophagus; they were even symbolically deprived of their entrails and mummified (an animal's belly with entrails was prepared for the ceremony). Alternatively, the candidates were symbolically drowned or decapitated. In imitation of the Orphic myth of Dionysus Zagreus, a rite was held in which the heart of a victim, supposedly a human child, was roasted and distributed among the participants to be eaten.

The baptism could be either by water or by fire, and the rites often included actions that had an exotic flavour. Sulfur torches were used during the baptism ceremony; they were dipped into water and then—contrary to the expectations of the observers—burned when drawn out of the water. In a dark room a script would suddenly become visible on a wall that had been prepared accordingly. Instructions still exist for producing a nimbus effect —the appearance of light around the head of a priest. The priest's head was shaved and prepared with a protective ointment; then a circular metal receptacle for alcohol was fixed on his head; it was set aflame in a dark room and would shine for some seconds. In the Dionysus and Isis mysteries, the initiation was sometimes accomplished by a "sacred marriage," a sacral copulation. Two cases are known in which a priest speaking from the statue of the god ordered a credulous woman to come to the temple and be the god's concubine, the part of the god being enacted by the priest.

The initiation ceremonies were usually accompanied by music and dance and often included a large cast of actors. In the Dionysiac societies, especially elaborate provisions were made for mimic representations. The names of the sacred roles varied from place to place; among the roles were: Dionysus and Ariadne (a vegetation goddess and wife of Dionysus), Palaemon (a marine deity), Aphrodite (the goddess of love and beauty), Proteurhythmos (the inventor of elegant rhythm), the "foster-father of Dionysus," Kore, Demeter, Asclepius (the god of medicine), Pan (the god of flocks and shepherds), Curetes (long-haired youths), nymphs (minor nature goddesses), shepherds, sileni and satyrs (creatures of the wild, part man and part beast), maenads (female attendants who shared in the nocturnal orgiastic rites of Dionysus), the "guardian of the grotto," and centaurs (a race of beings half man and half horse).

The ceremonies always contained a prayer for the welfare of the emperor and for the good fortune of the whole Roman Empire. In fact, the amalgamation of religion and politics was sometimes so close that the designation "imperial mysteries" is used. The pattern of imperial mystery ceremonies could vary widely. This was especially true of the Dionysiac rites. In the clubs of the upper middle class and wealthy, for example, the festivals were chiefly social events. But the members of these communities were grateful for the security and peace and for the opportunity to make a good living that the emperor guaranteed to them. They felt loyalty toward the Roman Empire and expressed this by ceremonies of the imperial mysteries.

Dionysus was the patron god of the important international society of actors, and their reunions were celebrated in the mode of Dionysiac Mysteries. When an emperor travelled in the empire, responsibility for dignified receptions of him was handed over to the society of actors. Because his route was known beforehand, a voyage of the emperor was turned into a series of pompous festivals that were organized in a manner closely resembling mystery ceremonies.

The meetings of the mystery clubs were often named after the common meal. The Dionysiac meetings were called *stibas* ("straw") because the participants ate their dinner sitting on straw. The meals of the followers of Sarapis and Attis were called *klinē* ("couch"), because the diners lay on couches.

Seasonal festivals. The religions of Dionysus and Demeter and of Isis and the Great Mother had something of an ecclesiastical year. The seasonal festivals were inherited from old tribal ceremonies that had been closely associated with the sowing and reaping of corn and with the production of wine. The dates varied greatly according to the geographical conditions and the emphasis of the seasonal rites in the country in which the mysteries had originated. Dionysiac festivals were held in all four seasons; vintage and tasting of the new wine were the most important occasions. But the religion of Dionysus was closely associated with that of Demeter, and, thus, sowing and reaping were also celebrated in Dionysiac festivals. In the religion of the Great Mother, a hilarious spring festival celebrating the renewal of life was enacted in Rome.

Festivals connected with agriculture

The festivals of the Isis religion were connected with the three Egyptian seasons caused by the cycle of the Nile River (inundation, sowing, and reaping). About July 19, when the whole country was almost desiccated by the heat and the drought, the high waters of the new flood miraculously arrived from Ethiopia. On that day, just before sunrise, Sirius (the Dog Star, or the star of Isis) would make its first appearance of the season on the horizon. This was the sacred New Year's Day for the Egyptians, and the festival of the Nile flood was their greatest festival. There were, in addition, the festivals of sowing and reaping. But because the Egyptian year was a solar year of 365 days without intercalation (leap years), the seasonal festivals that were fixed upon a particular date were retarded by one day every four years and complete confusion resulted. The Romans fixed the calendar of Egypt by introducing an intercalary day every fourth year. In Roman times, important Isis festivals were held on December 25, January 6, and March 5. The March festival, as it was celebrated in Corinth, is described at length in Apuleius' *Metamorphoses*, or *The Golden Ass*. It was a spring festival that celebrated the beginning of the seafaring season. A ship was carried on a cart (*carrus navalis*) through the city. It was followed by a procession of choruses, candidates, *mystai* in bright clothes wearing masks, and priests carrying the insignia of the goddess. The ship was let into the sea, and the participants returned to the temple, where initiation ceremonies, banquets, and dances were held.

In the religion of Sol, the festivals were determined by astronomy. The greatest festival was held on December 24–25, at the time of the winter solstice. Because from this date the length of the day began to increase, it was regarded as the day of the rebirth of the god and of the renovation of life.

Literature. The mystery communities had religious hymns, but almost nothing of them has been preserved. The initial words of some hymns from the Sta. Prisca Mithraeum in Rome are known, and some Isiac poems exist. More important is a text of 40 sentences in which the goddess Isis reveals herself; it was found at four different and geographically distant places and was probably exhibited in every Isis sanctuary. Narratives of the miracles wrought by the gods were preserved in many temple libraries; examples of these narratives, on papyrus and on stone, have been found. According to a recent theory, the literary genre of the romance was developed from these narratives. The last part of the *Metamorphoses* of Apuleius is an Isis text and narrates in detail the initiation into the Egyptian mysteries.

Hermetic writings and *Chaldean Oracles*

Hermes Trismegistos, the Greek name for the Egyptian god Thoth, was the reputed author of treatises that have been preserved. Thoth was the scribe of the gods, the inventor of writing, and the patron of all the arts

dependent upon writing; he was sometimes thought of as an attendant of Isis and sometimes as the repository of all wisdom. These treatises are not exactly mystery texts, but they are works of revelation on occult subjects and on theology. Because the pagan mysteries had no official creed, each congregation of initiates was free to construct a theology of its own and to change it again. The Hermetic writings were attempts to provide a theology for a particular community. Although no authorized interpretation could exist for a doctrine that was in constant fluctuation and although none of the Hermetic treatises could claim to be the correct interpretation of the pagan mysteries, nevertheless, the texts give an instructive picture of spiritual life in mystery communities.

There are some contemporary texts that shed light on the mystery communities. Plutarch, the Greek biographer, wrote the philosophical treatise "About Isis and Osiris," which gives an interpretation of the Isis Mysteries. Arnobius, a 3rd-century Christian apologist, described an interesting semiphilosophical, semireligious mystery community known as the *viri novi* ("the new men"). Arnobius seems to have lived among them in North Africa for a time before his conversion to Christianity. They had a religious doctrine of the soul, with marked affinities to the teachings of the Neoplatonic thinkers Plotinus and Porphyry.

Only fragments are preserved of the *Chaldean Oracles,* a theosophical text in verse that was composed by Julianus the Theurgist and his son late in the 2nd century AD and had great influence on the Neoplatonists. The work combined Platonic elements with Persian or Babylonian creeds and was regarded by the later Neoplatonists as their basic religious book, something of a heathen bible. The doctrine of the *Chaldean Oracles* was associated with esoteric fire rituals. Julianus and his followers were called theurgists—*i.e.,* men who could perform divine operations. Their religion was partly one of meditation about the hidden and wondrous magical processes within the cosmos.

Theology. The creeds of the mystery religions were never worked out to the same extent that the Christian creeds were. Nevertheless, the doctrines of the mysteries may be called a theology. One of the central subjects in mystery writings was cosmogony—the theory of the origin or creation of the world. In the Hermetic treatises, in the *Chaldean Oracles,* and in the little known writings of Mithraism, the cosmogony was modelled after Plato's *Timaeus,* and it always dealt with the creation of the soul and with the soul's subsequent fate.

The myth of the soul

The theological doctrine of the soul and the myth about its celestial home, its fall, and its redemption were inseparable. The sequence is beautifully told in the "Hymn of the Soul," preserved in the *Acts of Thomas,* an apocryphal account of the journeys and death of the apostle in which some episodes were certainly transmitted from pagan mystery texts. The hero of the hymn, who represents the soul of man, is born in the Eastern (the yonder) Kingdom; immediately after his birth, he is sent by his parents on a pilgrimage into the world with instructions to take a pearl from the mouth of a dragon in the sea. Instead of wearing his heavenly garment, he dresses in earthly clothes, eats earthly food, and forgets his task. Then his parents send a letter to rouse him. As soon as he has read the letter, he awakes and remembers his task, takes the pearl, and begins the homeward journey. On the way, his brother (the Redeemer) comes to accompany him and leads him back home to his father's palace in the east. This myth is a figurative representation of the theological doctrine of the soul's fall and its return to heaven.

Many of the questions that were the subject of later Christian theological discussions were already eagerly debated in the mystery religions. In a Hermetic treatise, for example, the existence of God was proved from the evident order of the world. This argument, which had first been formulated by Zoroaster, a 7th-century Iranian prophet, was expressed in the form of questions: Who could have created the heavens and the stars, the sun and the moon, except God? Who could have made wind, water, fire, and earth (the elements), the seasons of the year, the crops, the animals, and man, except God?

Passionate debates were held about the question of whether man was subject to blind fate. The Stoics (a Greek and Roman school of philosophy holding that men should be free from passion and calmly accept all occurrences as unavoidable) had adopted the doctrine that all events are determined by the stars. Thus, for many Greeks and Romans astrology became the only sensible method of studying man's life and fortune. But, for others, the idea that man could achieve nothing by his own will was frightening, and they wanted to be liberated from this fear; the mystery religions promised to liberate them. The theology of the mystery religions admitted that the stars ruled the world and especially that the planets had evil influences. But the highest god of the religion (*e.g.,* Sarapis in the Isiac Mysteries) stood far above the stars and was their master. A man who decided to become a servant of this god stepped out of the circle of determination into the sphere of liberty. The god could suspend determination, because he ruled over the stars; he could unravel the threads of the Moirai (the three spinners of fate); he could save his servant from illness and prolong his life, even against the will of fate. In the Isis Mysteries there was a theology of grace foreshadowing Christian doctrine.

In many of the mystery cults, there was a marked tendency toward henotheism—the worship of one god without denying the existence of other gods. Thus, Isis was the essence of all pagan goddesses; Sarapis was the name uniting the gods Zeus, Pluto, Dionysus, Asclepius, Helios, and even the Jewish god YHWH (Yahweh). In the religion of Sol, an elaborate syncretistic theology was developed to show that all known gods of all nations were nothing but provisional names for the sun god.

RELIGIOUS ART AND ICONOGRAPHY

Much of Greco-Roman art was executed for use in the mystery communities. The Dionysiac monuments are by far superior to all others in artistic quality. This is to be expected, because the worship of Dionysus often took the form of a worship of beauty. Nevertheless, the other communities also produced a great number of art objects.

Superior artistic quality of Dionysiac art

Architecture. The mystery religions developed different types of edifices for their purposes. Every Greek city had temples and precincts of Dionysus. The Isis Mysteries adopted the Greek temples, frequently adding a cupola. Many Isis temples were modest in size, but the temple at Pergamum (modern Bergama, Turkey) was a great basilica with a vaulted roof and strong towers, in the fashion of the best Roman architecture. The Isis temple that the emperor Domitian erected on the Campus Martius (the Field of Mars) in Rome at the end of the 1st century AD was a stately building, and the Temple of Sarapis (the Sarapeum) at Alexandria was a huge construction. The subterranean basilica near Porta Maggiore in Rome (used by an Orphic or Pythagorean society) was a strong and magnificent structure, hidden in a large garden. The Mithraic sanctuaries were artificial caves illuminated from above by light shafts. They were built for communities of from 50 to 100 persons.

The buildings were designed to be functional for the religious ceremonies. The Mithraeum under the Church of S. Clemente at Rome contained a system of underground galleries for initiation ceremonies. Beneath the temple of the Egyptian gods at Pergamum, subterranean passages existed for the use of the priests. One of the paths led into the huge, hollow statue of the god, so that the priest could speak from the mouth of the statue. By another secret way, an officiant could climb the huge corner towers of the temple to make announcements from there. The Sarapeum at Alexandria was directed toward the east; on a certain day of the year, at a certain time, sunbeams directly struck the head of the god's statue. This same temple was so arranged that those waiting to be initiated could hire rooms in an adjacent building during the time of preparation before the ceremony.

Because the use of water was such an important element in most of the mystery rites, the location of the tem-

ples was often determined by the availability of water; Mithraic sanctuaries were always erected on the spot at which a fountain had its source. In the temples of Isis, a cistern for the holy water was required; in Delos and in a house at Pompeii in Italy, a system of water basins could imitate the flood of the Nile. The Dionysus temple at Corinth had an underground system of tubes and barrels that could be operated by buttons from the outside. The priest showed the worshippers of the god a barrel filled with water. They left the temple together, and the door was sealed from without. By pressing the buttons, the water was let out of the barrel, and wine was poured in. The following day, when the seal was removed, the spectator witnessed the Dionysiac miracle of water turned into wine.

On the ground floor of the Mithraic sanctuaries at Ostia, mosaic pavements showed the seven grades of the initiation and their symbols together with the ladder of the seven steps that led to religious salvation. In initiation ceremonies the mosaic was perhaps used to indicate the place where the different participants were to take their places.

Statuary. A great many statues were exhibited in the temples and shrines of the mystery gods. They were usually executed in the traditional Greek style. In the sanctuary of Isis and Sarapis at Thessalonica (modern Thessaloníki), in northern Greece, there were statues of a whole series of Greek goddesses, each of whom was identified with Isis in one way or another to show that the Egyptian goddess was the essence and synthesis of Greek religion. In the 4th century BC, the sculptor Bryaxis created a famous colossal statue of Sarapis in the temple at Alexandria. It represented the god—as a combination of the Greek gods Zeus (the father of the gods), Hades, and Dionysus—seated upon a throne, with Cerberus, the three-headed monster, beside him. An interesting statuette found at Cyrene (modern Shaḥḥāt, Libya) shows a female initiate of Isis. The woman is wrapped from feet to waist like a mummy; but the upper part of her body is free, and she is wearing the crown of Isis on her head. The statue thus showed how an initiate would first die and subsequently resurrect in triumph during the ceremony. Many terra-cotta statues of Isis and her son Horus have survived from Roman Egypt; they are similar to the later statues of the Christian Madonna and Child. Syrian statues of Jupiter Heliopolitanus represent the god in a rigid attitude, like a pillar. In the base of some of these statues are holes, into which sticks could be inserted for the purpose of carrying the statue in procession. In Mithraic sanctuaries a great number of statues, especially of the gods of the planets, were exhibited. Statues of the Mithraic time god were also frequent; they were often hollow and were constructed so that they could spit fire.

Reliefs. The Dionysiac reliefs are numerous. They show symbols of the religion, such as the shepherd's staff, the winnow (an ancient device for separating chaff from grain), and the phallus; they depict the gay life of satyrs and maenads, shepherds and shepherdesses; and they represent the "golden age" of the gods with tame and wild animals enjoying a peace that the god had instituted. A great, silver dish, dating from about the 4th century AD and found at Mildenhall, England, shows the swift and elegant dance of the maenads. Dionysiac sarcophagi represented Bacchic revels and the pastime of the Erotes and Psyches in afterlife. Many reliefs of the Isis Mysteries also survive. They display the mystical cista (a receptacle for carrying sacred objects) with the snake of Horus, the priest carrying the holy water in a procession, female attendants with a ladle, and a man in a dog's mask, who represents Anubis (the guardian god). Other Isiac reliefs show Isis riding on a dog, symbolic of her position as goddess of Sirius (the Dog Star).

In Mithraic caverns there was always a relief depicting the god sacrificing the bull. Representations of the sacramental meal were also frequent; a relief recently discovered in Konjic, Yugoslavia, shows the initiates at a banquet wearing masks, among them a lion, a raven, a soldier, and a Persian. Two reliefs—at Rome (now at Modena, Italy) and at Housesteads, England (the best preserved fort along Hadrian's Wall)—depict the creation of the world out of an initial egg; in this case, Orphic and Mithraic ideas were amalgamated. Other episodes of Mithraic mythology that were commonly displayed include the birth of Mithra from a rock with the shepherds who welcome him and his dealings with the sun god.

The stucco reliefs in the subterranean basilica near Porta Maggiore are of outstanding quality. In the central episode, Sappho—an early Greek poetess who supposedly killed herself in a "lover's leap" from the island of Leucas into the Ionian Sea—is shown leaping toward Apollo, the god of the sun; this symbolized the soul's transcendence into more favourable existence. Many of the reliefs in the basilica allegorize episodes from Greek mythology in the fashion of the Pythagoreans, who found a hidden religious or philosophical meaning behind the mythical tales of the Greek tradition.

Painting. There are few paintings from the temples of the mystery religions that have been preserved; nevertheless, some of these deserve comment. The superb Dionysiac frescoes of the Villa of the Mysteries (Villa dei Misteri) at Pompeii show the initiation of a girl into the Bacchic Mysteries: in one fresco she is lifting the cover of a sacred casket; in a second scene three followers of Dionysus are practicing lecanomancy (divination by the inspection of a bowl filled with water); in a third scene the girl is unveiling an erect phallus and because of this she is being flagellated; finally, she is seen dancing in happy bliss. A number of Isiac frescoes, preserved in the temple of Isis at Pompeii, show the sacred dance of the initiates, the presentation of an urn filled with the ritual holy water to the initiates, the coffin of Osiris and his resurrection, and episodes from the cycle of Io, a Greek heroine equated with Isis. Isiac frescoes dating from the time of the emperor Caligula in the 1st century AD are also found in the ruins on the Palatine at Rome. In the Mithraeum under Sta. Prisca in Rome, two layers of frescoes were found that show the procession of the initiates toward ritual sacrifice of a bull, called Suovetaurilia, and the sacred meal of the sun god and Mithra. Sometimes a fresco replaced the relief of the sacrifice of the bull. The initiation ceremonies are shown in the Mithraic sanctuary at Capua (in western Italy): the candidate, accompanied by the *mystagōgos*, is blindfolded, kneels down, and lies prostrate. At Rome, in the tomb of Vincentius and Vibia, who worshipped the god Sabazius (a Thracian form of Dionysus), frescoes show how Vibia was carried away by Death, as Kore had been carried away by Hades, how she was judged and acquitted, and how she was introduced by a "good angel" to the sacred meal of the blessed.

Mosaics. A mosaic at Antioch represents the Phoenix —the solar bird who died and resurrected from its own ashes and who was its own father and son at the same time—with sunrays encircling its head. A Dionysus mosaic at Cologne, Germany, depicts in several panels the life of satyrs and maenads and also Bacchic symbols such as the winnow (an implement of purification) and the oyster (which has to be liberated from the shell as the soul from the body). The room evidently was used for banquets and Dionysiac merrymaking.

MYSTERY RELIGIONS AND CHRISTIANITY

Christianity originated during the time of the Roman Empire, which was also the time at which the mysteries reached their height of popularity. This was by no means an accident. The Christian theologian Origen wrote in the 3rd century that it was part of the divine plan that Christ was born under the emperor Augustus: the whole Mediterranean world was united by the Romans, and the conditions for missionary work were more favourable than ever before. The simultaneousness of the propagation of the mystery religions and of Christianity and the striking similarities between them, however, demand some explanation of their relationship. The hypothesis of a mutual dependence has been proposed by scholars—especially a dependence of Christianity upon the mysteries—but such theories have been discarded. The similarities must rather be explained by parallel developments from similar origins. In both cases, national religions of a ritualistic type

Similarities between mysteries and Christianity

were transformed, and the transformation followed similar lines: from national to ecumenical religion, from ritualistic ceremonies and taboos to spiritual doctrines set down in books, from the idea of inherited tradition to the idea of revelation. The parallel development was fostered by the new conditions prevailing in the Roman Empire, in which the old political units were dissolved, and the whole civilized world was ruled by one monarch. People were free to move from one country to another and became cosmopolitan. The ideas of Greek philosophy penetrated everywhere in this society. Thus, under identical conditions, new forms of religious communities sprang from similar roots. The mystery religions and Christianity had many similar features—*e.g.*, a time of preparation before initiation and periods of fasting; baptism and banquets; vigils and early-morning ceremonies; pilgrimages and new names for the initiates. The purity demanded in the worship of Sol and in the Chaldean fire rites was similar to Christian standards. The first Christian communities resembled the mystery communities in big cities and seaports by providing social security and the feeling of brotherhood. In the Christian congregations of the first two centuries, the variety of rites and creeds was almost as great as in the mystery communities; few of the early Christian congregations could have been called orthodox according to later standards. The date of Christmas was purposely fixed on December 25 to push into the background the great festival of the sun god, and Epiphany on January 6 to supplant an Egyptian festival of the same day. The Easter ceremonies rivalled the pagan spring festivals. The religious art of the Christians continued the pagan art of the preceding generations. The Christian representations of the Madonna and child are clearly the continuation of the representations of Isis and her son suckling her breast. The statue of the Good Shepherd carrying his lost sheep and the pastoral themes on Christian sarcophagi were also taken over from pagan craftsmanship.

In theology the differences between early Christians, Gnostics (members—often Christian—of dualistic sects of the 2nd century AD), and pagan Hermetists were slight. In the large Gnostic library discovered at Naj'Ḥammādī, in upper Egypt, in 1945, Hermetic writings were found side-by-side with Christian Gnostic texts. The doctrine of the soul, as it was taught in Gnostic communities, was almost identical to that of the mysteries: the soul emanated from the Father, fell into the body, and had to return to its former home. The Greeks interpreted the national religions of the Greek Orient chiefly in terms of the philosophical and religious concepts elaborated by Plato. Interpretation in Platonic concepts was also the means by which the Judeo-Christian set of creeds was thoroughly assimilated to Greek ideas by the early Christian thinkers Clement of Alexandria and Origen. Thus, the religions had a common conceptual framework. The doctrinal similarity is exemplified in the case of the pagan writer and philosopher Synesius. When the people of Cyrene wanted the most able man of the city to be their bishop, they chose him, and he was able to accept the election without sacrificing his intellectual honesty. In his pagan period he wrote hymns that closely follow the fire theology of the *Chaldean Oracles*; later he wrote hymns to Christ. The doctrine is almost identical.

The similarity of the religious vocabulary is also great. Greek life was characterized by such things as democratic institutions, seafaring, gymnasium and athletic games, theatre, and philosophy. The mystery religions adopted many expressions from these domains: they spoke of the assembly (*ekklēsia*) of the *mystai*; the voyage of life; the ship, the anchor, and the port of religion; and the wreath of the initiate; life was a stage and man the actor. The Christians took over the entire terminology; but many pagan words were strangely twisted in order to fit into the Christian world: the service of the state (*leitourgia*) became the ritual, or liturgy, of the church; the decree of the assembly and the opinions of the philosophers (*dogma*) became the fixed doctrine of Christianity; the correct opinion (*orthē doxa*) about things became orthodoxy.

Differences between mysteries and Christianity

There are also great differences between Christianity and the mysteries. Mystery religions, as a rule, can be traced back to tribal origins, Christianity to a historical person. The holy stories of the mysteries were myths; the Gospels of the New Testament, however, relate historical events. The books that the mystery communities used in Roman times cannot possibly be compared to the New Testament. The essential features of Christianity were fixed once and for all in this book; the mystery doctrines, however, always remained in a much greater state of fluidity. The theology of the mysteries was developed to a far lesser degree than the Christian theology. There are no parallels in Christianity to the sexual rites in the Dionysiac and Isiac religion, with the exception of a few aberrant Gnostic communities. The cult of rulers in the manner of the imperial mysteries was impossible in Jewish and Christian worship.

The mysteries declined quickly when the emperor Constantine raised Christianity to the status of the state religion. After a short period of toleration, the pagan religions were prohibited. The property of the pagan gods was confiscated, and the temples were destroyed. The precious metal from which Constantine's gold pieces were coined was taken from heathen temple treasuries. To show the beginning of a new era, the capital of the empire was transferred to the new Christian city of Constantinople. The centres of pagan resistance were Rome and Alexandria: in Rome the old aristocracy clung to the mysteries, and in Alexandria the pagan Neoplatonist philosophers expounded the mystery doctrines. When Julian the Apostate, Roman emperor from AD 361 to 363, tried to re-establish pagan worship, he found allies at Rome and Alexandria. After his death, the pagan opposition to Christianity continued for one more generation. The Roman aristocrats multiplied their efforts to maintain the piety of the mysteries, and the pagan philosophers tried to refine their theology by oversubtle interpretations. In 391, however, the Sarapeum at Alexandria was demolished, and in 394 the opposition of the Roman aristocracy was crushed in the battle at the Frigidus River (modern stream of Vipacco, Italy; stream of Vipava, Yugoslavia).

Only remnants of the mystery doctrines, amalgamated with Platonism, were transmitted by a few philosophers and individualists to the religious thinkers of the Byzantine Empire. The mystery religions exerted some influence on the thinkers of the Middle Ages and the philosophers of the Italian Renaissance.

General: J.G. FRAZER, *The Golden Bough*, 3rd ed., 12 vol. (1911–15, reprinted 1963), a famous and influential treatise on ancient religion, especially on Adonis, Attis, Osiris, Dionysus, and Demeter; M.P. NILSSON, *Geschichte der griechischen Religion*, 2nd ed. (1955; Eng. trans., *A History of the Greek Religion*, 2nd ed., 1963), the best handbook on the whole subject of Greek religion.

Greek mysteries: E. ROHDE, *Psyche*, 2nd ed. (1897; Eng. trans., 1925), by the first author to understand the religion of Dionysos; L.R. FARNELL, *The Cults of the Greek States*, 5 vol. (1896–1909), a careful and conscientious collection and interpretation of the sources for Demeter and Dionysus; J.E. HARRISON, *Prolegomena to the Study of the Greek Religion*, 2nd ed. (1908), original and readable accounts about Demeter, Dionysus, and Orphics; E.R. DODDS, *The Greeks and the Irrational* (1951), a famous book, relevant especially for Dionysiac and Orphic religion.

Mysteries in the Roman Empire: F. CUMONT, *Les Religions orientales dans le paganisme Romain*, 4th ed. (1928; Eng. trans. of 2nd French ed., *Oriental Religions in Roman Paganism*, 1911, reprinted 1956), the best general account; A.D. NOCK, *Conversion* (1933), a well-written and original study of the relation of Oriental cults and Christianity; *Early Gentile Christianity and Its Hellenistic Background* (1964), a learned collection of articles; M.P. NILSSON, *The Dionysiac Mysteries of the Hellenistic and Roman Age* (1957), a clear and scholarly survey of the religion of Dionysus in later times; R. MERKELBACH, *Roman und Mysterium in der Antike* (1962), on the ancient romances as mystery texts; *Isisfeste in griechischrömischer Zeit* (1963), treats the Isis festivals and their relationship to Christian festivals.

(R.Me.)

Mysticism

Mysticism, a quest for a hidden truth or wisdom ("the treasure hidden in the centres of our souls"), in the 20th century is experiencing a renewed interest and understanding and even a mood of expectancy similar to that which had marked its role in previous eras. Such a mood stems in part from the feeling of alienation that many persons experience in the modern world. Put down as a religion of the elite, mysticism (or the mystical faculty of perceiving transcendental reality) is said by many to belong to all men, though few use it. The British author Aldous Huxley has stated that "a totally unmystical world would be a world totally blind and insane," and the Indian poet Rabindranath Tagore has noted that "Man has a feeling that he is truly represented in something which exceeds himself."

NATURE AND SIGNIFICANCE

The goal of mysticism is union with the divine or sacred. The path to that union is usually developed by following four stages: purgation (of bodily desires), purification (of the will), illumination (of the mind), and unification (of one's will or being with the divine). If "the object of man's existence is to be a Man, that is, to re-establish the harmony which originally belonged between him and the divinized state before the separation took place which disturbed the equilibrium" (*The Life and Doctrine of Paracelsus*), mysticism will always be a part of the way of return to the source of being, a way of counteracting the experience of alienation. Mysticism has always held —and parapsychology also seems to suggest—that the discovery of a nonphysical element in man's personality is of utmost significance in his quest for equilibrium in a world of apparent chaos.

Re-establishment of the harmony between man and the divine

Mysticism's apparent denial, or self-negating, is part of a psychological process or strategy that does not really deny the person. In spite of its lunatic fringe, the maturer forms of mysticism satisfy the claims of rationality, ecstasy, and righteousness.

There is obviously something nonmental, alogical, paradoxical, and unpredictable about the mystical phenomenon, but it is not, therefore, irrational or antirational or "religion without thought." Rather, as Zen (Buddhist intuitive sect) masters say, it is knowledge of the most adequate kind, only it cannot be expressed in words. If there is a mystery about mystical experience, it is something it shares with life and consciousness. Mysticism, a form of living in depth, indicates that man, a meeting ground of various levels of reality, is more than one-dimensional. Despite the interaction and correspondence between levels—"What is below is like what is above; what is above is like what is below" (*Tabula Smaragdina*, "Emerata Tablet," a work on alchemy attributed to Hermes Trismegistus)—they are not to be equated or confused. At once a praxis (technique) and a gnosis (esoteric knowledge), mysticism consists of a way or discipline.

Mysticism and religion

The relationship of the religion of faith to mysticism ("personal religion raised to the highest power") is ambiguous, a mixture of respect and misgivings. Though mysticism may be associated with religion, it need not be. The mystic often represents a type that the religious institution (*e.g.*, church) does not and cannot produce and does not know what to do with if and when one appears. As William Ralph Inge, an English theologian, commented, "institutionalism and mysticism have been uneasy bedfellows." Although mysticism has been the core of Hinduism and Buddhism, it has been little more than a minor strand—and, frequently, a disturbing element—in Judaism, Christianity, and Islām. As the 15th- to 16th-century Italian political philosopher Niccolò Machiavelli had noted of the 13th-century Christian monastic leaders St. Francis and St. Dominic, they had saved religion but destroyed the church.

The founders of religion may have been incipient or advanced mystics, but the inner compulsions of their experience have proved less amenable to dogmas, creeds, and institutional restrictions, which are bound to be outward and majority oriented. There are religions of authority and the religion of the spirit. Thus, there is a paradox: if the mystic minority is distrusted or maltreated, religious life loses its sap; on the other hand, these "peculiar people" do not easily fit into society, with the requirements of a prescriptive community composed of less sensitive seekers of safety and religious routine. Though no deeply religious person can be without a touch of mysticism, and no mystic can be, in the deepest sense, other than religious, the dialogue between mystics and conventional religionists has been far from happy. From both sides there is a constant need for restatement and revaluation, a greater tolerance, a union of free men's worship. Though it validates religion, mysticism also tends to escape the fetters of organized religion.

RELATION OF MYSTICAL EXPERIENCE TO OTHER KINDS OF EXPERIENCE

Mysticism shares a common world with magic, theurgy (power of persuading the supernatural), prayer, worship, religion, metaphysics (transcendent levels of reality), and even science. It may not be always easy to distinguish mysticism from these but its approach and emphasis are different. Though there is an element of magic, psychism, and the occult in much of what passes for mysticism, it is not to be equated with a science of the unseen or with voices and visions. Powers of the occult (or *siddhis*) are viewed as real, but they can also be dangerous and are not of interest to genuine mystics, who have warned against their likely misuse.

Prayer and worship may form part of mysticism, but they are viewed as means and not as essence; also, they are usually continuations of sensory experience, whereas mysticism is a pure unitary consciousness, or a union with God. As for science, it is analytic and discursive and expresses its findings in precise and abstract formulas; mysticism, however, like poetry, depends more on paradoxes and an unusual use of language. Philosophies may lead to or follow from mysticism, but they are not the same. Nature mysticism is another prominent variant, to which poets and artists are particularly prone. This has often been described or dismissed as pantheism (the divine in all), though it is perhaps other than a simple assertion of identity.

Emotionalism and purified emotion are quite different. Emotionalism, a kind of unsuccessful ecstasy, may arise from unpurged elements in the being; it could also be a concession or inability to hold the flow or touch from above. The natural state of man and, even more, that of the true mystic is serene and not agitated, not at the mercy of what the medieval mystical book *The Cloud of Unknowing* calls "monkey tricks of the soul." "Be still, and still, and know." Mysticism, among the many forms of experience, confirms the claims of religion and is viewed as providing a foretaste of the life after death.

DEFINITIONS OF MYSTICISM AND MYSTICAL EXPERIENCE

Differences between mysticism and similar phenomena. To define is to limit, and no single definition will cover every aspect of mysticism. Some have objected to the word itself and believed that "enlightenment" or "illumination" might be better. Though they meet, mysticism has to be distinguished from prophetic religions as well as from shamanism (a belief system built around psychic transformations). Working through chosen individuals—not necessarily saints and chosen for no other reason than God's will—prophetic religions emphasize action to a far greater extent than most forms of mysticism, with its penchant for inwardness and the beyond. Though in ecstasy the barriers seem to disappear, in prophetism God and man are rarely identified. Shamanism, a technique of ecstasy generally found in Siberia and Central Asia but with parallels in primitive society, provides a sort of correspondence with the purgative stage of mysticism (in which physical needs are negated). The closeness to paranormal (or supernatural) phenomena seems more pronounced, however, in shamanism. Both the shaman and the mystic, as communicants with a world beyond normal experience, reveal an identity of goal, if not of practice and content.

Basic patterns. Paradigmatic pronouncements in regard to mysticism pose problems of their own. The classic Indian formula—"that thou art," *tat tvam asi* (*Chāndogya Upaniṣad,* 6.9)—is hedged in with the profoundest ambiguity. The difficulty reappears in the thought of the medieval Christian mystic Meister Eckehart, who had the church raising questions for such unguarded statements as "The knower and the known are one. God and I, we are one in knowledge" and "There is no distinction between us."

Mysticism as a third kind of knowledge

Mysticism may be defined as the belief in a third kind of knowledge, the other two being sense knowledge and knowledge by inference. Adolf Lasson has written:

> The essence of Mysticism is the assertion of an intuition which transcends the temporal categories of the understanding. . . . Rationalism cannot conduct us to the essence of things; we therefore need intellectual vision.

This same view was held by the 3rd-century-AD Greek philosopher Plotinus. But the pattern misses the other dominant quality of mystical experience—love, or union through love. The medieval, theistic view of mysticism (as of religious life) was that it was "a stretching out of the soul into God through the urge of love, an experimental knowledge of God through unifying love." Its other name was joy, and the endeavour of the mystic to grasp the divine essence or ultimate reality helped him to enjoy the blessedness of actual communion with the highest. This was considered both a science and an art. As a science; *i.e.,* intuitive knowledge or the "science of ultimates," mysticism is viewed as being able to help in "the overcoming of creatureliness," and also as being able to maintain "the tendency to stress up to an extreme and exaggerated point the non-rational aspect of religion."

Reality, a kingdom of values, is viewed not as a faceless infinite, an impersonal something or somewhat. If not an ego, it is a being, and most mystics would call it God. Mysticism arises when man tries to bring the urge toward a communion with God—a "Being conceived as the supreme and ultimate reality," according to the British scholar William Ralph Inge—toward a higher consciousness and being in relation with the other contents of his mind and total personality, when he tries to realize the presence of the living God in the soul and in nature or, more generally, in the attempt to realize (in thought and feeling) the immanence of the temporal in the eternal. A 19th-century scholar, Otto Pfleiderer, indicated that religious mysticism is "the immediate feeling of unity of the self with God; it is nothing, therefore, but the fundamental feeling of religion, the religious life at its very heart and centre." Against such exclusive concentration the British writer Richard Nettleship suggests a corrective element, that of wholeness and symbolism. "Mysticism is the consciousness that everything that we experience is an element, and only an element, in fact, *i.e.* that in being what it is, it is symbolic of something else."

Introvertive mysticism. Certain forms of mysticism, however, would seem to strive toward a naked encounter with the Whole or All, without and beyond symbols. Of this kind of direct apprehension of the absolute, introvertive mysticism offers examples from different times and traditions. Instead of looking out, the gaze turns inward, toward the unchanging, the undifferentiated "One without a second." The process by which this state is attained is by a blotting out or suppression of all physical sensations—indeed, of the entire empirical content of consciousness. *Cittavṛttinirodha* ("the holding or stopping of the mind stuff") was how the 2nd-century-BC Indian mystic Patañjali described it. The model of introvertive mysticism comes from the *Māṇḍūkya Upaniṣad:*

Unitary consciousness—One without a second

> The Fourth, [aspect of self] say the wise, . . . is not the knowledge of the senses, nor is it relative knowledge, nor yet inferential knowledge. Beyond the senses, beyond the understanding, beyond all expression is The Fourth. It is pure unitary consciousness wherein [all] awareness of the world and of multiplicity is completely obliterated. It is ineffable peace. It is the supreme good. It is One without a second. It is the Self. (From *The Upanishads, Breath of the Eternal;* trans. by Swami Prabhavananda and Frederick Manchester.)

Other definitions and experiences of mysticism. Such undifferentiated unity or union between the individual and the supreme self is unacceptable to certain traditions and temperaments. The Jewish philosopher Martin Buber emphasized an "I–Thou" relationship: "All real living is meeting," and one Thou cannot become It. But even his own "unforgettable experience" of union he would explain as "illusory." With a wider range, a British scholar, R.C. Zaehner, has tried to establish different kinds, or types, of mysticism: of isolation, the separation of spirit and matter, eternity from time; pantheistic, or "pan-enhenic," in which the soul is the universe—all creaturely existence is one; the theistic, in which the soul feels identified with God; and the beatific, with its hope of deification when "the perishable puts on the imperishable."

Definitions of mysticism include a bewildering variety, ranging from the biological through the psychological to the theological. The origin of the word and certain of its features strongly suggest the possibility that mysticism is the science of a hidden life. But there is also a growing belief among 20th-century scholars that "the people of the hidden" should not remain hidden too long and should come out in the open, befitting an era of "open development" and "open realization." Some 20th-century scientists, among them physicists, biologists, and paleontologists, have shown a marked mystical bias. A biologist, Ludwig von Bertalanffy, has confessed to "peak experiences" of a great unity and liberation from ego boundary: "In moments of scientific discovery I have an intuitive insight into a grand design." He finds no necessary opposition between the rational way of thinking and intuitive experience culminating in what the mystics have tried to express. Both have their place and may coexist. Earlier there had been a sharp dichotomy between scientific and mystical knowledge. The logic of levels may never be amenable to analysis or intellectual understanding, but that is not to deny the role of reason.

Twentieth-century views of mysticism

Attitudes toward mysticism since the middle of the 20th century have been considerably modified by an awareness of subliminal consciousness, extrasensory perceptions, and, above all, an evolutionary perspective. The Roman Catholic paleontologist Teilhard de Chardin asked if in an expanding universe mysticism would not burst the limits of narrow cults and religious rigidity and move toward an ecumenical future. In a larger view, mysticism has not so much to be defined as renewed and redefined.

UNIVERSAL TYPES OF MYSTICAL EXPERIENCE

Intellectual and contemplative forms. Mystical experience, which is centred in a seeking for unity, or union, admits of wide variations but, nevertheless, falls into recognizable types: mild and extreme, extrovertive and introvertive, and theistic and nontheistic. Another well-known typology—corresponding to the faculties of thinking, willing, and feeling—employs the Indian formula, the respective ways of knowledge (*jñāna*), works (*karma*), and devotion (*bhakti*). Exclusive claims have been made on behalf of each, though maturer mystics have tried to accord to each its place and also to arrive at a synthesis, as in the *Bhagavadgītā* (Hindu sacred scripture). Depending on the powers of discrimination, the intellectual or the contemplative type tries to reach the Highest, the One, or the Godhead behind God. In its approach toward the supreme identity it tends to be chary of multiplicity, "to deny the world that it may find reality." Plotinus was "ashamed of being in the body." In the 17th century, Spinoza's nondenominational concept of intellectual love of God revealed a sense of aloofness or isolation reminiscent of the ancient Hindus.

Man, however, does not live by thought alone; to live is to work, and faith without works is dead. The mystic injunction is that works should be done in a spirit of nonattachment, with the ego sense (I, the doer) taken away. In a larger sense, not merely the doing of religious chores but all activity is offered to the Supreme. All life, according to many mystics, turns into a sacrament. "All life is *yoga* (meditation practice)."

Devotional forms. For the emotional type of person there is the mysticism of love and devotion. A theistic

attitude, or devotional mysticism, depends upon mutual attraction. In the words of a Ṣūfī poet, "I sought Him for thirty years, I thought that it was I who desired Him, but no, it was He who desired me." The path of devotion includes the rituals of prayer, worship, and adoration, which—if done with sincerity, inwardness, and understanding—can bring some of the most rewarding treasures of the religious life, including ecstasy (or *samādhi*). There is a paradox and a danger here: the paradox of avoiding the loss of personality, the danger of self-indulgence.

Ecstatic and erotic forms. Also, in an unpurified medium, the experiences may and do give rise to erotic feelings, a fact observed and duly warned against by the wiser spirits and the Fathers of the Church. (Zen Buddhism avoids both the overly personal and erotic suggestions.) Sometimes the distinction between *eros* (Greek: "erotic love") or *kāma* (Sanskrit: "sexual love") and *agapē* (Greek: "a higher love") or *prema* (Sanskrit: "higher love") can be thin. In the Indian tradition the Vaiṣnava (devotional) and Tantric (sexual) experiments were, in their apparently different ways, bold and honest attempts at sublimation, though the majority of these experiments turned out to be failures and disasters.

Use of drugs as aids to visionary experience

The same fate is likely to overtake the craze for psychedelic drugs and pharmacological aids to visionary experience—practices that are by no means new. A yogic writer, Patañjali, speaks of the use of *auṣadhi* (a medicinal herb) as a means to yogic experience, and the Vedas (Hindu scriptures) and *Tantras* (Hindu occultic writings) refer to wine as part of worship and the initiatory rites. The Greek Mysteries (religions of salvation) sometimes used sedatives and stimulants. Primarily meant to remove ethical, social, and mental inhibitions and to open up the subconscious no less than the subliminal, these techniques, as a rule, were frowned upon, even though those who took the help of such artificial aids had undergone prior training and discipline.

A whole new life-style and vocabulary have developed around medicinal mysticism in the 20th century. Peyote, mescaline, hashish, marijuana, *Cannabis indica*, LSD, and other similar products have become familiar to much of the world's population. The visions induced by such aids at best resemble the extrovertive type and cannot be easily equated with genuine mystical experience. According to taste, temperament, and tradition, the experience—a parody of creative spontaneity—may come from unexpected sources. In any case, utilizing such medicinal aids rarely achieves union with Self or God, and no permanent change of personality (in the mystical sense) has been known to occur.

GOAL OF MYSTICAL EXPERIENCE AND MYSTICISM

Experience of the divine or sacred. The goal of mysticism is "ghostly," a state or condition in which the soul is "one'd with God," according to the Western medieval work *The Cloud of Unknowing*. This "one-ing" is because all men, according to mystics, are called to their origin. Self-realization is basically one in intent with the injunctions of the Greek Mysteries: "Know thyself." This knowing, union, or communion with the divine and the sacred is of the essence of the ascent of man. As the only answer to the problem of identity, mystics look upon it as the final end, the *summum bonum*. At the journey's end waits the knowledge by identity. The direct, intuitive perception is more akin to revealed religion than to science and philosophy, though it is of itself a science, and philosophies spring from as well as lead to it.

Union with the divine or sacred. In the movement toward the goal there are, naturally, stages and processes, marked differently in different traditions. The discipline of prayer, purification, and contemplation culminates in the highest wordless union with the divine and the ultimate. As the process unfolds itself along the mystic way, an alteration of personality—a conversion, if not reintegration—occurs. The unregenerate "old man" (in Christianity) is replaced by the new being. The "twice born" (in Hinduism) becomes more than a metaphor or sacrosanct social arrangement. There is a change of level and mind. One of the aims or methods of mysticism is to make possible this change and conversion, a shift from the profane to the sacred, from "here" to "there": "Lead me from the unreal to the real, from darkness to light, from death to immortality" (*Bṛhadāraṇyaka Upaniṣad*). Before the transition, or the "great passage," is completed, however, the individual or pilgrim feels successively or simultaneously his oneness with nature, with people, and with things—an extension of awareness or expanded selfhood to which no limits can be assigned. Cosmic consciousness is thus a stage in a progressive self-discovery.

Conversion from the profane to the sacred

Experience of the universal. The nature of the goal, however, introduces a paradox. Like every other aim and activity, mysticism operates in a historical context. Yet, sooner or later, it also tends to reveal a timeless stance. The mystic is both in and out of time. The eternal now is a kind of release from the temporal order. Such a release may lead to a shift from the local to the universal, to a growing sense of unity of all experience. Though not a declared or conscious aim, this result could be looked upon as a not unworthy goal as well as a pragmatic standard.

To cure man of a provincialism of the spirit, from which more people suffer than either know or admit it, is one of the goals of a mysticism that has come of age. The true mystic is a cosmopolitan. In man's many-sided growth toward the real, a sane and mature mysticism leads to an ecumenical insight and obligation. Local colour, particulars, and uniqueness will not cease, but, in the perspective of the future and of wholeness, the universal alone will have survival value.

Experience of oneness with people. The apotheosized (divinized) field of consciousness is mysticism's ultimate goal and gift to the life of an evolving humanity. It alone is fitted to mediate between the anguish of existence and the serenity of essence, between *saṃsāra* ("cycle of birth and rebirth") and Nirvāṇa (the State of Bliss). According to an American Roman Catholic mystic, Thomas Merton, "The spiritual anguish of man has no cure but mysticism."

Though the mystic goal may seem to be tied to a transcendent reality, this does not mean a sundering of all relations and responsibilities. On the contrary, it is the guarantee of a set of altered relationships and a rehabilitation of what may be called the higher reason. Intuitions that sink into private fancy and morbidity have a short life to live. As for the mystic's "yonder," it is not spatially or posthumously remote but rather refers to a different order of reality and consciousness. The healthier forms of mysticism do not abjure action or the claims of love. It is an ancient maxim that one becomes what one loves. This is how the psychic birth repeats itself in the mystic soul, as stated, for example, by Meister Eckehart, a medieval German mystic: "It is more worthy of God that he should be born spiritually of every virgin, or of every good soul, than that he should have been born physically of Mary."

The claims of love versus mysticism

The mystic is not always amorous of the beyond, leaving an unredeemed world to its own ways. Not escape but, rather, victory is mysticism's inner urge and promise. The more sober among the mystics do not merely withdraw; they also return to the base and attempt the ancient alchemy, the transformation of men. A solitary salvation does not satisfy either head or heart.

MYSTICAL RELATIONSHIP BETWEEN MAN AND THE SACRED

Nature of the relationship. Within man is the soul of the holy, said Ralph Waldo Emerson in the 19th century. This is true of society, too. As the French sociologist Émile Durkheim saw it, the sacred is but a personified society. Mysticism, one might say, is the art and science of the holy. Theologically, it is but "the experience of the Holy Ghost, . . . the realization of the Spirit of Holiness." As the opposite of the profane and as a distinct and irreducible quality of the religious and mystical life, the sacred has always existed. It is indeed a mark of the real, and, when the German theologian Rudolf Otto isolated the sacred as a "quite distinctive category" of mystical apprehension, he had no lack of evidence. The emphasis, however, was not unanimously accepted. Some, like Inge,

thought the sacred might as well be elicited from such ultimate values as "truth, goodness, and beauty."

The "otherness" or unbridgeable gulf of the sacred

According to the respective world view, the interpretation or emphasis varies, but the universal core remains unaffected. The sacred is in its own way a coherent system, though not rational. The dualists no less than the theists insist on the unqualified and irreducible "otherness," the unbridgeable gulf, even when one speaks of union or communion. It is the distance that preserves the sacred.

Christian mystics, who often speak of "union with God," generally do not imply identity with the divine, since this might lead to heresy. The 16th-century Spanish mystic St. Teresa of Avila could write with impunity: "It is plain enough what unity is—two distinct things becoming one." But most others could not be so plain and had to use special strategy to cover up traces of possible deviation from what was permissible. Even if there had been a semblance of interpenetration between man and the divine, there could be no substantial identity. "Each of these," wrote the medieval Dutch mystic Jan van Ruysbroeck, "keeps its own nature. There is here a great distinction, for the creature never becomes God, nor does God ever become the creature." The same doctrine is preached in the Middle Ages by the mystic Heinrich Suso:

> In this merging of itself in God the spirit passes away and yet not wholly; for it receives indeed some attribute of God, but it does not become God by nature. It is still something that has been created out of nothing, and continues to be this everlastingly.

Identification of man with the divine, according to many the heart of mysticism, raises problems from other points of view as well. Pantheism, which asserts that all is God (or Nature), and God (or Nature) is all, is looked upon as a false doctrine in many religions. To John Calvin's leading question—"The Devil also must be God, substantially?"—the unsuspecting Spanish theologian and physician Michael Servetus had answered smilingly: "Do you doubt it?" The opinion cost him his life. The Hindus' *Upaniṣads*, however, insist on this identity in passage after passage. Closely looked at, this may not be simple pantheism but an identity in difference, a paradox present in even Vedānta (a Hindu monistic system). Islām has been fiercely critical of these claims of oneness and the medieval mystic Manṣūr ol-Ḥallāj had to pay with his life (922) for making the unorthodox announcement of his identity with the divine: *anā al-ḥaqq* ("I am the Creative Truth"). He was not the only one to speak in this manner. The more moderate Maḥmūd Shabestarī had reported an experience (*c.* 1320):

> In God there is no duality. In that presence "I" and "we" and "you" do not exist. "I" and "you" and "we" and "He" become one. Since in the unity there is no distinction, the Quest and the Way and the Seeker become one.

But Muslim theologians as a rule tended to dismiss those who "boasted of union with the Deity" as merely "babblers." In the Jewish tradition, it is generally considered improper and indecorous for any man to give a personal account of his own mystical experience.

The dimension of attraction and repulsion

Behind these and other interpretations, the reality of the sacred—and its persistent ambiguity—appears to be too true to be denied or ignored. Awe may or may not be the best part of man, but without it a necessary dimension is left out of the image of man, the dimension of what Otto called the *mysterium tremendum et fascinans* ("the mystery that repels and attracts"). The mystics are loath to leave this dimension out and, directly or indirectly, insist on its inclusion. The reason was suggested in the 5th–4th centuries BC by the Greek philosopher Plato, who maintained that the divine was the head and root of man. The mystic's is the eye, the third eye, with which the world beholds itself and knows itself divine. Though the vision is partial and passes away, there could be an ideal state of unbroken awareness of the Real Presence, an epiphany (manifestation).

According to the mystical point of view, the rational content of religion is not enough; it is not of the essence of religion. The sense of the holy, the mark of man's encounter with the "other," is usually invested with an ethical aura or undertone. This is how most people understand it. But this lowers its potency considerably. There is clearly an overplus, below good and evil and beyond good and evil. The numinous (spiritual) is not altogether free of the ominous. Thus, though the holy may be discussed, it cannot be well defined. It can, however, be experienced and evoked, as part of that wordless mystery that man must face—even if he is not able to explain satisfactorily—in his journey toward the real. This may happen early or late in his mystical journey, and the notion of evolution may not be applied to it uniformly.

The holy is not always and altogether a pleasant experience. Often shrouded in a fear that is more than fear, it is an inward dread and shuddering. The holy as awe-inspiring can be found in the Indian pantheon in such figures as Rudra and Kālī, the dark and wrathful faces of the divine, in which—in a collapse of finitude—majesty and unapproachability are inexplicably blended. The feeling of being consumed in the presence of the divine is a profound expression of man's relation to the holy. As for the ultimate mystical identity with the Supreme, Self, God, or the Unknowable, that also confirms the nonrational and suprarational nature of the experience in which ego, logic, and grammar are shattered alike. A frightful and traumatic adventure, not unlike the Greek Mystery rites, it can erupt at every crisis, break through an insulated universe. A clergyman cited by William Starbuck, an American psychologist of religion, spoke of having experienced

> a [silent] presence [in the night], all the more felt because it was not seen. I could not any more have doubted that *He* was there than that I was. Indeed, I felt myself to be, if possible, the less real of the two.

Diminution apart, the holy generally gives rise to a sense of energy and urgency, which may take different forms. At a higher level, the consuming fire of love reported by mystics could be an extension or refinement of the same energy, for "Love is nothing else than quenched Wrath." The "nothing else" may be an exaggeration, but such paradoxes of the religious life—*e.g.*, the unity of opposites—meet man at every turn. The void in Buddhism, like the nothing in Western mysticism, may be a numinous ideogram of the "wholly other."

Means and modes of the relationship. As means to meet the divine, some mystics have taken recourse to fasting, breath control, meditation, ecstasy, simplification, autosuggestion, and monoideism (absorption in a single idea). Rituals, in some cases, provide contact. An old method is the *via negativa* ("negative way"): "the emptier your mind, the more susceptible are you to the working of the presence." In other words, the impediments have to be removed. Among other indirect—but no less effective—means would be the shock therapy of the blood-curdling images that one notes in Tibetan iconography and symbology, which have their links with the archaic and the chthonian (infernal). On more negotiable levels, works of art—as far apart as Sung (Chinese) paintings, Gothic cathedrals, medieval temple architecture in India, the Egyptian Sphinx, music like *Missa Solemnis* (Roman Catholic solemn mass), or Sanskrit (Hindu) hymns—are accredited conductors of the numinous. Darkness, solitude, silence, and emptiness are sometimes enough for the sensitive soul, and the doors of perception open to a wider world beyond. A wide stretch of land or cranes flying against a cloudy sky were enough to throw the 19th-century Indian saint Ramakrishna into transport. But, always, it is less the object than something seen through the object, a bodiless presence, that forms the essence. Without symbols in which the holy is embodied, the experience of the holy vanishes.

The *via negativa*

Though it creates a sense of awe and exaltation, the idea of the holy also produces a mood of dependence, leading to action aimed at appeasing the deity or the powers behind the universe. At first, the policy of appeasement may have been inspired by fear and hope of reward. But, since the deity is not ultimately malevolent, it could also evolve into an idea of grace. Mystical theology, both in the East and in the West, has sometimes been divided

over the issue whether the union with the divine is the result of one's unaided effort or supernatural grace.

The various approaches to the divine

The approaches to the divine or sacred are various rather than uniform. Moving through physical, intellectual, devotional, and symbolic rituals and disciplines, it moves toward the ultimate goal: the annihilation of the self, *unio mystica* ("mystical union") in Western Christianity, *mokṣa* ("salvation") in Hinduism, Nirvāṇa (the State of Bliss) in Buddhism, and *fanā'* ("the snuffing out of self") in Islām. Though the words differ, the experiences are perhaps allied, if not the same. In a Ṣūfī (Islāmic mystical) poem the divine voice speaks exultantly:

> Annihilate yourself gloriously and joyously in Me, and in Me you shall find yourself; so long as you do not realize your nothingness, you will never reach the heights of immortality.

The description could as well be applied to the Buddhist *śūnyatā* ("void") and the self-negating of the Christian mystics.

The ultimate has been, as a rule, thought of as something "other" and apart, even if in mysticism what is sought is union or unity. Hierophany (manifestation of the holy) implies a choice and a distinction: between that which manifests the sacred and that which does not. Also, though a hierophany may represent a historic event that does not minimize its larger validity (and in any culture there may be local as well as general hierophanies), a hierarchy is not unlikely. On occasions, the sacred may manifest itself in something profane. Ideally, to a mystic, "the integrated quality of the cosmos is itself a hierophany." From this follows the possibility of consecrating the whole of life, so that by sacramental transformation, at any moment, "the flash of a trembling glance" may be inserted into the great time and project the man amphibian (having dual life) into eternity. Deification, without doubt one of the goals of the mystical life and a fundamental concept of orthodox Christendom, is part of the dialectics of the sacred. The alchemic undertone, in the man–God idea, has never wholly been extinguished. But, as part of the continuing paradox, one should also mention a resistance to the sacred. Depending on the ambivalence of the response to the sacred, which at once repels and attracts, the resistance is ultimately a flight from reality.

SEMANTICS AND SYMBOLISM IN MYSTICAL EXPERIENCE

Union of opposites. Mystical experience is flanked with a communication hazard, a "polar identity." The linguistic liberties and extravagances are part of the logical impossibility of having to describe one order of experience in terms of another. Hence, the rhetoric of mysticism is largely one of symbols and paradoxes. The most striking of the strategies, as the medieval Christian scholar Nicholas of Cusa put it, is *coincidentia oppositorum* ("union of opposites"). Since the opposites coincide without ceasing to be themselves, this also becomes an acceptable definition of God, or the nature of the Ground. God, said Heracleitus, is day and night, summer and winter, war and peace, and satiety and hunger—all opposites. A 5th- to 6th-century-AD Christian mystical writer called Dionysius the Areopagite advised people to

Role of symbols and paradoxes

> strip off all questions in order that we may attain a naked knowledge of that Unknowing and that we may begin to see the superessential Darkness which is hidden by the light that is in existent things.

This use of language or view of things is obviously not normal.

Old myths and archetypes are full of examples of such dichotomy. The Zoroastrian tradition has Ormazd (the Good Lord) and Ahriman (the Lie); the Gnostic myth speaks of Christ and Satan as brothers; and the same idea is found in the Vedas, where the *suras* ("good spirits") and *asuras* ("bad spirits") are shown to be cousins. In a different context there is the androgyne ("man-woman"), the *ardhanārīśvara* in Indian myth. As for the Hindu *jīvanmukta*, the liberated individual, he is liberated from duality. This is also part of what the Lord Kṛṣṇa (Krishna) said, when he asked the hero Arjuna to rise above the three *guṇas* ("modes"). The Tantras refer to the union of Śiva (a Hindu god) and Śakti (Śiva's consort) in one's own body and consciousness and provide appropriate practices to this end. The Chinese had their Yang and Yin (opposites), the Tibetans their Yab and Yum (opposites), and Buddhism its *saṃsāra* and Nirvāṇa as aspects of the Same. In *Prajñāpāramitā*, a Mahāyāna (northern Buddhist) text, the Illumined Ones are supposed to engage in a laughter in which all distinctions cease to exist.

Emptiness and fullness. Mystical experience permits complementary and apparently contradictory methods of expression: *via affirmativa* ("affirmative way," or fullness) as well as *via negativa* ("negative way," or emptiness). For fullness and freedom both are needed. This is because the reality affirmed contains its own opposite. In fact, the apparent negations—*neti-neti*, ("not this, not that") of the *Upaniṣads*, the *śūnyatā* ("void") of the Buddhists, or the Darkness beyond Light of Dionysius—perform a double function. They state a condition of being as well as its utter freedom from every determination. As Dionysius explains it, "While God possesses all the attributes of the universe, being the universal Cause, yet in a stricter sense He does not possess them, since He transcends them all." The "negative way," a way of turning the back upon the finite, is part of an old, positive, verified insight, at once the last freedom and, as far as many men are concerned, perhaps a lost freedom.

Symbolism of divine messengers. Experiences relating to these realities could not at any time have been common or widespread and must have come mainly through consecrated channels: yogis (Hindu meditation practitioners), gurus (Hindu teachers), prophets, mystics, saints, and spiritual masters of the inner life. This channeling through human agents has given rise to a host of divine messengers: a hierarchy of angels, intermediaries, and incarnations, singly or in succession. This manner of approaching or receiving the divine or holy is the justification of *avatāras* ("incarnations of God") and the man-God in various religions. "God was made man in order that man might be made God."

The mystical experience is a renovation of life at its root; that is, of the forgotten language of symbols and symbolism. The mystic participates in two worlds at once, the profane and the sacred. Rituals and ceremonies become the means of integration with a higher reality and consciousness. But symbols cannot be deliberately manufactured, nor do they make an arbitrary system. "Being for ever communicating its essence" is the source of their abundance, potency, and unity. Even a nontheistic mysticism, such as Buddhism, has deployed symbols freely, of which perhaps the most well-known is the formula *oṃ maṇi padme hūṃ* ("the jewel in the lotus").

Participation in two worlds at once

Symbols point beyond themselves, participate in that to which they point, open up levels of reality that are otherwise closed to man, unlock dimensions and elements of the soul that correspond to reality and cannot be produced intentionally or invented. Symbols may be inner or outer. To some, nature symbolism comes easily.

Symbolism of love and marriage. A far more risky but inescapable mode of symbolism than pantheism has been the use of the analogy of human love and marriage. Not all the mystics have been deniers or champions of repression. The soul, it may be added, is always feminine. The Christian mystics St. Bernard and St. John of the Cross, the Islāmic Ṣūfī poets, and the Hindu Dravidian and Vaiṣṇava saints could teach lovers. Not only the church but the faithful are viewed to be among Christ's brides and speak the language of love. "O that you would kiss me with the kisses of your mouth!" The speaker is the bride, thirsting for God. St. Bernard has shown that through carnal, mercenary, filial, and nuptial love the life of man moves toward the mystery of grace and union.

The hermeneutics (critical interpretation) of "the Bridegroom-Word" is that "the soul's return is her conversion to the Word, to be reformed through Him and to be conformed to Him." In the West, the roots of the tradition go back to the Song of Solomon in the Bible, not, perhaps, the best of models. The Hindu *līlās* ("love plays") of Rādhā and Kṛṣṇa have been freely misunderstood in spite of the repeated disclaimer that the events

described are not facts but symbols. The charge of immorality has been loudest against the Tantras, which had made a subtle, bold, and strict experiment in sublimation, whose inner sense may fail to be intelligible even to those who are attracted by it. That the marriage symbol should find a readier response among the brides of Christ is only to be expected. In *The Interior Castle*, St. Teresa has been fairly outspoken: "He has bound Himself to her as firmly as two human beings are joined in wedlock and will never separate Himself from her." But this was not a monopoly of nuns. The medieval theologian Richard of Saint-Victor has described as well as explained the "steep stairway of love" made up of betrothal, marriage, wedlock, and fruitfulness. In a slightly different set of symbols, St. John of the Cross states that after the soul has driven away from itself all that is contrary to the divine will, it is "transformed in God by love."

The notion of the "stairway of love"

Symbolism of the journey. Another prominent mystical symbol is the way, quest, or pilgrimage. Having lost the paradise of his soul, man, as the 16th-century physician and alchemist Paracelsus says, is a wanderer ever. A Christian monk, St. Bonaventure, has written about the mind's journey to God, and an English mystic, Walter Hilton, has described the Christian journey thus:

> Right as a true pilgrim going to Jerusalem, leaveth behind him his house and land, wife and child, and maketh himself poor and bare from all that he hath, that he may go lightly without letting: right so, if thou wilt be a ghostly pilgrim, thou shalt make thyself naked from all that thou wouldst be at Jerusalem, and at none other place but there." (From *The Ladder of Perfection.*)

According to the Ṣūfīs, the pilgrim is the perceptive or intuitional sense of man. Aided by attraction, devotion, and elevation, the journey leads, by way of many a wine shop (divine love), to the tavern (illumination), "the journey to God in God." In his *Conference of the Birds*, the 12th-century Persian Ṣūfī ʿAṭṭār refers to the seven valleys en route to the king's hidden palace: the valleys of quest, love, knowledge, detachment, unity, amazement, and, finally, annihilation. Others have gone further and spoken of "annihilation of annihilation." In the symbolic universe, denudation may be viewed as a way of fullness.

Men are called to the journey inward or upward because of a homing instinct. Eckehart put the matter simply: earth cannot escape the sky. All men are called to their origin, which implies God's need of man. A mutual attraction, the tendency toward the Divine cannot be stifled indefinitely, since it returns after every banishment. For some, paradise is not enough; it is too localized and perhaps perishable. They strain toward eternity, a leap beyond history into the incommunicable forever. A white radiance to some, to others it is "a ring of pure and bright light." The Veda speaks of the *kālahaṃsa* ("the swan of time") winging back to the sky and nest, eternity.

Essentially a way of return, *ricorso*, the final aim of mysticism is transfiguration. But

> by what alchemy shall this lead of mortality be turned into that gold of divine Being? But if they are not in their essence contraries? If they are manifestations of one Reality, identical in substance? Then indeed a divine transmutation becomes conceivable. (From Sri Aurobindo, *The Life Divine.*)

This is a clue to the Vedas, those hymns to the mystic fire and the inner sense of sacrifice, burning forever on "the altar Mind." Hence the abundance of solar and fire images: birds of fire, the fire of the sun, and the isles of fire. The symbol systems of the world religions and mysticisms are profound illuminations of the human–divine mystery. Be it the cave of the heart or the lotus of the heart, "the dwelling place of that which is the Essence of the universe," the third eye, or the eye of wisdom—the symbols all refer back to the wisdom entering the aspiring soul on its way toward progressive self-understanding. "I saw my Lord with the Eye of the Heart. I said, 'Who art Thou?' and he answered, 'thou'." Throughout the ages man, *homo symbolicus*, has been but exploring the endless miracle of being. Mystical experience is a living encyclopaedia of equations and correspondences, pointer readings that partly reveal and partly conceal.

Solar and fire symbolism

PSYCHOLOGICAL ASPECTS OF MYSTICISM

Awareness. Mysticism has been accused of passing off psychological states for metaphysical statements. But the psychological base has never been questioned seriously. It would, however, be proper to call it autology (the science of self). If the word psychology is to be retained, it must be in the original sense of the word now discarded. The contrast between the old and the new has been well expressed by the Russian philosopher Peter Ouspensky:

> Never in history has psychology stood at so low a level, lost all touch with its origin and meaning, perhaps the oldest science and, unfortunately, in its most essential features, a forgotten science, the science of his possible evolution.

Mysticism is that science in which the psychology of man mingles with the psychology of God. The major change or orientation is from the level of the profane to the sacred, an awareness of the divine in man and outside. The source and goal of such a psychology was revealed in the 18th-century Methodist leader John Wesley's dying words: "The best of all is this, that God is with us."

A mark of the mystic life is the great access of energy and enlarged awareness, so much so that the man who obtains the vision becomes, as it were, another being. Mansions of the mind, *maqām* (Arabic: "place"), and *bhūmi* (Sanskrit: "land"), open up to the gaze of the initiate, a wayfarer of the worlds. This means a renewal or conversion until one knows that the earth alone is not man's teacher. The mystic begins to draw his sustenance from supersensuous sources. He has "drunk the Infinite like a giant's wine," and a hidden bliss, knowledge, and power begin to sweep through the gates of his senses.

Role of identification. The state of energizing is facilitated by controlled attention. It is customary to fix the mind on some object or idea, some focus of contemplation. According to the Indian formula, to worship God one must become like him (*devam bhutva devam yajet*). Exercises, physical no less than mental, including methods of worship and prayer, have been developed to this end until one becomes what one contemplates. The ranges and creative aspects of the mind are part of the psychology of the mystics and one of the oldest traditions of mankind. The old Indian psychology divided consciousness into three provinces: waking state (*jāgrat*), dream state (*svapna*), and sleep state (*suṣupti*), and added a fourth (*turīya*), which is the consciousness of man's pure self-existence or being. The fourfold scale represents the degrees of the ladder of being by which man climbs back to the source, the absolute divine. The change, from "here" to "there," is not an uneventful process. There come dry periods, deviations, violent alterations, and temptations. If there are raptures and blue heavens, there are python agonies and absolute abandonments, howling deserts and "dark nights of the soul" to go through. Tears of joy, horripilation (bristling of the hair), stigmata (bodily marks or pains), and parapsychological phenomena have been known to develop.

Indian states of consciousness

The earlier phases of a naturalistic psychology had no qualms in relegating most of these experiences to the scrap heap of obsolete and archaic vanities, disorders, and morbidities—in a word, hallucination. One reason for such overall denigration was that complacent aliens to the mystical life did not care to distinguish between abnormal and supernormal phenomena. To them all were the same, at best some kind of religious sport. An American Quaker philosopher, Rufus Jones, has noted that psychology, as 20th-century man knows it, is empirical and possesses no ladder by which it can transcend the empirical order.

According to mystics, most men live in a prison, the walls thick with ego, the senses, and restricting interests. But some prisoners develop a passion to scale the walls and move toward an unwalled horizon, an adventure of ideas, if nothing more. Thus, the hypothesis that there might be cherubs and seraphs (angels of knowledge and of love) who call and guide men in the upward way is difficult to ignore. But if the distinction between love and knowledge is at all valid, the achievements of men would

seem to be the products of love, since, as Aristotle maintained, the intellect by itself moves nothing. Without "the driving and drawing that we feel in the heart," mysticism would lack power and might sink into quiescence, as has sometimes happened. To will what the Supreme wills is the supreme secret, the *primum mobile*. "Nothing burns in hell but self-will" (*Theologia Germanica,* ch. 34). The mystic approaches this knowledge and mobility even when he is compelled to withdraw from society for long or short periods. But withdrawal without return is not complete. As scientists of the psyche, the mystics insisted on the primacy of the inner factors. Modern psychoanalysis claims to have made available to man's knowledge areas of darkness beneath the conscious levels. However revealing these evidences of the ape and the tiger, psychoanalysis is debarred from understanding the superconscious, and it is viewed by mystics as being less than correct in its reading of the irrational in man. The inescapable pessimism of the psychoanalytic conclusion stands in contrast to the possibilities of self-development and sublimation to which mystics have always pointed.

Among other discoveries on the mystical way is that of ambivalence, or the alternate ways of looking at the world: temporal as against eternal. The double vision characterizes the saint whose life forms a point of intersection between time and timelessness. Mystical psychology assumes a transcendental faculty, in the hiddenness, beyond the threshold. It is committed to a breakthrough and could never have sustained itself without constant verification. In many ways a guarded secret, meant for the competent few, the experiment has hazards and could upset any but the most disciplined. The rousing of energy, the infusion of grace, and confrontation of the levels of reality create tensions and difficulties. Hence, the insistence on moderation and balance on all hands. "The higher the love, the greater the pain," a voice had consoled a 13th-century German mystic, Mechthild von Magdeburg. "Believe me, children," wrote a 14th-century German mystic, Johann Tauler, "one who would know much about these matters would often have to keep to his bed, for his bodily frame could not support this."

These upheavals of "mystic ill health" are part of a developing consciousness that has to move through and adjust to habits of inertia and resistance in the system and to an inability to support the emerging powers and their demands. A little imbalance now and then should take no one by surprise. The possibility of ranges of consciousness without thinking is one of the basic premises of yogic or mystical psychology. It constitutes a confutation of the formula of the 17th-century French philosopher René Descartes: *cogito ergo sum* ("I think; therefore, I am"). Being can exist without *cogito* (or *ratio*, "reason") in a direct awareness of things that is the function of intuition, *prajñā*.

Ranges of consciousness without thinking

SYSTEMATIC EXPOSITION OF MYSTICAL EXPERIENCE

Attempts of mystics to record the nature of their experiences. The theory or interpretation of mysticism is not mysticism. Generally, there are two sides to the theory: philosophical and practical. There may be another: confessional and justificatory. Though some mystics have been content to record what happened, others have worked out manuals of praxis (techniques), or *sādhāna*. As a rule, mystical method, experience, and exegesis cannot be sharply set apart from one another. However ineffable, raids on the inarticulate and expositions of the same have not ceased. The expositions have formed part of a particular framework of culture, tradition, and temperament. The 8th- to 9th-century-AD Indian philosopher Śaṅkara and the 16th-century Spanish mystic St. John of the Cross are not likely to talk in the same tone or accent. However universal in intent, all expositions tend to be localized.

Under present conditions, the study of comparative mysticism as well as the spirit of the age make it possible and perhaps mandatory for modern man to move toward an open and untethered mysticism, the "ocean of tomorrow." Indications of this change in attitude and emphasis are not wanting, especially in the 20th-century writings of the Indian mystic philosopher Sri Aurobindo and Teilhard de Chardin, who represent something totally new but allied. R.C. Zaehner has explained that both, though unknown to each other,

> not only accepted the theory of evolution, but enthusiastically acclaimed it, indeed were almost obsessed with it. Both were profoundly influenced by Bergson, both were deeply dissatisfied with organized religion, and both were vitally concerned not only with individual salvation or "liberation," but also with the collective salvation of mankind.

The value and meaning of mystical experience. Among the attempts to explain the value and meaning of mystical experience, a few features may be indicated. Claimed to be a guarantee for order and reconciliation, mysticism does not take away mystery from the world, nor is it essentially irrational. Though in their penchant for the beyond or God-intoxication some mystics have inclined to reject the world, the maturer variety has not divided the world of spirit and matter but has tried to mediate between spirit and matter with the help of emanations, correspondences, and a hierarchy of the real. As a giver of life, mysticism is meant to fulfill and not to destroy. Thus, it need not be world negating.

Pointing to a scale of senses and levels of mind, mysticism provides an escape from a life of uninspired existence. It magnifies man and gives him a hope and destiny to fulfill. With its abiding sense of the "more," mysticism may be called the religion of man or the religion of maturity. It offers not irrational developments or inducements but the working out of inherent potentials. Evolution, according to mystics, is not yet ended.

The mystical life is not for those who are well adjusted and other oriented. In Ramakrishna's homely phrase, at some point or other one has to "take the plunge." A change so radical calls for a kind of attention other than what most people seem prepared to give. To make it his supreme business one must have a call to holy living. He who seeks the divine must consecrate himself to God and to God only.

Problems of communication and understanding. The problem of communication, of tidings from another country, is obvious. Transvaluation of values is not easy to accept, adjust to, or express. The dialogue between mystical and other pursuits is an unsolved problem. After he had undergone a spiritual experience, the 13th-century Christian philosopher St. Thomas Aquinas is reported to have said, "I have seen that which makes all that I have written and taught look small to me. My writing days are over." This, from the author of the voluminous *Summa theologica* ("Summary of Theology"), is not without its importance.

Even if it is difficult to describe visions and dangerous to systematize, the direction in which mysticism points is clear: relational transcendence. The 20th-century crises and the mass media suggest the possibility of a mysticism brought up to date that will serve "the Creative Intention that past ages have called God." Whether it comes through symbols, systems, paradigmatic examples, or extreme situations, there will probably always be some response to the call of the real.

MYSTICISM AS A SOCIAL FACTOR

Mystical experience is no doubt solo, the experience of a singular person. But more than "a flight of the alone to the Alone," it could also be a redemption of solitude no less than of society. In the mystic experience, as Jakob Böhme said, the world is not destroyed but remade. At times a protest against heteronomy (*i.e.*, external authority and ecclesiastical machinery), mysticism has expressed itself in diverse backgrounds and flourished during dark periods of history.

Because of its other-worldly bias, the belief still persists that the solitary mystic, absorbed in a vertical relation with God or reality, owes no social responsibility. Altogether an outsider, he has deliberately undergone a civil death. This is not an ideal or wholly accurate picture. "A Mystic who is not of supreme service to the Society is not a Mystic at all" (from preface to R.D. Ranade, *Mysticism in Maharashtra*). According to Zen Buddhism, the great

The mystic as a man of action "doing nothing"

contemplative—even when "sitting quietly, doing nothing"—has been a man of action, perhaps the only kind of action that leaves no bitter residue behind. The less extravagant forms of mysticism represent attitudes and principles of charity, detachment, and dedication, which should guide the relation of the individual to the group. The mystics have fought the inner battle and won, creating themselves and their world.

Mysticism proves the individual's capacity to rise above the conditioning factors of nature, nurture, and society and to transform collective life, though this has not been generally recognized. With a hidden and potent force, mystics have tried, as best as circumstances permitted, to mend the universal ill. As in the classic resolve of the *bodhisattva* ("buddha-to-be"), they have looked forward to universal enlightenment. If the attempt by mystics to create a new order or a better society has failed, the incapacity or defection of the majority may be the reason for the failure.

"Revolution" is a word too often profaned. The change suggested is mainly, if not wholly, from without. In such contrived salvation by compulsion, the inner core is hardly touched. "But it is an eternal law that there can be no compulsion in the realm of the spirit. It is essentially a world of free creative choices" (Rufus Jones, *Some Exponents of Mystical Religion*). Mystics insist on a change of consciousness, a slower and more difficult process, and also on a scrupulous equation between ends and means. Impatience, deviations, and subterfuges in this respect can be costly, ironic, and instructive. According to mystics, the individuals who will most help the future of humanity will be those who recognize the unfinished and ultimate revolution—the evolution of consciousness—as the destiny and therefore the great need of all men as of society.

Holiness does not mean a retreat from or a rejection of the world. To be a mystic or a seer is not the same thing as being a spectator on the fence. As the Swedish secretary-general of the United Nations, Dag Hammarskjöld, proved with his life, in the modern era the road to holiness necessarily passes through the world of action. Many with a mystical frame of mind look beyond what mystics call quasi-revolutions to a great life—an entire civilization, the civilization of consciousness. The need of synthesis places its stake on the future and the All.

> The outcome of the world, the gates of the future, the entry into the super-human—these are not thrown open to a few of the privileged nor to one chosen people to the exclusion of all others. They will open only to an advance of *all together*. (From Teilhard de Chardin, *The Phenomenon of Man*.)

According to mystics, here may be the outline of a revolution whose message has reached but a few. The hope of a Kingdom of Heaven within man and a City of God without remains one of mysticism's final gifts to the life of what many mystics view as an evolving humanity.

BIBLIOGRAPHY. WILLIAM JAMES, *The Varieties of Religious Experience* (1902, many later editions), marks the beginning of an intelligent and general interest in the subject, in which the reality of the experience is established and its four characteristics (freely adapted by later writers) clearly brought out. RICHARD M. BUCKE, *Cosmic Consciousness: A Study in the Evolution of the Human Mind* (1905, many later editions), introduced two important ideas as one, ideas that would recur, with modifications, in later writings. RUFUS M. JONES, *Studies in Mystical Religion* (1908, reprinted 1970), provided a balanced and liberal attitude that emphasized its experiential quality, its value as a practical guide, and the presence of a mystical brotherhood through the centuries. EVELYN UNDERHILL, *Mysticism*, 12th ed. rev. (1957), has been a pioneer work, though its insistence on the Mystic Way has been questioned. REYNOLD A. NICHOLSON, *The Mystics of Islam* (1913, reprinted 1966), is one of the earliest studies in Ṣūfism that still holds interest. SRI AUROBINDO, *The Synthesis of Yoga* (first published, serially, 1914-21, later in book form), with much collateral illumination, explains the idea of Integral Yoga. JAMES BISSETT PRATT, *The Religious Consciousness: A Psychological Study* (1920), is critical but sympathetic. HENRI BERGSON, *Les Deux sources de la morale et de la religion*, 3rd ed. (1932; Eng. trans., *Two Sources of Morality and Religion*, 1935), forms part of a general thesis on creative evolution and, paradoxically, on the need for mysticism in an age of mechanization. GERSHOM G. SCHOLEM, *Major Trends in Jewish Mysticism*, 3rd rev. ed. (1954), clearly brings out the distinction that the concept of union is not an essential of mystical experience as understood in the Jewish tradition. ALDOUS HUXLEY, *The Perennial Philosophy* (1946), is an anthology with sophisticated, sometimes cynical, commentary and with an ascetic bias. PIERRE LECOMTE DU NOUY, *Human Destiny* (1947), attempts to mediate between science and faith and appeals to modern man to act as a responsible actor in evolution. JACQUES DE MARQUETTE, *Introduction to Comparative Mysticism* (1949), is a fair and straightforward survey in which its relevance to modern life and thought is brought out and an awareness of possibilities hinted at. R.C. ZAEHNER, *Mysticism, Sacred and Profane* (1957), beginning as a caveat against the use of drugs for transcendental experience, goes on to make critical distinctions between four types of mysticism. D.T. SUZUKI, *Mysticism: Christian and Buddhist* (1957), offers a sympathetic study of contrasts as well as some resemblances between two traditions. RUDOLF OTTO, *Das Heilige*, 9th ed. (1922; Eng. trans., *The Idea of the Holy*, 1958), is indispensable, but the "otherness" and ambiguity of the sacred, according to some mystics, seems to have been overemphasized. RADHAKAMAL MUKERJEE, *The Theory and Art of Mysticism* (1960), is an overall study, particularly good with regard to the Eastern material. WALTER T. STACE, *Mysticism and Philosophy* (1960), is balanced and analytic but singles out introvertive mysticism as more genuine and superior. SIDNEY SPENCER, *Mysticism in World Religion* (1963), is a helpful anthology with a reliable introduction to the field of comparative mysticism. PIERRE TEILHARD DE CHARDIN, *Le Phénomène humain* (1955; Eng. trans., *The Phenomenon of Man*, 1959), though its scientific accuracy has been questioned, its poetic and impassioned attempt to mediate between religious insights and a hope for man and the future has made it the object of much attention.

(S.K.G.)

Myth and Mythology

Myth is a collective term used for one kind of symbolic communication and specifically indicates one basic form of religious symbolism, as distinguished from symbolic behaviour (cult, ritual) and symbolic places or objects (such as temples and icons). Myths (in the plural) are specific accounts concerning gods or superhuman beings and extraordinary events or circumstances in a time that is altogether different from that of ordinary human experience. As with all religious symbolization, there is no attempt to prove that these unusual, transcendent, or divine events are "possible," or otherwise to justify them. For this reason, every myth presents itself as authoritative and always as an account of facts, no matter how completely different they may be from the ordinary world. The original Greek term for myth (*mythos*) denotes "word" in the sense of a decisive, final pronouncement. It differs from *logos*, the word whose validity or truth can be argued and demonstrated. Because myths present extraordinary events without trying to justify them, people have sometimes assumed that myths are simply unprovable and false stories and thus have made the word myth a synonym for fable. In the study of religion, however, the difference between myth and fable must be borne in mind.

The term mythology is used in two distinct ways. It is the study of myth, but it is also the body of myths given in a particular religious tradition.

NATURE AND SIGNIFICANCE

Myth occurs in the history of all human traditions and communities and is a basic constituent of human culture. People in every culture or tradition have developed a stock of myths in addition to other early forms of literature (such as legends and fairy tales). Because the variety of mythical themes, characters, and styles of narration is so great, it is difficult to make general statements about the nature of myths, which in their details indicate what the self-image of people in a given civilization is. The study of myths thus claims a place next to the study of language, art, philosophy, and science.

The primacy of myth

The primacy of myth stands out most clearly in certain practical situations. In the middle of the 19th century, for instance, a newly appointed British governor of New Zealand, Sir George Grey, found himself face to face with

the problem of how to come to terms with the warlike Maori. He learned their language, but that was not enough to understand what caused their military, social, and political upheaval. To understand the intention of Maori chiefs in negotiations, he found it above all necessary to study their frequent references and allusions to Maori mythology. Similarly, other government officials and Christian missionaries of the 19th and 20th centuries made extensive efforts to understand the mythologies of nations or tribes, because only such understanding made communication possible. The extensive studies of various mythologies were not only a means to an end, whether the efficient administration or the conversion of people, but they also amounted to a discovery that was then new to Europeans: myths present the model for man's behaviour. The world of myth is a continuous source of the knowledge needed for crucial problems in man's existence: war and peace, life and death, truth and falsehood, good and evil.

DEFINITIONS OF MYTH AND MYTHOLOGY

Unity of meaning and variety of description. Distinguished philosophers and folklorists represent opposite extremes in the study of mythology: the former aim at the most general statements possible and focus on myth as one general factor in human thought; the latter emphasize the variety of myths. Between the two, there lies a wide spectrum of interpretations, yet the two tendencies remain discernible in most attempts at definition, in harmony with the distinct attitudes prevailing in the study of man. On one hand, efforts are made to fathom the inner meaning of myths because of the authoritative, indeed revelatory, function they have for human existence. Many scholars, such as Mircea Eliade, a historian of religion, emphasize that myth narrates sacred history; and whether or not scholars agree with Rudolf Otto, a German theologian, that experience of the holy is a unique experience, they believe that myth is to be understood as a religious phenomenon and cannot be fully, or cannot at all be, explained in terms of nonreligious (*e.g.*, literary, psychological, sociological, or economic) categories. This tendency leads to sharp distinctions between myths and other, nonsacred forms of literature. On the other hand, there is a tendency to deal with myth in terms of a general theory of man that may be inspired biologically, psychologically, or any other way.

It is possible, however, to stress the sacred character of myth and therefore its uniqueness. It is also possible to describe and list the themes of various accounts and thus place myths and other narratives side by side. Whichever way one leans, in the delineation of myth, it is useful to venture comparisons and contrasts with other manifestations of oral tradition.

Characteristic contents of myths

Myths are accounts with an absolute authority that is implied rather than stated; they relate events and states of affairs surpassing the ordinary human world, yet basic to that world; the time in which the related events take place is altogether different from the ordinary historical time of human experience (and in most cases is unimaginably long ago); the actors in the narrative are usually gods or other extraordinary beings (such as animals, plants, the very first people, or specific great men who changed the human condition). Many other forms of literature share in one or more of the features of this definition of myth without becoming mythical.

Relation of myths to other forms. *Etiological tales.* The etiological tale seems closest to myth. In modern usage the term etiology is used to refer to the description or assignment of causes (Greek *aitia*). Accordingly, an etiological tale explains the origin of a custom, a peculiar condition or feature in nature, or the human or divine world. Many tales explain the origin of rocks or mountains. Others, such as the famous Hindu narrative that states that the blue neck of the god Śiva is the result of a poison he drank in primordial times, explain iconographic features. According to Karl Kerényi, a classicist, however, the original meaning of *aitia* (the word from which etiology derives) was not merely that of "explanatory causes" but an indication of a sort of "primeval condition" and thus, by implication, first principles or primary states that produce everything always.

Modern usage of these terms is vague, and the vagueness unnecessarily obscures the distinction between etiological tale and myth. Generalizing, it can be said that the typical etiological tale answers the question *why* such and such is the case, and the typical myth answers the question *whence* and thus indicates the *basis* of something or the validity of a custom. As a rule, the etiological tale has an amusing quality, and the etiological theme often seems to be added to a mythical narrative as an afterthought. In other words, the etiology is not the distinctive characteristic of myth. The story of the god Śiva's neck turning blue as a result of the poison he drank illustrates the transition from myth to etiological tale as well as the distinction between the two. In some presumably earlier versions, the etiological motif did not occur. The earlier versions narrated a series of creational events, among which was the episode in which Śiva drank a deadly poison (which had mysteriously turned up and threatened the whole creation) in order to save the world from the danger. The story of his neck turning blue as a result seems to have been added as an afterthought in later versions. When etiological passages occur in mythical narratives, it is these passages that are prone to the greatest change in the course of time because of the entertaining quality of etiological tales. Even if etiologies occur as features in myths, etiological tales are a distinct category and do not share in the claim to truth that typifies myth.

Fairy tales and folktales. The fairy tale tells of extraordinary beings and events and, in that respect, resembles myth, though it differs markedly in other respects. The time suggested by the fairy tale is the time of man's ordinary experience. Whereas the typical fairy tale opens with: "Once upon a time . . .," the typical myth begins with: "In the beginning. . . ." The fairy tale carries no authority, even if sometimes a moral is presented. Its outstanding quality is entertainment. Like the fairy tale, folktales can be collectively distinguished from myth. In all cases the miraculous plays an important part, but the intent remains entertainment. Thus, this whole group of narratives is quite different from myth, even if historically many characters in the fairy tale or folktale (*e.g.*, ogres, witches, wizards, werewolves, and giants) may be transformations of figures in a past mythological tradition (see also FOLKLORE; FOLK LITERATURE).

Fables. The Latin word *fabula* originally carried about the same meaning as Greek *mythos*; but, like *mythos*, it also came to be used with the meaning of fictitious or untrue story. The same emphasis exists in the English "fable." Something untrue can be referred to as a "mere fable," and fictitious and instructive stories like those of Aesop, an ancient Greek storyteller, are called fables. Genuine myths, on the contrary, are not presented as fictitious or untrue.

Resemblance of sagas to myth

Sagas and epics. Sagas are tales with a claim to truth, and in that important respect they resemble myths. The time of action, however, is a specific time in the past (not unspecified as in the fairy tale, nor an altogether different time as in the case of myth). In many primitive traditions that have no pronounced interest in history, saga-like tales are virtually indistinguishable from myths. The word *saga* (literally "things said") is Old Norse, and there are a great many examples of the form in medieval Scandinavian literature. In addition to defined periods in the past, the saga usually stresses specific locations. In this respect too, sagas resemble the myths of certain traditions (as in Tuamotuan religion in the Pacific). The epic can be seen as an extension of the saga. The time of action is presented as a specific time in the past. As in the saga, the protagonists are usually great ancestors of the race or nations, heroes, and heroines. Sometimes again as in the saga, superhuman bringers of good fortune play a role (*e.g.*, Gesar in the Tibetan epic; Kṛṣṇa in the *Mahābhārata*, a Hindu scripture). The epic as such, however, is not of a mythical character. Instead, it presupposes the reality of myths and a knowledge of myth among the listeners.

Legends. The notion of time in legends is like that in sagas. The protagonists, unlike those in the sagas, are

as a rule great religious figures. The legend, however, carries no authority comparable to that of myth. Rather, the legend illustrates a truth that is known from another (usually mythological) source.

It is to be noted that this list of literary types is a list that conforms by and large to Western scholarly views. Other traditions, whether of "primitive" or "advanced" civilizations, have their own classifications. In most of these other traditions, however, a basic distinction is somehow made between "true" and "fictitious," whereby the "true" stories correspond to what Westerners would understand as genuine myths.

FUNCTIONS OF MYTH AND MYTHOLOGY

Explanatory and narrative. The first function of myths that strikes the outside observer of any tradition is that of explanation. Natural, social, cultural, and biological facts are explained by myth. This is not to say, however, that myths become identical with etiological tales. A North American Indian (Abnaki [Wabanaki]) myth, for example, explains the origin of corn: a lonesome man meets a beautiful woman with long, light hair; she promises to remain with him if he does what she tells him; she tells him in detail how to make a fire and drag her over the burned ground; as a result of these acts, he will see her silken hair (viz., of the cornstalk) appear and have corn seeds for his use. Henceforth, whenever the Indians see her hair, they know that she has not forgotten them. Obviously, a myth such as this one functions as an explanation, but, just as obviously, the narrative form distinguishes it from a straightforward answer to an intellectual question about causes. The function of explanation and the narrative form go together, and myths have thus been significant in many traditional systems of education.

Justifying or validating. A great variety of myths answer questions about the nature and foundation of ritual and cultic customs. According to myths from the island of Ceram (Indonesia), in the beginning human life was not complete, or not yet "human": vegetation and animals did not exist, and there was neither death nor sexuality. In a mysterious manner Hainuwele, a girl with extraordinary gift-bestowing powers, appears. The people kill her at the end of their great annual celebration, and, as a result of this first killing, life as man knows it comes into being. With a certain circularity that often occurs in mythology, the myth validates the cultic celebration that itself occurs in the myth. The mythical account has an optimistic tone, since its events make life "livable." The cult can be understood as a commemoration of those first events. Hence, the myth can be said to validate life itself together with the cultic celebration. Comparable myths are told in a number of root-cropper societies.

Cultic or ritual validation

Bloody sacrifices are typical of traditional peasant cultures. In most cases such customs are related to mythical events. Among important themes validating the cultic proceedings are the necessity of death (*e.g.*, the grain "dies" to yield a harvest), the renewal of time, and the significance of woman and sexuality. New Year's celebrations, often accompanied by a temporary abandonment of all rules, often are related to or justified by mythical themes concerning a return to chaos and a return of the dead.

Dynasties and ruling families in several ancient civilizations found justification of their positions in myths, which state that they originated in the world of the gods or in heaven or from the sun or the moon (as in China, Egypt, Babylon, the Hittite Empire, Polynesia, the Inca Empire, and India). Social classes also can be validated by myths; the best known are the mythologically established classes of ancient Indo-European traditions: the sacerdotal, warrior, and producing classes. No cultural tradition exists without some mythological foundation for marriage and for funerary customs. Also, many myths account for specific groups of a social or socioreligious nature, such as medicine men, shamans (men having curative and psychic transformation powers), and priests.

Other functions. *Descriptive.* The descriptive function of myth is linked with the authoritative presentation of facts that transcend ordinary reason and observation. Myths can describe the origin of the world, the end of the world, or a paradisiacal state. Thus, a myth is capable of describing what persons, using reason and observation, can never "see for themselves." Perhaps even more than the explanations that are provided, this descriptive function accounts for the educational value of myths in traditional societies. Myths set the pattern for theoretical as well as practical instruction. In primitive traditions they form the only available model of instruction, in the absence of any separate philosophical enquiry. The descriptive function of myth expresses a perennial human need and is a reminder that modern men do not have to regard myth as something that comes to an end with the termination of primitive or classical civilizations.

Controlling the universe. In every mythological tradition one myth or cluster of myths tends to be central. In comparison to these, other myths—whether about the first shaman, the establishment of a secret society, or anything else—relate more to a specific sector of society or more specialized functions. The central mythology as a rule is primarily occupied with the creation that is presupposed in all other creations; *i.e.*, cosmogony (origin of the cosmos). In many events, on which the well-being of man's world depends, references are made to the beginnings of the world. Among such events are enthronements of kings, which in some traditions (as in Fiji and in ancient India) were associated with a creation or re-creation of the world. Such associations are not to be viewed merely as products of power-hungry monarchies. Creation myths also play a significant role in healing the sick; they are recited (*e.g.*, among the Navajo Indians of North America) when an individual man's world—his individual life—is in jeopardy.

Magical and poetic-artistic functions. Healings through the recitation of the cosmogony, referred to above, can be examples of the magical function. Equally "magical" is the example of an old Norse poet, who was to renew his poetic inspiration by recalling the myth of the god Odin's acquisition of poetic power.

The poetic–artistic function of myths in archaic and primitive traditions cannot be overestimated. In civilizations in which great specialization and separation of art forms have not yet occurred, mythical themes and images are a "given" source of all expression. The creative force of well-developed mythologies also influenced later cultural and artistic developments.

THE STUDY OF MYTH AND MYTHOLOGY

A determined study of myth developed in the West, especially since the 18th century. Much of its material came from the study of the classics, from which it also derived some of its methods of interpretation.

Brief history of the study. The growth of a philosophical interest in ancient Greece furthered allegorical interpretations of myth; *i.e.*, finding other or supposedly deeper meanings hidden below the surface of mythical texts. Such meanings usually involved phenomena of nature or human morals. Related to this was a tendency toward rationalism or pragmatism, especially when interpreters, aided by faulty etymologies, took the opportunity to stress the value of the ideas or the civic sense of their own time. Of special and long-lasting influence was Euhemerism (named after Euhemerus, a Greek writer who flourished about 300 BC), according to which certain gods were originally great people venerated because of their benefacts to mankind.

Influence of Euhemerism

The early Church Fathers continued with concepts that were general in late antiquity, particularly a modified Euhemerism, according to which mere men were raised to superhuman, demonic status because of their great evil deeds. The Middle Ages did not add greatly to the study of myth, and, despite some elaborate works of historical and etymological erudition (which did not stand up to modern criticism), neither did the Renaissance.

Early in 18th-century Italy, Giambattista Vico, a philosopher, building on traditional scholarship—especially in law and philosophy—was the first to make a clear case for the role of man's creative imagination in the forma-

tion of distinct myths at successive cultural stages, but his work had no influence in his century. The notion that pagan myths were distortions of the biblical revelation in paradise was first expressed in the Renaissance and continued to find favour in the 18th century, alongside other earlier theories. At the same time, Enlightenment philosophy, reports from voyages of discovery, and missionary reports (especially the reports of Jesuits on North American Indians) contributed to 18th-century scholarship and fostered a desire for objectivity. Bernhard Le Bovier de Fontenelle, a French scholar, compared Greek and American myths and theorized on a universal human predisposition toward mythology. Around 1800, the growing fascination of the Romantics for human speech, the postulation of an Indo-European language family, the study of Sanskrit, and the growth of comparative studies, especially in history and philology, all gave a firm footing to the study of myth. The interest in myth was greatly stimulated in Germany by Friedrich Schelling's philosophy of mythology. Scholarly interest in myth declined during the heyday of evolutionism but re-emerged around 1900 among ethnologists as well as some philologists. Many depth-psychological studies followed in the wake of the discoveries of Sigmund Freud. A renewed interest in myth was fostered by new approaches in sociology and anthropology and by various philosophical studies. In the history of religions, Eliade, for example, has stressed that myth is best understood as narrating sacred history and cannot be explained in terms of nonreligious (literary, psychological, sociological, or economic) categories. Among some classicists (*e.g.*, Karl Kerényi) and others, a conscious resumption of Romantic ideas is noticeable (see also RELIGION, STUDY OF).

Basic modes of approach. *Rationalistic.* Many types of rationalistic explanation of myth have found adherents since antiquity. They have in common the fact that they posit a definable system of thought as the cause of mythological texts. Allegorical interpretations are examples of this, for it is typical of allegory that it can be rendered adequately in terms of a clear idea, though myths as a rule do not really present such ideas. Also since antiquity, many (*e.g.*, David Hume, an English philosopher) have attributed the creation of myths to fear. This too can usually be regarded as a rationalistic interpretation, if it posits a known system of psychological functions.

Romantic. Georg Johann Hamann, a German philosopher, and William Blake, the English mystic and writer, both rejected as a rationalistic construct the notion of "natural religion," a type of religion supposedly common to all mankind. Schelling was convinced that the Absolute is expressed in myth but that this expression also occurs in terms of certain contradictions and that it is the task of philosophy to regain the transcendent unity of the Absolute. Schelling's metaphysical concern has been a stimulus for subsequent discussions. Many Romantic studies were less visionary and have been Romantic only in the sense of stressing emotion as a factor in the creation of myths, sometimes bordering on sentimentality. Also Romantic is the long-lingering explanation of myth as an expression of man's experience of nature.

Rejection of "natural religion"

Comparative. Since the Romantic movement, all study of myth has been comparative. This is not to say that a comparative study as such is Romantic, for comparative attempts were made earlier. But the fact remains that in the 19th century and later, even the most specialized studies have made generalizations about more than one tradition and at the very least have had to take comparative works by others into account. Philosophical enquiry aiming at an understanding of the function of myth assumes the possibility of a comparative approach.

Folkloristic. The classical folkloristic approach is that of Wilhelm Mannhardt, a German scholar, who attempted to collect data on the "lower mythology," which he considered more or less homogeneous in ancient and popular peasant traditions and basic to all formation of myth. Sir James Frazer, an English anthropologist, and the brothers Grimm (Jacob and Wilhelm), German philologists, are well known for their collections of folklore, and the American folklorist Stith Thompson for his classification of folk literature. Collecting and classifying mythological themes have remained the principal contribution of folklore.

Functional. Marcel Mauss, a French sociologist, spoke of "total social facts" in reference to religious symbols and myths and their irreducibility in terms of other functions. Bronisław Malinowski, an anthropologist, changed the emphasis and attributed the necessity of myth to the functions it fulfilled in primitive cultures: justifying and preserving social, ethical, pragmatic, aesthetic, and religious customs and institutions. Functionalism, especially as an interpretation of myth as a mirror of social relationships, has had a wide appeal to anthropologists in Britain and America.

Structural. Structural approaches begin with the observation that myths throughout the world resemble each other and proceed to define the resemblance. Some structuralists (*e.g.*, anthropologist Claude Lévi-Strauss, in France) look for the resemblance in a certain logical coherency in analogy to patterns in linguistics. Others emphasize the total view of the world manifest in all aspects of a community's life.

MYTH IN HUMAN CULTURE

Myth and psychology. The paramount importance of Freud's investigations for the study of myth is his view that the formation of concepts does not depend on cultural history. Until Freud, all study of myth had assumed that historical analyses and an understanding of stages of development of human consciousness were absolutely necessary. Freud's analysis of the psyche created an independent, transhistorical mechanism, based not on cultural history but on a biological conception of man. The fact that he made use of anthropological views that have since been refuted (*e.g.*, totemic [symbolic animal] sacrifice as the earliest ritual custom, which he related to the first parricide) does not change this. Symbolizations of guilt feeling or symbolic expressions of wish fulfillment are not limited to specific times in history and occur in myths as in dreams. Criticism of Freudian methods has been levelled against the explanation of myths in terms of only one theme (the Oedipus complex; a psychosexual concept concerned with guilt) and in terms of the "repression" of conscious ideas. In Switzerland, the psychoanalyst Carl Jung, like Freud, was stimulated by a theory that no longer has much support; *i.e.*, the theory of Lucien Lévy-Bruhl, a French philosopher, associating myth with prelogical mentality. This, according to Lévy-Bruhl, was a type of thought that supposedly would have been common to archaic mankind, that was still common to primitives, and in which people supposedly experienced a "mystical participation" with the objects of thought, rather than a separation of subject and object. Jung's theory of the "collective unconscious," which bears resemblance to Lévy-Bruhl's theory, enabled him to regard the foundation of mythical images as positive and creative, in contrast with Freud's negative evaluation. For Jung, archetypes are the specific images that arise from the collective unconscious and form the basis of the human psyche. In principle, however, these images that make up myths are, like the Freudian mechanism, transhistorical. Critics of Jung have been hesitant to accept his neo-romantic reasonings concerning the collective unconscious as an eternal source of meaning. The criticism has come not only from Freudians but also from critical students of Jung himself (see also CONCEPT FORMATION).

Freud's creation of a transhistorical method

Myth and society. Myth is obviously related to questions about language, because it is a matter of human communication, and to questions of man's social life, because the narration of myths is proper to a community and to communal tradition. There is no general agreement, however, on the precise nature of these relationships. The reason for the uncertainty is not difficult to detect. The methods used by modern science allow for empirical investigation and inference, but the classification and segmentations of language and society that can thus be established leave an essential part of the subject untouched. Some linguists, reflecting on their own discipline, have spoken explicitly of the need for a more en-

compassing science; *e.g.*, a new general science of semeiology, whose task it should be to study all signs central to social life; and a new science of psychology, which would begin with "the problem of characterizing various systems of human knowledge and belief." The study of society and of language can only begin with what is given in human speech and social relations, but in each case it is confronted by a coherence of traditions that is not directly open to research. This is the area in which mythology functions.

Intricacy and variety of relationships

The following mythological conceptions exemplify the intricacy and variety of the relationships between myth and society. The Lugbara (a tribe in northwestern Uganda and the adjoining Congo region) make use of a certain conceptual system to relate their sociopolitical order to two hero ancestors, who in turn are related to the creation of the universe. The narrations about their descent from their hero ancestors are saga-like, though the earlier "history" is presented in myths. It is remarkable, however, that the one conceptual scheme of the Lugbara social system relates the mythical and the genealogical (nonmythical) past and in its entirety is expressed in spatial rather than temporal–historical categories. Ancient China does not present an extensive system of myths and in this respect differs markedly from postclassical China, with its vast numbers of myths and gods. Instead, in ancient China, literary references are made to figures and developments that seem historical but are in fact historicizations of earlier myths whose mythical form was abandoned. Many of these references, especially in words attributed to Confucius, have to do with the nature of the state and the quality of rulers. Similarly, the Roman historian Livy's history of Rome presents the origin, the governmental forms, and the social forms of the city in terms of a historicization of earlier (Indo-European) mythological materials. The Indian institutions of class and caste are embedded in myth, and precisely for that reason they present a strong force in the empirical reality of Indian society. The variety of mythological influences on societies does not facilitate an overall system of interpretation, but an understanding of myth in each instance has a bearing on an understanding of social relations. Also, a particular conception of history is often taken for granted in modern studies of societies and social change, perhaps too uncritically. Indeed, some scholars have argued in various ways that the appeal made to history by nations or social groups is itself mythological by nature.

Myth and science. Some students have drawn attention to the changes occurring in the "reality" reflected and assumed in myths. Such "reality" is never final but changes continually in history. Questions about the changes of "reality" have especially occupied philosophers and historians of science, for an image of reality is basic to any scientific pursuit, beginning with the earliest philosophical enquiries into the nature of the world. Though it is not necessary to identify the images of reality in science with myth, the parallels of science and myth and the mythological dimension of science as such should be noted.

Scientific models as paradigms

Parallels. The function of models in physics, biology, medicine, and other sciences resembles that of myth as paradigms (patterns) for the human world. In medicine, looking upon the human body as a machine and viewing the human brain as a computer are models that are easy to understand as examples. Once a model has gained acceptance, it is difficult to replace, and in this respect it resembles myth, while at the same time, just as in myth, there may be a great variety of interpretations. In the period after René Descartes, 17th century, it was simply assumed that the universe could be explained in terms of minute corpuscles, their motion and interaction, and that entities of another sort did not exist. The absolutistic bent of many models in the history of science most resembles myth. There are, however, important differences. Despite the difficulty of replacing models in science, replacement does occur, and an awareness of the limitations of models has grown strong in modern science. This awareness of scientists makes the difference evident, for, as a rule, a myth cannot be regarded as replaceable by the community in which it functions, although an outside observer might record changes and even replacements. Moreover, models in science have their value only for specific scientists. Hence, they function only for a small segment of society, even though, for instance, a medical theory held in academic circles in one century can filter down into folk medicine in the next. As a rule, myth has a much wider impact.

Mythological dimensions of science. In spite of the distance between scientific models and myths, there are reasons to speak of mythological dimensions and components of science. The history of science has made clear that modern science did not come about in its entirety as a rebellion against myth, nor at its birth did it suddenly shake off the shackles of myth. In ancient Greece, the naturalists of Miletus, long regarded as the originators of science, developed views of the universe that were in fact very close to the creation myths of their time. Precursors of modern science, such as Nicholas of Cusa, Johannes Kepler, Sir Isaac Newton, and Gottfried Leibniz, were involved in metaphysical problems of which the traditional, indeed mythological, character is evident. Among these problems were the nature of infinity and the omnipotence of God. Clear remnants of mythological views are seen in the English physician William Harvey's association of the circulation of the blood with the planetary movements and Darwin's explanation of woman's sexual cycles by the tides of the ocean.

Several thinkers (*e.g.*, Paul Tillich, a theologian, and the philosophers Karl Jaspers and G. Gusdorf) have argued convincingly that a mythological dimension is constitutive of all science. Myth is that which is taken for granted when thought begins. It is at the same time the limit science reaches in its own course: certain elementary ideas or principles are found to be of such lucidity that no further definition can be undertaken. In recent scientific researches, especially in astronomy and biology, questions of teleology (final ends) have gained in importance, as distinct from earlier concerns with questions of origin. These recent concerns stimulate discussion about the limits of what can be scientifically explained, and they reveal anew a mythological dimension to human knowledge. It should be underlined that there are such mythological dimensions to science in the same way that there are to society. They do not make the study of science (as of society) itself a mythological affair.

Myth and religion. The place of myth in various traditions differs; and within some religious traditions there is opposition.

Relation to ritual and other practices. The idea that the principal function of a myth is to explain a ritual had adherents before anyone tried to make a case for it. At the beginning of the 20th century, many scholars thought of myths in their earliest forms as statements of what is being done and what is desirable, and they found support in what Frazer called "sympathetic magic." According to this view, the narration of myth developed to explain and accompany magical procedures that were first meant to fulfill human desires and later grew into true religious cult.

The Myth-Ritual school

In a much more articulate way, biblical scholars stressed the necessity to look for the situation in life and custom (the "Sitz im Leben") that mythical texts originally possessed. A number of scholars, mainly in Britain and the Scandinavian countries and usually referred to as the Myth-Ritual school, have concentrated on the ritual purposes of myths. Their work has not extended far beyond the philological study of the ancient Near East and Islām and has focussed almost exclusively on rituals connected with sacred kingship and New Year's celebrations.

The existence of connections between myths and cultic behaviour is certain, but there is no solid ground for the suggestion that, in general, ritual is chronologically first and myth an added explanation. In the first place, it is not correct to regard genuine myths as etiologies. Secondly, if it were only the myth (later) that made the sense of the ritual (earlier) explicit, the meaning of the ritual remains a riddle. Endeavours to solve this problem have not met

with general approval. Evolutionists since Frazer have largely thought of early man's behaviour as something primitive and irrational and have posited slowly growing intellectual powers that demanded explanations. Other attempts, betraying influences of Existentialist philosophy, have seen earliest myth as something not in need of words because it was "alive and lived."

The view that has seemed to many to be closest to the truth begins with the recognition that there is no universal law governing the relationship between myth and ritual. An absolute chronology, establishing which of the two came first, is outside the reach of scholarship. It is quite certain that there is no ritual without myth, but there are many myths without ritual. Most often the content of important myths concerning the origin of the world reflects the dominant cultural form of a tradition. Hunters' societies have myths that tell of the origin of game animals and hunting customs, agricultural civilizations tend to give weight to agricultural practices in their myths, pastoral cultures to pastoral practices, and so on. Thus, many myths present models of necessary acts and organizations and relate these to primordial times. Myths in specific archaic traditions deal with harvest customs, initiation ceremonies, circumcision and subincision (cutting open the urethra on the underside of the penis), the customs of secret societies, the use of ceremonial masks, cannibalistic and headhunting customs, or special skills and crafts.

Relation to religious symbolism and iconography. Sacred objects are found in all religious traditions, and sacred images (icons) in most. They are analogous to the myths because they represent sacred realities or figures, as myths do in narrative form. Representing does not mean copying of natural or human forms. In this respect religious symbolism is immediately related to myths because they also narrate extraordinary things. Many symbolic representations have their sources in myths. Representations in human form or perfectly "natural" human forms are rare. The famous sculptures of divine figures in classical Greece (as by Phidias and Praxiteles) are the exception, and they were exceptional even in the religion of Greece. Everywhere, less naturalistic forms have always been preferred in cultic practices and in the representation of mythical themes. Geometric and animal figures—*e.g.*, on cultic vessels as well as on images of deities—abound in the history of religions. Of special significance is the use of sacred masks: in the mysteries of Dionysus, a Hellenistic salvation cult, and the indigenous traditions of Australia, America, prehistoric Europe, and elsewhere (see also SYMBOLISM AND ICONOGRAPHY, RELIGIOUS).

Relation to sacred texts. The relation of myth to the sacred texts of the great religions naturally depends on the character of the religion in question. The Old Testament contains much mythological material, yet the religion of Israel was in many respects critical of myths in the same manner in which it rejected any representation of God in natural forms. Similar antimythological tendencies exist in the religions that have their roots in Israel. The New Testament of Christianity in some instances derogates myths by describing them as "godless" and "silly." Islām's emphasis on the transcendence of God, attested in the Qur'ān, is strongly antimythological. Many scholars have pointed out, however, that all these antimythological tendencies are correlated to mythological motifs, especially motifs concerning the end of time (eschatology). In other traditions with sacred scriptures, such as Hinduism and Buddhism, opposition to myths is not dominant.

Biblical and Qur'ānic criticism of myth

Myth and the arts. *Oral traditions and written literature.* Myths in ancient civilizations are known only by virtue of the fact that they became part of a written tradition. In the case of Greece, virtually all myths are "literature" in the form in which they survived, the oldest source being the epics of Homer, a Greek poet of the 8th century BC. Though it is difficult to speak in detail about the original function of many myths when they were alive in oral tradition, scholars are in a better position to understand the importance that myths had for literary artists and the mythological function that literature inherited. The heroes and heroines of epic literature are in many instances narrative rejuvenations of gods and goddesses in myths, and, although scholarly work in this area is far from complete, it is safe to suggest that among the mythical themes that have appealed to epic poets are themes of the culture hero or bringer of salvation and of shamanism. The epic itself can take on certain mythological functions. The Homeric epic became the basis of education in classical Greece. The great epics of India (*Mahābhārata* and *Rāmāyaṇa*) came to function as encyclopaedias of knowledge and provided models for all human existence. Generally, whether literature makes use of mythical motifs or not, the power of the literary word, the sheer felicitous formulation of political, aesthetic, or other certainties, has a spell that is akin to that of myth.

Visual arts. In principle, the sort of relationship that exists between myth and literature exists also with respect to the other arts. In the case of architecture and sculpture, documentation begins much earlier, and it is difficult to imagine their beginnings without myth. Moreover, data owed to archaeological discoveries confirm the primacy of mythical representations. Among the earliest known architectural occupations of man are prehistoric megalithic and sepulchral structures. Mythological details cannot be recovered, but mythical images most likely dictated the shape. Grave monuments of rulers are among the most famous remains of several ancient historical civilizations as well (*e.g.*, the Egyptian pyramids; and the sepulchral structures of Chinese rulers since the Chou period, *c.* 1122–221 BC). There is worldwide evidence in archaic cultures of a mythological orientation in which man established his place in the cosmos with respect to north, south, east, and west, as well as to the vault of heaven and the world below; and such mythological views formed the model of his building activity. As late as the 1st century AD, the Roman architect Vitruvius, summarizing the building lore of the classical world, spoke of the different orders of building with explicit reference to temples and the specific gods and goddesses for whom they were appropriate. Not by coincidence did Vitruvius consider the pillar the principal element, and not by coincidence is the history of architecture linked with temples. The pillar is the archaic mythological image of what connects man's world with heaven. This imagery already existed in hunters' cultures, but it continued in the Neolithic period with a growing interest in firm dwelling places for gods and people. The strict separation between religious and civil architecture that modern man is inclined to take for granted is not applicable for most cultures and periods, and perhaps it is not altogether applicable even in modern times. A certain general mythology, equally normative for civil and religious buildings, is visible in ruling architectural fashions. Classicism, for example, can be seen as a mythology that set a model for building city halls and courthouses, as well as churches. Classical and medieval India has produced a vast literature on architecture and art, setting side by side instructions for temples and houses and complete indications for town planning.

Mythological aspects of architecture

When art ceases to represent mythological matters or no longer produces vessels, instruments, or images used for cultic purposes, it still represents something different from what is naturally given. This fact can be considered in two distinct perspectives. First, it is possible to insist on the universal mythological dimension of man and to look upon what seems to be abandonment of mythological forms as something that in fact is only a change in mythology. Secondly, one can insist on the actual abandonment of myth. These two possibilities are analogous to the positive and negative attitudes that religions have developed toward myth. Factual study of myths and of artifacts by themselves does not suffice to decide the matter, because the choice depends heavily on one's theory of art.

Performing arts. Myth is one of the principal roots of drama. Even in the very "literary," refined tragedies of classical Greece this is clear, not only because of the many mythological subjects treated and the setting of the

Myth as a source of the drama and the dance

performances (organized by the city-state at the festival of Dionysus) but especially because of playwrights', such as Aeschylus', mythlike presentation of events and facts, which may be interpreted in various ways like myth, "at once moral, religious, and purely human," and relating to the community as a whole. The citizens made up the chorus, the crucial part of early Greek tragedy. Theodor Gaster, an American historian of religion, has shown in detail that in the ancient Near East the interrelationship of myth and ritual created drama. Elsewhere, dramatic presentations (as in Japanese Nō plays and the Javanese *wayang*) are similarly rooted in myth. Western distinctions between "religious" and "entertaining" have a very limited value here.

Dance has even earlier rights than the other performing arts in experiencing and expressing mythological characters, and it is a universal form. Dance as an expression of myth, though attested universally, is also a form that is most difficult to comprehend for many people today, because the decay of ritual behaviour typifies modern secularization. In spite of a continuing interest in ballet and some revival of folk dancing, dance as a form of art has perhaps become further removed from myth than any other form of art in the Western world.

Music. Music in its primary rhythmic function is related to dance and thus to myth. Music nevertheless is least dependent on myth but is regarded in many traditions as creative, and hence mythical, in itself. It sometimes is used (as myth is) in healing the sick (*e.g.*, tarantism, a form of hysteria appearing in Italy in the 15th–17th centuries and reportedly cured by frenzied dancing). Although most of such religious purposes of music in modern Western history have declined, mythical themes (*e.g.*, in opera and oratorio) have not ceased.

Mass media. The modern means of radio, film, and television have had an effect on religious symbolism, but equally striking is the fact that—like the printing press, newspapers, magazines, and pocket-books—they have provided channels for old mythological themes. Communication as such has become much more important than it was before, because the reader, listener, or viewer is much more passive than the participant in earlier ceremonies. Inevitably, the mass media try to increase their principal power, viz., their power of suggestion. This development has led to a general increase in receptivity for myth, to the exclusion of ritual. Among the mythological types that are most appealing are those that most resemble the heroes of ancient and classical myths (sports heroes, movie stars, astronauts, and other celebrities). Whatever the details or the order of popularity may be, the modern audience, like all earlier audiences, looks for models by which all things can be measured.

Modern mythological models

MAJOR TYPES OF MYTH

Myths of origin. "Cosmogony" and "creation" are used as synonyms, yet properly speaking, cosmogony is the best general term because it refers to the origin of the world, whereas "creation myth" implies a creator and something created, a suggestion that does not fit a number of myths that, for example, speak of the origin of the world as a growth or emanation, rather than an act. Furthermore, the term origin should be used with some caution for cosmogonic events (as well as for other myths of beginnings), because the origin of the world hardly ever seems the focal point of a mythological narrative—which is not a matter of enquiry into the first cause of things. Instead, cosmogonic myths are concerned with origins in the sense of the foundation (or validity or "ground") of the world as it is. Creation stories in both primitive and advanced cultures frequently speak of the act of creation as a fashioning of the earth that was already present before the act. In African cosmogonies, especially, the earth is pre-existent. A creation out of nothing (*creatio ex nihilo*) occurs as a theme only in certain more philosophical traditions. Water, though important everywhere as source of life and image of endless "potentiality," has a special role in Asia and North America, where the creator (often an animal) is assisted by another figure, who dives for earth in the primordial ocean. The earth-diver helper sometimes develops into an opponent, or Satan-like character, in culturally advanced areas; *e.g.*, those touched by Zoroastrianism, an Iranian religion that was dualistic. Though hardly an "explanation" in the ordinary sense of the word, the theme accounts for the fact that evil is constitutive of the cosmos without holding the creator responsible for it. Other widely diffused motifs are: the cosmogonic egg, found in the Pacific world, parts of Europe and southern Asia, and in very advanced cultures (*e.g.*, Hinduism); the world parents (usually in the image of sky and earth); and creation through sacrifice or through a primordial battle. Creation through the word of the creator also occurs outside the Old Testament account (in Polynesia).

Cosmogony sets the pattern for everything else in most traditions; other myths relate to it or derive from it. Because man's inhabitable world, the cosmos, is the crucial issue, no matter how variegated the contents may be and how different from one period to another, cosmogony probably is the clearest expression of man's basic mythological propensity. All cosmogonic accounts have certain formal features in common. They speak of irreconcilable opposites (*e.g.*, heaven and earth, darkness and light) and, at the same time, of events or things totally outside the common range of perception and reason (*e.g.*, a "time" in which heaven and earth were not yet separated, and darkness and light intermingled). In other words, the basic ingredients of man's world and orientation are presupposed and yet nevertheless are realized, constituted, or brought about anew in the narration. The narrative can arrive at such a reconstitution only by transcending the limits of ordinary perception and reason.

Common features in cosmogonic and creation myths

Because the cosmos is man's world, the origin of man is immediately linked to the cosmogony. Man, for instance, is placed on the earth by God, or in some other way his origin is from heaven. Nevertheless, it is only in mythologies that have been influenced by philosophical reflections that the place of man becomes the conspicuous centre of the cosmogony (*e.g.*, Pythagoreanism, a Greek mystical philosophical system; Orphism, a Greek mystical religious movement; Gnosticism, a heretical Christian dualistic and esoteric movement; and Tantrism, a Hindu and Buddhist esoteric meditation system). Man is sometimes said to have ascended from the depths of the earth (as in Zuni, an American Indian people, mythology) or from a certain rock or tree of cultic significance. These images are often related to the idea of a realm of the ancestors as the origin of newborn children. Man is also said to be fashioned from the dust of the ground (as in Genesis) or from a mixture of clay and blood (as in the Babylonian creation myth). In all cases, however, man has a particular place (because of his duties to the gods or because of his limitations or gifts), even though—especially in many hunters' civilizations (*e.g.*, the African Bushmen and many North American Indian tribes)—the harmony of man and other forms of nature is emphasized.

There are innumerable tales of origin, very many of which belong to etiological tales rather than myth proper. The most undeniable mythical group of tales of origin are those that relate the origins of institutions. Certain initiation ceremonies or ritual acts are said to be founded in the beginning, in mythical times, and therefore they have their validity. Thus according to Raffaele Pettazzoni, an Italian historian of religion, myth forms "the Magna Charta of every institution" (see also CREATION, MYTHS AND DOCTRINES OF).

Myths of eschatology and destruction. Myths of eschatology by definition deal with "the end." The end, being the opposite of the cosmogony, means first and foremost the origin of death but also, in a wider sense, the end of the world. Special forms of eschatology are given in messianism (belief in a coming salvation figure) and millennialism (belief in a 1,000-year reign of the elect).

Myths about the origin of death, which is not considered "natural," are probably as widely diffused as creation stories. Three themes can be distinguished, even though they usually overlap. First, there are many myths that speak of a primordial time in which death did not exist

The origin of death

and relate that it came about as a result of an error or as a punishment or simply because the creator decided the earth would get too crowded otherwise. Secondly, many myths, usually in more "advanced" cultures, describe a paradise and a creator who first intended man to be immortal, so that the coming of death, in whatever manner it arrives, leads to a fall from paradise and is viewed as a tragedy. The third theme links death with sexuality and birth. Each of the three themes and their combinations occur with infinite variations. Possibly the third theme, linking death and generation, should be seen as a necessary existential coherency that was strongly experienced in the early planters' (root croppers') cultures.

Expectations of a cataclysmic end of the world are also expressed by myths. A universal conflagration with a final battle and defeat of the gods is part of Germanic mythology and has parallels in other Indo-European eschatological imageries. In many primitive religions specific expectations about the end of the world do occur but until recently have not received much scholarly attention. Many eschatological views of the universe are linked with religious movements that as a rule are spurred by historical events (see also ESCHATOLOGY).

Myths of culture heroes and soteriological myths. A great many nonliterate traditions have myths about a culture hero, who generally is not responsible for the creation but who completed the world and made it fit for human life; in short, he created culture. Outstanding examples of such culture heroes are Maui in Polynesia and Prometheus in Greek mythology. The bringer of culture is often also the bringer of health. Thus, the culture hero of the Woodlands and Plains Indians in North America is at the same time related to the foundation of the medicine society. A comparable figure occurs in many classical traditions as the "good son"; *e.g.*, Horus, the son of the god Osiris in Egypt, or the figure of the king in the Psalms. Health and (spiritual) salvation are synonymous, and this is implied in the Greek words *sōtēr* ("saviour") and *sōtēria* ("salvation"). Related to soteriological myths in many cases is the hope for a final and total salvation in which the "good" powers will triumph (such as through the Saoshyant, the saviour in Zoroastrianism; see also SALVATION).

Messianic and millenarian myths. Eschatological certainty and hope for a new world surge up from time to time in many civilizations, both primitive and advanced. In Melanesia, Africa, South America, and Siberia, innumerable religious movements have occurred in this century. Christian elements are usually visible, but the basic thrust in virtually all cases is indigenous. These cults and movements centre around prophetic leaders, often emphasize the return of the dead at the renewal to come, and are convinced of a catastrophic end, both historical and cosmic, of the present world. In many cases, the culture hero is expected to return and lead in battle against the evil (colonialist) forces. In the history of Judaism and Christianity, as in many primitive millenarian and messianic movements, there is an expectation of a new heaven and a new earth (see also MESSIAH AND MESSIANIC MOVEMENTS; MILLENNIALISM; TRIBAL RELIGIOUS MOVEMENTS, NEW).

Myths of time and eternity. The regularity of the heavenly bodies has made a great impression on people everywhere. The sky is the very image of transcendence, and the immutable order in the course of sun, moon, and stars suggests a time that transcends man's. That "transcendent time" is eternity. Many myths and mythological images concern themselves with the relationship between eternity and time on earth. The number four for the number of world ages figures most prominently. Ancient Persia knew of a complete world age of 12,000 years, divided in four periods of 3,000 each, at the end of which Ormazd (the Wise Lord) would conquer Ahriman (the Lie). Similarly, the Book of Daniel (in the Old Testament) mentions four kingdoms—of gold, silver, bronze, and a mixture of iron and clay, respectively—after which God will establish an everlasting kingdom. Four world ages, sometimes associated with metals, occur also in classical writers and in later speculations on history. Judaism developed the view of a 1,000-year period between the four world ages and the everlasting kingdom (hence the words millennium and millenarian). Although other numbers occur (three, six, seven, 12, and 72), four is dominant. In ancient Mexico this world was held to be preceded by four other worlds. India, in both Hindu and Buddhist texts, has developed the most complex system of world ages and worlds that arise and come to an end. Here too the number four is important; *e.g.*, the four ages (*yugas*) of decreasing length and increasing evil. Many writings, often with large numbers that have been considered fantastic by humanistic scholars, reflect exact astronomical observations and calculations. Some mythologies—*e.g.*, those of the Maya in Central America—have developed sophisticated views interrelating time and space. Mythological accounts of repetitions of worlds after their destruction occur not only in India but elsewhere, such as in Orphism and Stoic philosophy in ancient Greece (see also CHRISTIAN MYTH AND LEGEND; CALENDAR).

The ages of the world

Myths of providence and destiny. There is a broad range of mythical motifs between astrological calculations and devotional self-surrender, and there are many occasions at which a man may be filled with doubt about his own fate or the fate of his community. In some myths divine supremacy is marked by a god's mastery over fate. Marduk, the patron god of Babylon, acquires the "tablets of fate" in his primordial battle preceding the creation. There is no doubt about Zeus's supremacy in the Greek poet Hesiod's genealogical account of the gods, yet in later Greek texts even Zeus can be spoken of as powerless against fate, as in *Alcestis* by Euripides, a Greek dramatist. The same Euripides nevertheless can use the terms natural law or world reason as synonyms for Zeus. Mythological views of providence, destiny, or fate are given precise shades of meaning vis-à-vis dominant views in a tradition concerning justice and divine law, the philosophical problem of determinism, the theological problems of theodicy (justification of a good god with observable facts of evil), and of predestination. An important difference in mythological accounts of providence exists between those traditions that speak of the creation of the world as a result of God's will (as in Judaism, Christianity, and Islām) and those that attribute a more limited significance to worldly phenomena (as Buddhism does; see also PROVIDENCE, RELIGIOUS DOCTRINES AND MYTHS OF).

Cyclical time

Myths of rebirth and renewal. Myths of archaic traditions generally imply a conception of the world, nature, and man in terms of cyclical time. According to mythical lore, the Australian Aborigine at birth is really reincarnated through his mother into profane life. At his initiation he re-enters sacred time, and through his burial ceremony he returns to his original "spirit" state. Similar statements could be made about many tribal peoples, since the reality of their myths is first and foremost the reality of cosmic cycles. Special myths are narrated in many places in preparation for initiation procedures. In agricultural societies, in addition to the themes of cosmic renewal, renewal through birth, and rebirth through initiation ceremonies at the attainment of manhood and womanhood, the theme of seasonal renewal is of great importance. The cyclical concept of time in all these traditions is present in many of the great religious and philosophical systems, such as Brahmanism (a Hindu system), Buddhism, and Platonism, and to some extent is at variance with the idea of linear time that is typical of the historic religions (Judaism, Christianity, Islām). Jews, Christians, or Muslims, or indeed any culture cannot completely disregard the cyclical patterns of the seasons, work, festivities, or existence, which seem to be engraved on man's perception of the world.

Myths of memory and forgetting. Some of the North American medicine men claim to remember their prenatal existence. Such memory, according to their mythology, is lost in most common people. Similar myths of memory and forgetting are related to the hierarchy that exists in all archaic societies. The fundamental knowledge of the world, transcending ordinary consciousness, is not equal-

ly clear and available to everyone. Myths of memory can take the form of collective nostalgias. The Yaruros in South America, a very primitive tribe, ignorant of all agricultural and pastoral life, are one of many tribes in the course of modern Western cultural expansion that gave up the struggle for their own social and cultural existence. They expressed a yearning to return to the Great Mother ruling the land of the dead and awaiting them in her paradise. Less tragically, however, mythologies of memory and forgetting have a role in many traditions. They are of great significance in traditions that hold the idea of rebirth or reincarnation. Some people are said to remember previous existences, and a few (among them the Buddha), the very first. The veil of *māyā* ("illusion") in many Indian stories prevents a man from remembering his true origin and goal. All Gnosticism knows about a similar forgetfulness that must be resisted. In ancient Greece, Mnemosyne (Memory), the mother of the muses, is said to know everything, past, present, and future. She is the Memory that is the basis of all life and creativity. Forgetting the true order and origin of things is often tantamount to death (as in the case of Lethe, the river of death, which destroys memory, in Greek mythology). Anamnesis, "commemoration" or "recollection," is one of the crucial parts of the Christian celebration of the Communion. Through the anamnesis, the passion and death of the Lord is "applied" to the congregation. In philosophy, the imagery of forgetting and remembering occurs in the thought of Śaṅkara, a medieval Indian philosopher, and Plato in connection with the paramount calling of the thinker and the difficulty of living up to that calling.

Myths of high beings and celestial gods. Supreme celestial deities occur in many mythologies, with various qualities and attributes, in many shapes, and with great diversity in cultic significance. A cardinal distinction exists between the supreme being in many archaic or nonliterate traditions and the God of the great monotheistic systems (Judaism, Christianity, and Islām). Even though certain qualities seem alike in many cases (*e.g.*, transcendence, omniscience), the God of the latter arose historically in a reaction to polytheistic views and practices and demonstrates his supremacy accordingly, whereas the more archaic types of supreme beings nowhere show that militant feature in their mythologies. Another related general consideration about high beings and celestial gods is that their supremacy does not necessarily involve exclusion of other supreme beings. Outstanding examples are Viṣṇu, Śiva, and the great goddess in Hindu literature, who are each described as supreme yet do not reduce the "reality" of the others. "Supremacy" is not as unambiguous and general a term as it seems, and in Hinduism it refers first and foremost to the *perfection* of a deity in himself.

Distinction between high gods and one, unique God

The sky is considered sacred everywhere and is often related to or identical with the highest divinity. Nevertheless, supreme beings are always more than what can be explained from celestial phenomena alone, for they are often called creators of the world, founders of the order of the world, and protectors of law; and they are praised for their eternity and goodness. Often, the supreme being that created the world does not—or has ceased to—receive attention in the cult, although he may still be invoked in moments of great crisis. In a good many ancient agricultural societies, a male creator-god's place seems to have been occupied by a great goddess. The great goddess (as in the ancient Near East and India) is venerated principally because of her omnipotence, especially her power over life. The sky god-creator sometimes cedes to a divinity that is also related to the sky but apparently is experienced more concretely because of his activity. Such a divinity (especially in pastoral cultures) can be a god of atmospheric phenomena (storm, rain, thunder, or lightning), whose power for the good of the people is extolled. In spite of his power, however, he is one of several gods, and in some cases (Yahweh in ancient Israel and Allāh in Islām) one such god regains the full creative function of early creator gods, and in him all "true" divinity becomes concentrated. Also, a divinity related to the sun can take on the place of eminence; this has happened in some ancient imperial traditions (*e.g.*, Egypt; Inca Empire). Among sky gods who remained important in the mythologies of great ancient civilizations are Zeus in Greece, Jupiter in Rome, and T'ien in China.

Myths, tales, and legends concerning founders of religions and other religious figures. Founders of religions are by definition historical figures. Consequently, they cannot be part of myth, which describes events in other than historical time. Information concerning the founders of great religions (Confucius, Zoroaster, the Buddha, Moses, Jesus, Mani, Muḥammad), however, is couched in legendary materials that have many mythological features. The same thing can be said about many other religious figures (prophets, saints, or gurus, *i.e.*, Hindu spiritual teachers). The traditions that have preserved the memory of their founders have, as a rule, carefully guarded those elements that functioned most mythologically, in the proper sense that they stated most categorically realities that could not be known in any ordinary fashion or that raised the founder above ordinary historical conditions. Examples are the account of Jesus' prayer in Gethsemane, which no one heard according to the text itself, his statement that he was before Abraham, and his prophecies. Buddhist texts state that the Buddha not merely surpassed all *yogins* in knowledge of previous existences but, in fact, had conquered time. Well-known too are his predictions concerning the course and decline of Buddhism and (in Mahāyāna texts) his promises as to the future spiritual attainments of the *bodhisattvas*. Other examples are Muḥammad's eschatological teachings in the Qur'ān and those of Zoroaster.

Mythological features in records of historical figures

Myths of kings and ascetics. Genuine myths concerning kings are found only in traditions that know a form of sacred kingship. From ancient Babylon come preserved temple records concerning offerings to kings who were considered divine. Hymns addressed to them make references to the king's union with a goddess; *i.e.*, the mythological motif of the "sacred marriage." One of the epithets for the king in ancient Egypt was "endowed with life" or "imparting life." The twofold meaning of the epithet is significant and can serve to make the mythology of sacred kingship understandable in other places as well, because the function of the king is in fact double. He mediates between the divine world and the world of man, representing each to the other. Hence, in Egypt a sacrifice by an individual was understood as offered to the king and at the same time by the king. The king's role of mediator and protector brings royal mythologies close to myths of cultural heroes. Solemn procedures on which kings become divinized occur relatively late in history. An early and most conspicuous case of such an apotheosis (becoming divine) is that of Alexander the Great. Similarly, in later times, apotheosis took place for Roman emperors. A great many legends have accumulated around the figures of kings, resembling fairy tales or sagas rather than myths (*e.g.*, around King Aśoka of India and King Arthur of England). Stories about Frederick I Barbarossa, a medieval Holy Roman emperor, and Emperor Charles have a somewhat eschatological mythical flavour, because they are said to dwell each in his mountain (in the Kyffhäuser and the Unterberg, respectively) until a certain future moment.

Most narratives about great ascetics, as well as other saints, are much more like legends than myths. There are, however, instances of saints or ascetics who are presented as a more than worldly model, so that a case can almost be made for the mythological function of their legends (*e.g.*, al-Hallāj in Islām and St. Francis in Christianity). In the case of traditions that have asceticism as an integral part, certain figures and the legends around them do indeed function as paradigms (see also HERO WORSHIP; SACRED KINGSHIP; ASCETICISM).

Myths of transformation. Countless stories exist concerning the origin of peculiar rocks, properties of animals, plants, stars, or other features in the world. By nature, the majority of these accounts are etiological tales rather than myths. A number of myths, however, speak of cosmic changes brought about at the end of primordial

times. Also, an altogether different and extensive mythology exists concerning initiation rites and other "rites of passage" that involve transformations of man's being.

Cosmic transformation may concern an original world, without proper human means of existence and also without death, that was transformed through a new event (*e.g.*, the death of Hainuwele, a type of primal being known as a dema-deity) into the world known to mankind, a truly inhabitable world with vegetation, animals, and other necessities that had not existed before.

On a wider scale are myths that could be appendages to cosmogonic myths but that have not turned into mere etiologies. Many myths akin to the type of the dema-deity (like Hainuwele) and to the culture-hero type (like Prometheus, the giver of fire to the Greeks) account for events —such as the invention of agriculture, domestication of animals, and the use of fire—that have transformed the world for the benefit of man. Many others are just as closely related to cosmogonic accounts but tell of "setbacks" in primordial times. In agricultural societies, for example, myths have been collected that ascribe the unevenness of land or the formation of mountains to an ancient mishap or evil force.

Realization of the contents of myths

In "rites of passage" (*e.g.*, rites accompanying birth, attainment of maturity, marriage, death) the contents of myths are realized perhaps more fully than anywhere else. In each case the intention of the rites is that man's mode of being be affected, indeed transformed. Through the birth ceremony the child "becomes" a person, and through initiation an adolescent "becomes" an adult, a member of the men's society, or a warrior. There is a great variety of customs in different communities and traditions, but everywhere these rites actualize the cosmic processes and realities known from the myths. In many traditions the myths of the community are conveyed to the novice at the time of his initiation. In the major world religions, rites of passage have not come to an end, as evidenced in such ceremonies as circumcision, Baptism, weddings, and mortuary rites. In all instances, the rites derive their meaning from the core of the tradition, and for that reason man's being is transformed. In some cases the transformation derived from the dominant myth is far-reaching. The initiated shaman is able to transcend the ordinary human conditions and overcome conditions that would cause the death of a noninitiate. Through his initiation he is believed to have gone through death and thus conquered it. In certain Hermetic (a Hellenistic occultic, magical tradition) and Gnostic texts the certainty of attaining divine being is clearly expressed.

Myths and tales illustrating religious doctrines or reaffirming standards of conduct. The term myth is not properly applicable to most narratives that have as their explicit purpose the illustration of a doctrine or standard of conduct. Illustrations of this sort are allegorical rather than mythical. Familiar examples are the "myths" in Plato's dialogues and the parables of the New Testament. Illustrative tales have a considerable role also in Ṣūfism (Islāmic mysticism), rabbinic (Jewish biblical interpretive) literature, Ḥasidism (Jewish pietism), and Zen (intuitive) Buddhism. The nonmythological character is clear because the point made by the narrative is known or is supposed to be known from another source. Illustrative tales have a more subservient function than myths. They may clarify something to an individual or a group but do not take the place of the revelatory character of myth. The authority of myth sets a standard for conduct, whereas the illustrative tale by contrast makes a case for a certain superior authority or conduct.

Other types of myths and typologies. The types of myths presented thus far form a descriptive list of frequently occurring themes. This list is neither exhaustive nor the only one possible. A great many other themes (the great flood; myths related to totemism; souls, external souls, and guardian angels; weddings; thefts; and so on) have been left aside or have merely been touched on. Different and much longer lists could be drawn up. The greatest problem, however, remains that of defining myth and the effect one's definition has on typology. Crucial is the dichotomy, which is usually implied rather than stated, between the tendency of some to view myth as a lasting dimension of all human life and the tendency of others to regard myth as a stage in the development of human consciousness, which is important but past. Although the latter tendency has been prevalent in scholarship, the former now deserves attention. A typology of myths that begins with the recognition of a lasting mythological dimension of human existence is inclined toward a certain hierarchy of mythical themes. Examples are Mircea Eliade's insistence on the primacy of cosmogonic accounts or, earlier, Friedrich Schelling's interest in theogony as the basic myth.

The two tendencies, however, are a matter of philosophical commitment. This means that the decisive criterion of mythological classification cannot be found only by considering all available mythologies. The point of view is a crucial factor, and the issue is far from closed at the present state of scholarship.

MYTH IN MODERN SOCIETY

Secularization of myth and mythology. The problem of the secularization of myth is almost entirely a problem of definition. If one has decided, however, to regard myth as product of a past that has come to an end, insuperable difficulties arise in establishing the historical moment when that past period was terminated. It is virtually impossible to state with accuracy when a certain mythical theme becomes a "mere" literary theme or to determine in general when myths are no longer being created. It is more fruitful, as well as more defensible in view of the study of religious facts, to recognize that symbols, myths, and rituals are all subject to change in the course of time. Secularization is not an irreversible process that takes place once and for all, eventually leaving all myths devoid of their religious function. It is rather a process that takes place time and again in history. Secularization movements and mythification (or symbolization) movements are distinct aspects of the same historical processes. The formation of epic literature is an early example of secularization of myth. Nevertheless, epic literature itself can resume certain mythical functions.

Although the form of secularization brought about in modern history is one of many such forms, it is a new and complex type, to which many factors have contributed. Scientific, particularly astronomic, discoveries of the late medieval and Renaissance periods were accompanied by a new trust in cosmic laws and an increasingly abstract notion of God. More or less Euhemeristic historical accounts that were common in the Middle Ages and were a symptom of a certain secularization process themselves gave way to history writing, focussing on psychological, social, and economic facts. In philosophy, naturalism of various sorts opposed notions of transcendence that earlier systems had taken for granted. These are a few of the factors in the modern secularization of mythological views. The most common tendency in modern society has been to regard the characters and events in mythical accounts as not real or as by-products of realities that are not transcendent, but rather immanent.

Secularization with mythification

This secularization in modern society, like earlier secularization processes, is accompanied by forms of mythification. Though there is no general agreement on these matters, some of the most prominent features of modern society are mythological by nature. The aversion to transcendent realities has prototypes in ancient religious systems (especially Buddhism).

To recognize the myths that are dominant in one's own society is always difficult. The outline of myths from a past period, however, can be seen quite clearly; *e.g.*, the Marxist eschatological myth of the withering away of the state. This is not surprising, because a myth has its authority not by proving itself but by presenting itself. In this sense the authority of a myth indeed "goes without saying," and the myth can be outlined in detail only when its authority is no longer unquestioned but has been rejected or overcome in some manner by another, more comprehensive myth.

Demythologization of major religious traditions. Demythologization should be distinguished from seculariza-

tion. Every living mythology has to come to terms with the world in which it is transmitted and, therefore, inevitably goes through processes of secularization. Demythologization, however, refers to the conscious efforts people make to purify a religious tradition of its mythological elements. The term demythologization (*Entmythologisierung*) has been coined by Rudolf Bultmann, a German theologian and New Testament scholar. In the strict sense of the word, demythologizing efforts have been limited to theological discussions in 20th-century Christianity (see also CHRISTIAN MYTH AND LEGEND).

Survivals in modern consciousness and behaviour: superstitions and tales. E.B. Tylor, an English anthropologist of the 19th century, used the word survival for customs and beliefs that continued to be adhered to long after the context in which they had their meaning had ceased to exist. They connote the impression of superstitions, and hence the word survival usually has a slightly derogatory overtone. There are many survivals of myth in this sense. The myth of "the noble savage," well-known from Jean-Jacques Rousseau, an 18th-century French-Swiss moralist, can be understood as a survival of a paradisical mythology: Western man expected to find evidence of paradise on earth.

Once more, however, the suggestion that at one time myths ruled supreme and that all that now remain are mere remnants is to be avoided. The secularization process in modern society has affected two of the three forms of symbolization most adversely, viz., symbolic behaviour (cult, ritual, liturgy) and symbolic objects (sacred places and the sacredness of the earth itself) but not symbolic communication (myth). Indeed, the most striking feature of modern Western society is its insistence on communication (*e.g.*, freedom of the press). Because as a rule no reasons are adduced or believed to be necessary to justify this insistence, this modern sense of communication is mythological in structure.

Survival of symbolic communication

Commonly accepted forms of mythology in modern society, however, do not permeate all parts of that society or fulfill all needs. In all likelihood, no society has ever been perfectly homogeneous in its myths. In modern society a number of profound mythological needs are filled by myths borrowed from submerged or alien traditions. Modern society's neglect of cosmic symbolism (which typified all archaic tradition) has elicited a certain reaction and has led various "subcultures" to an interest in cosmic coherencies (such as astrology). The great scientific possibilities opened up by the 20th century have everything to do with the rise of a new literature, resembling myths, and often with an eschatological tenet (*e.g.*, science fiction).

Political and social uses of myth in modern times. In western European countries that have experienced anticlerical movements, it has been observed that politics has taken over the role that was played by religion or myth in previous times. This should not, however, lead to the conclusion that myth was ever apolitical or asocial. At all times reasons used to solidify a political unit, whether a village or a nation, have had a mythological component. In recent times, however, people have begun to think of social and political "ideologies" in terms of mythical functions, and conscious endeavours have been made to utilize myth for social and political purposes. The most conspicuous example has been the Nazi endeavour to revive Germanic mythology. The vast majority of sociopolitical uses of myth, however, are less conscious efforts. Marxism can be regarded as "a new *tao*" or way of nature, according to Robert Charles Zaehner, an English historian of religion, and the word ideology in much contemporary parlance could be replaced by the term mythology without harm. Finally, crucial terms in modern sociopolitical discussion, such as "freedom" and "equality," although they have a long and complex philosophical history, are usually posited in a manner quite analogous to the function of myth presenting its own authority.

Nabokov, Vladimir

One of the contemporary novelists most admired by critics, Vladimir Vladimirovich Nabokov, of Russian birth but from his 20th year a resident in western Europe and the United States, used a highly chiselled and lucid prose to express by allegory, parody, and sardonic jest a very personal vision of the world. With the exception of *Lolita,* Nabokov's greatest popular success, his writing was generally too involuted to permit precise description, and more than perhaps any other celebrated 20th-century author, he left it to the reader to interpret his work.

© Philippe Halsman

Nabokov, 1968.

Nabokov was born in St. Petersburg (now Leningrad), Russia, on April 23, 1899, into an old aristocratic family. His father, V.D. Nabokov, was a leader of the pre-Revolutionary liberal Constitutional Democratic Party (Kadets) in Russia and the author of numerous books and articles on criminal law and politics, among them *The Provisional Government* (1922; Eng. trans. 1970), one of the primary sources on the downfall of the Kerensky regime. In 1922, after the family had settled in Berlin, V.D. Nabokov was assassinated by a reactionary rightist while shielding another man at a public meeting; and although his novelist son disclaimed any influence of this event upon his art, the theme of assassination by mistake has figured prominently in Nabokov's novels. Nabokov's enormous affection for his father and for the milieu in which he was raised is shown in his autobiography *Speak, Memory* (revised version, 1967).

Early verse collections

Nabokov published two collections of verse, *Poems* (1916) and *Two Paths* (1918), before leaving Russia in 1919. He and his family made their way to England, and he attended Trinity College, Cambridge, on a scholarship provided for the sons of prominent Russians in exile. While at Cambridge he first studied zoology but soon switched to French and Russian literature; he graduated with first-class honours in 1922 and subsequently wrote that his almost effortless attainment of this degree was "one of the very few 'utilitarian' sins on my conscience." While still in England he continued to write poetry, mainly in Russian but also in English, and two collections of his Russian poetry, *The Cluster* and *The Empyrean Path,* appeared in 1923. In Nabokov's mature opinion these poems were "polished and sterile."

Between 1922 and 1940 Nabokov lived in Germany and France, and while continuing to write poetry, he experimented with drama and even collaborated on several unproduced motion-picture scenarios. By 1925 he settled upon prose as his main genre. His first short story had already been published in Berlin in 1924. His first novel, *Mashenka* (*Mary,* 1970), appeared in 1926; it was avowedly autobiographical and contains descriptions of the young Nabokov's first serious romance as well as of the Nabokov family estate, both of which are also described in *Speak, Memory.* Nabokov did not again draw so heavily upon his personal experience as he had in *Mashenka* until his episodic novel about an émigré professor of entomology in the United States, *Pnin* (1957), which is to some extent based on his experiences while teaching (1948–58) Russian and European literature at Cornell University, Ithaca, New York.

His second novel, *King, Queen, Knave,* which appeared in 1928, marked his turn to a highly stylized form that characterized his art thereafter. His chess novel, *The Defense,* followed two years later and won him recognition as the best of the younger Russian émigré writers. In the next five years he produced four novels and a novella. Of these, *Despair* and *Invitation to a Beheading* were his first works of importance and foreshadowed his later fame.

Work in Germany and France

During his years of European emigration Nabokov lived in a state of happy and continual semipenury. All of his Russian novels were published in very small editions in Berlin and Paris. His first two novels had German translations, and the money he obtained for them he used for butterfly hunting expeditions (he eventually published 18 scientific papers on entomology). But until his best-seller *Lolita* (1955), no book he wrote in Russian or English produced more than a few hundred dollars. During the period in which he wrote his first eight novels, he made his living in Berlin and later in Paris by giving lessons in tennis, Russian, and English and from occasional walk-on parts in films (now forgotten). His wife, the former Véra Evseyevna Slonim, whom he married in 1925, worked as a translator. From the time of the loss of his home in Russia, Nabokov's only attachment was to what he termed the "unreal estate" of memory and art. He never purchased a house, preferring instead to live in a series of houses rented from other professors on sabbatical leave. Even after great wealth came to him with the success of *Lolita* and the subsequent great interest in his previous work, Nabokov and his family (he and his wife had one son, Dmitri) chose to live (from 1959) in genteelly shabby quarters in a Swiss hotel.

The subject matter of Nabokov's novels is principally the problem of art itself presented in various figurative disguises. Thus, *The Defense* seemingly is about chess, *Despair* about murder, and *Invitation to a Beheading* a political story, but all three works make statements about art that are central to understanding the book as a whole. The same may be said of his plays, *Sobytiye* ("The Event"), published in 1938, and *The Waltz Invention.* The problem of art again appears in Nabokov's best novel

in Russian, *The Gift,* the story of a young artist's development in the spectral world of post-World War I Berlin. This novel, with its reliance on literary parody, was a turning point: serious use of parody thereafter became a key device in Nabokov's art. His first novels in English, *The Real Life of Sebastian Knight* (1941) and *Bend Sinister* (1947), do not rank with his best Russian work. *Pale Fire* (1962), however, a novel consisting of a long poem and a commentary on it by a mad literary pedant, extends and completes Nabokov's mastery of unorthodox structure, first shown in *The Gift* and present also in *Solus Rex,* a Russian novel that began to appear serially in 1940 but was never completed. *Lolita* (1955), with its antihero, Humbert Humbert, who is possessed by an overpowering desire for very young girls, is yet another of Nabokov's subtle allegories: love examined in the light of its seeming opposite, lechery. *Ada* (1969), Nabokov's 17th and longest novel, is a parody of the family chronicle form. All of his earlier themes come into play in the novel, and because the work is a medley of Russian, French, and English it is his most difficult work.

First novels in English

Nabokov's major critical works are an irreverent book about Nikolay Gogol (1944) and a monumental four-volume translation of, and commentary on, Pushkin's *Eugene Onegin* (1964). What he called the "present, final version" of the autobiographical *Speak, Memory,* concerning his European years, was published in 1967, after which he began work on a sequel, *Speak On, Memory,* concerning the American years.

As Nabokov's reputation grew in the 1930s so did the ferocity of the attacks made upon him. His idiosyncratic, somewhat aloof style and unusual novelistic concerns were interpreted as snobbery by his detractors—although his best Russian critic, Vladislav Khodasevich, insisted that Nabokov's aristocratic view was appropriate to his subject matters: problems of art masked by allegory.

Nabokov's reputation varies greatly from country to country. In his native land he was not only not published because he was a "White Russian émigré" (he became a U.S. citizen in 1945) but was condemned for other reasons. Critics of strong social convictions in the West also generally hold him in low esteem. But within the intellectual émigré community in Paris and Berlin between 1919 and 1939, V. Sirin (the literary pseudonym used by Nabokov in those years) was credited with being "on a level with the most significant artists in contemporary European literature and occupying a place held by no one else in Russian literature." His reputation after 1940, when he changed from Russian to English after emigrating to the United States, mounted steadily until the 1970s, when he was acclaimed by a leading literary critic as "king over that battered mass society called contemporary fiction." He died in Montreux on July 2, 1977, of a virus infection.

MAJOR WORKS

NOVELS: In Russian (English translations after 1940 mainly by the author and his son Dmitri Nabokov): *Mashenka* (1926; *Mary,* trans. by Michael Glenny with Nabokov's assistance, 1970); *Korol-dama-valet* (1928; *King, Queen, Knave,* 1968); *Zashchita luzhina* (1930; *The Defense,* 1964); *Podvig* (1932; *Glory,* 1971); *Camera obscura* (1933; first Eng. trans. 1936, altered by Nabokov for U.S. version and retitled *Laughter in the Dark,* 1938); *Otchayaniye* (1934; *Despair,* 1937, altered and enlarged by Nabokov for U.S. version, 1966); *Priglasheniye na kazn* (1935; *Invitation to a Beheading,* 1959); *Dar* (incomplete 1935–36, complete 1952; *The Gift,* 1963). In English: *The Real Life of Sebastian Knight* (1941); *Bend Sinister* (1947); *Lolita* (1955); *Pnin* (1957); *Pale Fire,* including a long poem (1962); *Ada; or, Ardor: A Family Chronicle* (1969); *Transparent Things* (1972).

SHORT STORIES AND NOVELLAS: In Russian: *Soglyadatay* (1938), collects a novella and 12 short stories written 1930–36 (the title novella, first published 1930, was trans. as *The Eye,* 1965, and some of the stories have been trans. in later collections); *Vesna v Fialte i drugiye rasskazy* (1952), collects 14 short stories written 1931–40 (some trans. in later collections). In English: *Nabokov's Dozen* (1958), short stories and novella, some trans. from the Russian by the author and others; *Nabokov's Quartet* (1966), collects three novellas written in Russian in the 1930s and trans. by Dmitri Nabokov, with one published in English in 1959; *Nabokov's Congeries* (1969), collects stories written in Russian in the 1930s and trans. by Dmitri Nabokov and others, with some written in English; *A Russian Beauty, and Other Stories* (1973), 13 early stories trans. by Dmitri Nabokov and Simon Karlinsky in collaboration with the author; *Tyrants Destroyed, and Other Stories* (1975), 12 stories trans. from Russian by Nabokov and Dmitri Nabokov and one English story; *Details of a Sunset, and Other Stories* (1976), 13 early stories trans. by Nabokov and Dmitri Nabokov.

OTHER WORKS (MEMOIRS): *Conclusive Evidence: A Memoir* (1951); *Speak, Memory: An Autobiography Revisited* (1967), revised version of *Conclusive Evidence,* with new material and additions from *Drugiye berega* (1954); *Look at the Harlequins!* (1974), a pseudo-memoir. (POEMS): In Russian: *Poemy 1929–1951* (1952). In English: *Poems* (1959); *Poems and Problems* (1971), 39 Russian poems with English trans. by Nabokov and 14 English poems (published earlier in *Poems*). (PLAYS): *Sobytiye* (1938), a three-act comedy; *Izobretaniye valsa* (1938; *The Waltz Invention,* 1966). (CRITICAL BIOGRAPHY): *Nikolai Gogol* (1944). (TRANSLATIONS): *Three Russian Poets: Translations of Pushkin, Lermontov, and Tiutchev* (1944, with Dmitri Nabokov); Lermontov's *A Hero of Our Time* (1958, with introduction by Nabokov); Pushkin's *Eugene Onegin,* 4 vol. (1964, with introduction and commentary).

BIBLIOGRAPHY. VLADIMIR NABOKOV, *Speak, Memory* (1967), the author's autobiography up to 1940; three books by ANDREW FIELD, *Nabokov: His Life in Art* (1967), *Nabokov: A Bibliography* (1972), and *Nabokov: His Life in Part* (1977); C. NEWMAN and A. APPEL, JR. (eds.), *For Vladimir Nabokov on His Seventieth Birthday* (1971), a festschrift of reminiscences of Nabokov and critical articles and tributes first published in *Tri-Quarterly* magazine.

(A.Fi.)

Nāgāland

Nāgāland, a state of India, occupies a region of forested hills and mountains between Burma and the Brahmaputra Valley of upper Assam. It is bordered on the east by Burma, on the south by the Indian state of Manipur, and on the west and northwest by the Indian state of Assam; a small section extends north from the Burmese border into the Tirāp division of Arunachal Pradesh, an Indian union territory. Its total area is 6,366 square miles (16,488 square kilometres) and its population (1971) is 516,449. The capital is Kohīma.

How the word Nāga came into use to designate the many tribes and subtribes that occupy the area is still a matter of conjecture. Some derive the name from Sanskrit *nāga,* "snake"; some from Hindu *naṅgā,* "naked"; and some from *naga,* "belonging to the hills," "highlander." The most widely accepted view is that it is derived from *nok,* meaning "people," or "folk." The people once called themselves by their tribal names, such as Angami, Sema, or Ao, but the upsurge of nationalism that led to statehood made Nāga so popular that it became a matter of pride to be so designated. (For an associated physical feature, see BRAHMAPUTRA RIVER.)

History. Nāgāland has no early written history. The first reference to the Nāgas is found in chronicles of the neighbouring Ahom kingdom of Assam. These chronicles tell of an invasion of the region in 1228 (although scholars consider a later date more probable) and contain information regarding the Nāga tribes, their economy and customs, and indicate that the Ahom did not rule the country but maintained friendly relations with the Nāga chieftains. There were occasional clashes between the Nāgas and the Ahoms, and a Burmese invasion of Assam in 1816 led to an oppressive Burmese rule from 1819 until the establishment of British rule over Assam in 1826, after which the Nāga hill areas were gradually annexed to the British Empire. The advent of British administration, which by 1892 encompassed the whole of Nāga territory (except the wild and rugged Tuensang area in the northeast), brought an end to the practices of headhunting and intervillage raids, and the Nāgas settled down to a peaceful life of cultivation and trade.

Nāga separatism

When India became independent in 1947, a strong nationalist movement sought a union of the Nāga tribes, claiming that Nāgāland was a sovereign state separate from India, and a small armed force was organized among them. At the same time, however, there were

many political differences among the Nāgas. In 1957, after negotiations with a Nāga People's Convention at Kohīma, the Indian government placed the Nāga Hills district and Tuensang area under central administration.

This status, however, proved unsatisfactory to a large segment of the Nāgas, and unrest continued, taking the form of noncooperation with the Indian government, nonpayment of taxes, and armed conflicts. A rebel force engaged in action against the Indian army and committed acts of sabotage. The Indian government and representatives of the Nāgas, however, continued to negotiate, and an agreement reached at a Nāga People's Convention of July 1960 provided that Nāgāland should become a full state in the Indian Union. Nāga representatives found this solution acceptable because of the wide autonomy that would be granted to the new state. Nāgāland accordingly entered the Indian Union in 1962, and in 1964 a democratically elected government took office and proceeded to administer the state. Dissident factions within Nāgāland refused to accept this solution, however, and rebel activity continued, increasingly assuming the form of banditry and often motivated more by tribal rivalry and personal vendetta than by political aspiration. The state received substantial financial help from the central government, but relations were strained somewhat by the increasing presence of the Indian army in the territory. From June 1966 to March 1969 there was a ceasefire, and talks between the dissidents and the government of India continued throughout the period. In clashes that occurred after the breakdown of talks, evidence was produced suggesting that large numbers of Nāga dissidents had received training in China; it can be said with certainty that the Nāga underground had some contacts with the Chinese.

The dissidents became increasingly fragmented in the late 1960s, and several groups surrendered to the Indian army. In the early 1970s, however, a hard core of extremists were continuing their activities. A faction of the dissidents set up a self-styled government in the Tuensang area, but its activities were of minor significance.

The landscape. *Physiography.* Except for a few square miles of plain, the entire state is covered with ranges of hills that geologically are a part of the Himalayan system. They consist of sedimentary formations of the Tertiary Period (formed up to 65,000,000 years ago). The Nāga Hills rise abruptly from the Brahmaputra Plain in the north, initially to low hills of about 2,000 feet, which increase in height toward the east to more than 6,000 feet, with isolated peaks reaching 10,000 feet or more. The hills merge with the Pātkai Range, which separates Nāgāland from Burma and which reaches a height of 12,552 feet (3,826 metres) at Mt. Saramati, on the border. The northwest is drained by tributaries of the Brahmaputra. The southeast, comprising all of Tuensang and the southeastern part of Kohīma district, has an elevation of more than 4,000 feet and is drained by tributaries of the Chindwin River of Burma. The headstreams of the Barak flow through the southwest. The hills, clothed for the most part with dense forest, scrub, and grassland, are deeply dissected, though some slopes provide suitable sites for shifting cultivation. The higher slopes are covered with shallow, acidic, brown forest soils whereas there are comparatively deeper soils on the lower slopes.

Relief and drainage

Climate. Nāgāland has a wet monsoon climate, with the average annual rainfall varying between 70 inches in the southeast and more than 100 inches in the northeast. July and August are the rainiest months. The temperature is relatively low. Varying according to altitude, the summer temperature ranges between 70° F (21° C) and 104° F (40° C), while in winter it rarely goes below 39° F (4° C), although frost is common over higher elevations. Because of the high humidity, the summer is sultry, especially over the lower hills and in the valleys.

Vegetation and animal life. The hills are covered with luxuriant forest approximating in type that of the eastern Himalayas, except that there is no true alpine zone. The hill forests may be separated generally into evergreen, broad-leaved, and pine forests. But where the forests have been cleared for *jhum* (shifting cultivation), high grass, reeds, and scrub jungles have sprung up in profusion. There are many species of palm and several of calamus (climbing palms, or rattan). Below 4,000 feet occur wet monsoon and evergreen forests, with mahogany and other valuable timber species and varieties of bamboo. On the higher hills in the east and southeast, oak, pine, and other coniferous vegetation appear. The surveyed forest area of the state is about 777,000 acres.

In the lower hills, especially in the north and northeast, are found rhinoceroses, elephants, tigers, leopards, bears, sambar deer, buffalo, boars, and wild oxen. Also seen are several kinds of monkey, including the long tailed langur, flying lemur, and pink faced monkey. Porcupines, pangolins (scaly anteaters), goats, wild dogs, foxes, civets, and mongooses are also found. Game birds include wild fowl, partridges, woodcocks, and pheasant. The great Indian hornbill is the most treasured bird—for use in decoration and magic. The gayal, a domesticated breed of wild ox, is a prized animal. The colourful smaller animals and the wide variety of birds make the jungle attractive for tourists.

Animal life

Population. *Ethnic composition.* The Nāgas belong to the Indo-Mongoloid ethnic group. They have long been isolated and they lack cohesion as a single people—there are 17 major tribes and several subtribes. Though all have much in common, they differ in physique, dialect, and customs. The tribal groups have formed new affiliations and are using names hitherto unknown. The Chakhesangs, for example, are a combination of Chakru, Khezha, Sangtams, and a few Rengmas. Similarly, the Zeliangs are a mixed group of Zemis, Liangmais, and others. The big Konyak tribe has two sharply distinguished divisions, one ruled by powerful autocratic chiefs and the other, which now calls itself Shaymnyuyungmang, more democratic.

The Angamis, Chakhesang, Zeliangs, Rengmas, and Kukis are southern tribes living in the Kohīma district. The Tuensang district in the east is the home of the Konyaks and the Upper Konyaks, occupying the north and northeast, and the Phoms, Changs, Sangtam, Yimchungrs, Khienmungans, Sangtams, and a large number of subtribes, occupying the west and south. The major tribes in the western district of Mokokchūng are the Aos, Lhotas, and Semas.

Languages. The Nāga tribes do not have a common language, and there are 60 spoken dialects. In some areas dialects vary even from village to village. The languages all belong to the Sino-Tibetan family. Intertribal conversation generally is carried on through broken Assamese, which is also now commonly used and is called Nagamese. Many Nāgas have also become acquainted with Hindi and English.

Religion. The traditional religion of the Nāga tribes is not based on any deep-rooted philosophy and does not demand any spiritual or mystic participation of its followers. Generally, all tribes give special status to the sun and the moon. Nevertheless, there is a vague conception of a supreme creator, and there are many minor deities. Nature is seen to be alive with invisible forces, with which priests and medicine men mediate. They also lead rites and festivals, bless the marriage bed, and protect the craftsman at his work. Nāga ideas of afterlife vary from tribe to tribe, but there is wide agreement that the soul does not perish at death.

With the advent of British rule, Christianity was introduced. The American Baptist Mission and various church unions were active, especially in the Kohīma and Mokokchūng districts. Out of the total population, about 67 percent are now Christian, about 11 percent Hindu, and less than 1 percent Muslim, the rest belonging to other faiths.

Rural–urban distribution. Nāgāland is extremely rural. About 90 percent of its population live in isolated villages. There are altogether some 860 villages and three urban centres. The villages are normally large, many having more than 5,000 inhabitants. Their size and singular character is striking even in the wilder Tuensang border ranges. Built on the most prominent points along the ridges of the hills, they were formerly stockaded; some had village gates—massive wooden doors approached by

Nāga villages

narrow, sunken, winding paths. The Aos and Lhotas set out their houses in streets, frequently along the top of a ridge. The villages are usually divided into *khels,* or quarters, each with its own headmen and administration. The houses are fairly large, sometimes very large, reflecting the status of the owner. Many are built on stilts. Different areas are dominated by different tribal groups, which have well-defined portions of lands and sources of water. Tuensang district is comparatively densely populated (83 persons per square mile). Kohīma, Mokokchūng and Dimāpur are the only urban centres, with 21,398, 17,381, and 12,292 inhabitants (1971), respectively. Urban growth has been very rapid since 1961.

Administration. In common with the other states of India, the administration of Nāgāland is conducted by a council of ministers, which is headed by a chief minister and is responsible to the Nāga legislative assembly. The legislative assembly has 52 members. The state is divided into three administrative districts—Kohīma, Mokokchūng, and Tuensang—each under a deputy commissioner and magistrate. The deputy commissioner is responsible for the maintenance of law and order, revenue, and criminal administration. Each district is divided into three subdivisions headed by subdivisional officers responsible to the deputy commissioner.

Provisions for tribal autonomy

The administration of Nāgāland differs from other states in that wider autonomy has been provided in the constitution to the tribal communities. Each tribe has three local councils—the village council, the range council, and the tribal council. These deal with disputes involving breaches of customary laws and usages. Appeals are made to the Nāga Tribunal in respect of cases decided according to customary law. Special provisions were made for Tuensang, which was not placed under the direct jurisdiction of the assembly but was put under a regional council consisting of elected representatives of all the tribes in the district, to which the governor might also nominate members. The deputy commissioner is its ex officio chairman. It elects representatives from among its members to the legislative assembly.

Social conditions. This hill and forest land, hitherto an underdeveloped region, has been witnessing a sociocultural renaissance. From its formation in 1964, the popular democratic government rapidly established a good measure of stability and directed its efforts toward improving social conditions through systematic planning. Under a special plan, inaugurated in 1958, the highest item of expenditure was on roads, and greater emphasis was given to public health and water supply. Simultaneously, elaborate educational and community development programs were undertaken.

In 1957 there were 12 hospitals, 18 dispensaries, and five mobile medical units in Nāgāland. By the 1970s there were 28 hospitals, 77 dispensaries, and a large mobile unit to serve the interior villages. Because of the high incidence of tuberculosis, a hospital was established to treat victims of the disease. Malaria is another major health problem, and an antimalaria unit with trained personnel has been deployed. Under extensive community development programs, drinking water has been supplied to over 800 villages.

In 1971 about 27 percent of the population was literate. Since then there has been much educational development, and the literacy percentage has been increasing at a rapid pace. There are four colleges for general education, all affiliated with Gauhāti University in Assam. Also, there are 33 high schools, about 150 junior high schools, and nearly 2,000 primary schools, as well as a limited number of technical schools, basic training schools, and schools for special education.

The social and economic welfare activities of the state include consumer trading societies; farming and dairy, marketing, and other cooperatives; and adult literacy centres, libraries, youth clubs, and women's societies.

The economy. *Agriculture and forestry.* Agriculture is the mainstay of the economy. About 90 percent of all workers are cultivators. Autumn and winter rice, small millets, pulses (edible seeds), oil seeds, fibres, sugarcane, potato, and tobacco are the principal crops. Production, however, is inadequate, and Nāgāland has to depend largely on imports from neighbouring states. This deficiency may be attributed to inadequacy of fertile, cultivable land and the common practice of shifting, or *jhum,* cultivation.

Cultivation practices

Under shifting cultivation the jungle on the hill slopes is cleared and the undergrowth is burned down. The ground is then lightly hoed and sown for two successive years. After two harvests, the land is allowed to remain fallow for eight to ten years. In higher or otherwise unsuitable regions, *jhum* is replaced by terrace cultivation. The Angamis of Kohīma district excel in the art of terracing and irrigation. The implements of the cultivator include the light hoe, *dao* (a heavy knife), and sickle. Except in the plains, the plow is not used. Agriculture is undergoing slow but steady transformation, and wasteful practices are being progressively replaced by improved methods.

Forestry is a primary source of income and employment. Quantities of fine timber, such as mahogany, are produced, as well as timber for fuel and forest products.

Minerals. It is believed that there are rich deposits of minerals in Nāgāland, but limestone and low-grade coal are the only two known at present. The limestone, ranging in colour from light gray to a deep blue, makes an excellent building stone. Low-grade coal occurs in the Wokha, Mokokchūng, and Naginimārā areas. Naginimārā is the only producing area at present but proposals have been made to mine coal from other areas. Many of the coal measures contain iron ore in the form of clay, ironstone, and impure limonite. Salt is locally produced from brine wells. Petroleum seepages occur in the Dikhu Valley, and the geological homogeneity of northern Nāgāland with the oil and coalbearing area of Upper Assam suggests the presence of exploitable oil reserves.

Industry. Lack of raw materials, financial resources, and power, and, above all, poorly developed transport and communication have hindered the development of industry. In 1970 there were in the state some 25 small bakeries, 18 motor vehicle service and repair shops, six rice mills, and 12 cabinet and furniture factories. A sugar mill was under construction at Dimāpur and was expected to manufacture 2,800,000 gallons of alcohol for wine production; it will be the first manufacturing industry of any importance in the state. A small fruit-canning centre is located at Chanki.

Power. Electric power generation started only after World War II. Two small hydroelectric schemes begun by Nāga entrepreneurs were subsequently taken over by the state government. By the early 1970s all the district headquarters and even some of the subdivisional administrative centres had electricity.

Cottage industry. Even though the state is devoid of manufacturing industries, cottage industry is common. Nāgas are noted weavers and expert in basketry, woodwork, and pottery. They weave beautiful shawls, handsome ties, and colourful skirts. Cottage industry, however, suffers from lack of raw materials and improved tools, competition from outside, and the absence of a sufficiently wide market.

Communications. Nāgāland depends mostly on roads for communication. The North-East Frontier Railway runs along the south bank of the Brahmaputra River and provides the single rail link to Nāgāland. It extends a little way across the Assam border. The total length of railway line within Nāgāland is only five miles.

There are only a few all-weather roads. A national highway runs from Dimāpur through the southern part of the state, via Kohīma to Imphāl, the capital of Manipur. The second important road runs from Amguri, in the Sibsāgar district of Assam, to Mokokchūng, via Tuli and Merangkong village. The third important road links Tuensang with Mokokchūng. And Mokokchūng, Zunheboto, Kohīma, and Phek are also connected with short all-weather roads. There is a total of 2,209 miles of road in Nāgāland, and more roads were under construction. Post and telegraph communications have developed rapidly since 1964. There are telephone exchanges at Kohīma, Dimāpur, and Mokokchūng.

Cultural life. Nāga society contains varying patterns of local organization, ranging from near dictatorship to ex-

treme democracy. Among the Semas and Changs there is a system of hereditary chieftainship. The Konyaks are ruled by powerful chiefs, or *āngs*, whose word is law and who are held to be sacred. The Aos have councils of elders representing the main family groups in the village. The Angamis, Lhotas, Rengmas, and others are democratically run.

Tribal institutions and customs

A prominent village institution is the *morung* (communal house, or dormitory), for young unmarried men. Some tribes have communal houses for unmarried girls also. Formerly, skulls and other trophies of war were hung in the *morungs*. The pillars are still carved with striking representation of tigers, hornbills, and human and other figures.

The basic interest of every Nāga is in his family, the clan, the *khel*, and the village, and the Nāgas are passionately attached to their land and traditional customs. A central feature of their lives is the Feast of Merit, consisting of a series of ceremonies that finally culminate with the sacrifices of oxen (called *mithun* by the Nāgas).

Although there is no matriarchy among the Nāgas, women hold a high and honourable position. They work on equal terms with men in the fields and make their influence felt in the tribal councils.

The people have a rich vein of poetic thought that is little known outside the state. They have a passion for beauty and colour that inspires them to decorate almost everything they use or wear, and their poetry, folk songs, tales, and folklore all express an exuberant concern for life, romance, and a love of chivalry.

BIBLIOGRAPHY. The *Census of India, 1961, Nagaland,* gives a general account of the state together with important data on geographic, economic, cultural, and social aspects. ANAND V.K. MAJOR, *Nagaland in Transition* (1967), is a traveller's account of Nāgāland. *The Gazetteer of India*, vol. 1, *Country and People* (1965), contains ten chapters written by eminent scholars on the physiography, climate, geology, flora, fauna, people, languages, religion, social structure, and life of all states of the Indian Union. See also ELWIN VERRIER, *Nagaland* (1961); and the *Statistical Handbook of Nagaland* (1967), an invaluable publication for statistical data.

(M.B.)

Nāgārjuna

From the 3rd century AD onward the Buddhist traditions in India, China, Korea, Japan, and Tibet have paid homage to a much-revered monk by the name of Nāgārjuna, whose spiritual insight and power to destroy evil were regarded as phenomenal. The fact that various texts ascribe different religious qualities to him and give dates for his life that range over 500 years suggests that the references available may pertain to several persons and may include some imaginary accounts. At the base of these traditions, however, stands an astute philosopher who clarified the meaning of the significant Buddhist term *śūnyatā* "emptiness" and became the founder of the Mādhyamika, or Madhyamaka ("Middle Path"), school of Buddhism. Such a feat was recognized not only as an intellectual but also as a deep spiritual achievement, so it is not surprising that within a hundred years after his death there were reports of devotees honouring him as a Buddha. In later centuries he was recognized as a patriarch by several Buddhist schools.

Traditional accounts of life

The earliest available biographical account of Nāgārjuna is in Chinese, supplied about AD 405 by a renowned Buddhist translator, Kumārajīva. It agrees with other Chinese and Tibetan accounts that Nāgārjuna was born in South India into a Brahmin (Hindu priestly caste) family. The stories of his boyhood are contradictory in historical terms but indicate that he possessed an extraordinary intellectual capacity and underwent a spiritual conversion when he learned the profound meanings of the doctrines of Mahāyāna (Great Vehicle) Buddhism, now the predominant form of Buddhism in East Asia. According to Kumārajīva's account, after Nāgārjuna had learned some basic Buddhist views, but without complete satisfaction, a "Mahānāga *bodhisattva*"—"a chief Nāgā [literally "serpent"; also the name of a hill tribe of South India], who was on the path to enlightenment"—took pity on him and presented him with the most profound Mahāyāna verses. Nāgārjuna mastered these in a short time and propagated the truth (*dharma*) in India, successfully defeating many opponents in scholastic philosophical debates. Traditional accounts also suggest that he lived to an old age and then decided to end his life.

Various elements of Nāgārjuna's biographies are supported by some historical materials. Present scholarship indicates that Nāgārjuna could have lived as early as AD 50 and as late as AD 280. A common consensus gives his dates as AD 150–250. The claim that he lived in South India is supported by some archaeological evidence: by a letter (*Suhṛllekha*, "Friendly Letter") credited to him, written to a king of the Sātavāhana dynasty, possibly Yajñaśrī (*c.* 173–202); and perhaps by his name, which includes the name of the Nāgā people, who lived in South India. While there is no evidence regarding Nāgārjuna's parents or his boyhood training, his knowledge of several Hindu philosophical positions expressed in his later critical expositions supports the tradition of a Brahmin family background. It is not known how widely accepted his critique of Hindu and early Buddhist philosophical-psychological interpretations was, but the fact that he had disciples who carried on his critique indicates some pervasive influence of his effort.

Influence and works

Nāgārjuna's influence has continued through the followers of the Mādhyamika school of Buddhism, whose critical examination of philosophical positions and whose didactic expositions have been studied down to the present day in many Far Eastern schools as part of the Chinese Buddhist Canon (*Ta-ts'ang Ching*). Similarly, 17 Mādhyamika treatises are contained in the Tanjur part of the Tibetan Buddhist Canon. Not all of these are credited to Nāgārjuna, and some traditionally credited to him are probably not by him. Two basic writings that are substantially his are available at present in Sanskrit; they are *Mūlamadhyamakakārikā* (*Mādhyamika Kārikā*, "Fundamentals of the Middle Way") and *Vigrahavyāvartanī* ("Averting the Arguments"), both critical analyses of false views about how existence arises, the means of knowledge, and the nature of reality. Three important Mādhymika texts attributed to Nāgārjuna and extant only in Chinese are *Ta-chih-tu-lun* (*Mahāprajñāpāramitā-śāstra*, "Great Perfection of Wisdom Treatise"), *Shi-chu-p'i-p'o-sha-lun* (*Daśabhūmi-vibhāṣā-śāstra*, "Illumination of the Ten Levels Treatise"), and *Shih-erh-men-lun* (*Dvādaśa-dvāra-*[*nikāya-*]*śāstra*, "Twelvefold Entrance Treatise"). The following three texts are found only in the Tibetan canon and are accepted by most scholars as compositions of Nāgārjuna: *Rigs pa drug ca paḥi tshig leḥur byas pa shes bya ba* (*Yukti-ṣaṣṭikā*, "Sixty Verses on Union"), *Ston pa ñid bdun cu paḥi tsig leḥur byas pa shes bya ba* (*Śūnyatā-saptati*, "Seventy Verses on Emptiness"), and *Shib mo rnam par ḥtag pa shes bya baḥi mdo* (*Vaidalya-sūtra*, "Sacred Text of the Vaidalya Type").

Besides the verses of Mādhyamika analysis there are a large number of Tantric (magical) and medical works attributed by Tibetan tradition to a "Nāgārjuna." There are also references in late Indian materials to a great *siddha*, or sorcerer, by the name of Nāgārjuna, who acquired his magical power through Tantric practices; *e.g.*, employment of magical spells and diagrams, and gaining access to nonphysical planes of existence through diet and meditation. Closely allied with these tales are stories of a powerful alchemist who, among other accomplishments, discovered the elixir of immortality. Due to the lack of concrete historical data, or because of conflicting accounts, the reports of a great sorcerer are generally not accepted outside the Tibetan tradition as applying to the 2nd-century philosopher.

Something of the Mādhyamika philosopher's life and attitude can be gleaned from his writings. His critical analytic verses, his didactic treatises, letters and hymns indicate his deep concern to practice "nonattachment" (*i.e.*, perceiving the emptiness of all things and hence becoming detached from them) in engagement with people. Through rigorous logical argumentation, as found in the *Mādhyamika Kārikā*, he criticized both Buddhist and Hindu views on existence. Most of his polemics, however,

were directed toward the explanations of existence offered by the Buddhist schools of Sthaviravāda and Sarvāstivāda. Nāgārjuna's position is closely allied to, and probably dependent on, that found in the early Mahāyāna literature known as the *Prajñāpāramitā-sūtras* ("Perfection of Wisdom Verses"), in which texts the notion of *śūnyatā* (emptiness, void) is an important term for the wayfarer on the path to enlightenment and becomes the distinguishing term in the Mādhyamika school. It indicates that the nature of existence is relational: there is no soul, no thing, no concept independent of its context; all things are empty of an absolute reality and exist only in relation to conditions. There is no eternal reality behind changing forms; even unconditioned Nirvāṇa (enlightenment) is not independent of the changing forms of existence. Those beings who have perfected wisdom perceive Nirvāṇa and the changing flux of existence together. This perfection transforms the other "perfections" that are part of the *bodhisattva*'s (Buddha-to-be's) course, such as morality, endurance, and meditation. The perfection of wisdom releases the ardent striver for perfection from even attachment to "perfection" that fails to perceive the relational character of the moment. From Nāgārjuna's point of view, then, participating in scholarly debates, writing explanations of the Buddha's teaching, and celebrating freedom from illusion and pain in hymns were considered to be consistent with the highest truth that does not separate wisdom from compassion.

Nagoya

Nagoya, a city of Japan and the capital of Aichi Prefecture (*ken*), is one of that country's leading industrial centres and ports. It is located at the head of Ise-wan (Ise Bay) on the Pacific coastal strip of the Chūbu (midland) area of Honshu, 160 miles (260 kilometres) west of Tokyo and 90 miles east of Ōsaka. With an area of 126 square miles (326 square kilometres), Nagoya's population in the early 1970s was over 2,000,000, making it the fourth largest city of Japan. The city stretches for about 10 miles from east to west and approximately 14 miles north to south.

History. The history of old Nagoya began in 1610, when a great castle was erected by the first shogun of the Tokugawa family for his son Yoshinao as daimyo (feudal lord) of Owari, one of the three powerful collateral houses of the Tokugawa shogunate. Around the castle were houses of samurai (warriors). South of them, a new castle-town for commerce was built, to which the merchants and craftsmen of Kiyosu, three miles northwest of Nagoya, were ordered to move. From that time Nagoya grew as a castle-town of the Tokugawa family and became the greatest city in the Tokai region. By the end of the 17th century, Nagoya had a population of 100,000, and at the beginning of Meiji era (1868), it had increased to 130,000.

Beginnings as a castle-town

Atsuta, a part of modern Nagoya and to the south of old Nagoya, was an ancient political centre of Owari Province. Atsuta-jingū (Atsuta Shrine) and the Ise-jingū (Grand Shrine of Ise) are the oldest and most highly esteemed shrines in Japan. Especially in the Middle Ages, Atsuta was a famous stage town on the Tōkaidō Highway, the main overland transportation artery of Japan.

After the Meiji Restoration (1868), Nagoya experienced a recession resulting from the abolition of castle and stage towns. In the 1880s the economy began to develop, and many of the present factories, banks, and firms were established. In 1889 Nagoya became a municipality with a population of 157,000 and an area of five square miles; in the same year the National Railways' Tōkaidō Main Line was completed. The Kansai Main Line and the Chūō Main Line were constructed in 1895 and 1900, respectively, giving a further impetus to the city's expansion; and modern industries manufacturing textiles, ceramics, and timepieces, cement, machinery, woodwork, flour, and beer were established.

The area of the city grew larger through the consolidation of neighbouring towns and villages. In 1907 the entire southern region, including the port of Atsuta, whose initial phase of construction had been completed in the same year, was merged into the city. Heavy industry was developed after World War I. During World War II, Nagoya became the centre of Japan's aircraft

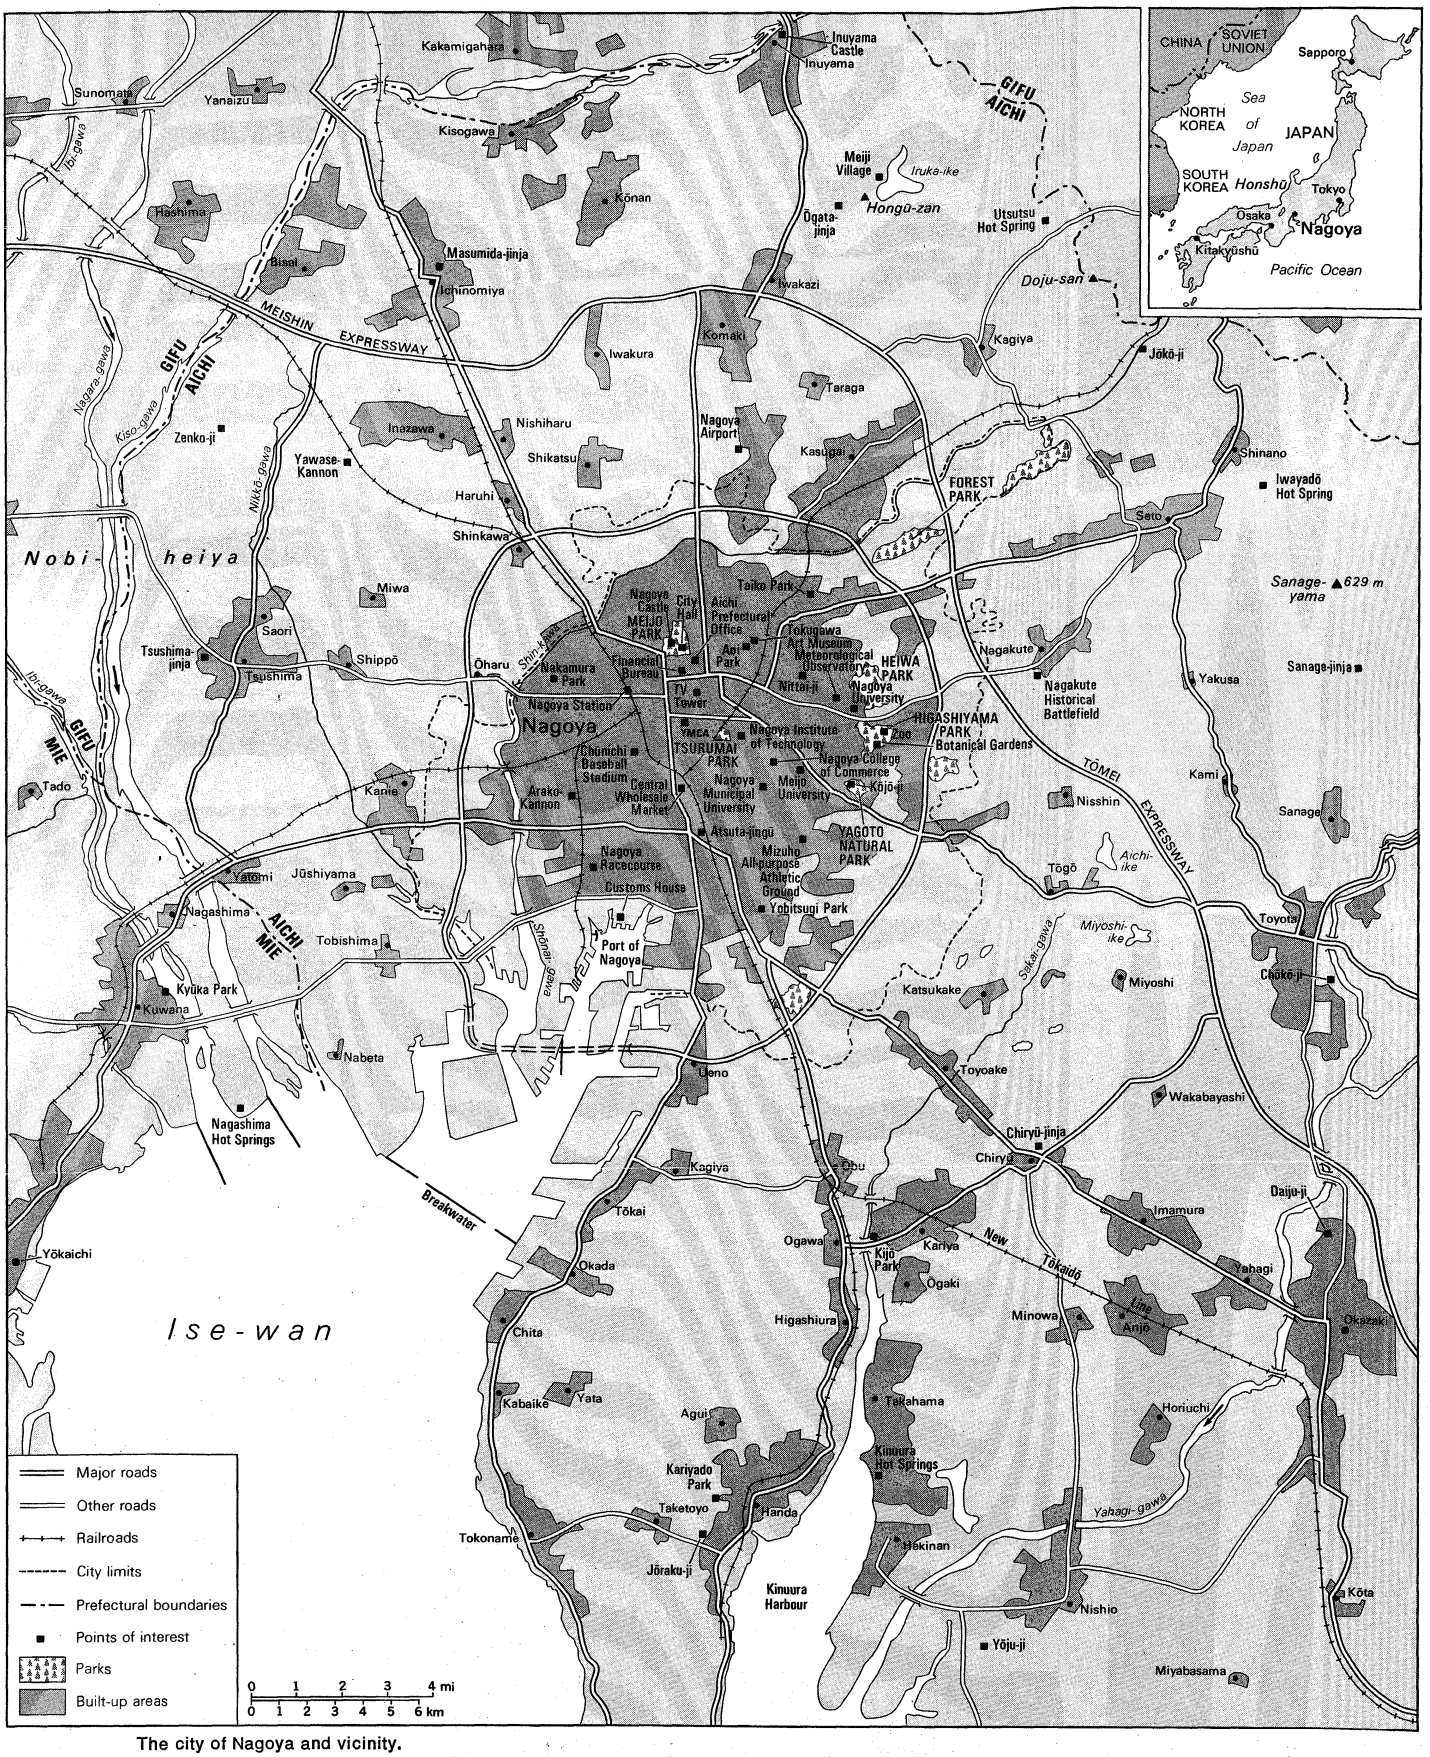
Plaza and office buildings in downtown Nagoya.



The city of Nagoya and vicinity.

industry, and by 1941 the population of the city had reached 1,379,000.

Nagoya suffered serious damage from massive air raids in 1945. Nearly half of the entire city area was destroyed, and by the end of the war the population had been reduced to 500,000. In the postwar period, however, industry was re-established. Littoral districts were reclaimed on a large scale, and many large plants were built. The

population began to increase and by 1957 numbered about 1,400,000. With further consolidation of neighbouring cities, towns, and villages, the population grew to over 2,000,000 by 1970.

The "Central Capital"

The contemporary city. Nagoya, sometimes called Chū-kyō ("Central Capital"), lies between Tokyo and Ōsaka. The city developed on a low, level plain, the Nobi-heiya, that faces Ise-wan on the south and extends toward the Japanese Alps to the north. Most of the city is 26 feet to 34 feet above sea level, out of danger from floods. In the eastern part, much new residential construction has taken place; Owari Hill in the northeast rises to 650 feet (198 metres). Lower land in the west is less urbanized. The southern part of the city (former Atsuta), facing on Ise-wan and including the industrial area and harbour, is for the most part reclaimed land, much of it at or below sea level.

Climate. Nagoya's climate is generally temperate and is especially mild in spring and fall. The average annual temperature is about 59° F (15° C). In winter the temperature sometimes falls as low as 19° F (−7° C), and in summer it often rises to over 97° F (36° C). Nagoya averages 61 inches (1,525 millimetres) of annual precipitation, 75 percent of which falls in a seven-month period from April through October.

Environmental pollution in Nagoya has become a significant issue in regard to the people's health. Fish sometimes die from water pollution in the Kiso-gawa (Kiso River), which supplies the city's drinking water.

City plan. The planning area of Greater Nagoya encompasses 195 square miles (510 square kilometres). Nagoya and 16 neighbouring towns and villages are included in the area, which is divided into an urbanization promotion area (covering 93 percent of the total area) and an urbanization control area. Within the promotion area, definite plans for urban facilities, including parks, streets, and sewerage systems, have been formulated. In the control area, private construction is severely restricted.

Transportation. Nagoya Station is the centre of the transportation network, upon which the railways, the subway lines, and the bus lines that provide transport within the city all converge. A system of highways serves the metropolitan area, and two new high-speed city subway lines were completed in 1971. The city is served by the Japanese National Railways (JNR); the New Main (Trunk) Line between Ōsaka and Tokyo stops at Nagoya. A rail network runs northward to Toyama on the Sea of Japan and southward to the city of Ise and the Kishū region. The city is linked to other countries through its port, from which canals lead inland to the industrial areas, and by Nagoya Airport, on the north side of the city.

Population density and distribution

Demography. The population of the city of Nagoya in 1970 was 2,036,000. Population density was 16,193 persons per square mile (6,252 per square kilometre). There has been a large-scale emigration from the city to the suburbs and surrounding areas. Since the rate of increase of the population as a whole is diminishing, the population of the city is likely to increase only gradually, or to remain static.

Housing. The city has undertaken urban renewal programs and is enforcing strict adherence to the land-use plan. The construction of high-rise apartments is being promoted in the built-up areas, and large housing projects are being built on the fringes of the city.

Industrial production

Economic life. Production of timepieces, bicycles, and sewing machines began in the early stages of Nagoya's economic development, and textile and woodworking machinery industries also grew. The development of Nagoya's port, especially after World War II, and the advantages of the city's central location and abundant hydroelectric power from the rivers of central Honshū stimulated the development of heavy industry. Steel mills were constructed, which were followed by new plants turning out special steels, chemicals, oil, and petrochemicals, as the area's automobile, aviation, and shipbuilding industries flourished.

With the movement of population to the suburbs, many big stores (supermarkets) have been built. Since the mid-1960s, manufacturing plants have tended to move outside the city. In spite of its modern industrial development, cottage industries and traditional handicrafts continue to flourish in the area. Nagoya cloisonné and Seto pottery, to cite only two examples, are famous throughout Japan.

Accompanying the city's industrial growth has been its development as a commercial and financial centre.

Political and governmental institutions. The Nagoya City Assembly consists of 76 assemblymen, whose term of office is four years; they are elected directly by the citizens from 14 constituencies that correspond to administrative wards. The assembly is convened by an elected mayor, who exercises general supervision over the city as its administration chief and principal representative.

Public utilities. The city's water supply is obtained from three purification plants and the Aichi Prefectural Water System. The city's industrial water is taken from the Shōnai-gawa, from the treated water from the Chitose sewage-disposal plant, and from the Oharu purification plant; the prefecture's industrial water is from the Aichi Waterway.

Municipal sewage is handled by 12 sewage-disposal plants, two sludge-treatment plants, and 24 pumping stations. Electricity is supplied by Chūbu Electric Power Company.

Health and safety. The death rate decreased after World War II as a result of the improvement and expansion of public health services and facilities. Main causes of death are adult diseases and traffic accidents.

Many buildings, especially dwellings, are still constructed of wood. In spite of Nagoya's modern street plan, traffic congestion often delayed fire engines, and the Fire Bureau, therefore, increased the number of fire brigades and substations throughout the city. The increase of tall buildings and an underground shopping area have introduced new fire-fighting problems.

Nagoya is notorious for the frequent occurrence of traffic accidents. In traffic deaths it ranks first or second in the nation every year.

Education. Although there were only 260 schools and 192,000 students in 1935, there were 800 schools and more than 500,000 students in the 1970s. The number of students in higher education also increased dramatically: in the 1970s there were 55 colleges or universities in Aichi Prefecture, including 33 in Nagoya. Nagoya Medical College, founded in 1931 and based on a medical school of the Meiji era, became Nagoya Imperial University in 1939. After World War II it became Nagoya University. Other universities include Nagoya Institute of Technology, Aichi Prefectural University, and Nagoya Municipal University.

Historic sites and cultural institutions

Cultural life. Nagoya abounds in cultural assets and has many fine works of art and buildings of architectural value. One of them was Nagoya Castle, built in 1610–12, which was reduced to ashes in the fire raid in May 1945. In 1959 the castle was rebuilt, in ferroconcrete, and is now a historical museum and the city's most famous landmark. The Tokugawa Art Museum, opened in 1945, is the only museum that has preserved the collection of the Tokugawa family; it owns about 12,000 art treasures. It is located northeast of the city, adjacent to Hōsa Library and Tokugawa Park. The sacred Atsuta-jinjū is in the south of the city. The Nagoya Municipal Science Museum includes an astronomical building with a planetarium.

Nagoya Public Hall at Tsurumai Park is used for music concerts and similar functions. Citizen Hall, used for various kinds of entertainment, was completed in 1972. Other institutions include Aichi Cultural Center, Aichi Art Museum, Chūnichi Hall, and Misono Theatre.

The media. Nagoya is the home of one of Japan's foremost local newspapers, the *Chūnichi shimbun*. The *Asahi shimbun* and the *Mainichi shimbun* also have offices in the city. In the 1970s there were six television and four radio broadcasting companies. The Chūbu-Nippon Broadcasting Company, established in 1951, was the first private broadcasting company in Japan.

Recreation. Nagoya has about 300 parks, among which the Higashiyama Park, in the eastern hill district, is particularly noteworthy for its zoological and botanical gardens. After World War II, the Heiwa (Peace) Park was established nearby; it contains about 188,500 tombs from 280 temples in the downtown district.

Mizuho All-Purpose Athletic Ground, in the southeast of the city, has an athletic ground and facilities for many sports and games. Aichi Gymnasium and Nagoya Municipal Gymnasium are open to the public. Chūnichi Baseball Stadium, the home field of the locally popular Chūnichi Dragons, a professional baseball team, has a seating capacity of 30,000.

BIBLIOGRAPHY. *Nagoya City* (1971), provides information on the contemporary city; *City Planning for the City of Nagoya* (1962), deals with past city planning programs—both are issued by the city of Nagoya and are available in English. *The Outline of Municipal Government*, published annually by the city, describes its administration. There are two historical works (in Japanese) of significance—"The History of Nagoya City," 12 vol. (1916), which covers the city's history from ancient times to the Meiji era; and "The History of Nagoya City in the Taisho-Showa Era," 8 vol. (1946–53), edited by EIJIRO HONJO, an economic historian.

(T.Ma.)

Nairobi

Nairobi, the capital city of the Republic of Kenya, is located in the highlands of south central Kenya and is situated on the Athi Plains near the foot of the Gikuyu Escarpment. It lies about 300 miles (480 kilometres) northwest of the Indian Ocean port of Mombasa and about 160 miles due east of Lake Victoria. With a population of more than 500,000, it is one of the major cities of East Africa. In 1963 its area was increased from 35 to 264 square miles.

The city originated in the late 19th century as a colonial railway settlement, taking its name from a small stream known to the Masai people as Enkare Nairobi (Cold Water). The modern city includes within its limits Nairobi National Park—a 44-square-mile game reserve containing giraffes, gazelles, lions, zebras, and other animals. Nairobi is a centre for trade and transport, as well as for administration (for an associated physical feature, see EAST AFRICAN MOUNTAINS).

History. Nairobi was originally the site of a water hole used by Masai herdsmen, but a railway encampment established there in the late 1890s became the nucleus of the modern city. When the railhead arrived there in 1899, the British colonial capital of Ukamba Province was transferred from Machakos to the site, and Nairobi became the capital of the British East Africa Protectorate in 1905. From about 1900 onward, when a small Indian bazaar was established at Nairobi, the city was a trading centre.

From its modest beginnings, Nairobi's development has paralleled the transformation that Kenya has experienced in the 20th century. The city has attracted a stream of migration from rural Kenya that has made it one of the largest cities in tropical Africa. As early as 1901 a municipal committee was established to administer the affairs of the settlement. It was declared a municipality in 1919 and was then governed by a municipal corporation. In 1928 a town council was created with an elected mayor, deputy mayor, and other appointed officers. In 1954 Nairobi was granted city status. Kenya's 1963 constitution expanded the municipal area, as mentioned, from 35 to 264 square miles; the enlarged municipality, known as the Nairobi Area, is an independent unit administered by the Nairobi City Council.

The city's expansion

The rapid changes in the area and status of Nairobi were paralleled by its population growth. In 1919, when the city covered an area of about ten square miles, its population was about 10,000. The 1948 census reported the population to be almost 120,000. The present population, as mentioned, is more than a half million. The Nairobi greater planning area, furthermore, today extends beyond the city's boundaries into the adjoining districts of the neighbouring provinces.

The natural setting. Nairobi is located approximately 80 miles to the south of the Equator, at a height of about 5,000 feet. To the northwest rise the highlands that form part of the Aberdare Range, which is bounded farther to the west by the East African Rift Valley. To the southeast lie the Athi-Kapiti Plains, over which the city has spread. Much of the western half of the city is built on the northwest to southeast ridges more than 5,000 feet above sea level. In the extreme east the land drops to altitudes of between 4,000 and 5,000 feet.

Climate. Nairobi enjoys a stimulating climate that reflects the moderating influence of its high altitude. The noonday temperature rarely rises above 80° F (27° C). The mean annual rainfall varies from less than 30 inches in the drier and lower parts to well over 50 inches in the wetter fringes to the north.

The four seasons

Four seasons may be distinguished. The season from December to March is characterized by northeasterly winds accompanied by sunny and warm weather with occasional showers. From late March to May the rainy season occurs, accompanied by light and variable northeasterly to southeasterly winds. Occasional dry periods may also occur. From about June to October southeast moisture-laden monsoon winds predominate, bringing cloudy and overcast skies. Low temperatures prevail, cold may be experienced at higher altitudes, and fog and drizzle are common. A transitional season follows in November, when less rain falls.

Vegetation and animal life. The vegetation of Nairobi reflects the transitional nature of its location. The higher and western half of the city site, standing on rich volcanic soil, formerly had a forest cover that is still represented by a semideciduous type of vegetation. Elsewhere the most prevalent form of vegetation is the savanna type (park-like grassland) found on the plains, which are dotted by various species of thorn (acacia) trees.

Nairobi National Park

The grasslands and forest of the game reserve (Nairobi National Park) form an ideal habitat for some of East Africa's mammals. The herbivores (animals feeding on plants) that thrive there, and the predators that feed on them, such as the lion, leopard, and cheetah, are major attractions for visitors.

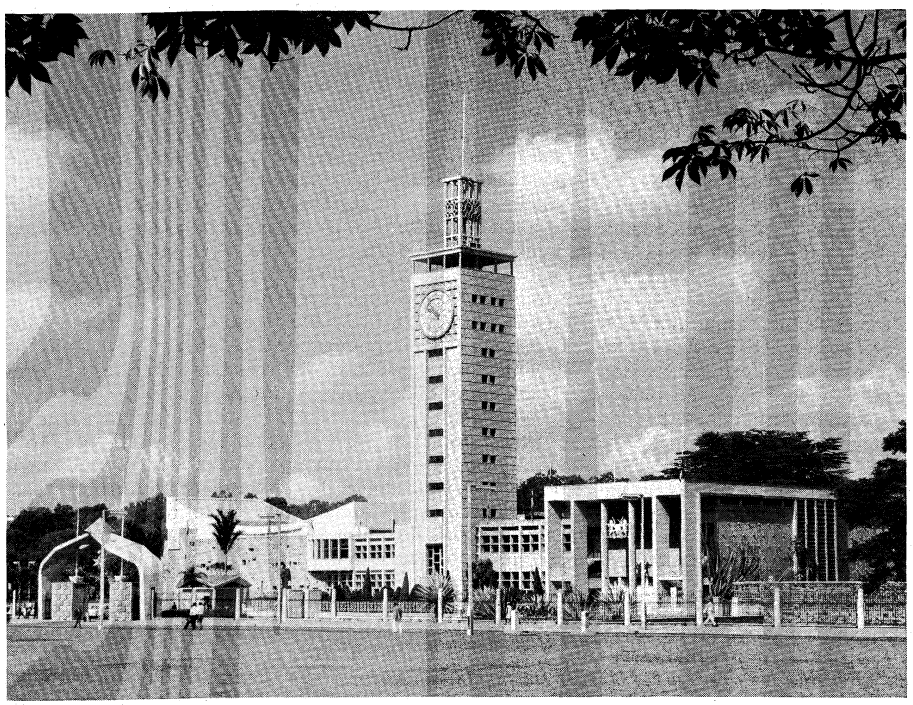
The contemporary city. *Demography.* Nairobi is one of the most rapidly growing urban centres in Africa. The 1969 census showed that the total population had increased from 344,000 in 1962 to 509,000. The annual growth rate between these years was almost 5 percent.

In 1948 the proportion of Africans to non-Africans was 54 percent to 46 percent. In 1962 the proportion of Nairobians within the city's pre-1963 boundaries had changed to 59 percent Africans and 41 percent non-Africans. The 1969 census showed that 83 percent of the population was African and 17 percent was non-African. Of the African population 97 percent was Kenyan. The majority of the non-Africans were aliens.

Ethnic groups

Among the Kenyan Africans the Kikuyu ethnic group accounted for 47 percent of the population, the Luhya 16 percent, and the Luo and Kamba each 15 percent. Various other ethnic groups constitute the remaining 8 percent.

Approximately 59 percent of the total population of the city in 1969 was concentrated in the central area, which included Eastlands, Eastleigh, and the census divisions of Parklands, Ngara, Juja, Racecourse, Mathare, and Central. Eastlands alone had approximately 24 percent of the total. This inequality in the distribution of population is reflected in the density pattern. The 1969 census showed an outer region of very low density, mostly under 1,300 persons per square mile; a medium to low density area extending roughly from the industrial area just south of the city centre to the extreme west of the city limits with densities ranging from 3,200 to 5,800 persons per square mile; and the central area, which contained well over half of the total population, with average densities that were usually well over 32,000 persons per square mile. The Racecourse, Bahati, and Jericho districts had 51,000 to 64,000 persons per square mile, and the housing estates of Maisha, Mbotela, Maka-



Parliament buildings, Nairobi, Kenya.
Authenticated News International

dara, and Maringo in Eastlands well over 64,000 persons per square mile.

The central part of the city and some of the main housing estates conform to the rectangular pattern with parallel streets and right angle intersections common to many Western cities. In other parts of the city this pattern has been considerably modified by the nature of the land. The pattern of the ridges in the extreme west and north determines the direction of the main streets that converge on the central core of the city.

Upper Nairobi, which lies to the west and north, includes most of the residential land. The Dagoretti area in the extreme west is a former rural part of Kiambu District. The remainder of the northern part of Nairobi is made up of a number of low-density housing estates that were formerly European residential areas. Close to the central part of the city are the Parklands and Eastleigh residential areas. These constituted one of the main Asian residential areas until about 1960; they still have a large proportion of Asians, as well as some African residents. Other Asian areas included what are now Nairobi West and the districts known as South C and South B.

Most of the city's population is to be found in the 15 housing estates located to the east of the city centre and the main industrial area to the south. The eastern part of the city, commonly known as Eastlands, was formerly reserved for Africans, and the majority of the African population still lives in this area. New housing estates continue to develop on the unused land that extends to Embakasi Airport, nine miles to the southeast.

The industrial district

A considerable area of flat land southeast of the city centre is reserved for industrial development. The industrial area lies between Eastlands and the main Nairobi–Mombasa road, which runs to the southeast, also extending southeastward to the Embakasi Airport. Part of the area is undeveloped land. It is provided with railway sidings and access roads. Considerable areas of agricultural land also lie within the city's boundaries: in the east, north of the airport, are large ranches; in the extreme north are rich farmlands that have been invaded by built-up areas.

The city centre is a well-defined area bounded by Uhuru (Freedom) Highway to the west, the railway station to the south, and Government Road to the north. In the centre is the city square with the principal public buildings and ministerial offices. To the north and east are two of the main retail shopping areas.

Housing and architectural features. Most city dwellers are accommodated in rented houses or in those supplied by employers. The city council, the government, and various large employers have played an important part in the provision of accommodations. The city has been fortunate in the availability of excellent local building stone. Most of the houses are built of stone or brick, and the majority have running water and toilets. Due to the influx of population, however, the city is far from meeting the total demand for housing.

Architectural landmarks

Among the city's architectural landmarks in the central area are the Parliament Building, the law courts, the city hall, the ministerial offices (including the office of the president), and the Roman Catholic cathedral. There is also a well-planned commercial centre.

Economic life. As well as being pre-eminent in the economic life of Kenya and the seat of national government, Nairobi also plays a significant role in the community of East African states. It is the headquarters of the East African Community's railways, harbours, and airways corporations. In addition, the city accommodates some United Nations regional services, as well as a number of foreign diplomatic missions.

Public services employ the largest proportion of wage earners (28 percent of the city total), followed by commerce (19 percent) and industry (18 percent). Nairobi is the principal industrial centre of the country. The railway workshop is the largest single industrial employer. Light manufacturing industries produce beverages, cigarettes, and processed foods. The city's commercial and industrial pre-eminence exerts a strong attraction upon the population in other parts of Kenya and beyond. Nairobi has modern banking facilities, including the National Bank of Kenya Ltd. and a stock exchange.

Transport and communication. Located to the southeast of East Africa's agricultural heartland, Nairobi is connected to Mombasa on the coast as well as to Uganda in the interior by the East African Railways Corporation. Paved all-weather roads also run to Kisumu on Lake Victoria in west Kenya, northward to the Gikumbo (Mt. Kenya) region, southeastward to Mombasa, and northwestward to Uganda. A paved highway to Namanga and Arusha in Tanzania is under construction. The increasing volume of both local and through traffic poses a constant planning problem. Nairobi has also become a focus for Eastern Africa air traffic. Embakasi is one of the principal international airports in Africa.

Governmental institutions. As the national capital, Nairobi has come to dominate much of the political activity in the rest of the country. In addition to parliamentary institutions, it contains the headquarters of the ruling party, the Kenya African National Union (KANU). The city government is composed of a mayor, aldermen, and councillors.

Power generation

The city possesses a modern piped water supply and has a waterborne sanitation system that is in advance of many other African cities. Electricity is obtained from Uganda's hydroelectric source on the Nile at Jinja and is conveyed to the city by high-tension transmission lines; the East African Power and Lighting Company, Ltd. is the distributing agency. The increasing electrical needs of Nairobi are also being supplied by the Upper Tana Hydro-Electric Scheme in southeastern Kenya.

In the planning of the city, emphasis has been placed on maintaining a high standard in public health. The sewer system is being extended, but many homes are still dependent on the use of septic tanks.

The city population is served by the Kenyatta National Hospital, which also serves as the teaching hospital for the National University in Nairobi. There are three other large independent hospitals, as well as a number of smaller private nursing homes.

There is a well-equipped central fire station. Law and order are maintained by the Nairobi Area Police Division, which is supported by a mechanized unit that assists in the patrolling of the expanding urban area.

Education. The rapid rate of growth in the city has demanded constant expansion of educational facilities. There are a large number of primary schools; the schools that formerly enrolled only non-Africans are now integrated into the national system and provide education for all children. The total number of enrolled primary school pupils in 1969 was 56,000, of which 30,000 were boys and 26,000 were girls. In addition, there are schools for handicapped children. There are also a number of well-staffed secondary schools. While some privately run secondary schools still exist, most now form part of the integrated system of education. The National University, of which Kenyatta College is a constituent part, is also located in the city, as is the Kenya Polytechnic and Kabete Technical and Trade School.

The National University

Cultural and other services. The University College Library, the Kenya National Archives, and McMillan Memorial Library are located in the centre of the city. A museum close to the centre accommodates treasures of Kenya's past. Also in the area are the cultural centre, the main campus of the university, the Kenya National Theatre, the East African Conservatoire of Music, and the Sorsbie Art Gallery.

Mass-communication media include two English and one Swahili daily newspaper and two Swahili weeklies. The Voice of Kenya radio and television services—broadcast in Swahili, English, and vernacular languages—are administered by the Ministry of Information and Broadcasting.

(S.H.O.)

Names

A name is a word or group of words used to refer to an individual entity (real or imaginary); the name singles out this entity by directly pointing to it, not by specifying it as a member of a class. For instance, it is possible to refer to the same entity, in this case a river, in two distinct ways: (1) "The Colorado is a beautiful river," and (2) "The river that flows through Austin is beautiful." Because there is only one river that flows through Austin, Texas, the subject of sentence (2) is unambiguously identified, and the reference of the sentence is fully individual. The subject of sentence (2), however, is not a name but rather a nominal (noun) phrase that specifies one member of the whole class of rivers by indicating a unique property of it. The word Colorado in sentence (1), on the other hand, is a name, because it directly points to the specific river. The fact that there is more than one river called Colorado, and that more specific information is sometimes needed to identify the one being discussed (*e.g.*, "I prefer the Texan Colorado to the California one"), does not change the status of "Colorado" as a name, because each of the two rivers is referred to in the way required by the definition.

Names and appellatives. A general appellative (*i.e.*, a common noun) capable of being used in reference to a whole class of entities can also be used with an individual reference. For instance, if an inhabitant of Austin, Texas, says, "Let's go swimming today, not in the pool but in the river," there is no doubt that the word river has a unique, individual reference to one single river, namely, the Colorado. This fact, however, does not make a name out of it; "river" is here a common noun, but its reference is specified by the extralinguistic context of the situation in which the sentence was said. Some names seem to belong more to the category of appellatives, or common nouns, than to the category of names like Colorado in "the Colorado River." For example, names like Big River, Red River, Stony Brook, and Cedar Hill may sometimes have their origin in a specific use of a general noun. If a sentence like "After five days of marching, we had to cross a river, the big one, not one of the smaller ones" is used very often, the name Big River may result. Such names are, however, much more frequently given as directly descriptive names. The similarity of names of this type with expressions like those exemplified in sentence (2) above is deceptive. There is, after all, more than one big river, so that the specification "the big river" is not complete. The full identification of one single river as the reference of this sentence is given by the situational context. Therefore, apart from certain special expressions (like "the big one, not one of the smaller ones"), names like Big River, Red River, and so on have the same status as names like Colorado.

Formal means for marking names

In some languages, a name is differentiated from an appellative (common noun) by formal means. The difference is sometimes indicated by the script; *e.g.*, languages using alphabets such as the Latin, Greek, Cyrillic, Armenian, and Georgian use a capital letter at the beginning of a name. (But, on the contrary, in German all nouns, not only names, are written with an initial capital.) There are examples of a purely grammatical differentiation of names as well, such as the usual absence of the articles "a" or "an" in English; *e.g.*, "Yesterday I saw an archer practicing his art" and "Yesterday I saw (Bill) Archer practicing his art."

The distinction between names and appellatives (common nouns) is generally clear: names are used in individual reference, appellatives can be used in reference to all members of a class or to any number of them (*e.g.*, river, hill, man, girl, car, table, virtue, and so on). Nevertheless, there are some borderline cases. For instance, a nation can be conceived as an individualized entity, so that "Americans," "Englishmen," and "Spaniards" are names; on the other hand, it is clear that other groups of people are not conceived in this way, so that expressions like "soldiers," "sailors," and "clergy" are not names. It is difficult to decide on the status of expressions like the "Baptists," "Adventists," and "spiritists." In a similar way, if all vehicles produced by Henry Ford are Fords and if one can buy an individual Ford as well, is "Ford" a name? It probably is, or approaches that status; but names of this type frequently lose the character of names and develop into common nouns. Expressions like "the Roman Catholic Church," "the Ministry of Education" (of a specific state) also have a dubious position as to

their status as real names. The uncertainty in this respect is indicated by the vacillation in the use of capital letters in various languages. This overlapping has a long history and is reflected in modern terminology. The Greeks used the term noun (*onoma*) for both the common noun and the name; when they wished to make a distinction, they specified the name as a proper noun (*onoma kyrion*). It is in this tradition that the term proper noun, or proper name, is used for a name, and noun, general noun, or common noun, for an appellative.

THE SCIENCE OF ONOMASTICS

Categories of names. The science that studies names in all their aspects is called onomastics (or onomatology—an obsolete word). The subject of this science is broad because almost everything can have a name and because the study of names theoretically encompasses all languages, all geographical and cultural regions, and all historical epochs. For practical purposes, some divisions of the subject are necessary; *e.g.*, by language (as the study of Kiowa or Provençal names) or by geographical, historical, or similar partitions (the study of the names in India, of the Levant at the time of the Crusades, and so forth). Another division (usually combined with the preceding ones) is given by the character of the names themselves; in a very broad categorization, names of persons, or personal names, are discerned on the one hand, and names of places, or place-names, on the other. In the most precise terminology, a set of personal names is called anthroponymy and their study is called anthroponomastics. A set of place-names is called toponymy, and their study is called toponomastics. In a looser usage, however, the term onomastics is used for personal names and their study, and the term toponymy is used for place-names and their study. The term toponymy itself can be understood in two ways, even in the exact terminology: either it is taken in the broadest possible way as including inhabited places, buildings, roads, countries, mountains, rivers, lakes, oceans, stars, and so on, or it is restricted to inhabited places (cities, towns, villages, hamlets). If the latter alternative is the understanding of the term toponymy, then the uninhabited places (*e.g.*, fields, small parts of forests) are called microtoponymy; names of streets, roads, and the like are called hodonymy; names of bodies of water, hydronymy; names of mountains, oronymy. Additional terms are not generally used (though one occasionally hears words like chrematonymy—names of things).

Divisions within onomastics

In any case, different categories of names frequently must be studied together, because there are transitions. For instance, many place-names are derived from personal names (*e.g.*, Washington), many names of planets and stars are derived from the names of mythological characters (*e.g.*, Venus, Mars, Alpha Centauri), and many personal names are derived from place-names, names of nations, and other such names (*e.g.*, Austerlitz, Napoleon's battlefield; French; Scott). There is also a division of names into primary and secondary ones. Neptune is primarily the name of a Roman god; transferred to the name of a planet, it is a secondary name.

Forms of personal names. There are many subdivisions and terms within the category of personal names. Originally, one name was given to a person at an early period of life—in Europe (and later in America), normally at Baptism. This is called either simply the name, the baptismal or Christian name, or the forename; in the U.S. and Canada it is usually called the first or given name. Because many people received the same name (given name), they were differentiated by surnames (of the type John Redhead, John Hunter, John Scott). Many of these surnames became fixed and hereditary in individual families. These are called either surnames or family names, and in the U.S. and Canada they are frequently known as last names. Thus the basic pattern is given + family name, together called the name or the personal name. There are exceptions concerning this sequence. Among the Chinese and Hungarians, for example, the family name precedes the given name: Mao Tse-tung, Nagy István. The Hungarians usually switch the order when they write English; thus, Nagy István becomes István (or Stephen) Nagy. The Chinese, however, maintain the order of family name first.

Surnames and family names

There are variations in the basic pattern. In the U.S. and Canada the usual practice is to insert another name (frequently expressed in writing only by the initial letter) between the given and the family name. This is the second, or middle, name. It may be the original family name of a married woman inserted between the first and the last name of her husband, the maiden name of one's mother, the family name of a girl retained as a second name after her marriage, as well as other names. In Europe, such a second name is less common and is usually acquired at Baptism (or, eventually, at Confirmation). In most European countries, the first baptismal name is the important one, and the second one (third, and so forth) can be omitted. In German usage, however, the baptismal name immediately preceding the family name is the most important one. For example, if one of the baptismal names in Johann Sebastian Bach or Johann Wolfgang von Goethe is to be omitted, it would be Johann. (But in a sequence like Johann Nepomucenus Nestroy, the shorter form is Johann Nestroy, because Nepomucenus is only an attribute discerning one of the numerous saints who had the name Johann.) British usage varies in this respect, but sometimes follows the German pattern—*e.g.*, W. Sidney Allen.

In a few areas, above all in Iceland and the Soviet Union, the so-called patronymic (*i.e.*, a name derived from the given name of the father) is inserted between the given and the family name. In Russian, if the father's name is Ivan Krylov, then the son's name, for example, will be Pyotr (given) Ivanovich (patronymic) Krylov (family), and the daughter's name will be, for example, Varvara Ivanovna Krylova. The usual form of address in Russian—among acquaintances, neighbours, colleagues at work, and inclusive superiors—is by the given name and the patronymic.

Use of patronymics

The terms maiden name and girl's name are sometimes used for the original family name of a married woman. Nickname is used in reference to surnames (which have not developed into family names), mainly of the jocose type; *e.g.*, a thickish Mr. John Smith is called Fatty. A surname, also called a byname or to-name (obsolete), can be used to differentiate persons with the same family names if they belong to different families and if given names are not used among them. In a village, there may be several families with the name Jones; if they are not called or referred to by first names, they may be known as Jones at the Pond, Jones the Redhead, and so forth. Hypocoristic forms of names are those that are used in familiar, friendly, or intimate situations (usually shortened or otherwise modified); *e.g.*, Tom for Thomas, Jim for James. Some of these forms are also used as given names, particularly in the U.S.

THE NAMING PROCESS

One of the most important elements of the naming process concerns the meaning and associations of the name. In this case the term meaning is radically different from that in the case of common nouns, in which the "meaning" is their ability to be used in reference to a class of entities, to denote or designate them. As was noted above, the absence of this ability to refer to a class of entities is typical of a name. If the meaning of a typical common noun, such as automobile, is considered, it can be seen that it denotes a certain type of vehicle. On the other hand, if the word automobile itself is considered, one can see that it consists of a Greek element, *auto* "self," and a Latin one, *mobilis* "movable," so that the sum of the meanings of the constituent parts of the word suggests a gloss like "self-movable," "self-mover." The meaning of a name involves that which the constituent parts suggest. In this sense, the "meaning" of a name like Red River is obvious. To get a "meaning" of a name like Philip, however, one must go back to its original Greek version, Philippos, which means "lover of horses." This "meaning" of names frequently gets lost, however. There are several causes for this, one being that the name may be

Loss of original meaning of names

accepted into another language, as were the Indian place-names in America (*e.g.*, Oshkosh, Chicago, Kankakee), and the Greek and other names transferred to Europe and America via Christianity. In addition, names may cease to be understood as a result of language change; *e.g.*, the place-name Birmingham was understandable in Old English as "habitation of Biorma's people," and the originally Germanic name Gerard was once understood as "strong spear" (*Ger-hardo*). Names also changed by shortening (*e.g.*, Los Angeles, from El Pueblo de la Reina de los Angeles de la Porciúncula "Town of the Queen of Angels of Porciuncula," one of the titles of the Virgin Mary in the Roman Catholic Church) and by scribal error (*e.g.*, Pria in France, a misread medieval abbreviation of Pradaria, "meadow"). Another cause of the loss of meaning in names is that the "meaning" simply fades out by constant use of the word as a name. No one thinks of the meaning "ford for oxen" when speaking about Oxford, and no one realizes a discrepancy if Mr. White has a dark complexion. Finally, it sometimes happens that a name has no "meaning" from the beginning. For instance, the place-name Tonolo and the family name Bréal were created from random sequences of sounds.

Choice of personal names. Names that have no "meaning" (above all not for the person who chooses the name) still can have associations. Although "Mary" and "John" may have no specific "meaning," they were the names of important persons in the Christian religion and therefore have been used very frequently. An association may be so strong that it overwhelms the "meaning" of a name, even a disagreeable meaning; *e.g.*, the association with the cult of St. Demetrios made the name Demetrios one of the most popular in the Greek Orthodox Church, though its meaning is "belonging to [the pagan goddess] Demeter." On the other hand, such an association may more or less completely fade out and be combined with or replaced by other associations, such as a national tradition (Patrick in Ireland, Yves in Brittany, István in Hungary, Ivan in Russia) or with a family tradition (Louis in the Bourbon family, Wilhelm among the Hohenzollerns, Henry in the Ford family). On a less elevated level, there is the example of a rich uncle making a given name more than eligible. A name can be associated, correctly or not, with various prestige factors, or its choice may be influenced simply by fashion. Another source of names, often extraordinary ones, was the occasional habit in Roman Catholic countries of giving a child the name of the patron saint whose day of celebration coincides with the child's day of birth (or Baptism); many names like Hyacinthus X, or Narcissus Y, were produced in this way.

"Good" and "bad" names

In the majority of cases, children are given "good," likable, and propitious names. In some cultures (*e.g.*, in some parts of sub-Saharan Africa, formerly in China, and sporadically in ancient Greece), however, the children are (or were) sometimes given "bad" names with meanings like "ugly," "disagreeable," or "crippled." The purpose of such names, which are called apotropaic names, is to make the child undesirable to demons.

The choosing of a given name is a highly private and individual matter. All the circumstances just mentioned can be motives for the choice, in addition to many other personal reasons, such as a consideration for the relatives' names or a simple liking of the phonetic shape of a given name. This wish to give a likable name may go so far that a sequence of sounds is chosen that sounds pleasant to the person who makes the choice but that has no relation to the existing stock of names or to the words of the language; *e.g.*, "Gwyned" was invented as a name of a girl and has no "meaning" or associations. This phenomenon is relatively common in the U.S.

Choice of place-names. Place-names are less personal, less intimate, and a matter of public concern. The usual pattern is that the national Ministry of the Interior (or its equivalent) keeps an official list of place-names, particularly of place-names that form administrative units, together with lists of districts, counties, and the like. This function may also be performed by the ministry or agency that supervises the postal service. Bodies endowed with authority provide or choose new place-names if there is a need to create them on a greater scale; *e.g.*, the U.S. Board on Geographic Names.

International cooperation (performed above all by the Universal Postal Union) is necessary, because names of identical places may vary from language to language. Particularly difficult are place-names originally written in scripts other than the Latin (Roman) one (the official script of the Universal Postal Union), such as Arabic, Chinese, Cyrillic, and the Indic writing systems. But even within the Latin script, there are two basic types of difficulties. First, one place can have different names (or modifications of a name) in various languages—*e.g.*, French Nice and Italian Nizza; German München, English and French Munich, and Italian Monaco. A very difficult situation arises when a place is generally better known by its international name than by its original one; *e.g.*, Dublin is Baile Átha Cliath in Irish. Confusion may also be caused by names that are translated; *e.g.*, the Rocky Mountains are in German Felsengebirge and in Russian Skalistye Gory. There are also names with the same written form but with varying pronunciations; *e.g.*, for Paris, the accent, pronunciation of vowels, and pronunciation of consonants change from French to German to English.

The second difficulty involves the actual printing of all the letters with diacritical marks that are necessary for different alphabets of the Latin script. Because many printing firms lack the various marks, some possibly confusing omissions or modifications can hardly be avoided; *e.g.*, the dot over the *I* in Turkish İstanbul, and the bar through the *l* in Polish Kołobrzeg are frequently omitted. International cooperation is also necessary and is developing in connection with the choice of place-names in outer space, particularly on the surface of the moon.

HISTORICAL AND CROSS-CULTURAL DEVELOPMENT OF NAMES

Legal aspects of naming. While place-names are considered a public matter, personal names also seem to be getting more regimented by various laws and regulations. Great Britain and the United States are practically the only countries that adhere to the principle of Roman law that a person has the right to use and change his name as he pleases, except for fraudulent purposes. The first important regulation concerning given names was the decision of the Council of Trent (1563), which specified that the Roman Catholic priest administering Baptism should make certain that children are given names of Catholic saints; if the parents were to insist on another name, the priest should administer Baptism in that name but add the name of a saint as the second baptismal name. This regulation, still a valid part of Canon Law, was directed against the Protestant custom (spreading at that time) of giving children names of important persons from the Old Testament otherwise unconnected with Christianity (*e.g.*, Abraham, Samuel, Rachel). In this respect the regulation was successful in Catholic countries, but it did not succeed in stopping the use of given (baptismal) names like Cesare in Italy (from Latin Caesar).

Naming regulations of the Council of Trent

The next important law was passed in France. The French Revolution first gave complete freedom in naming; the result was some very fanciful given names like Mort aux Aristocrates, Racine de la Liberté, or even Café Billard. To stop this, a law was passed in 1803 that restricted given names to "names of persons known from ancient history" and "names used in various calendars." Again, the law was successful in its main intention; in addition, it prevented the spread of controversial given names such as Marat and Robespierre and of literary names such as Aramis, d'Artagnan, and Romeo. Very reasonably, the law never was interpreted too narrowly, so that feminine given names such as Jeanette and Henriette, for example, have been admitted, though they were not legal because no calendar contains them. This law is still valid in France.

Similar laws were passed, at various times, in the states of eastern Europe, where the given name can be chosen only from names known and established as such, the ex-

act formulation varying from country to country. One of the results of this legislation is that the repertory of Russian given names today is more or less exactly the same as that of 60 years ago, when the Orthodox Church was paramount. In non-Russian areas of the Soviet Union, Catholic (in Lithuania), Muslim (in the Uzbek S.S.R. and Tadzik S.S.R., etc.), and other names are used, sometimes without any ecclesiastical association whatsoever. In the Caucasus, for example, there are given names such as Soslan and Dzerassa, drawn from Caucasian mythology.

In regard to family names, the most important regulation was made at the Council of Trent (1563); it was decreed that every parish must keep complete registers of baptisms, with the names of the child and those of his parents and grandparents. This had been done before, but not so systematically. The new practice (soon followed in Protestant parishes) helped to establish the family names. There is not much legislation concerning family names, because two basic assumptions are taken for granted: that the bride will accept the bridegroom's family name by marriage and that their children will automatically have the family name of the parents. Legal institutions like the West German one permitting the bride to add her original family name to her new one in a hyphenated form (Inka Schmidt, when married to Karl Neumann, may become Inka Neumann-Schmidt), or the practice of outstanding British families to combine the family names of the married couple in a hyphenated form (Beatrix Curzon and Frederic Cholmondeley become Beatrix Cholmondeley-Curzon and Frederic Cholmondeley-Curzon) are rather rare.

Assumptions concerning family names

In the majority of cases, the law is concerned with names mainly in cases of divorce, adoption, and illegitimacy. After a divorce, the wife is usually allowed to eventually reassume her maiden name, and in Germany, for example, can be forced to do so if judged as the guilty party and if her former husband so desires. In adoption procedures, either the family name of the adopting person is accepted or a hyphenated form is created. Illegitimate children usually receive the family name of their mother.

In the eastern European states, in which legislation changed the basic assumptions concerning the family name, a different and unusual situation has developed. When a Czech girl, Anna Klímová, for example, marries a Josef Novák, both may retain their original family names, or the girl may become Anna Nováková, or, more remarkably, the man may become Josef Klíma, accepting the bride's family name. This must be decided by mutual consensus, and such a consensus is also the basis for the children's names. The purported reason for this legislation is the full equality of women. (There is, however, one loophole in the system, namely, the Russian patronymic: this is automatically derived from the father's name, whereas equality understood in this way would demand a choice between the father's or the mother's name.)

The development of personal names. *European patterns of naming.* The development of personal names was a complicated one. In the old Indo-European system, a person had one name, which could be of two types: a compound substantive or a non-compound one. Noncompound names may originally have been given to less outstanding members of the tribe and their children. The compound names frequently associate the bearer with a god (they are called theophoric names) or state his virtues, abilities, skills, possessions, and so forth. The association of the meanings of the parts of the compound was sometimes only a loose one, as is particularly observable in German anthroponymy (see below). Examples of compound names include the Sanskrit Viṣṇuputra "son of Viṣṇu," Devadatta "given by god," Devarāja "god-king." From old Iran come the Avestan name Hōrmizāfrīd "benediction of Ahura Mazdā" and the Old Persian name Mithradates "given by Mithra" (two Iranian gods). Among Greek names there are also many theophoric names, such as Herodotos "given by Hera," Isidoros "given by Isis" (modern Isidore), or Theodoros (modern Theodore) and Dorotheos (modern only in the feminine form, Dorothy), both "given by god." There are many other similar Greek names; *e.g.*, Astyanax "lord of the city," Perikles "very famous," and Demosthenes "strength of the people." Platon "broad (in shoulders)" is a noncompound Greek name.

Compound and noncompound names

The compound names of the Celts include Vercingetorix "great king of warriors," Orgetorix "king of killers," Rextugenos "son of justice." Noncompound Celtic names were, for example, Artos "bear" and Galba "big." Examples of Germanic compound names include Heriberhto "army + resplendent" (modern Herbert), Huguberhto "resplendent by thought" (modern Hubert), Godofrido "divine peace" (modern Gottfried and Friedrich and Geoffrey), Frideriko "peace + powerful" (modern Frederic), and Theodobaldo "people + valiant." Among the noncompound Germanic names is Karl (or Charles), in the Latin form Carolus, meaning "man." Vladimir "governs the world," Vladislav "rule + glory," and Miroslav "world + glory" are typical Slavic compound names.

The Latin system of personal names was quite different and probably developed under Etruscan influence. In the oldest times the Romans seemingly had only one name; *e.g.*, Romulus, Remus, Manius. From the beginning of historical times, however, the Roman personal name consisted of a praenomen (given name, forename) and a nomen (or *nomen gentile*). The use of the praenomen was limited to intimate contacts, and its choice was strictly restricted to fewer than 20 names, among them Gaius, Gnaeus, Marcus, Quintus, Publius, Tiberius, and Titus. The subsequent nomen was hereditary in each gens (a related group of families, like the Scottish clan); examples include Antonius, Aurelius, Claudius, Cornelius, Fabius, Horatius, Julius, Lucius, Maccius, Tullius, and some others. Because the choice of both the praenomen and the nomen was restricted, the patrician families and later all families started using a hereditary name, called a cognomen. These cognomina developed from original surnames; *e.g.*, Cicero "bean," Pictor "painter," Plautus "flat foot," Tacitus "silent." In this way, the Roman name consisted of three parts: Marcus Tullius Cicero, Gaius Julius Caesar. In addition, a person might have acquired an individual surname, called an agnomen: Publius Cornelius Scipio Africanus was so named because of his successful war in Africa.

Roman system: praenomen, nomen, and cognomen

This system of naming was used during the whole republican epoch and later in the empire. Toward the end of the empire, however, the naming pattern began to change and subsequently was lost. One reason was that more persons used names lacking any real relation to themselves. For instance, a slave (and then his children) used the praenomen and the nomen of the master who set him free; *e.g.*, had Marcus Tullius Cicero freed a Syrian slave, the name of the latter might have been Marcus Tullius Syrus. The number of affranchised slaves grew constantly, particularly after the victory of the Christian religion. Also, a free inhabitant of the empire who was granted Roman citizenship acquired the praenomen and nomen of the magistrate who made the decision. Thus, in AD 212 all free noncitizens were given citizenship by the emperor Caracalla, with the result that hundreds of thousands of persons prefixed Marcus Aurelius before their name (be it Greek, Syrian, African, or any other). In this way, Roman names lost their significance. Another influence was introduced by the Christians, who belonged to social classes that were not particularly concerned with the habits of the Roman higher class and who preferred names connected with their own religion; *e.g.*, from its founders (Petrus, Paulus, Joannes, Maria, Timotheus) or from the new martyrs, frequently persons with simple Latin or Greek surname-like names (such as Stephanos "wreath" [modern Stephen], Laurentius "laurel" [modern Lawrence], and Sidonius "coming from Sidon in Phoenicia" [modern Sidney]). Simple names like these were sometimes called *signum*. The Christians, however, soon started creating their own names; *e.g.*, Benedictus "blessed," Desiderius "desiring (salvation)," Renatus "reborn (by Baptism)," modern René.

Christian and non-Christian given names

With the spread of Christianity, this stock of names spread into territories that did not belong to the Roman Empire, but the diffusion was slow. In both the Germanic and the Slavic sphere (half of which came under the influence of the Eastern Church), the use of many of the original non-Christian names was continued, partly by tradition and partly because some of the bearers of these names became saints themselves. In this way, the repertory of given names was set, in general, somewhere around the 12th century. A notable addition to it was the influx of Old Testament names brought by the Reformation (Adlai, Benjamin, and so on). Certain names have left no trace of their ephemeral existence—*e.g.*, Puritan names such as Humility, Be Faithful, Kill Sin; French revolutionary names; and Russian postrevolutionary names such as Mels (an acronym containing the initial letters of Marx, Engels, Lenin, and Stalin). American fanciful given names for girls, such as Claretta, Elizene, Gwyned, and Marilla, are also relatively insignificant in impact, though the group is growing.

Family names. Family names came into use in the later Middle Ages (beginning roughly in the 11th century); the process was completed by the end of the 16th century. The use of family names seems to have originated in aristocratic families and in big cities, where they developed from original individual surnames when the latter became hereditary. Whereas a surname varies from father to son, and can even be changed within the lifespan of a person, a hereditary surname that develops into a family name better preserves the continuation of the family, be it for prestige or for the easier handling of official property records and other matters. Family names frequently developed (via surnames) from hypocoristic forms of given names; *e.g.*, from Henry came Harry, Harris, Hal, Halkin; from Gilbert came Gibbs, Gibbons, Gibbin, Gipps, Gilbye, Gilpin; and from Gregory there developed Gregg, Grigg, Greggs, Griggs, Greig. Other sources of family names are original nicknames—Biggs, Little, Grant (grand, large), Greathead, Cruikshank, Beaver, Hogg, Partridge: occupations—Archer, Clark, Clerk, Clarkson (son of a clerk), Bond, Bonds, Bound, Bundy (bondman); and place-names—Wallace (man from Wales), Allington, Murray, Hardes, Whitney (places in England), Fields, Holmes, Brookes, Woods (from microtoponyms).

A great number of family names come from patronymic surnames; in English, they are usually formed by the suffixation of "-son." Patronymic surnames can be formed from the father's given name or from any of its variants. Therefore, there is not only the form Richardson, but also Dickson, Dixon, Dickinson; and Henryson, Harrison, Henderson; Gilbertson, Gibson; and Gregson, Grigson. Some English patronymics, particularly in old families, are formed with a prefixed "Fitz-" (*e.g.*, Fitzgerald), which goes back to Norman French *fis* "son." In contradistinction to English, the Scottish patronymics are formed by a prefixed "Mac" or "Mc" (McGregor), the Irish with "O" (O'Brien) or "Mc" or "Mac," and the Welsh with "P-" (Powell "son of Howel"). In Modern Greek, patronymics are formed by suffixation; *e.g.*, Dimitriopoulos "son of Dimitrios."

French family names

The development of family names is similar in all of Europe. For example, French names such as Jaquet, Jacquot, Jacotot, Jacotin, Cottet, Cottin, Cotin, Jacquin, Jacquinet, Jacquinot, Jacquart, Jacquier all derive from Jacques; Davignon, Decaen, Derennes, and Beauvais developed from the place-names Avignon, Caen, and so forth; Breton, Lebreton, Lenormand come from the names of districts; Clerk, Leclerc, Duclerc, Auclerk, Clergue (*cf.* English Clark), Boucher, Boulanger, Masson designate professions ("butcher," "baker," "mason"); and Roux, Leroux, Roussel, Rousseau, Lerouge, Roujon are all variants of "red" (*i.e.*, red hair). Roughly the same scheme exists everywhere in Europe. Some family names can be traced to nicknames that must have their origin in incidents and attitudes that cannot be understood now; *e.g.*, Czech family names such as Nejezchleba "Don't eat bread!" and Skočdopole "Jump into the field!"

The development is slighty different among Jews. While living in ghettos, they used only given names. After the end of the 18th and the beginning of the 19th century, they chose or were given family names. Many of these names (which vary in the individual languages) are derived from religious vocations: Cantor, Canterini, Kantorowicz (lower priest); Kohn, Cohen, Cahen, Kaan, Kahane (priest); Levi, Halévy, Löwy (name of the tribe of priests). Many are derived from place-names—Morpurgo (Marburg)—or from nicknames—Hirsch ("deer" in German). Frequently, particularly in Austria, the Jews were given derisory family names, such as Eberstark "strong as boar," Rosenduft "fragrance of roses," and Hitzig "hot," from Itzick, a mocking form of Isaac.

The only outstanding exception to this European pattern of naming occurs with the names of kings, who use one of their given names. Some royal families have what could be called family names; *e.g.*, the Hohenzollerns (more correctly, Hohenzollers) of Prussia. The British royal family accepted the name Windsor only in 1917 (this was changed to Mountbatten-Windsor for the future members of the family who will not enjoy princely status). The pope of the Roman Catholic Church abandons his personal name after his election and chooses a single name, sometimes associated with his intentions; *e.g.*, Pope Paul VI chose the name Paulus because of St. Paul's missionary activities and travels.

Other patterns of naming. Names and naming practices in other cultural areas show a strong similarity in the basic trends. Among the ancient Assyrian and Babylonian names are theophoric designations such as Ashurbanipal, meaning "Ashur [a god] created son," and Nabukudurriusur (Nebuchadrezzar of the Bible), translated as "Nabu [a god] protected the estate." The Phoenician (Carthaginian) name Hannibal means "grace of Baal" (a god). The Hebrew Yehonatan, Yonatan (*i.e.*, Jonathan) means "God gave," Rafa'el (Rafael) is translated as "God cured." There are also nontheophoric names such as Laban (from Hebrew *lavan* "white"). The Aramaic surname of the fisherman Simon, Kepha, meaning "stone," became famous in the New Testament as Petros (Peter), the Greek translation of the name (*petra* "rock, stone").

Theophoric names

The more complicated structure of Arabic society brought an independent development similar to the European one. Given names such as Muḥammad, Ibrāhīm (=Abraham), Manṣur "victor, ʿAlī "exalted," ʿAbd Allāh "slave of Allāh" are differentiated by surnames such as Ibn ʿAbbās "son of ʿAbbās," al-Baghdādī "from Baghdad," al-Ghazālī "the spinner." The Caucasian (*e.g.*, Ossetic) personal name consists of a given name preceded by the name of the tribe (gens) in the genitive plural; the name of the father may be inserted, thus giving Gaglojty Soslany fyrt Nafi "Nafi, son of Soslan, of [the gens of] Gaglo." Chinese society has had the institution of hereditary family names since the 4th century BC, but the number of these names has been reduced to some 200. Examples include Chan, Mao, and Lu. The choice of the given name was much freer, but recent legislation seems to have restricted it. In a similar way, there are not more than 300 Korean family names, but only three of them—Kim, Pak, and Yi—belong to the great majority of families in Korea. The given name is chosen, but its choice is limited by the practice that one of the two syllables of the name should be identical within a family for a generation; the whole given name should have an auspicious meaning.

By the 20th century, the originally European pattern of given name + family name had been introduced practically everywhere. Black Africa (*e.g.*, among the Yoruba) now has the "normal" pattern of personal names, but both the given and the family names are of vernacular stock. There are given names such as Olúṣolá "god [non-Christian] made greatness," Òṣunbúnmi "Osun [a river] gave me," and Adeyẹmí "crown befits me," and family names like Ajólore "who [is] a kind doer." Among the American Indians there are, surprisingly, practically no theophoric names. Instead, the Indians used names related to the totem, to animals indicated by omens or dreams, and to successful incidents in life. Those North American

Indians who did not accept English names now use the English translation of their names as last names (which sometimes are not hereditary); *e.g.*, John Sleeping Owl, Mary Little Bear.

Place-names. *Descriptive and commemorative place-names.* If the "meanings" of place-names and the motives for their choice are examined, several broad types may be discerned. Descriptive names indicate a characteristic feature of the entity; *e.g.*, Rocky Mountains, North Sea, Newcastle. The chosen feature is sometimes only illusory or brought by chance, as in the case of the Pacific Ocean (only a small part of it was calm, or pacific, when first seen and named). Honorific and commemorative names are another broad category. Examples include Constantinople (formerly called Byzantium, renamed Konstantinoupolis "city of Constantine" because that emperor made it the capital of the Roman Empire); Aphrodisias "[the town of] Aphrodite" (in Asia Minor), changed into Stauropolis "city of the cross" with the advent of Christianity; Cartagena, transferred to Colombia (South America) in commemoration of Cartagena in Spain (Cartagena in Spain was in turn developed from Latin Carthago Nova, a translation of the name given to the town by the Phoenician settlers in commemoration of Carthage, the Phoenician rival of Rome); Nieuw Amsterdam, commemorative of the Dutch capital, changed to New York (honorific for the Duke of York). Among the numerous benedictory, wishful names are the Russian Vladivostok "govern the East!" (founded and named by Russians as their main base on the Pacific coast), Cape of Good Hope (a renaming of a more descriptive Cape of Tempests), and Greek Pontus Euxinus (now the Black Sea) "hospitable sea" (a renaming of Pontus Axeinos "inhospitable sea"). In most cases, however, place-names do not have a "meaning" at all, particularly not for the general user.

Types of place-names

Place-names reflecting historical influences. Place-names are frequently accepted into the language of a new population. The toponymy of the United States illustrates this well. Spanish names are numerous in the South and Southwest; *e.g.*, Florida, San Antonio, Santa Fe, Las Cruces, and San Diego, all of which are Spanish names of Roman Catholic saints or holidays. French names occur frequently in the Southeast and the central U.S. (*e.g.*, La Nouvelle Orléans, changed into New Orleans; Baton Rouge; St. Louis; Louisiana); Dutch names are found in the East (Haarlem changed into Harlem); Indian names are interspersed everywhere; and, finally, English names are superimposed over all the rest. An examination of all these names, which are now used by a mostly English-speaking population, could not fail to yield some information about the colonization of the United States, even if the history were not known.

In the same way, the place-names of Britain reflect its history. Above all, there are Celtic names; *e.g.*, Eboracum (named for a tree), partly translated as Eoforwic, which changed into York. Roman names are also numerous; *e.g.*, Castra "military camp," changed into Chester, and Lindum Colonia "Colony Lindum" (which itself is Celtic, *linne* + *dunom* "town at the lake") is now Lincoln. There are, in addition, Anglo-Saxon names (*e.g.*, Whittingham "habitation of Hwita's people"), a few Scandinavian names (*e.g.*, Badby, in which *-by* is the Scandinavian element instead of English *-bury* "castle"), and Norman names (*e.g.*, Richmond, from a personal name consisting of *rīki* "rich, powerful" + *mond* "world").

Changes in place-names

Any country's toponymy consists of various layers. In France there are Celtic names such as Lucodunos "shining town" that became Latinized into Lugdunum and changed into the modern form Lyon; Greek names such as Agathe (Tyche) "good (luck)," which has become Agde; Roman names such as Forum Julii "marketplace of Julius," modern Fréjus; and old Germanic names such as Clarbec "clear brook" (*klar* + *Bach* in German). Most important is the fact that place-names can be used as a source of information themselves, even if other forms of evidence are lacking; for instance, because Moskva (=Moscow) is a Finnish name (Finnish *kva* "water"), and other Finnish toponyms are present in the central Soviet Union, the prehistoric presence of Finnish tribes in that location can be presumed. Names of rivers are particularly important for this purpose, because they are very conservative and usually are taken over by a new population. A considerable number of river names in western and central Europe show remarkable similarity (*e.g.*, Esera in Spain, Isère in France, Ysar in Belgium, Isar in Bavaria, Jizera in Czechoslovakia) and are the only evidence of a pre-Celtic Indo-European population of those regions.

In a similar way, names are also indicative of cultural and political trends. Singapore (Sanskrit Siṃhapura "castle of lions"), for example, testifies to the cultural influence of India in the area. Particularly significant in this respect are deliberate changes of names caused by changes in political power, ideology, and so forth. Changes such as Nieuw Amsterdam becoming New York, or Léopoldville (named after the king of Belgium who acquired the Congo) becoming Kinshassa, are very common. Some cases of renaming do not lack humour: La Roche-sur-Yon in France was rebuilt by Napoleon and renamed Napoléon-Vendée, which was changed to Bourbon-Vendée under the Restoration; during the 100 days of Napoleon's return from Elba and in the subsequent second Restoration, the cycle was repeated once more, and only the Third Republic restored the old name. Renaming also shows examples of cynicism: Lyon, which had rebelled against the revolutionary covenant, was punished by systematic demolition and a massacre of its inhabitants; the ruins of the city were renamed Commune-Affranchie "Liberated Commune." Changes of place-names are sometimes made systematically; when the territory called Alto Adige in Italian and Südtirol (South Tirol) in German became part of Italy after World War I, for instance, a systematic effort was made to give or to return to these territories the Italian character in both place-names and personal names. The Russian Revolution brought a change of names that were reminiscent of the old regime and ideology; *e.g.*, St. Petersburg (changed into a more Slavic Petrograd by the tsar during the war) became Leningrad, Caricyn (from *car* "emperor") became Stalingrad (and then Volgograd in the late 1950s), Yekaterinodar (from Yekaterina [=Catherine], an empress) became Krasnodar (from *krasny* "red"), but Arkhangelsk "town of archangels" somehow escaped notice.

BIBLIOGRAPHY

Books: C.W. BARDSLEY, *Dictionary of English and Welsh Surnames* (1901, reprinted 1967), good for quick reference concerning individual names; C.H. L'ESTRANGE EWEN, *A History of Surnames of the British Isles* (1931, reprinted 1968), contains rich information and a bibliography; E.G. WITHYCOMBE (comp.), *Oxford Dictionary of English Christian Names*, 2nd ed. (1950), indicates the provenience of names listed; L.G. PINE, *The Story of Surnames* (1965), readable and well informed; H.L. MENCKEN, *American Language*, suppl. 2 (1948), a survey of American naming; E. EKWALL, *Concise Oxford Dictionary of English Place-Names*, 4th ed. (1960), a handy reference that gives the provenience of place-names; J.B. JOHNSTON, *Place-Names of Scotland*, 3rd ed. (1934); P.W. JOYCE, *Origin and History of Irish Names of Places*, 7th ed., 3 vol. (1920), partly antiquated, but still of great value; G.R. STEWART, *Names on the Land*, 3rd ed. (1967), gives the origin of American place-names, readable and very instructive because it not only provides the etymology of names, but indicates why they were chosen; and E. PULGRAM, *Theory of Names* (1954; reprinted by the American Name Society from *Beiträge zur Namenforschung*, 1954), treats theoretical problems, such as the distinction between names and common nouns.

Journal: Names, quarterly journal of the American Name Society (1953–).

The study of names is plagued with imaginative and fantastic, but unfounded and unscholarly, publications; therefore, caution should be exercised in the choice of sources.

(L.Zg.)

Namib Desert

The Namib is a cool coastal desert extending for 1,200 miles (1,900 kilometres) along the Atlantic coast of southwestern Africa, from Moçâmedes in Angola southward across South West Africa to the Olifants River in the Cape

Province of South Africa. It reaches inland 80 to 100 miles to the foot of the Great Escarpment of southern Africa. Its southern portion merges with the Kalahari Desert on the plateau atop the escarpment. Its name is derived from the Nama language, implying "an area where there is nothing."

The Namib is arid and is almost totally uninhabited, except for several towns. It is important because of the trade routes which cross it, its mineral deposits, the fisheries of the bordering sea, and its increasing utilization for recreation.

Landscape. The desert basically consists of a relatively smooth platform of truncated bedrock of various types and ages. Mica-schist and other metamorphics and granite and similar intrusives predominate. The platform rises gradually from the coast to about 3,000 feet at the foot of the escarpment. Scattered isolated mountains rise steeply and abruptly above the platform, and, in the northern half, streams have carved deep, steep-walled gorges into it.

In much of the southern half of the desert the platform is surmounted by a vast expanse of sand—yellow-gray near the coast and brick-red inland—which is derived from the Orange River, as well as from other rivers that flow westward from the escarpment but never reach the sea. The dunes are arrayed in lines that run from north-northwest to south-southeast, with individual dunes having lengths of ten to 20 miles and reaching heights of 200 to 800 feet. The troughs between are interrupted by smaller transverse dunes. The extreme southern coastal area consists of wind-scoured bedrock and a few rapidly moving crescent-shaped barchan (*i.e.*, convex to the wind) dunes. The northern third—the Kaokoveld region—consists of gravel plains and rock platforms occurring between scattered, rugged mountains, interspersed with a few large dune fields.

Drainage and soils. Being an almost rainless area, the Namib has a poorly developed and fragmentary drainage pattern. Water from the interior plateau flows through or into the desert. In the northern half the larger streams reach the sea, but between the Kuiseb and the Orange rivers, every stream terminates in a vlei (salt pan or mud flat) against or among the dunes.

A portion of the water of major streams seeps through the sands of the stream beds. The underflow of the Kuiseb River has been tapped 25 miles inland to provide water supplies for Walvis Bay and Swakopmund. A pipeline 80 miles long supplies Lüderitz with water from the seepage of the Koichab, a stream that terminates in the dunes. Only the Cunene and the Orange rivers flow permanently on the surface. Other streams have surface flow only after heavy rainfall in the interior plateaus—they normally flow for no more than a few days in several years.

Large areas of the Namib are completely soilless, with bedrock at the surface. Other areas are covered with shifting sand. Soils that do occur are often highly saline, impregnated with gypsum, or cemented firmly by calcium carbonate, forming a calcrete layer just below the surface. Arable soils in the Namib are limited to floodplains and terraces of major rivers and are subject to occasional inundation.

Climate. The coastal area is almost totally rainless, yet its air is almost always at or near the saturation point. The cold Benguela Current flows northward along the coast, chilling the air above it, and thus producing fog. This cool air moves inland as a southwest sea breeze, creating a temperature inversion about 1,000 feet thick, with fog below and hot, dry air above.

Temperature range

At the coast, there is little difference in temperature between day and night or between winter and summer. Temperatures are usually in the 50s or 60s (Fahrenheit). Along the inland margins, summer temperatures normally reach the high 80s; only in areas sheltered from the cooling sea breeze (lee sides of mountains and bottoms of canyons) do temperatures frequently approach those expected in low-latitude deserts—*i.e.*, in excess of 100° F. Freezing temperatures occur occasionally along the inner edge of the desert.

On a few days each year, usually in fall or spring, "Berg," or mountain, winds, blowing from the east, bring high temperatures (over 100° F), together with dry air and clouds of dust, across the desert to the coast itself. The rare rains occur in spring and fall, usually as short-lived torrential thunderstorms.

Average annual precipitation at the coast is approximately one-half inch, increasing inland, until it reaches two inches at the foot of the escarpment. Some years, however, have no rain at all. Dew, on the other hand, is heavy, and for some types of vegetation is more important than the rainfall. In the extreme south, some winter precipitation occurs from frontal storms passing farther south over the Cape region; on rare occasions, snow may fall on the higher southern mountains.

Vegetation and animal life. Six vegetational regions may be identified in the Namib: (1) the coastal region, with highly succulent vegetation, which uses moisture derived from the fog; (2) the almost completely barren Outer Namib; (3) the steppes of the Inner Namib, which in many years are barren, but which in wet years are covered with short grasses, both annual and perennial; (4) the dunes of the Inner Namib, which produce a surprisingly rich flora of bushes and tall grasses; (5) the larger river channels, along which large trees, particularly acacias, grow; and (6) the southern winter rainfall area, where a succulent bush growth occurs. A curious Namib plant is *Welwitschia mirabilis*, whose two gigantic leaves sprawl over the surface of the ground from the crest of its huge root crown.

The plains and dunes of the Inner Namib support large numbers of antelope (especially gemsbok and springbok) and ostriches and some zebras. The dunes of the Outer Namib have various types of insects and reptiles, especially beetles, geckos, and snakes, but virtually no mammals. The shore area is densely populated by marine birds (notably flamingos, pelicans, and, in the southern part, penguins), as well as a few jackals, some rodents, and two colonies of seals. Large quantities of guano are scraped annually from the rocks of several offshore islands, and from one artificial platform.

The inhabitants. A few Bushmen roamed the Namib until early in the present century, gathering whatever was edible along the shore, hunting in the Inner Namib, and often depending for water upon the bitter juices of the tsama (a species of watermelon). Today a few hundred Ovahimba and Ovatjimba Herero tribesmen herd cattle and goats from waterhole to waterhole in the desert part of the Kaokoveld, living in their traditional manner. A few Topnaar Namas ("Hottentots") graze their sheep and goats on the riverine vegetation along the Kuiseb River.

Towns

Walvis Bay is a modern port city with a 1970 population of 23,500, composed of 8,320 whites (predominately Afrikaners, but including a considerable number of English and Germans); 3,210 Coloureds (mixed white, Malay, and Nama), chiefly from the Cape Town area and associated with the fishing industry; and 11,930 Africans, consisting partly of local Nama families, but largely of male Ovambos (Ambos) from Angola and the northern part of South West Africa, working at the port under short-term labour contracts. The port serves as a base for pilchard and whitefish fleets, which supply both shore canneries and cannery ships on the open sea. It is also the major transhipment port for South West Africa, exporting ore, hides, wool, tinned fish, fish oil and meal, and frozen lobster, and importing petroleum, foodstuffs, and manufactured goods from Europe, the United States, and Japan.

Lüderitz, a small town on a shallow, rock-strewn harbour, has a small trade with Walvis Bay and Cape Town and is the base of a crayfish (lobster) industry. Oranjemund, a company town of the Consolidated Diamond Mines, is a base for large-scale diamond mining in the alluvial gravels along the southern coast.

Swakopmund, the summer capital for South West Africa and a popular coastal resort town, still retains much of its former German atmosphere. The coastal area for nearly 100 miles north of Swakopmund is becoming increasingly

popular as a recreational area in general and for fishing in particular.

The innermost region of the desert in its southern two-thirds is divided into "farms" (*i.e.*, ranches), devoted chiefly to the raising of karakul sheep. Sheep-raising, however, suffers severely from recurrent droughts.

Transport. The desert is crossed by rail lines that link the ports of Lüderitz and Walvis Bay with South Africa. A tarred road from Walvis Bay also runs into the interior. Graded roads connect Oranjemund with Lüderitz, and thence with the interior, and a graded road runs from Swakopmund northward along the coast for about 150 miles. Two areas are completely roadless—the Kaokoveld in the north and the area between Walvis Bay and Lüderitz. The entire area between the Kuiseb and Orange rivers is a diamond area that remains closed completely to public entry except for the road and rail access to Lüderitz. There are airports with regularly scheduled passenger service located near Walvis Bay; at Lüderitz; and at Alexander Bay, to the south of the Orange River.

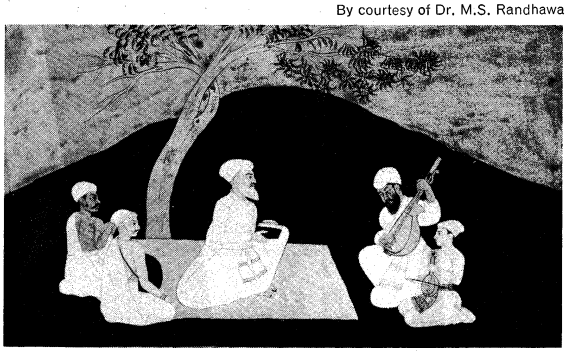
WELLINGTON, *Southern Africa: A Geographical Study*, 2 vol. (1955), a textbook of the geography of southern Africa, with a description of the Namib emphasizing physical aspects.

(R.F.Lo.)

Nānak

Nānak, a religious teacher of the Punjab (Pañjāb), commands a particular importance in the history of Indian devotional religion. Although born a Hindu, he marks the beginning of the Sikh community, and among modern Sikhs he enjoys a particular affection as the first of their Gurūs and as the supreme master of Punjabi devotional hymnody.

By courtesy of Dr. M.S. Randhawa



Nānak (centre), painting in the Mughal style, *c.* 1689. In the collection of Mahant Indresh Charan Dass, Dehra Dūn, Uttar Pradesh, India.

What little information there is about Nānak's life has been handed down mainly through legend and tradition. There is no doubt that he was born in 1469, probably on April 15th, in the village of Rāi Bhoi dī Talvaṇḍī, 40 miles southwest of Lahore. His father was a member of a subcaste of the mercantile Khatrī caste. The relatively high social rank of the Kahtrīs distinguishes Nānak from other Indian religious reformers of the period and may have helped promote the initial growth of his following. He married the daughter of a Khatrī, who bore him two sons.

For several years Nānak worked in a granary until his religious vocation drew him away from both family and employment, and in the tradition of Indian religious mendicants, he embarked on a lengthy journey, probably travelling to the Muslim and Hindu religious centres of India, perhaps even to places beyond its borders. Neither the actual route nor the places he visited can be positively identified.

References found in four of his hymns suggest that Nānak was present at attacks Bābur (an invading Mughal ruler) launched on Saidpur and Lahore, so it seems safe to conclude that by 1520 he had returned from his travels and was living in the Punjab.

Founder of Sikh community

The remaining years of his life were spent in Kartārpur, another village of central Punjab. Tradition holds that the village was actually built by a wealthy admirer to honour Nānak. It was presumably during this final period that the foundations of the new Sikh community were laid. By this time it must be assumed that Nānak was recognized as a Gurū, an inspired teacher of religious truth, and that, in accordance with the custom of India, disciples who accepted him as their Gurū gathered around him in Kartārpur. Some probably remained as permanent residents of the village; many more made periodic visits to obtain his blessing. All of them listened to the teachings expressed there in numerous devotional hymns intended for communal singing, many of which survive to this day.

The actual year of Nānak's death is disputed, tradition being divided between 1538 and 1539. Of these two possibilities, the latter appears to be the more likely. One of his disciples, Aṅgad, was chosen by Nānak as his spiritual successor, and following Nānak's death he assumed the leadership of the young Sikh community as Guru Aṅgad.

In view of the size of the following that Nānak attracted, numerous anecdotes concerning the deeds of the Gurū began to circulate within the community soon after his death. Many of these were borrowed from the current Hindu and Muslim traditions, and others were suggested by Nānak's own works. These anecdotes were called *sākhīs*, or "testimonies," and the anthologies into which they were gathered in rough chronological order are known as *Janam-sākhīs*. The interest of the narrators and compilers of the *Janam-sākhīs* has largely concentrated on the childhood of Nānak and above all on his travels. Amongst the earlier traditions are tales of visits he is supposed to have made to Baghdad and Mecca. Ceylon is a later addition, and later still the Gurū is said to have travelled as far east as China and as far west as Rome. Today the *Janam-sākhīs* offer a substantial corpus of hagiographical material, and the more important of these collections continue to be the basis of "biographies" of Nānak.

Doctrine

Nānak's message can be briefly summarized as a doctrine of salvation through disciplined meditation on the divine name. Salvation is understood in terms of escape from the transmigratory round of death and rebirth to a mystical union with God. The divine name signifies the total manifestation of God, a single Being, immanent both in the created world and within the human spirit. Meditation must be strictly inward, and all external aids such as idols, temples, mosques, scriptures, and set prayers are explicitly rejected. The Muslim influence is relatively slight; the influence of Hindu mystical and devotional beliefs is much more apparent. Always, though, the coherence and beauty of Nānak's own expression dominates early Sikh theology.

Nanking

Nanking (Nan-jing in Pin-yin romanization), capital of Kiangsu Province in central eastern China, is a port on the Yangtze River (*q.v.*) and a major industrial and communications centre. Rich in history, it served seven times as the capital of regional empires, twice as the seat of revolutionary governments, once (during World War II) as the site of a puppet regime, and twice as the capital of a united China (the second time from 1928 to 1937). In the early 1970s its population was estimated at about 2,300,000. The name Nanking (Southern Capital) was introduced in 1421 during the Ming dynasty.

History. Nanking's recorded history dates back to the Eastern Chou dynasty (8th to 3rd centuries BC), when it was held successively by the states of Wu, Yüeh, and Ch'u. In 221 BC, when the Ch'in annexed it, it was called Chin-ling. Under the Ch'in (221–206 BC) and Han dynasties (206 BC to AD 220), Nanking—named, respectively, Mo-ling and Tan-yang—remained a prefecture within the unified empire.

Early history

Nanking—under the name of Chien-yeh—emerged as the political and cultural centre of Southeast China during the period of the Three Kingdoms, when Sun Chien and his son Sun Ch'üan made it the capital of the kingdom of Wu from 229 to 280. In 317 the Eastern Chin dynasty (317 to 419), fleeing foreign invaders in North China, again chose the city as a capital. Renamed Chien-k'ang, Nanking became a haven for northern families in exile. After the fall of the Eastern Chin, Nanking, under four successive dynasties—Liu-Sung (from 420 to 479); Southern Ch'i (479 to 502); Liang (502 to 557); and Ch'en (557 to 589)—was the seat of government of the regional empires south of the Yangtze.

These regimes were dominated by military men whose rivalries weakened the government. But in Nanking progress was made in areas other than politics. Bountiful harvests, coupled with tea and silk industries, supported a booming economy. Culturally, the Six Dynasties—as the dynasties that ruled from 220 to 589 are idiomatically known—produced a galaxy of scholars, poets, artists, and philosophers. The works of Wang Hsi-chih and Ku K'ai-chih set the canons of calligraphy and painting, respectively. The publication of *Wen hsüan* ("Literary Selections") and of *Wen-hsin tiao-lung* (a classic in literary criticism), the evolution of what has come to be known as the Six Dynasties essay style, a blending of poetry and prose, and the invention by Shen-yüeh (a 6th-century courtier) of the system of determining the four tones of the Chinese language (which permits one syllable to be spoken in four different ways, thus serving four different characters with four different meanings) were achievements of this period. In philosophy, the so-called *ch'ing-t'an* ("pure discourse") movement, spiritually akin to a form of Taoism, found many adherents who held themselves aloof from politics. Hundreds of Buddhist temples were built; voluminous Buddhist scriptures were edited and transcribed; and thousands, including Emperor Wu Ti of the Liang dynasty, who ruled in the 6th century AD, took monastic vows.

From 581 to 1368, under the successive unified empires of the Sui, T'ang, Sung, and Yüan dynasties, Nanking reverted to the status of a prefectural city. Various names were given the city: Chiang-chou and Tan-yang under the Sui; Chiang-chou, Chin-ling, and Pai-hsia in early T'ang; Sheng-chou in late T'ang; and Chin-ling again under the Five dynasties in the 10th century; Chien-k'ang under the Sung; and Chi-ch'ing under the Yüan. When the Southern T'ang briefly maintained a regional regime in the city from 937 to 975, Nanking enjoyed much intellectual creativity (the ruler Hou-chu himself being a poet of consummate skill) and was the scene of new construction, notably, the octagonal stone pagoda of the Ch'i-hsia-shih Temple and the crosstown channel of the Ch'in-huai Ho. Another period of prominence occurred during the Southern Sung dynasty (1126 to 1279 AD), when Yo Fei used the city as his base for resistance against the Tatars in North China.

In 1368 Emperor Hung-wu, founder of the Ming dynasty, made Nanking the capital of a united China. Naming the city Ying-t'ien-fu (Responding to Heaven), he built a grand Imperial palace and a gigantic city wall, made of brick, 60 feet high and 32 miles long, with 13 gates. In addition, earth ramparts were prepared to form the basis for a still larger outer wall, 60 miles in length, with 18 gates. In 1421, however, Hung-wu's son, the Yung-lo emperor, moved the capital to Peking. The city became a subsidiary capital and was renamed Nanking.

The growth of trade and industry, however, brought new wealth to Nanking, especially to Hsia-kuan, the city's foremost port and suburb. Weaving, pottery, printing, and brocade making were the leading industries. Oceangoing vessels used by Cheng Ho in his famous 15th-century expeditions to the South Seas were built in the shipyards to the northwest of the city. An Imperial college—the Kuo-tzu chien—attracted students from all over the empire, as well as from Japan, Korea, Okinawa, and Thailand. The scholars of this college helped compile the *Yung-lo ta-tien* ("Yung-lo Emperor's Encyclopaedia"); its printing plant issued fine editions of many classics, as well as such important works as *Pen-ts'ao kang-mu* ("Great Pharmacopoeia").

In the Ch'ing dynasty (1644 to 1911), Nanking, renamed Chiang-ning, became the government seat of the viceroy of Kiang-nan (who governed the provinces of Kiangsu, Kiangsi, and Anhwei). In 1842 the treaty ending the Opium War was signed there. A decade later, in 1853, the city was taken by the Taiping revolutionary forces under the leadership of Hung Hsiu-ch'üan. As the capital of *T'ai-p'ing T'ien-kuo* (Heavenly Kingdom of Peace), Nanking became a commune practicing universal brotherhood, equality of the sexes, and communal ownership of property. Despite the construction of palaces for Hung and his lieutenants, there was widespread destruction of public buildings, of temples, and of the city wall. When the Taipings were overthrown in 1864, the city was nearly prostrate.

The Taiping capital

Recovery took decades. Although it was sanctioned by the treaties of Tientsin concluded with France in 1858, foreign trade did not begin until 1899. By that time, modern industry and communication had reached the city. In 1908 the Shanghai–Nanking railroad was opened, followed by a railroad from the port city of Tientsin in Hopeh Province to P'u-k'ou, on the northern bank of the Yangtze opposite Nanking, which opened four years later. Such economic growth, however, was overshadowed by the revolution of 1911. After the uprising had begun upstream at Wu-ch'ang in Hupeh Province, the revolutionary leaders proclaimed Nanking the seat of the provisional government of the Republic of China, and the democratic constitution of 1912 was adopted there before the first president, Yüan Shih-k'ai, moved the capital to Peking. Thus, within 60 years, Nanking was twice at the centre of the revolution to overthrow the Manchu dynasty.

Under the infant Republic of China, Nanking was governed by warlords for over a decade. Sun Yat-sen, leader of the Kuomintang (Nationalist Party), embittered by politicians' intrigues centred in Peking, vowed to make Nanking the Nationalist capital. Accordingly, when his follower Chiang Kai-shek achieved national unification in 1928, the Nationalist government made Nanking once more the capital of a united China. Remarkable progress was made in developing communications, industries, and natural resources. Physically, too, the city acquired a new look; modern boulevards and government buildings were constructed; new railroad stations and airfields were built; and the Sun Yat-sen Mausoleum was erected.

Such achievements were, however, cut short by the war against Japan. Nanking fell in 1937. In the sack of the city that followed, more than 40,000 civilians were slaughtered. The city was then ruled by puppet governments until Japan's defeat in 1945. From 1946 to 1949,

Nanking resumed its status as the capital of Chiang Kai-shek's Nationalist government. It was then threatened by the rising power of the Chinese Communists, whose forces took the city in 1949. When the People's Republic of China was proclaimed on October 1, 1949, Nanking was once again abandoned in favour of Peking as the national capital. In the administrative reorganization of 1952, it was made the provincial capital of Kiangsu, replacing the nearby city of Chen-chiang.

The contemporary city. *Location, extent, and climate.* Nanking is situated on the southeast bank of the Yangtze, some 160 miles from Shanghai (215 miles by water, 193 miles by rail). In addition to the city proper, which occupies the area enclosed by the walls, the municipality of Nanking includes territory extending to the town of Lung-tan in the east and to the borders of Chiang-ning County (*hsien*) in the south, Pa-kua-chou Island in the Yangtze, and an area north of the Yangtze from P'u-k'ou to the Anhwei border between the county lines of Liu-ho and Chiang-p'u. Included in the municipality are both urban and rural districts.

The four seasons are clearly distinguishable. The hot summer months are from July to September, while winter lasts from December until March. Spring and autumn are both mild and pleasant. January and July mean temperatures are about 37° F (3° C) and 81° F (27° C), respectively. The average annual rainfall is 36 inches, the bulk of it falling between June and August.

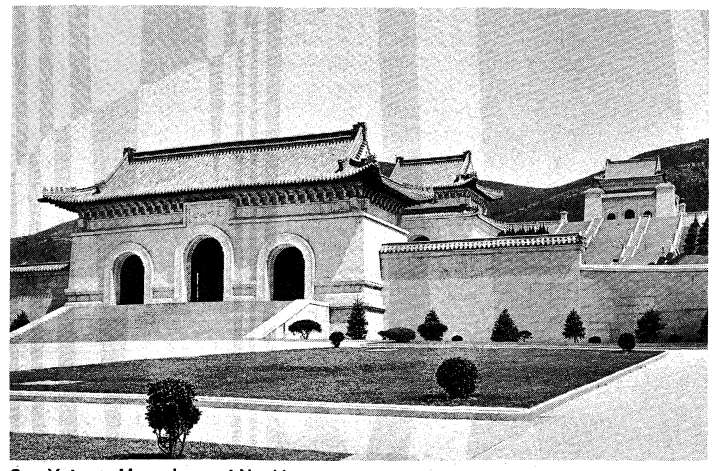
City layout and landmarks. The city of Nanking resembles a gourd, with its tip pointing northwest, toward Hsia-kuan, its base resting against the Ch'in-huai Ho (Ch'in-huai River) on the west and south and the foothills of the Tzu-chin Shan (Purple-Gold Mountain) on the east, and with its middle dented inward by Hsüan-wu Hu (Mystic Martial Lake) on the northeast and Moch'ou Hu (Lake of No Sorrow) on the southwest. The skyline suggests spaciousness and grandeur. Blue-glazed tiles adorning the gates, parklike scenery along the streets, lotus blossoms and tea pavilions on the lakes, and temples half hidden in the hills—all these are characteristic sights in Nanking.

The city's four districts

The city is comprised of four districts. The north district, from I-chiang Men (a city gate) to the Ku Lou (Drum Tower), traversed by Chung-shan Avenue as its axis, contains such landmarks as Pei Chi Ko (North Pole Pavilion) and Chi-ming Shih (Cockcrow Temple); the central district, surrounding Hsin Chieh K'ou (New Crossroads), is the business centre of the city; to the south is situated the populous old city—traditionally famous for entertainment; the east district, containing the former Ming palace and the municipal airfield, lies east of the central district.

Forming an integral part of the life of the city are its immediate outskirts. To the south is the Yü Hua T'ai (Terrace of the Rain of Flowers), noted for its five-colour pebbles and a Communist martyrs' memorial. In the eastern outskirts, on the magnificent Tzu-chin Shan range of hills, are the emperor Hung-wu's mausoleum, the mausoleum of Sun Yat-sen, and the Ling Ko Shih (Temple of the Valley of Spirits). Other scenic spots include Yen-tzu Chi (Swallow's Bluff) in the north and Ch'i Hsia Shan (Abode of Clouds Mountain) farther to the northeast.

Transportation. Nanking's major avenue of commerce is the Yangtze River, which is from 2,700 to 3,900 feet wide in the vicinity of Hsia-kuan, the hub of the city's river traffic. Hsia-kuan is also the terminus of the Shanghai–Nanking railroad and the Tientsin–P'u-k'ou railroad. In 1968 the ferry between P'u-k'ou and Hsia-kuan was replaced by the Yangtze bridge, 20,100 feet in length, with a double-track railroad on its lower deck and a four-lane highway on the upper deck. A third railroad leading south, the Nanking–Wu-hu railroad, which extends to T'ung-ling in Anhwei Province, will eventually connect with the Kiangsi–Chekiang railroad; a loop line through the eastern suburbs links it with the Shanghai–Nanking line. Nanking is also served by a municipal railway that runs eight miles from the centre of the city to Hsia-kuan.



Sun Yat-sen Mausoleum at Nanking.
Ewing Galloway

Major highways fan out from the East Gate to Chenchiang via Chü-jung, to Shanghai via Wu-hsi, and to Hangchow via I-hsing and Ch'ang-hsing. Other highways lead from P'u-k'ou to Ch'u-hsien, Pang-pu, and Ho-fei in eastern Anhwei and from the South Gate to Ma-an-shan, Tang-t'u, and Wu-hu in southeastern Anhwei, where there are connections with the Chekiang road system. Nanking lies on the routes of all major air services: Shanghai to Wu-han and Chungking; Canton to Tsinan, Peking, and Mukden; and Shanghai to Cheng-chou, Sian, and Lan-chou.

Demography and economic life. In 1970 Nanking was estimated by the United Nations to have a population of 2,300,000. Despite the industrial growth of the past two decades, the city retains a traditional feature—the existence of a substantial rural population within the municipality. The people speak Mandarin with a marked local accent that is pedestrian in character.

For centuries, Nanking was noted for its satins, pongees (home-woven silks), velvets, brocades, porcelainware, paper, and ink sticks. Modern industry was actively promoted by the Nationalists. The city's major industrial expansion, however, has taken place since the 1950s. In the early 1970s Nanking was the largest industrial centre in Kiangsu (excluding Shanghai, which is a special municipality). Its chief industries are iron and steel; machine building; farm equipment; motor vehicles (trucks, jeeps, autos); cement; oil refining; chemicals, fertilizers and insecticides; thermoelectric plants; arsenals; and coal mining. No less important are textiles, silk and silk piece goods, synthetic fibres, food processing, optical instruments, radios, pharmaceuticals, clocks, and fountain pens.

The city's industries

More than 80,000 acres of land in the municipality's rural districts are under cultivation, the major agricultural products being rice, wheat, corn, beans, vegetables, and watermelon. *Pai-ho* (lily bulbs), cherries, apples, water chestnuts, lotus roots, pine nuts, and peanuts (groundnuts) are grown on the hills and on the shores of the lakes. Along the canals and creeks, farmers raise large flocks of ducks; the Nanking Duck, preserved in salt and pressed, is one of China's food delicacies.

Imports from abroad consist primarily of industrial equipment for new plant installations. In addition to the city's manufactured goods, exports include eggs, poultry, tea, rice, wheat, beans, cotton, and peanuts.

Political institutions. Government authority is vested in the Nanking Municipal People's Council, elected by the Nanking Municipal People's Congress and composed of the mayor, deputy mayors, and some 40 council members. Serving under the council are numerous bureaus and commissions in charge of civil affairs, public security, justice, planning, finance, food, taxation, industry, commerce, labour, culture, education, public health, physical culture and sports, projects of municipal construction, and public services.

Administratively, the city is divided into districts (*ch'ü*).

Below the district, police substations supervise the population, while street mayoralties handle civil affairs in the same sub-area. Neighbourhood associations help mediate disputes, carry out literacy campaigns, and promote sanitation, welfare, and the continuous "weeding out of bourgeois elements." Inclusion of rural areas in the municipality reflects the government's policy to reduce town-and-country differences by maintaining integrated urban–rural units surrounding the city proper.

Health. Nanking made great progress in public health and medicine in the Nationalist period. Under the present regime, the Chinese Communist Party launches numerous drives to teach the population hygiene, disease-prevention methods, and the value of exercise for physical fitness. In 1967 there were 45 hospitals in Nanking; clinics and health stations are maintained by all neighbourhood associations. A significant recent trend is the designation of individual hospitals for specialization in specific branches of medicine. Nanking is also a centre for training doctors in traditional Chinese medicine—the complementary use of modern and traditional medicine being considered of prime importance.

Education and cultural life. Nanking inherited an excellent school system from Nationalist days. In 1949 there were 300 primary and middle schools, while the National Central University and the U.S. missionary colleges (the University of Nanking and Ginling Girls College) were among the leading institutions of higher education in the country.

Since the 1950s, considerable change has taken place in the city's educational system. Instruction in the primary schools stresses Chinese language, arithmetic, foreign language, geography, and history; Maoist thought; military and physical training; revolutionary art and literature; and labour. In the middle schools, mathematics, physics, chemistry, biology, geography, and proletarian ideology are high priority subjects. Since the Cultural Revolution of 1966 to 1969, the period of school attendance has been reduced, and students are sent on graduation to spend one or two years at physical labour in factories or communes. There has also been a notable increase in teacher-training schools, vocational–technical schools, and part-time agricultural middle schools.

The universities

Paramount among the universities are the Nanking University and the Nanking Technical University. There are about a dozen technical institutes in agriculture, geology, pharmacy, hydraulic engineering, aeronautical engineering, mechanical engineering, civil and chemical engineering, and the food industry. Admission is based not only on examination but also on practical experience and political orientation.

Numerous research agencies and scientific societies are located in Nanking. These include a branch of the Chinese Academy of Sciences, the Tzu-chin Shan Astronomical Observatory, and the Sun Yat-sen Botanical Garden, as well as various research institutes. Prominent among the museums are the Nanking Museum, the Museum of the Heavenly Kingdom of Great Peace, and the Kiangsu Provincial Museum. An important cultural centre for the general public is the Workers' Cultural Palace. The Nanking Library, having absorbed the Sinological Library of Kiangsu Province, contains about 2,300,000 volumes.

Nanking's principal newspaper is *Hsin-hua jih-pao* ("New China Daily"); the city is within easy reach of the newspapers of Peking and Shanghai, such as the *Jen-min jih-pao*, the *Kuang-ming jih-pao*, the *Ta-kung pao*, and the *Wen-hui pao*. While television is not yet available to everyone, radio broadcasts bring the day's news to every farm, factory, school, and home. *Ta-tze-pao*, or large-character wall posters, enjoyed great vogue during the Cultural Revolution.

Basketball, tennis, soccer, and track and field are popular sports, and gymnasiums and sports grounds are found in all parts of the city and suburbs. The Wu-t'ai Shan Stadium in the centre of the city provides accommodation for major sports events. The public at large, however, finds its recreation in the many beautiful parks and resorts.

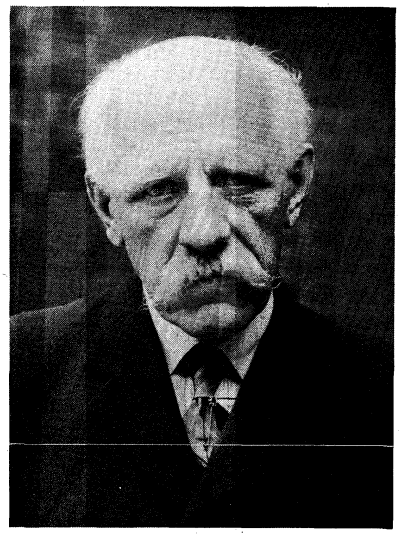
TREGEAR, *An Economic Geography of China* (1970). TSUI CHI, *A Short History of Chinese Civilization* (1942), and IMMANUAL C.Y. HSU, *The Rise of Modern China* (1970), contain general references to Nanking's history. For accounts of specific epochs, see A.F. LINDSAY, *Ti-ping Tien-kwoh: The History of the Ti-ping Revolution*, 2 vol. (1866); PAUL M.A. LINEBARGER, *The China of Chiang Kai-shek* (1941); and HAROLD J. TIMPERLEY (ed.), *What War Means: The Japanese Terror in China* (1938). Glimpses of contemporary Nanking may be found in HUGO PORTISCH, *So soh ich China* (1965; Eng. trans., *Red China Today*, 1965); and in REWI ALLEY'S article on Nanking in *Eastern Horizon*, vol. 10, no. 2 (1971). Helpful information may also be found in two current magazines—*China Reconstructs* and the *Far Eastern Economic Review*.

(P.–C.K.)

Nansen, Fridtjof

One of the most imaginative and intrepid of Arctic explorers and an oceanographer of note, Fridtjof Nansen was also an artist and statesman. But today he is best remembered for his work for the relief of suffering peoples. Nansen was born at Store-Frøen near Christiania (now Oslo), Norway, on Oct. 10, 1861. He went to school in Christiania where, in 1880, he passed his entrance examination to the university. He chose to study zoology in the expectation that fieldwork would give him the chance of an outdoor life and enable him to make use of his artistic talents. Although scientific work was always closest to his heart, he first attained fame as an explorer.

EB Inc.



Nansen.

Explorer. As a young man Nansen was a great outdoor athlete, an accomplished skater and skier, and a keen hunter and fisherman. He thus developed an excellent physique, which gave him the stamina and endurance needed later on his journeys to the Arctic. In 1882 when he joined the sealing ship "Viking" for a voyage to the Greenland waters, Nansen first saw at a distance Greenland's mighty ice cap. It occurred to him that it ought to be possible to cross it, and gradually he developed a plan, which he announced in 1887. Instead of starting from the inhabited west coast he would start from the east coast, and by cutting off his means of retreat would force himself to go forward. The expedition of six left Norway in May 1888. In Iceland the group joined a sealing ship bound for east Greenland waters, and after various difficulties the crossing started on August 15. After enduring storms and intense cold, they reached the highest point of the journey (8,920 feet) on September 5 and struck the west coast at Ameralik fjord on September 26. They were forced to winter at the settlement of Godthaab, where Nansen took the opportunity to study the Eskimos and gather material for his book *Eskimoliv* (1891; English

Crossing Greenland's ice cap

translation *Eskimo Life*, 1893). The party returned home in triumph in May 1889.

In 1890 Nansen presented before the Norwegian Geographical society a plan for an even more hazardous expedition, and in 1892 he laid it before the Royal Geographical society in London. Having collected evidence showing that the ice of the polar sea drifted from Siberia toward Spitsbergen, he proposed to build a ship of such a shape that it would be lifted but not crushed when caught by the ice and to let this ship freeze in off eastern Siberia in order to be carried from there by the currents. Though his plan was severely criticized by contemporary Arctic explorers, the Norwegian Parliament granted two-thirds of the estimated expenses, and the rest was raised by subscriptions from King Oscar II and private individuals. His ship, "Fram" (*i.e.*, "Forward"; now preserved outside Oslo), was built according to his ideas.

With a complement of 13 men, the "Fram" sailed from Christiania on June 24, 1893. On September 22 she was enclosed by the ice in 78°50′ N, 133°37′ E; she froze in, and the long drift began. She bore the pressure of the ice perfectly. On March 14, 1895, Nansen, being satisfied that the "Fram" would continue to drift safely, left her in 84°4′ N, 102°27′ E, and started northward with dogsleds and kayaks, accompanied by one F.H. Johansen. On April 8 they turned back from 86°14′ N, the highest latitude then yet reached by man, and headed toward Franz Josef Land. As they approached the northern islands progress was hampered by open water and, because of the advanced season, they wintered on Frederick Jackson Island (named by Nansen after the British Arctic explorer) where they stayed from Aug. 26, 1895, to May 19, 1896. They built a hut of stone and covered it with a roof of walrus hides and lived during the winter mainly on polar bear and walrus meat, using the blubber as fuel. On their way to Spitsbergen they encountered Frederick Jackson and his party of the Jackson-Harmsworth expedition, on June 17, and returned to Norway in his ship "Windward," reaching Vardø on August 13. The "Fram" also reached Norway safely, having drifted north to 85°57′. Nansen and his companions on board the "Fram" were given a rousing welcome, which reached its climax on arrival in Christiania on September 9. His two-volume account of the expedition, *Fram over Polhavet* (English translation *Farthest North*), appeared in 1897.

Scientist. Nansen's success as an explorer was due largely to his careful evaluation of the difficulties that might be encountered, his clear reasoning, which was never influenced by the opinions of others, his willingness to accept a calculated risk, his thorough planning, and his meticulous attention to detail. Many of these traits can be recognized in his scientific writings. In 1882 he was appointed curator of zoology at the Bergen museum. He wrote papers on zoological and histological subjects, illustrated by excellent drawings. For one of his papers, "The Structure and Combination of Histological Elements of the Central Nervous System" (1887), the Christiania university conferred upon him the degree of doctor of philosophy. Though the paper contained so many novel interpretations that the committee that had to examine it accepted it with doubt, it is now considered a classic.

Work in oceanography

On his return from the "Fram" expedition in 1896, a professorship in zoology was established for Nansen at the Christiania university, but his interests shifted from zoology to physical oceanography; and in 1908 his status was changed to professor of oceanography. During 1896–1917 he devoted most of his time and energy to scientific work. He edited the report of the scientific results of his expedition and himself wrote some of the most important parts. He participated in the establishment of the International Council for the Exploration of the Sea and for some time directed the council's central laboratory in Christiania. In 1900 he joined the "Michael Sars" on a cruise in the Norwegian Sea. In 1910 he made a cruise in the "Frithjof" through the northeastern North Atlantic; in 1912 he visited the Spitsbergen waters on board his own yacht "Veslemoy," and in 1914 he joined B. Helland-Hansen on an oceanographic cruise to the Azores in the "Armauer Hansen." In 1913 Nansen travelled through the Barents Sea and the Kara Sea to the mouth of the Yenisey River and back through Siberia. He published the results of his cruises in numerous papers, partly in cooperation with Helland-Hansen. His lasting contributions to oceanography comprise improvement and design of instruments, explanation of the wind-driven currents of the seas, discussions of the waters of the Arctic, and explanation of the manner in which deep- and bottom-water is formed.

Nansen also dealt with other subjects: for instance, his *Nord i Tåkeheimen* (2 vol., 1911, English translation *In Northern Mists*, 1911) gives a critical review of the exploration of the northern regions from early times up to the beginning of the 16th century. Nansen's papers are all stimulating, but he wrote so fluently that he was likely to be verbose and his attention to detail made his presentation cumbersome. His great literary talent is, on the other hand, evident in his popular accounts of his journeys, many of which he himself illustrated.

Statesman and humanitarian. As Nansen grew older he became more and more interested in the relations between individuals and nations. In 1905 he took a lively part in the discussion about the dissolution of the union between Norway and Sweden. His attitude may be summarized by his words: "Any union in which the one people is restrained in exercising its freedom is and will remain a danger." On the establishment of the Norwegian monarchy, Nansen was appointed its first minister in London (1906–08). In 1917, during World War I, he was appointed head of a Norwegian commission to the United States and negotiated a satisfactory agreement with the U.S. government about the import of essential supplies to Norway.

At the first assembly of the League of Nations in 1920, the Norwegian delegation was headed by Nansen, who was to remain one of the outstanding members of the assembly until his death. With his tall and bony frame, his snow-white hair, his flowing moustache, and his broad-brimmed hat at a rakish angle, he made a striking figure in Geneva.

Work with the League of Nations

In April 1920 the council of the League of Nations gave Nansen his first great task, appointing him high commissioner responsible for the repatriation from Russia of about 500,000 prisoners of war from the former German and Austro-Hungarian armies. The Soviet government would not recognize the League of Nations but negotiated with Nansen personally, and in September 1922 he reported to the third assembly of the League that his task was completed and that 427,886 prisoners of war had been repatriated.

In August 1921 Nansen was asked by the International Committee of the Red Cross to direct an effort to bring relief to famine-stricken Russia. He accepted, and on August 15 a conference in Geneva, at which 13 governments and 48 Red Cross organizations were represented, appointed him high commissioner of this new venture. On August 27 he concluded an agreement with the Soviet government authorizing him to open in Moscow an office of the "International Russian Relief Executive." Nansen's request to the League for financial assistance was turned down, but by appealing to private organizations and by addressing large public meetings he succeeded in raising the necessary funds.

On July 5, 1922, on Nansen's initiative, an international agreement was signed in Geneva introducing the identification card for displaced persons known as the "Nansen passport." In 1931 the Nansen International Office for Refugees was created in Geneva (after Nansen's death); it cared mainly for the "White" Russians, for the Armenians from Turkey and, later, for the Jews from Germany.

In 1922 Nansen was awarded the Nobel Peace Prize; he used the prize money for the furtherance of international relief work.

Nansen died at his home at Lysaker near Oslo on May 13, 1930.

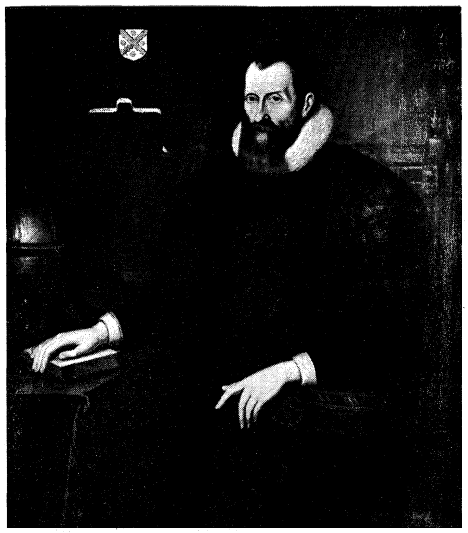
Napier, John

The invention of logarithms by the distinguished Scottish mathematician, John Napier (Neper), provided science and mathematics with a vastly improved and rapid method of notation and calculation. Active in church-state affairs all his life, he also wrote an influential work in support of Protestantism. He was born at Merchiston Castle, near Edinburgh, in 1550. At the age of 13, he entered the University of St. Andrews, but his stay appears to have been short, and he left without taking a degree.

By courtesy of the University of Edinburgh; photograph, the Scottish National Portrait Gallery



Napier, oil painting by an unknown artist, 1616. In the collection of the University of Edinburgh.

Little is known of his early life, but it is thought that he travelled abroad, as was then the custom of the sons of the Scottish landed gentry. He was certainly back home in 1571, and he stayed either at Merchiston or at Gartness for the rest of his life. He married the following year. A few years after his wife's death in 1579, he married again.

Protestant partisan

Napier's life was spent amid bitter religious dissensions. A passionate and uncompromising Protestant, in his dealings with the Church of Rome he sought no quarter and gave none. It was well known that James VI of Scotland hoped to succeed Elizabeth I to the English throne, and it was suspected that he had sought the help of the Catholic Philip II of Spain to achieve this end. Panic stricken at the peril that seemed to be impending, the general assembly of the Scottish Church, a body with which Napier was closely associated, begged James to deal effectively with the Roman Catholics, and on three occasions Napier was a member of a committee appointed to make representations to the king concerning the welfare of the church and to urge him to see that "justice be done against the enemies of God's Church."

In January 1594, Napier addressed to the king a letter that forms the dedication of his *Plaine Discovery of the Whole Revelation of Saint John*, a work that, while it professed to be of a strictly scholarly character, was calculated to influence contemporary events. In it he declared:

> Let it be your Majesty's continuall study to reforme the universall enormities of your country, and first to begin at your Majesty's owne house, familie and court, and purge the same of all suspicion of Papists and Atheists and Newtrals, whereof this Revelation forthtelleth that the number shall greatly increase in these latter daies.

The work occupies a prominent place in Scottish ecclesiastical history.

Following the publication of this work, Napier seems to have occupied himself with the invention of secret instruments of war, for in a manuscript collection now at Lambeth Palace, London, there is a document bearing his signature, enumerating various inventions "designed by the Grace of God, and the worke of expert craftsmen" for the defense of his country. These inventions included two kinds of burning mirrors, a piece of artillery, and a metal chariot from which shot could be discharged through small holes.

Mathematical contributions

Napier devoted most of his leisure to the study of mathematics, particularly to devising methods of facilitating computation, and it is with the greatest of these, logarithms, that his name is associated. He began working on logarithms probably as early as 1594, gradually elaborating his computational system whereby roots, products, and quotients could be quickly determined from tables showing powers of a fixed number used as a base.

His contributions to this powerful mathematical invention are contained in two treatises: *Mirifici Logarithmorum Canonis Descriptio*, which was published in 1614 (*Description of the Marvelous Canon of Logarithms*, 1857), and *Mirifici Logarithmorum Canonis Constructio*, which did not appear until 1619, two years after his death (*Construction of the Marvelous Canon of Logarithms*, 1889). In the former, he outlined the steps that had led to his invention.

Logarithms were meant to simplify calculations, especially multiplication, such as those needed in astronomy. Napier discovered that the basis for this computation was a relationship between an arithmetical progression—a sequence of numbers in which each number is obtained, following a geometric progression, from the one immediately preceding it by multiplying by a constant factor, which may be greater than unity (*e.g.*, the sequence 2, 4, 8, 16 . . .) or less than unity (*e.g.*, 8, 4, 2, 1, ½ . . .).

In the *Descriptio*, besides giving an account of the nature of logarithms, Napier confined himself to an account of the use to which they might be put. He promised to explain the method of their construction in a later work. This was the *Constructio*, which claims attention because of the systematic use in its pages of the decimal point to separate the fractional from the integral part of a number. Decimal fractions had already been introduced by the Flemish mathematician Simon Stevin in 1586, but his notation was unwieldy. The use of a point as the separator occurs frequently in the *Constructio*. Joost Bürgi, the Swiss mathematician, between 1603 and 1611 independently invented a system of logarithms, which he published in 1620. But Napier worked on logarithms earlier than Bürgi and has the priority due to his prior date of publication in 1614.

Although Napier's invention of logarithms overshadows all his other mathematical work, he made other mathematical contributions. In 1617 he published his *Rabdologiae, seu Numerationis per Virgulas Libri Duo* (*Study of Divining Rods, or Two Books of Numbering by Means of Rods*, 1667); in this he described ingenious methods of multiplying and dividing of small rods known as Napier's bones, a device that was the forerunner of the slide rule. He also made important contributions to spherical trigonometry, particularly by reducing the number of equations used to express trigonometrical relationships from ten to two general statements. He is also credited with certain trigonometrical relations—Napier's analogies—but it seems likely that the English mathematician Henry Briggs had a share in these. He died at Merchiston on April 4, 1617.

BIBLIOGRAPHY. The most exhaustive account of the life and work of John Napier is the *Napier Tercentenary Memorial Volume* (1915), ed. by C.G. KNOTT, which consists of articles on different aspects of Napier's work by a number of writers, each expert in his particular field. There is an English translation of the *Mirifici Logarithmorum Canonis Constructio* by WILLIAM RAE MACDONALD (1889). It contains a catalogue of all Napier's works and is compiled with great care and thoroughness. See also the article "Logarithms," by J.W.L. GLAISHER, in the *Encyclopædia Britannica*, 11th ed., vol. 16; and *An Account of the Life, Writings and Inventions of John Napier of Merchiston by* DAVID STEWART, EARL OF BUCHAN, and WALTER MINTO (1787).

(J.F.S.)

Naples

Naples (Italian Napoli, ancient Neapolis, or "New Town"), the great port city, intellectual centre, and financial capital of southern Italy, lies on the western shore of the Italian peninsula. It is 120 miles southeast of Rome and 210 miles northwest of the country's southernmost point. Situated between two furnaces of volcanic activity, Mt. Vesuvius (*q.v.*) on the west and the Campi Flegrei (Phlegraean Fields) on the east, the city curves around one of the most beautiful and celebrated bays of the world and climbs the encircling hills. The 18-mile-wide entrance to the bay from the Tyrrhenian Sea is flanked by the islands of Ischia (to the west) and Capri (to the east).

Naples, sometimes characterized as the most mysterious of European cities, has a multinational, multicultural, multilevel heritage, the complexity of which can be discerned in its streets, buildings, social attitudes, and customs. The past continually thrusts through the surface of the present, and history is an essential guide to modern Naples, which was the home of some 1,259,000 people at the 1971 census.

HISTORY OF NAPLES

Foundations and the Roman era. It seems probable that Neapolis, the "new town," was founded in about 600 BC by Greek colonists, but the community was captured by the Romans in 326 BC and subsequently played an important role as a Roman ally in the wars of the period. Under the Roman Empire the settlement was enriched with temples, gymnasiums, baths, aqueducts, hippodromes, and arenas; during the time of Marcus Tullius Cicero, the great Roman man of letters, many upper-class Romans were attracted to Neapolis, not least because of its Greek manners and way of life. It was also the favourite residence of many of the emperors: Nero made his first appearance on the stage in one of its theatres, and Marcus Aurelius lived in the city and frequented its schools. Poets who were associated with the city included Virgil, who composed his *Georgics* there. The numerous catacombs outside the city were built in the later centuries of Roman rule, with the earliest Christian foundations there dating from the 4th century AD.

Classical associations

The medieval and modern periods. In the wake of the barbarian invasions that accompanied the collapse of Rome, Naples was conquered in 536, acknowledged Byzantine suzerainty after 552, and, gradually experiencing a return to prosperity, became a Byzantine dukedom in the 7th century. The city was soon fighting to preserve its independence against attacks by Lombards, Saracen pirates, and Normans. It finally capitulated to the feudal Norman kingdom of Sicily in 1139, and its intellectual climate (where Latin had now replaced Greek), as well as its prosperity, subsequently suffered. A period of dynastic manoeuvring ensued, culminating in the city's asserting its independence again by welcoming Charles I of Anjou in 1266. He made Naples his capital, and, during his reign and those of his Angevin and Aragonese successors, it increased in size, population, and prosperity, becoming famous for the number and beauty of its palaces and churches. Following further succession disputes, Naples became a possession of the Spanish Habsburgs, whose viceroys ruled, often autocratically, from 1503 to 1704. The city developed considerably during this period, its street pattern was restructured, and it weathered both epidemics (notably that of 1656) and unrest (notably the dramatic 1647 uprising led by Tomaso Aniello, a fisherman better known as Masaniello). In 1734 Naples became the capital of an independent kingdom of Sicily, undergoing further embellishments at the hand of Prince Charles of Bourbon (later Charles III of Spain). In 1799 his son Ferdinand was ousted by a French revolutionary army, and the Parthenopean Republic was proclaimed. In 1806 Napoleon's brother Joseph Bonaparte was crowned king of Naples, but in 1815 a turbulent period was ended with the restoration of Ferdinand under the title "king of the two Sicilies." The city played its part in the movement toward Italian unity, finally becoming a part of the larger entity in 1860. The 19th and 20th centuries were marked by increasing industrialization, with associated symptoms of urban squalor and unrest, and the city suffered heavily in air attacks and ground fighting associated with the campaigns of World War II. The postwar period witnessed a number of attempts to improve conditions of life in the city, which, nevertheless, retains much of its traditional, crowded exuberance and an architectural heritage reflecting its complex past.

THE CONTEMPORARY CITY

The Neapolitan character. Generations of observers have described Naples as a vast popular theatre, and although there have been changes behind the scenes since the late 1960s, the outward spectacle has not altered much. Against the dramatic backdrop of Vesuvius and the bay, with the seafront embellished by two fortified castles, the decor is still one of moldering palaces and oft-rebuilt churches. The narrow streets (occasionally transformed into staircases) clamber up hillsides covered increasingly by new buildings. Neapolitans still live intensively in the street, which remains the market, playground, workshop, and living room for a good part of the population. The spectacle is colourful and extraordinarily animated. The casual visitor could regard it as a high-decibel comic opera, but to the actors it was, in the past, a real-life melodrama, often a tragedy. Today suffering is less wide-spread and less acute. Until well past the middle of the 20th century the mass of Neapolitans lived the way the urban poor all over Europe had lived for centuries. They were poor without much hope of changing their lot, except through emigration or crime, both of which flourished.

Poverty as a traditional way of life

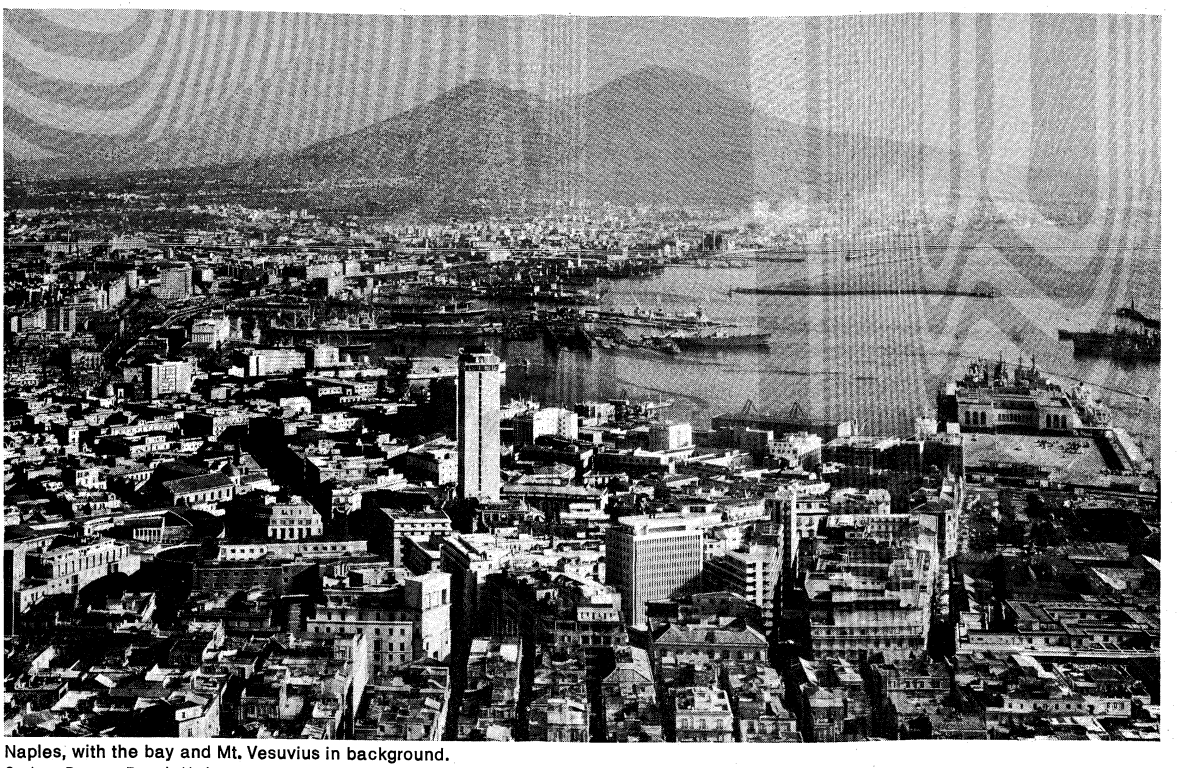
Two refuges from suffering were music and religion; the music that the Neapolitans created themselves was often gay, and their religion was passionate and personal. Their strength came from the family and spread to embrace the neighbourhood and finally the whole community. Their local patois became so developed that it was virtually a separate language. The little marvels of local cuisine—different kinds of pizza, pasta, and shellfish dishes—were all ways of making poverty more digestible.

Most of the time workers made ends meet somehow without regular employment. As late in the 20th century as 1951, when the population was 1,011,919, only 200,431 Neapolitans had regular jobs. This meant that there were fewer wage earners in the city than there were families (222,047). Since that time, things have improved noticeably, not to the point of general prosperity but at least above the level of general despair.

As prosperity and progress expand, the picturesque evaporates. Now that so many people can afford radios, television, and tickets to the cinema and now that the tourist industry is an important part of the economy, the Neapolitan "language" is disappearing. The gaily painted market cart is vanishing in favour of the three-wheeled delivery van, the street musician is rarely seen, and the hurdy-gurdy man is almost extinct.

Most neighbourhoods still string garlands of coloured electric bulbs, festoon the church, and open the festival of the parish patron saint with a parade of relics and banners through the streets; but the celebrations are less fervent and of shorter duration. The festival of our Lady of Piedigrotta still occupies six days of the calendar, and the streets around the church are illuminated, but most of the merrymaking and fireworks are confined to a single night. The parade of floats and the song and dance contests have been removed to a public park two miles away to keep the main street clear.

Neapolitans seem to revel in human contact. What could be deplored elsewhere as overcrowding has long been normal there. In their centuries of bare survival Neapolitans learned how to make inhuman conditions tolerable by preserving respect for the individual. In a society of nobodies, everybody, it appears, is somebody. No one is excluded as unworthy: children are to be seen and heard, and the elderly are welcome to act as if they were still in charge.



Naples, with the bay and Mt. Vesuvius in background.
Gaetano Barons—Bavaria-Verlag

In maintaining their mutual respect, in keeping their family and neighbourhood structure, in maintaining their gaiety and enterprise, in continuing a lively dialogue with their saints, the people of Naples may have found the solution to a problem that bedevils other metropolitan populations: how to live happily under modern urban conditions.

Another folk tradition, disrespect for authority, is still lively. Now that Neapolitans have automobiles and motor bicycles, they roar up one-way streets the wrong way and make forbidden turns, taking care only to avoid squashing street urchins even more heedless than they. On street corners, properly clad matrons hold market baskets of contraband cigarettes for sale.

The role of crime

Thievery, most of it petty, is another Naples tradition with many adepts. The local tourist board has warned visitors that parked automobiles are likely to be rifled, if not stolen. Handbag snatching in the early 1970s was epidemic during the tourist season. Yet, in contrast with some other great Western cities, violent crime against persons is fairly rare in Naples. It was not always thus. Murder in the streets was common until the way was lighted in about 1770 by hundreds of street-corner shrines, privately installed following a campaign by Father Rocco, a Dominican priest whose objectives were as much civic as religious.

The blind violence and criminality of the slums were organized in the 19th century by the Camorra, a secret society somewhat similar to the Sicilian Mafia. The liberation of Naples in 1943 was the occasion of the birth of a new Camorra, dominating what may have been the biggest black-market operation in Europe.

Planning and the urban economy. The improvement visible in Naples is the result of the concerted action of state planning and fiscal agencies and of companies either owned or controlled by the national government. Local enterprise is associated with the programs. New roads, port installations, modernized transport and communications, and expansion of energy production furnished the base for restructuring the economy of the region. A wedge of land between the freight yards and the waterfront in the east end of town was developed as an industrial zone. Existing industry was modernized and enlarged, and new industries were introduced.

A small but significant example was the Municipal Milk Central, which, after modernization of methods and machinery in 1966, was able to double production and sales and eliminate losses in three years. This implies an improvement in the health and purchasing power of the community, as well as an expansion of dairy farming in the region.

Under the Bourbons, Naples had an early start in industry, with foundation of the porcelain factory at the royal palace of Capodimonte in 1740 and the development of silk and other textile production soon after. In 1818 the first steamboat on the Mediterranean was launched at the royal shipyards. Remodelling of the port was begun in 1826. In 1839 Italy's first railway chugged along the five miles from Naples to the court resort of Portici. The first funicular railway on the peninsula was opened to the heights of Vomero in 1880 to the lilt of the new, prize-winning song from the Lady of Piedigrotta festival, "Funiculì-Funiculà." The first steel mill opened at the end of the 19th century, but the industry did not add significantly to national production until the 1970s. Among the newer industries in the region are electronics and petroleum products. The tourist industry, aided by state financing and planning, also expanded at the end of the 1960s. The crescent of the bay is set with tourist gems—Capri, Ischia, Vesuvius, Herculaneum, Pompeii, and Sorrento —and just to the south on the Gulf of Salerno are Amalfi and Paestum. The greatly augmented number of ferries, high-speed boats (*alsiscafi*), helicopters, and motor coaches serving tourists add to the air pollution already heavy from industrial fallout. The famous view is veiled with smog, except when the wind veers from its prevailing direction.

Water pollution in Naples is as bad as it is in every major port city in Italy. The waters that were once the siren Parthenope's home are closed to swimmers, and the celebrated shellfish are infected with hepatitis.

Topography and architecture. The old volcanic site of the city is pierced with man-made galleries, some of which have yet to be fully explored and some of which were opened by the Romans. During World War II the tunnels served as bomb shelters. Today some uncharted passage occasionally gives way, tumbling houses and leaving gaping craters in the streets: from 1959 to 1971 some 200 Neapolitans lost their lives in such collapses. The best known of the grottoes are the catacombs of S.

The catacombs

Gennaro and S. Gaudioso—some of them sculptured and frescoed—in the northern slopes, and the traffic tunnels (of very early origin) passing under Collina di Posillipo (Posillipo Hill) from the western edge of town.

At the foot of this hilly peninsula is the little port of Mergellina, from which the four miles of urban coastline curve westward to the giant commercial port. Along the first stretch toward the centre of town lies the 1,000-yard-long Villa Comunale, a somewhat seedy but happy public park that contains the Aquirio (Aquarium) and several outdoor musical cafés, which are augmented by scores of ambulant vendors of food, drink, and toys. Families promenading beneath the dusty trees amid the cheery clamour bring a turn-of-the-century innocence to the 1970s. The seafront is bordered by the sweeping Via Caracciolo, while along the inland border of the park runs the Riviera di Chiaia, which denotes the name of the whole neighbourhood. The name *chiaia* derives from the Latin *plaga* ("beach, flatland"), from which the French extracted *plage* and the Italians *spiaggia,* a development too simple for Naples.

The Chiaia was a favourite residence of foreigners, particularly the British, in the late 18th and early 19th centuries. The Museo Principe Diego Arangona Pignatelli Cortes, full of period furnishings, was begun as the residence of Sir John Acton, prime minister for the last Bourbon king.

Today one of the choice residential sections is Vomero, on the heights just above. Three funiculars descend to different quarters of the older part of the city. A spur off the Vomero heights was fortified in 1329 by King Robert of Anjou, and the installation was rebuilt in the form of a six-pointed star by the Spanish in 1537. This vast mass of masonry, known as the Castel Sant'Elmo, which still dominates Naples, was a key to the city's defense for centuries. The adjacent Museo di S. Martino was built in the 14th century as a monastery and largely remade in the 16th and 18th centuries. Its collections are concerned mostly with the city itself (of which there is a magnificent view from Room 25), including a Nativity scene peopled by hundreds of the traditional, locally made clay figurines.

From Chiaia the waterfront road, changing its name to Via Partenope, swings through the ancient *borgo marinaro* of Sta. Lucia below the headland of Pizzofalcone. Its picturesque squalor has given way to luxury hotels that look out over the tiny harbour bordered by yacht clubs and the renowned dockside restaurants. The west side of the harbour is formed by a causeway, the south side by the island the ancients called Megarus (Isola di Megaride), where Lucullus had one of his several Neapolitan villas. In the 12th century the Normans built a fortified castle there, expanded by their successors, the Hauenstauffens, and further enlarged and embellished by the Angevin kings of the 13th century. The hulking, sheer-walled, adobe-coloured bulk is today a military installation.

A little farther along, past the bathing beach and another public park (Giardini Litoranei), is the major port for the ferries that crisscross the bay, and just beyond is the New Maritime Terminal for ocean liners. The importance of the passenger port (until then Italy's largest) was greatly reduced in the 1970s with curtailment of many shipping services.

The Castel Nuovo

Up on the shore, to the west of the big Piazza Municipio, is the moated, turreted Castel Nuovo (New Castle), built in 1279–82 by Robert I of Anjou. It is also often called the Maschio Angioino (Angevin Fortress), one of the many local landmarks to bear two names, used interchangeably. In the mid-15th century the castle was extensively rebuilt by Alfonso I of Aragon, who also added a sculptured marble triumphal arch to the entry, one of the most distinguished Renaissance works in Naples. Still loyal to the Angevins, the barons of Apulia in 1486 mounted a conspiracy against the Aragonese. Ferdinand I, also called Ferrante, who reigned from 1458 to 1494, announced the betrothal of his niece to the son of one of the plotters and invited them all to a banquet at the castle, from which they did not emerge alive. The banquet room, called the Barons' Hall, is now the meeting place of the Naples Municipal Council. The municipal offices are at the opposite end of the oblong Piazza Municipio, in a building erected in 1819 for the ministerial offices of Ferdinand I (Ferdinand IV of Naples).

The castle grounds extend westward to abut the garden of the 17th-century Palazzo Reale (Royal Palace), through which lies the entrance to the Biblioteca Nazionale (National Library). Having grown out of the Farnese collection, the library contains many prizes, including the papyrus discovered at Herculaneum in 1752. Also in the palace are government offices, some restored state apartments, and a 1768 court theatre. The palace, which was built by Domenico Fontana for the Spanish viceroy, was damaged by fire in 1837, again in 1942 by aerial bombs, and again, more seriously, by Allied military occupation. The facade on the Piazza del Plebiscito remains almost as it was originally designed, with the addition of statues representing eight of Naples' ruling dynasties, from Roger Guiscard to Victor Emmanuel II of Savoy and Italy.

The piazza is now devoted in large part to service as an open-air bus terminal. The entire semicircle of the western side is occupied by a colonnade erected by Murat in 1810, in the centre of which King Ferdinand I placed, seven years later, the church of S. Francesco di Paola, fulfilling a vow he had made when praying for the return of his kingdom.

North of the piazza is the smaller Piazza Trieste e Trento. It is also called the Piazza S. Ferdinando because of the 17th-century church (like most Neapolitan churches, extensively rebuilt later) of that name, where the "Stabat Mater" of Pergolesi, written for the archconfraternity of the church, is performed every Good Friday. Below the church and adjacent to the Royal Palace is the renowned Teatro S. Carlo, home of Neapolitan opera. It was built between March and November 1737; the facade was added in 1810, and the interior was rebuilt after a fire in 1816. The acoustics of the six-tiered interior are considered perfect for bel canto: Rossini, Bellini, and Donizetti all wrote operas for the S. Carlo.

The Teatro S. Carlo

Across the street is one of the entrances to the cruciform Galleria Umberto I. The arcades of shops and offices, adrip with carvings, rise to a barrel-vaulted roof of glass on iron trellises. The mosaic pavements are dotted with busy café tables.

One of the galleria's entries opens onto the Via Roma, still often called the Toledo, the name the street bore for centuries after its construction by the Spanish viceroy in 1536. To the west of this main avenue he constructed the dozen tiny streets of quarters for his soldiers. Today's inhabitants of the *quartieri* overflow into the narrow, stepped streets, the *gradini.*

At the top of the street and a little to the right is the Museo Archeologico Nazionale, a red brick pile thrown up in 1586 as a cavalry barracks, used by the university in 1616–1777, and in 1790 remodelled to receive the royal collections, the nucleus of which were the Farnese collection, inherited by Charles III from his mother, Isabella of Spain, born Elisabetta Farnese. Charles had begun construction of Capodimonte palace on the hills above the city in 1738 to house the family treasures; but the discoveries at Herculaneum, Pompeii, and other nearby sites soon overflowed the palace, and everything was moved to the museum in town, remodelled for its new function. The Biblioteca Nazionale was removed to the Palazzo Reale and the National Gallery of Paintings to Capodimonte (1957). The Farnese marbles, most of them looted from the public baths of Rome, remain, as do the evocative murals from the villas of Pompeii, Herculaneum, and Stabbia, the Pompeiian mosaics, the Herculaneum bronzes, and a superb sampling of Greek and Roman art.

The Bourbons built the Piazza Dante in the mid-18th century halfway up the Toledo, where a gateway had been erected in 1625 and rebuilt in 1797. The Via Porta Alba behind the gate was once crowded with pizzerias, and many an expatriate establishment in the Italian section of American cities still bears the nostalgic name.

Directly eastward the Via S. Pietro a Maiella begins, named for the recently restored church (late 13th–early 14th century) dedicated to S. Pietro Angeleri, a cleric from the Montagna della Maiella (Maiella Mountains) who became Pope Celestine V in 1294, abdicated after six months, and died in 1296 as a prisoner of his successor, Boniface VIII. The former monastery adjacent to the church became the famous Conservatory of Music in 1816, comprised of four other existing schools of music. Its origins ultimately trace back to 1537, making it the oldest conservatory in the Occident. In the Teatro Bellini (1874), a few streets to the north, a local tenor named Enrico Caruso made his debut in 1894.

Going east the street changes its name to the Via Tribunali, at the far end of which is the Naples tribunal, where local lawyers give performances perhaps surpassed only by the singers at the S. Carlo. The courts building is known as the Vicaria and as the Castel Capuano, for it was founded by the Norman William I, enlarged and fortified by Frederick II, and frequently used as a royal residence by King Ladislas and by Queen Joan II. Behind the castle is the beautiful Renaissance gateway (1484)—one of Italy's finest—designed by Giuliano da Maiano. The piazza between the castle and the gate is one of the big outdoor markets for the farmers who bring in their produce from nearby Poggioreale. The next gateway to the south, Porta Nolana, marks the beginning of the fish market along the Via Carmignano, which terminates at the church of Sta. Maria del Carmine, a 12th-century foundation since restored many times (campanile, 1631; facade, 1766). Connected with the Masaniello revolt of 1647, it is still the church of simple fisherfolk and sailors, its cloisters hung with crude and touching ex-votos.

Gateways and the markets

The Via Tribunali was the middle one of the three *decumani* of ancient Neapolis. The upper, just to the north, is now the Via dell' Anticaglia. South of the Via Tribunali the lower *decumanus* changes its name many times in its east–west course of about one mile—the vias Pasquale Scura, Domenico Capitelli, Benedetto Croce, Largo Corpo di Napoli, S. Biagio dei Librai, Vicaria Vecchia, and Forcella—but is usually referred to by one name, as a single entity: Spaccanapoli, the street that sliced ancient Naples in two. At right angles to the three axes, small streets ran down toward the harbour. The layout unchanged, this antique, original city—little expanded in area until the Angevin epoch—is still the heart of old Naples. After the cholera epidemic of 1884, Premier Agostino Depretis decreed the *sventramento* ("gutting") of the slums of the Porto and Mercato districts, and from the Piazza Bovio a straight, ugly street was driven to slant up to the central railroad station. It was named the Corso Umberto I, but the people call it the Rettifilo.

The site of Neapolis is sprinkled with churches (more than 50 of the city's 135 ancient churches) and palaces (perhaps 100). Along the Via Tribunali there are, for example, seven churches. One of these is the recently restored French Gothic church of S. Lorenzo Maggiore, established by Charles I of Anjou on the site of a 6th-century church and built over a corner of the Greco-Roman forum of Neapolis, remains of which lie underneath. Another is S. Paolo Maggiore, 1591–1603, which incorporates in its facade Corinthian columns of a Greek temple to the Dioscuri that once stood on the site.

Crossing Tribunali and the other *decumani*, the Via del Duomo runs down to the bay. The cathedral Duomo was built 1294–1323 on the site of the 5th-century basilica of Stefania. It adjoins the 4th-century basilica—the first in Naples—of Sta. Restituta, containing the small baptistery of S. Giovanni in Fonte, which has some 5th-century mosaics. Both the cathedral and Sta. Restituta have suffered earthquake and restoration, and a good deal of what can be seen is of 18th- and 19th-century origin. The facade retains its original doorways, however. In the summer of 1971 remains of a 5th-century BC Greek temple were found under the floor.

The cathedral is dedicated to S. Gennaro (St. Januarius), the patron saint of the city. His two festivals, the first Saturday in May and the seven days that follow September 19, the day of the saint's decapitation in AD 305, are genuinely popular festivals and genuinely festive. The saint's reliquary is paraded through the decorated streets, and the church is jammed for the liquefaction of his blood. If the congealed blood, contained in two phials, fails to liquefy, hordes of Neapolitans expect ill fortune for their city. They recall that in 1527 there was a plague, in 1569 a famine, and in 1941 eruption of Vesuvius and aerial bombardment.

The festivals of San Gennaro

Along the Spaccanapoli there are four important churches and an unusually curious chapel. The Gesù Nuovo was, in the 15th century, the imposing palace of the Sanseverini, princes of Salerno, its facade an unbroken wall of white volcanic basalt and each stone shaped into a raised point. Its conversion into a Jesuit church was begun in 1584 and was completed in the 17th century. Across the way is the monastery of Sta. Chiara (now public offices), built (1310–28) for the Friars Minor as part of the Franciscan enclave established by Angevin King Robert and Queen Sancia of Majorca. Next to the church is the convent of the Poor Clares, the 14th-century cloister decorated with 18th-century majolica tiles. The church itself, approached through a 14th-century arch, burned for 48 hours after an incendiary bombing by the Allies in 1943. Reconsecrated in 1953, it has been restored to its original austere French Gothic. Some Angevin tombs, magnificent although bomb damaged, are still to be seen.

Farther east along the Spaccanapoli is the Dominican monastery where St. Thomas Aquinas, whose cell still exists, studied as a youth and returned to teach (1272–74). Among the students of a later age were the humanist Giovanni Pontano and the philosopher Giordano Bruno. In the adjacent church of S. Domenico Maggiore the main chapel holds the 13th-century painting of the crucifix that, it is said, spoke to St. Thomas, asking what he desired as a reward for his religious labours; he replied, "None other than thee." The 1289 church, incorporating a much older house of worship, has been rocked by earthquakes, gnawed by fires, and mutilated by restorers; it possesses a Titian "Annunciation" and Caravaggio's "Flagellation."

The much-restored apsidal end of the church presents its crenellations, patched piers, and walls to the Piazza S. Domenico, which, like the space before Gesù Nuovo, is decorated with a guglia (memorial column), this one to mark the end of the 1656 plague. Also on the piazza is one of the most noted coffee bars of Naples, a city that offers the best coffee in the world, according to natives, who, unlike the Viennese, drink it down without ceremony. The piazza is surrounded by four palaces: one built for the Del Balzo family in the 15th century (Del Balzo is Neapolitan for the noble Provençal name des Baux), the others for branches of the Sangro family, whose burial chapel is just off the piazza. Built at the end of the 14th century, the Capella Sansevero, also called Sta. Maria della Pietà dei Sangro, is noted for its implacably inspirational sculptures of the 18th century. Equally celebrated in Naples are the seven life-size, realistic terra-cotta figures grouped about a full-size, outstretched Christ (the 1492 "Pietà" of Guido Mazzoni) on the pavement in the right transept of Sant'Anna dei Lombardi (or Monteoliveto) to the southeast. The church, erected in 1414 and favoured by the Aragonese, contains much fine Renaissance sculpture. The Monteoliveto monastery is today a police barracks.

The Piazza S. Domenico

The Via Mezzocannone, which leads south out of the Piazza S. Domenico to the Rettifilo, borders the university, which was founded in 1224 by Emperor Frederick II for the purpose, as one critic wrote, of training "good Ghibelline clerks who could counter the influence of Popes and northern Guelfs." In addition to the original 18th-century installations in an old Jesuit monastery and the new (1887–1908) extensions, the University has some of its ten faculties located elsewhere. The Palazzo Giusso, near the church of S. Giovanni Maggiore, houses the Istituto Universitario Orientale (Oriental Institute), and the Palazzo Gravina (1539–41) is the School of Architecture.

The Palazzo Filomarino, rebuilt in 1512 on that part of

the Spaccanapoli that bears the name of Benedetto Croce, was the home of the scholar until his death in 1952. He bequeathed his excellent library and the palace to the Istituto Italiano per gli Studi Storici (Italian Institute for Historical Studies). To the right of the Filomarino is the 15th-century Palazzo Carafa della Spina, and farther down the Spaccanapoli are two other palaces of the same period belonging to members of the same family, the Carafa di Montorio and the Palazzo di Diomede Carafa. In the Via del Duomo the Renaissance Palazzo Duomo is now the Museo Civico Filangieri (Filangieri Civic Museum), with a collection of paintings, sculpture, and porcelains.

The housing problem

Scores of other palaces have been renovated by the municipality and by such local firms as the Bank of Naples. Many of the noble frontages are still pricked with little workshops that are literally holes in the wall, and most palaces are carved up into apartments, some among the most desirable in the city and others dark and dank with whole families jammed into *bassi* (one-room ground-floor apartments). It is thus that the historic heart of the city still beats vigorously, with few signs of the morbidity visible in other cities. It would seem to indicate that Neapolitans accept privations to cling to the old (and "old" is counted in millennia here) neighbourhood, but these are the same people who make 2,000 applications for every vacancy in modern public-housing developments.

Some of the new public housing has been erected on the hills that rise behind the city and that were until the end of the 1960s largely wooded areas and green fields. At the farthest and highest point, above the observatory (1819) and the catacombs, is the palace of Capodimonte in its splendid park. Started by Charles the III in 1738, it was finished a century later, a favourite royal residence. The art collections are mainly mediocre, possibly enhancing the impression made by the few masterpieces: Titian's "Danae with Nursemaid," Pieter Brueghel the Elder's "The Parable of the Blind," Jan Brueghel's "Winter Scene," a Masaccio "Crucifixion," two Goya portraits, and drawings by Michelangelo, Tintoretto, Raphael, and Rembrandt. The Farnese collection of arms and armour and the porcelain exhibitions are also of first quality.

The hilltop route from Capodimonte to Vomero once wound along country roads under chestnut trees through rural settlements; since the late 1960s it has been built up, including luxury housing erected illegally in green-belt reserves. It was reported at the beginning of 1972 that the desecration of the heights by profit seekers had been in vain: 80,000 new, high-priced rooms remained vacant.

BIBLIOGRAPHY

General: E. HUTTON, *Naples and Campania Revisited* (1958), a thorough treatment of the various districts of the city and its museums, galleries, churches, and palaces, with a sketch of the historical background; PETER GUNN, *The Companion Guide to Southern Italy* (1969), of which the early part deals with Naples and its environs, including Vesuvius, Herculaneum, and Pompeii.

The past: PETER GUNN, *Naples: A Palimpsest* (1961), largely a popular history, although there is some discussion of contemporary Naples; HAROLD ACTON, *The Bourbons of Naples, 1734–1825* (1956) and *The Last Bourbons of Naples, 1825–1861* (1961), a scholarly and detailed history of the Kingdom of Naples before it became part of the united Italy.

Chiefly photographic: KURT OTTO-WASOW, *The Bay of Naples,* with introduction and commentaries by WILLIAM SANSON (1960), colour photographs that stress the beauty of the city; JAN LUKAS, *Naples,* with an introduction by PETER GUNN (1965), buildings, streets, and monuments, with scenes from the daily life of the people; CAS OORTHUYS, *This Is Naples, Capri, Pompeii, Paestum* (1964), a compact paperback with evocative photographs of the city and its surroundings that includes explanatory notes.

Special topics: MORRIS WEST, *Children of the Sun* (1957), life in the slums of Naples and charitable work among the street urchins by Father Mario Borrelli, founder of the Casa dello Scugnizzo (House of Urchins); MARIO BORRELLI, *A Street Lamp and the Stars* (1963), his autobiography, written with the help of ANTHONY THORNE.

(B.E.)

Napoleon

Napoleon Bonaparte, a French general, as first consul and then as emperor of the French, carried out many reforms that left a lasting mark on the institutions of France and of much of western Europe. But his driving passion was the military expansion of French dominion, and, though at his fall he left France smaller than it had been at the outbreak of the Revolution in 1789, he was almost unanimously revered during his lifetime and until the end of the Second Empire under his nephew Napoleon III as one of history's great heroes.

Napoleon was born at Ajaccio on the island of Corsica on August 15, 1769, shortly after the cession of Corsica to France by the Genoese. He was the fourth, and second surviving, child of Carlo Buonaparte, a lawyer, and his wife, Letizia Ramolino. His father's family, of ancient Tuscan nobility, had emigrated to Corsica in the 16th century.

Carlo Buonaparte had married the beautiful and strong-willed Letizia when she was only 14 years old; they eventually had eight children to bring up in very difficult times. The French occupation of their native country was resisted by a number of Corsicans led by Pasquale Paoli. Carlo Buonaparte joined Paoli's party, but when Paoli had to flee, Buonaparte came to terms with the French. Winning the protection of the governor of Corsica, he was appointed assessor for the judicial district of Ajaccio in 1771. In 1778 he obtained the admission of his two eldest sons, Joseph and Napoleon, to the Collège d'Autun.

Early years and education in France

A Corsican by birth, heredity, and childhood associations, Napoleon continued for some time after his arrival in Continental France to regard himself a foreigner; yet from the age of nine he was educated in France as other Frenchmen were. While the tendency to see in Napoleon a reincarnation of some 14th century Italian *condottiere* is an overemphasis on one aspect of his character, he did, in fact, share neither the traditions nor the prejudices of his new country: remaining a Corsican in temperament, he was first and foremost, through both his education and his reading, a man of the 18th century.

Napoleon was educated at three schools: briefly at Au-

Giraudon

tun, for five years at the military college of Brienne, and finally for one year at the military academy in Paris. It was during Napoleon's year in Paris that his father died of a stomach cancer in February 1785, leaving his family in straitened circumstances. Napoleon, although not the eldest son, assumed the position of head of the family before he was 16. In September he graduated from the military academy, ranking 42nd in a class of 51.

He was made second lieutenant of artillery in the regiment of La Fère, a kind of training school for young artillery officers. Garrisoned at Valence, Napoleon continued his education, reading much, in particular works on strategy and tactics. He also wrote *Lettres sur la Corse*, in which he reveals his feeling for his native island. He went back to Corsica in September 1786 and did not rejoin his regiment until June 1788. By that time the agitation that was to culminate in the French Revolution had already begun. A reader of Voltaire and of Rousseau, Napoleon believed that a political change was imperative, but as a career officer he seems not to have seen any need for radical social reforms.

THE REVOLUTIONARY PERIOD

The Jacobin years. When in 1789 the National Assembly, which had convened to establish a constitutional monarchy, allowed Paoli to return to Corsica, Napoleon asked for leave and in September joined Paoli's group. But Paoli had no sympathy for the young man, whose father had deserted his cause and whom he considered to be a foreigner. Disappointed, Napoleon returned to France; and in April 1791 he was appointed first lieutenant to the 4th regiment of artillery, garrisoned at Valence. He at once joined the Jacobin club, a debating society initially favouring a constitutional monarchy, and soon became its president, making speeches against nobles, monks, and bishops. In September 1791 he got leave to go back to Corsica again for three months. Elected lieutenant colonel in the national guard, he soon fell out with Paoli, its commander in chief. When he failed to return to France, he was listed as a deserter in January 1792. But in April France declared war against Austria and his offense was forgiven.

Apparently through patronage, Napoleon was promoted to the rank of captain but did not rejoin his regiment. Instead he returned to Corsica in October 1792, where Paoli was exercising dictatorial powers and preparing to separate Corsica from France. Napoleon, however, joined the Corsican Jacobins, who opposed Paoli's policy. When civil war broke out in Corsica in April 1793, Paoli had the Buonaparte family condemned to "perpetual execration and infamy," whereupon they all fled to France.

Napoleon Bonaparte, as he may henceforth be called (though the family did not drop the spelling Buonaparte till after 1796), rejoined his regiment at Nice in June 1793. In his *Souper de Beaucaire*, written at this time, he argued vigorously for united action by all republicans rallied round the Jacobins, who were becoming progressively more radical, and the National Convention, the revolutionary assembly that in the preceding fall had abolished the monarchy. At the end of August 1793, the National Convention's troops had taken Marseilles but were halted before Toulon, where the royalists had called in British forces. With the commander of the National Convention's artillery wounded, Bonaparte got the post through the commissioner to the army, Antoine Saliceti, who was a Corsican deputy and a friend of Napoleon's family. Bonaparte was promoted to major in September and adjutant general in October. He received a bayonet wound on December 16, but on the next day the British troops, harassed by his artillery, evacuated Toulon. On December 22 Bonaparte, aged 24, was promoted to brigadier general in recognition of his decisive part in the capture of the town.

Capture of Toulon

Augustin de Robespierre, the commissioner to the army, wrote to his brother Maximilien, by then virtual head of the government and one of the leading figures of the Reign of Terror, praising the "transcendent merit" of the young republican officer. In February 1794 Bonaparte was appointed commandant of the artillery in the French Army of Italy. Robespierre fell from power in Paris on 9 Thermidor (July 27, 1794). When the news reached Nice, Bonaparte, regarded as a protégé of Robespierre, was arrested on a charge of conspiracy and treason. He was freed in September but was not restored to his command. The following March he refused an offer to command the artillery in the Army of the West, which was fighting the counter-revolution in the Vendée. The post seemed to hold no future for him, and he went to Paris to justify himself. Life was difficult on half pay, especially as he was carrying on an affair with Désirée Clary, daughter of a rich Marseilles businessman and sister of Julie, the bride of his elder brother, Joseph. Despite his efforts in Paris, Napoleon was unable to obtain a satisfactory command because he was feared for his intense ambition and for his relations with the "Montagnards," the more radical members of the National Convention. He then considered offering his services to the sultan of Turkey.

The Directory. Bonaparte was still in Paris in May 1795 when the National Convention, on the eve of its dispersal, submitted the new constitution of the year III of the First Republic to a referendum, together with decrees according to which two-thirds of the members of the National Convention were to be re-elected to the new legislative assemblies. The royalists, hoping that they would soon be able to restore the monarchy, instigated a revolt in Paris to prevent these measures from being put into effect. Vicomte Paul de Barras, who had been entrusted with dictatorial powers by the National Convention, was unwilling to rely on the commander of the troops of the interior; instead, knowing of Bonaparte's services at Toulon, he appointed him second in command. Thus, it was Napoleon who shot down the columns of rebels marching against the National Convention (13 Vendémiaire, year IV; October 5, 1795), thereby saving the National Convention and the republic.

Bonaparte became commander of the army of the interior and, consequently, was henceforth aware of every political development in France. He also became the respected adviser on military matters to the new government, the Directory. Lastly, he came to know an attractive Creole, Joséphine Tascher de La Pagerie, the widow of Gen. Alexandre de Beauharnais (guillotined during the Reign of Terror), the mother of two children, and a woman of many love affairs.

From every point of view, a new life was opening for Bonaparte. Having proved his loyalty to the Directory by dissolving a communistic group led by François Babeuf and an Italian, Filippo Buonarroti, whom Bonaparte had known in Corsica, he was appointed commander in chief of the Army of Italy in March 1796. He had been trying to obtain that post for several weeks so that he could personally conduct part of the plan of campaign adopted by the Directory on his advice. He married Joséphine on March 9 and left for the army two days later.

Commander in chief of Army of Italy

Arriving at his headquarters in Nice, Bonaparte found that his army, which on paper consisted of 43,000 men, numbered scarcely 30,000 ill-fed, ill-paid, and ill-equipped men. On March 28, 1796, he made his first proclamation to his troops:

> Soldiers, you are naked, badly fed . . . . Rich provinces and great towns will be in your power, and in them you will find honour, glory, wealth. Soldiers of Italy, will you be wanting in courage and steadfastness?

He took the offensive on April 12 and successively defeated and separated the Austrian and the Sardinian armies and then marched on Turin. King Victor Amadeus III of Sardinia asked for an armistice; and, at the peace treaty in Paris on May 15, Nice and Savoy, occupied by the French since 1792, were annexed to France. Bonaparte continued the war against the Austrians and occupied Milan but was held up at Mantua. While his army was besieging this great fortress, he signed armistices with the duke of Parma, the duke of Modena, and finally with Pope Pius VI.

At the same time, he took an interest in the political organization of Italy. A plan for its "republicanization" by a group of Italian "patriots" led by Buonarroti had to

be shelved when Buonarroti was arrested for complicity in Babeuf's conspiracy against the Directory. Thereafter, Bonaparte, without discarding the Italian patriots altogether, restricted their freedom of action. He set up a republican regime in Lombardy but kept a close watch on its leaders, and in October 1796 he created the Cisalpine Republic by merging Modena and Reggio nell'Emilia with the papal states of Bologna and Ferrara occupied by the French Army. Finally he sent an expedition to recover Corsica, which the British had evacuated.

Defeat of the Austrians and peace terms

Austrian armies advanced four times from the Alps to relieve Mantua but were defeated each time by Bonaparte. After the last Austrian defeat, at Rivoli in January 1797, Mantua capitulated. Next, he marched on Vienna. He was about 60 miles (100 kilometres) from that capital when the Austrians sued for an armistice. By the preliminaries of peace, Austria ceded the southern Netherlands to France and recognized the Lombard republic but received in exchange some territory belonging to the old Republic of Venice, which was partitioned between Austria, France, and Lombardy. Bonaparte then consolidated and reorganized the north Italian republics and encouraged Jacobin—radical republican—propaganda in Venetia. Some Italian patriots hoped that these developments would soon lead to the formation of a single and indivisible "Italian Republic" modelled on the French.

Meanwhile, Bonaparte grew uneasy at the successes of the royalists in the French elections in the spring of 1797 and advised the Directory to oppose them, if necessary, by force. In July it attempted a coup d'etat against the royalists and failed; thereupon Bonaparte sent Gen. Pierre Augereau to Paris, along with several officers and men. Augereau's successful coup d'etat of 18 Fructidor (September 4, 1797) eliminated the royalists' friends from the government and legislative councils and also enhanced Bonaparte's prestige. Thus, Bonaparte could conclude the peace Treaty of Campo Formio with Austria as he thought best. The Directory was displeased, however, because the Treaty had ceded Venice to the Austrians and did not secure the left bank of the Rhine for France. On the other hand, it raised Bonaparte's popularity to its peak, for he had gained victory for France after five years of war on the Continent.

Only the war at sea, against the British, continued. The directors, who wanted to launch an invasion of the British Isles, appointed Bonaparte to command the army assembled for this purpose along the English Channel. After a rapid inspection in February 1798, he announced that the operation could not be undertaken until France had command of the sea. Instead, he suggested that France strike at the sources of Great Britain's wealth by occupying Egypt and threatening the route to India. This proposal, seconded by Talleyrand, the foreign minister, was accepted by the directors, who were glad to get rid of their ambitious young general.

Failures in Egypt

The expedition, thanks to some fortunate coincidences, was at first a great success: Malta, the great fortress of the Knights Hospitallers of St. John of Jerusalem, was occupied on June 10, 1798, Alexandria taken by storm on July 1, and all the delta of the Nile rapidly overrun. On August 1, however, the French squadron at anchor in Abū Qīr Bay was completely destroyed by Adm. Horatio Nelson's fleet in the Battle of the Nile, so that Napoleon found himself confined to the land that he had conquered. He proceeded to introduce Western political institutions, administration, and technical skills in Egypt; but Turkey, nominally suzerain over Egypt, declared war on France in September. To prevent a Turkish invasion of Egypt and also perhaps to attempt a return to France by way of Anatolia, Bonaparte marched into Syria in February 1799. His progress northwest was halted at Acre, where the British withstood a seige, and in May Bonaparte began a disastrous retreat to Egypt.

The Battle of the Nile showed Europe that Bonaparte was not invincible, and Great Britain, Austria, Russia, and Turkey formed a new coalition against France. The French armies in Italy were defeated in the spring of 1799 and had to abandon the greater part of the peninsula. These defeats led to disturbances in France itself. The coup d'etat of 30 Prairial (June 18, 1799) expelled the men of moderate views from the Directory and brought into it men who were considered Jacobins. Yet the situation remained confused, and one of the new directors, Emmanuel Sieyès, was convinced that only military dictatorship could prevent a restoration of the monarchy: "I am looking for a sabre," he said. Bonaparte did not take long to make up his mind. He would leave his army and return to France—in order to save the republic, of course, but also to take advantage of the new circumstances and to seize power. The Directory had, in fact, ordered his return, but he had not received the order, so that it was actually in disregard of his instructions that he left Egypt with a few companions on August 22, 1799. Their two frigates surprisingly escaped interception by the British, and Bonaparte arrived in Paris on October 14.

By this time French victories in Switzerland and Holland had averted the danger of invasion, and the counter-revolutionary risings within France had more or less failed. A coup d'etat could therefore no longer be justified by any need to save the republic. Sieyès, however, had not given up his project, and now he had his "sabre." From the end of October he and Bonaparte were in league together planning the coup, and on 18–19 Brumaire, Year VIII (November 9–10, 1799), it was carried out: the directors were forced to resign, the members of the legislative councils were dispersed, and a new government, the Consulate, was set up. The three consuls were Bonaparte and two of the directors who had resigned, Sieyès and Pierre-Roger Ducos. But it was Bonaparte who was henceforth the master of France.

The coup of 18–19 Brumaire

THE CONSULATE

Consolidation of power. Bonaparte, now 30 years old, was thin and short and wore his hair cut close—*le petit tondu*, the "little crop-head," as he was called. Not much was known about his personality, but people had confidence in a man who had always been victorious (the Nile and Acre were forgotten) and who had managed to negotiate the brilliant Treaty of Campo Formio. He was expected to bring back peace, to end disorder, and to consolidate the political and social "conquests" of the Revolution. He was indeed exceptionally intelligent, prompt to make decisions, and indefatigably hardworking, but also insatiably ambitious. He seemed to be the man of the Revolution because it was due to the Revolution that he had climbed at so early an age to the highest place in the state. He was not to forget it: but more than a man of the Revolution, he was a man of the 18th century, the most enlightened of the enlightened despots, a true son of Voltaire. He did not believe in the sovereignty of the people, in the popular will, or in parliamentary debate. Yet he put his confidence more in reasoning than in reason and may be said to have preferred "men of talent"—mathematicians, jurists, and statesmen, for instance, however cynical or mercenary they might be—to "technicians" in the true sense of the word. He believed that an enlightened and firm will could do anything if it had the support of bayonets; he despised and feared the masses; and, as for public opinion, he considered that he could mold and direct it as he pleased. He has been called the most "civilian" of generals, but essentially he never ceased to be a soldier.

The military dictatorship

Bonaparte imposed a military dictatorship on France, but its true character was at first disguised by the Constitution of the Year VIII (4 Nivôse; December 25, 1799), drawn up by Sieyès. This constitution did not guarantee the "rights of man" or make any mention of "liberty, equality, and fraternity," but it did reassure the partisans of the Revolution by proclaiming the irrevocability of the sale of national property and by upholding the legislation against the émigrés. It gave immense powers to the first consul, leaving only a nominal role to his two colleagues. The first consul—namely, Bonaparte—was to appoint ministers, generals, civil servants, magistrates, and the members of the Council of State and even was to have an overwhelming influence in the choice of members for the three legislative assemblies, though their members

were theoretically to be chosen by universal suffrage. Submitted to a plebiscite, the constitution won by an overwhelming majority in February 1800.

Program of reforms. The Consulate's work of administrative reform, undertaken at Bonaparte's instigation, was to be more lasting than the constitution and so more important for France. At the head of the government was the Council of State, created by the first consul and often effectively presided over by him; it was to play an important part both as the source of the new legislation and as an administrative tribunal. At the head of the administration of the *départements* were the prefects, who carried on the tradition of the intendants of the *ancien régime*, supervising the application of the laws and acting as the instruments of centralization. The judicial system was profoundly changed: whereas from the beginning of the Revolution judges had been elected, henceforth they were to be nominated by the government, their independence assured by their irremovability from office. The police organization was greatly strengthened. The financial administration was considerably improved: instead of the municipalities, special officials were entrusted with the collecting of direct taxes; the franc was stabilized; and the Banque de France, owned partly by shareholders and partly by the state, was created. Education was transformed into a major public service; secondary education was given a semi-military organization, and the university faculties were re-established. Primary education, however, was still neglected.

Bonaparte shared Voltaire's belief that the people needed a religion. Personally, he was indifferent to religion: in Egypt he had said that he wanted to become a Muslim. Yet he considered that religious peace had to be restored to France. As early as 1796, when he was concluding the armistice in Italy with Pope Pius VI, he had tried to persuade the Pope to retract his briefs against the French priests who had accepted the Civil Constitution of the Clergy, which in practice nationalized the church. Pius VII, who succeeded Pius VI in March 1800, was more accommodating than his predecessor, and ten months after negotiations were opened with him a concordat was signed reconciling the church and the Revolution. The Pope recognized the French Republic and called for the resignation of all former bishops; new prelates were to be designated by the First Consul and instituted by the Pope; and the sale of the property of the clergy was officially recognized by Rome. The concordat, in fact, admitted freedom of worship and the lay character of the state.

Religious peace and concordat with Rome

The codification of the civil law, first undertaken in 1790, was at last completed under the Consulate. The code promulgated on March 21, 1804, and later known as the Code Napoléon, gave permanent form to the great gains of the Revolution: individual liberty, freedom of work, freedom of conscience, the lay character of the state, and equality before the law; but, at the same time, it protected landed property, gave greater liberty to employers, and showed little concern for employees. It maintained divorce but granted only limited legal rights to women.

The army received the most careful attention. The First Consul retained in outline the system instituted by the Revolution: recruitment by forced conscription but with the possibility of replacement by substitutes; the mixing of the conscripts with old soldiers; and the eligibility of all for promotion to the highest ranks. Nevertheless, the creation of the Academy of Saint-Cyr to produce infantry officers made it easier for the sons of bourgeois families to pursue a military career. Moreover, the École Polytechnique, founded by the National Convention, was militarized in order to provide officers for the artillery and engineers. Yet Bonaparte was not concerned about introducing new technical inventions into his army. He put his trust in the "legs of his soldiers": his basic strategic idea was a fast-moving army.

Military campaigns and uneasy peace. The First Consul spent the winter and spring of 1799–1800 reorganizing the army and preparing for an attack on Austria alone, Russia having withdrawn from the anti-French coalition. With his usual quick assessment of the situation, he saw the strategic importance of the Swiss Confederation, from which he would be free to outflank the Austrian armies either in Germany or in Italy as he might see fit. His past successes made him choose Italy. Taking his army across the Great St. Bernard Pass before the snow had melted, he appeared unexpectedly behind the Austrian army besieging Genoa. The Battle of Marengo in June gave the French command of the Po Valley as far as the Adige; and in December another French army defeated the Austrians in Germany. Austria was forced to sign the Treaty of Lunéville of February 1801, whereby France's right to the natural frontiers that Julius Caesar had given to Gaul, namely, the Rhine, the Alps, and the Pyrenees, was recognized.

Great Britain alone remained at war with France, but it soon tired of the struggle. Preliminaries of peace, concluded in London in October 1801, put an end to hostilities, and peace was signed at Amiens on March 27, 1802.

General peace was re-established in Europe. The first Consul's prestige increased still more; and his friends—at his suggestion—proposed that a "token of national gratitude" should be offered to him. In May 1802 it was decided that the French people should vote in referendum on the following question: "Shall Napoleon Bonaparte be consul for life?" In August an overwhelming vote granted him the prolongation of his consulate as well as the right to designate his successor.

Consul for life

Bonaparte's conception of international peace differed from that of the British, for whom the Treaty of Amiens represented an absolute limit beyond which they were under no circumstances prepared to go. The British even hoped to take back some of the concessions they had been forced to make. For Bonaparte, on the other hand, the Treaty of Amiens marked the starting point for a new French ascendancy. He was, first of all, intent on reserving half of Europe as a market for France without lowering customs duties—to the indignation of British merchants. To revive France's expansion overseas, he also intended to recover San Domingo (now Hispaniola, which had rebelled), to occupy Louisiana (ceded to France by Spain in 1800), perhaps to reconquer Egypt, and at any rate to extend French influence in the Mediterranean and in the Indian Ocean. Finally, on the Continent of Europe, he advanced beyond France's natural frontiers: incorporating Piedmont into France; imposing a more democratic, decentralized government on the Swiss Confederation; and in Germany compensating the princes dispossessed of territory on the Rhine under the Treaty of Lunéville with shares of the secularized ecclesiastical states.

Great Britain was alarmed by this expansion of France in peacetime and found it scarcely tolerable that one state should command the coastline of the Continent from Genoa to Antwerp. The immediate occasion of Franco-British rupture, however, was the problem of Malta. According to the Treaty of Amiens, the British, who had taken the island on the collapse of the French occupation, should have restored it to the Knights Hospitallers; but the British, on the pretext that the French had not yet evacuated certain Neapolitan ports, refused to leave the island. Franco-British relations became strained, and in May 1803 the British declared war.

THE EMPIRE

The peace settlement had brought about the life consulate; the return of war was to stimulate the formation of the empire. The British government, which would have been glad to see Bonaparte deposed or removed by assassination, renewed its subsidies to the French royalists, who resumed their agitation and plotting. When a British-financed assassination plot was uncovered in 1804, Bonaparte decided to react vigorously enough to deter his opponents from any more such attempts. The police believed that the real head of the conspiracy was the young Duc d'Enghien, a scion of the royal house of Bourbon, who was residing in Germany, a few miles across the frontier. Accordingly, with the agreement of Talleyrand and the police chief Joseph Fouché, the Duc was kidnapped on neutral soil and brought to Vincennes, where

British-financed assassination plot

he was tried and shot (March 21). This action provoked a resurgence of opposition among the old aristocracy but enhanced the influence of Fouché.

Founding the empire. In the hope of consolidating his own position, Fouché now suggested to Bonaparte that the best way to discourage conspiracy would be to transform the life consulate into a hereditary empire, which, because of the fact that there would be an heir, would remove all hope of changing the regime by assassination. Bonaparte readily accepted the suggestion, and on May 28, 1804, the empire was proclaimed.

Though there was little change in the organization of the government of France, Napoleon as emperor revived a number of institutions similar to those of the *ancien régime*. In the first place, he wanted to be consecrated by the pope himself, so that his coronation should be even more impressive than that of the kings of France. Pius VII agreed to come to Paris, and the ceremony, which seemed equally outrageous to royalists and to the old soldiers of the Revolution, took place in Notre-Dame on December 2, 1804. At the last moment, the Emperor took the crown from the Pope and set it on his own head himself.

The imperial regime also instituted its symbols and titles. Princely titles were brought back for the members of Napoleon's family in 1804, and an imperial nobility was created in 1808. As opposition was still lively, Napoleon intensified his propaganda and imposed an increasingly strict censorship on the press. A dictatorial regime allowed him to carry on his wars for years without worrying about French public opinion. Having been president of the Italian Republic (as the Cisalpine Republic was renamed) since January 1802, Napoleon in March 1805 was proclaimed king of Italy and crowned in Milan in May.

War with Britain. From 1803 to 1805 Napoleon had only the British to fight; and again France could hope for victory only by landing an army in the British Isles, whereas the British could defeat Napoleon only by forming a continental coalition against him. Napoleon began to prepare an invasion again, this time with greater conviction and on a larger scale. He gathered nearly 2,000 ships between Brest and Antwerp and concentrated his Grande Armée in the camp at Boulogne (1803). Even so, the problem was the same as in 1798: to cross the Channel, the French had to have control of the sea.

Still far inferior to the British Navy, the French fleet needed the help of the Spanish; and even then the two fleets together could not hope to defeat more than one of the British squadrons. Spain was induced to declare war on Great Britain in December 1804, and it was decided that French and Spanish squadrons massed in the Antilles should lure a British squadron into these waters and defeat it, thus making the balance roughly equal between the Franco-Spanish navy and the British. A battle in the entrance to the Channel could then be fought with some chance of success.

Franco-Spanish naval strategy

The plan failed. The French squadron from the Mediterranean, under Adm. Pierre de Villeneuve, found itself alone at the appointed meeting place in the Antilles. Pursued by Nelson and not daring to attack him, it turned back toward Europe and took refuge in Cádiz in July 1805; there the British blockaded it. Accused of cowardice by the angry Napoleon, Villeneuve resolved to run the blockade, with the support of a Spanish squadron; but on October 21, 1805, he was attacked by Nelson off Cape Trafalgar. Nelson was killed in the battle, but the Franco-Spanish fleet was totally destroyed. The British had won a decisive victory, which eliminated the danger of invasion and gave them freedom of movement at sea.

They had also succeeded in organizing a new anti-French coalition consisting of Austria, Russia, Sweden, and Naples. On July 24, 1805, three months before Trafalgar, Napoleon had ordered the Grande Armée from Boulogne to the Danube (thus ruling out an invasion of England even if the French had won at Trafalgar). In the week preceding Trafalgar, the Grande Armée won an outstanding victory over the Austrians at Ulm, and on November 13 Napoleon entered Vienna. On December 2, 1805, in his greatest victory he defeated the combined Austrian and Russian armies in the Battle of Austerlitz. By the Treaty of Pressburg, Austria renounced all influence in Italy and ceded Venetia and Dalmatia to Napoleon, as well as extensive territory in Germany to his protégés Bavaria, Württemberg, and Baden. The French then proceeded to dethrone the Bourbons in the kingdom of Naples, which was bestowed on Napoleon's brother Joseph. In July 1806 the Confederation of the Rhine was founded—soon to embrace all western Germany in a union under French protection.

Victories in Europe

In September 1806 Prussia entered the war against France, and on October 14 the Prussians armies were defeated at Jena and at Auerstädt. The Russians put up a better resistance at Eylau in February 1807 but were routed at Friedland in June. In Warsaw Napoleon fell in love with Countess Marie Walewska, a Polish patriot who hoped that Napoleon would resurrect her country. Napoleon had a son by her.

The Russian emperor Alexander I could have continued the struggle, but he was tired of the alliance with the British. He met Napoleon at Tilsit, in northern Prussia near the Russian frontier. There, on a raft anchored in the middle of the Niemen River, they signed treaties that created the Grand Duchy of Warsaw from the Polish provinces detached from Prussia and, in effect, divided control of Europe between the emperors, Napoleon taking the west and Alexander the east. Alexander even made a vague promise of a land attack against the British possessions in India.

Blockade and the peninsular campaign. As Napoleon could no longer think of invading England, he tried to induce capitulation by stifling the British economy. By closing all of Europe to British merchandise, he hoped to bring about a revolt of the British unemployed that could force the government to sue for peace. He forbade all trade with the British Isles, ordered the confiscation of all goods coming from English factories or from the British colonies, and condemned as fair prize not only every British ship but also every ship that had touched the coasts of England or its colonies.

For the blockade to succeed, it had to be enforced rigorously throughout Europe. But from the beginning, England's old ally Portugal showed itself reluctant to comply, for the blockade would mean its commercial ruin. Napoleon decided to break down Portuguese opposition by force. Charles IV of Spain let the French troops cross his kingdom, and they occupied Lisbon; but the prolonged presence of Napoleon's soldiers in the north of Spain led to insurrection. When Charles IV abdicated in favour of his son Ferdinand VII, Napoleon, seeing the opportunity to rid Europe of its last Bourbon rulers, summoned the Spanish royal family to Bayonne in April 1808 and obtained the abdication of both Charles and Ferdinand; they were interned in Talleyrand's château. After the bloody suppression of an uprising in Madrid, insurrection spread across the whole country, for the Spaniards would not accept Joseph Bonaparte, king of Naples, as their new king.

The subsequent defeat of his forces in Spain and Portugal were sensational blows to Napoleon's prestige. Soon the Iberian Peninsula, up in arms, became a bridgehead on the Continent for the British. Under the energetic Arthur Wellesley (later 1st duke of Wellington), in command from 1809, the Anglo-Spanish-Portuguese forces were to achieve decisive successes.

Defeats in Spain and Portugal

At the Congress of Erfurt (September–October 1808), a conference with Alexander I, Napoleon assembled a great concourse of princes to impress the Russian emperor in an attempt to extract promises of help. Whether impressed or not, Alexander would make no definite commitment. Alexander's refusal, furthermore, was partly prompted by Talleyrand, who had become dismayed by Napoleon's policies and was already negotiating with the Russian emperor behind his master's back.

By early 1809, however, with most of the Grande Armée thrown into Spain, Napoleon seemed on the point of overcoming the revolt. Then, in April, Austria launched an attack in Bavaria in the hope of rousing all Germany

against the French. Napoleon once again defeated the Habsburgs (July 6) and by the Treaty of Schönbrunn (October 14, 1809) obtained the Illyrian Provinces, thus rounding out the continental system.

Consolidation of empire. In 1810 Napoleon's fortunes were at their zenith, despite some failures in Spain and Portugal. He considered himself Charlemagne's heir. He repudiated Joséphine, who had not given him a child, so that he could marry Marie-Louise, daughter of the Austrian emperor Francis I. The birth of a son, the king of Rome, in March 1811 seemed to assure the future of his empire—now at its greatest extent, including not only the Illyrian Provinces but also Etruria (Tuscany), some of the Papal States, Holland, and the German states bordering the North Sea. The empire was surrounded by a ring of vassal states ruled over by the Emperor's relatives: the Kingdom of Westphalia (Jérôme Bonaparte); the Kingdom of Spain (Joseph Bonaparte); the Kingdom of Italy (with Eugène de Beauharnais, Joséphine's son, as viceroy); the Kingdom of Naples (Joachim Murat, Napoleon's brother-in-law); and the Principality of Lucca and Piombino (Félix Bacciochi, another brother-in-law). Finally, other territories were closely bound to the empire by treaties: the Swiss Confederation (of which Napoleon was the mediator), the Confederation of the Rhine, and the Grand Duchy of Warsaw. Even Austria seemed bound to France by Napoleon's marriage to Marie-Louise.

European unity and the roots of new nationalisms

The political map of Europe, which had been so complicated before 1796, was now greatly simplified. Yet the frontiers did not coincide either with geographical features or with "nationalities." Whatever he may later have said, Napoleon, while he was in power, was not interested in realizing either German or Italian unity. Yet by reducing the number of states, by pushing the frontiers about, by amalgamating populations, and by propagating institutions like those that the Revolution and nationalism had created in France, he prepared the ground for German and Italian unification. National feeling in Europe, stirred by French ideas and by contact with Frenchmen, in turn gave rise to the first resistance against French domination. From 1809 onward Spanish guerrillas, supported by British troops, were harassing the French, and the national Cortes, convened at Cádiz by the insurrectionaries, in 1812, promulgated a constitution inspired by the ideas of the French Revolution of 1789 and by British institutions.

Disaster in Russia and its aftermath. Since the Congress of Erfurt, the Russian emperor had shown himself less and less inclined to deal with Napoleon as a trusted partner. In the spring of 1812, therefore, Napoleon massed his forces in Poland to intimidate Alexander. After some last attempts at agreement, in late June his Grande Armée—about 453,000 men, including contingents extorted from Prussia and from Austria—began to cross the Niemen River. The Russians retreated, adopting a "scorched earth" policy. Napoleon's army did not reach the approaches to Moscow till the beginning of September. The Russian commander in chief, Mikhail I. Kutuzov, engaged it at Borodino on September 7. The fight was savage, bloody, and indecisive, but a week later Napoleon entered Moscow, which the Russians had abandoned. On that same day, a huge fire broke out, destroying the greater part of the town. Moreover, Alexander unexpectedly refused to treat with Napoleon. Withdrawal was necessary, and the premature onset of winter made it disastrous. After the difficult crossing of the Berezina River in November, fewer than 10,000 men fit for combat remained with Napoleon's main force.

This catastrophe heartened all the peoples of Europe to defy Napoleon. In Germany the news unleashed an outbreak of anti-French demonstrations. The Prussian contingents deserted the Grande Armée in December and turned against the French. The Austrians also withdrew their troops and adopted an increasingly hostile attitude, and in Italy the people began to turn their backs on Napoleon.

Even in France, signs of discontent with the regime were becoming more frequent. In Paris a malcontent general nearly succeeded in carrying out a coup d'etat after announcing, on October 23, 1812, that Napoleon had died in Russia. This incident was a major factor in Napoleon's decision to hasten back to France ahead of the Grande Armée. Arriving in Paris on December 18, he proceeded to stiffen the dictatorship, to raise money by various expedients, and to levy new troops.

Attempted coup d'etat in Paris

Thus, in 1813 the forces arrayed against France were no longer armies of mercenaries but were those of nations fighting for their freedom as the French had fought for theirs in 1792 and 1793; and the French themselves, for all their courage, had lost their former enthusiasm. The Emperor's ideal of conquest was no longer that of the nation.

In May 1813 Napoleon won some successes against the Russians and Prussians at the battles of Lützen and Bautzen, but his decimated army needed reinforcements. The armed mediation of Austria induced Napoleon to agree to an armistice, during which a congress was held at Prague. There, Austria proposed very favourable conditions: the French Empire was to return to its natural limits; the Grand Duchy of Warsaw and the Confederation of the Rhine were to be dissolved; and Prussia was to return to its frontiers of 1805. Napoleon made the mistake of hesitating too long. The congress closed on August 10 before his reply arrived, and Austria declared war.

The French were even worse off than in the spring. The allies were gaining new troops every day, as one German contingent after another left Napoleon to go over to the other side. The greatest debacle since Napoleon came to power was the Battle of Leipzig, or "Battle of the Nations" (October 16–19, 1813), in which the Grande Armée was torn to shreds. That defeat degenerated fast into collapse. The French armies in Spain, forced to retreat, had been defeated in June; and by October the British were attacking their defenses north of the Pyrenees. In Italy the Austrians took the offensive, crossed the Adige River, and occupied Romagna. Murat, now openly a traitor to the Emperor who had made him king of Naples, entered into negotiations with the Viennese court. The Dutch and the Belgians demonstrated against Napoleon.

Downfall and abdication. In January 1814 France was being attacked on all its frontiers. The allies cleverly announced that they were fighting not against the French people but against Napoleon alone, since in November 1813 he had rejected the terms offered by the Austrian foreign minister Metternich, which would have preserved the natural frontiers of France. The extraordinary strategic feats achieved by the Emperor during the first three months of 1814 with the army of young conscripts were not enough; he could neither defeat the allies, with their overwhelming numerical superiority, nor arouse the majority of French people from their resentful torpor. The Legislative Assembly and the Senate, formerly so docile, were now asking for peace and for civil and political liberties.

Four-nation pact against Napoleon

By the Treaty of Chaumont of March 1814, Austria, Russia, Prussia, and Great Britain bound themselves together for 20 years, undertook not to negotiate separately, and promised to continue the struggle till Napoleon was overthrown. When the allied armies arrived before Paris on March 30, Napoleon had moved east to attack their rear guard. The Parisian authorities, no longer overawed by the Emperor, lost no time in treating with the allies. As president of the provisional government, Talleyrand proclaimed the deposition of the Emperor and, without consulting the French people, began to negotiate with Louis XVIII, the brother of the executed Louis XVI. Napoleon had only reached Fontainebleau when he heard that Paris had capitulated. Persuaded by the majority of his marshals that further resistance was useless, he finally abdicated on April 6.

By the Treaty of Fontainebleau, the allies granted him the island of Elba as a sovereign principality with an annual income of 2,000,000 francs to be provided by France and a guard of 400 volunteers; also, he retained the title of emperor. After unsuccessfully trying to poison

himself, Napoleon spoke his farewell to his "Old Guard," and after a hazardous journey, during which he narrowly escaped assassination, he arrived at Elba on May 4.

ELBA AND THE HUNDRED DAYS

"I want from now on to live like a justice of the peace," Napoleon declared on his little island. But a man of such energy and imagination could hardly be expected to resign himself to defeat at the age of 45.

In France, moreover, the Bourbon Restoration was soon exposed to criticism. Though in 1814 the majority of the French people were tired of the Emperor, they had expressed no wish for the return of the Bourbons. They were strongly attached to the essential achievements of the Revolution, and Louis XVIII had come back "in the baggage train of the foreigners" with the last surviving émigrés who had "learnt nothing and forgotten nothing" and whose influence seemed to threaten most of the Revolution's achievements. The apathy of April 1814 quickly gave way to mistrust. Old hatreds were revived, resistance organized, and conspiracies formed.

From Elba, Napoleon kept a close watch on the Continent. He knew that some of the diplomats at Vienna, where a congress was deciding the fate of Europe, considered Elba, between Corsica and Italy, too close to France and to Italy and wanted to banish him to a distant island in the Atlantic. Also, he accused Austria of preventing Marie Louise and his son from coming to join him (in fact, she had taken a lover and had no intention of going to live with her husband). Finally, the French government refused to pay Napoleon's allowance so that he was in danger of being reduced to penury.

Napoleon's return to France

All these considerations drove Napoleon to action. Decisive as ever, he returned to France like a thunderbolt. On March 1, 1815, he landed at Cannes with a detachment of his guard. As he crossed the Alps, the republican peasants rallied round him, and near Grenoble he won over the soldiers dispatched to arrest him. On March 20 he was in Paris.

Napoleon was brought back to power as the embodiment of the spirit of the Revolution rather than as the emperor who had fallen a year before. To rally the mass of Frenchmen to his cause he should have allied himself with the Jacobins; but this he dared not do. Unable to escape from the bourgeoisie whose predominance he himself had assured and who feared above all else a revival of the socialist experiments of 1793 and 1794, he could only set up a political regime scarcely distinguishable from that of Louis XVIII. Enthusiasm ebbed fast, and the Napoleonic adventure seemed a dead end.

To oppose the allied troops massing on the frontiers, Napoleon mustered an army with which he marched into Belgium and defeated the Prussians at Ligny on June 16, 1815. Two days later, at Waterloo, he met the British under Wellington, the victor of the Peninsular War. A savage battle followed. Napoleon was in sight of victory when the Prussians under Gebhard Blücher arrived to reinforce the British, and soon, despite the heroism of the Old Guard, Napoleon was overthrown.

Back in Paris, Parliament forced Napoleon to abdicate; he did so, in favour of his son, on June 22, 1815. On July 3 he was at Rochefort, intending to take ship for the United States, but a British squadron prevented any French vessel from leaving the port. Napoleon then decided to appeal to the British government for protection. His request granted, he boarded the "Bellerophon" on July 15. The allies were agreed on one point: Napoleon was not to go back to Elba. Nor did they like the idea of his going off to America. It would have suited them if he had fallen a victim to the "White Terror" of the returned counter-revolutionaries or if Louis XVIII had had him summarily tried and executed. Great Britain had no choice but to send him to detention in a far-off island. The British government announced that the island of Saint Helena in the southern Atlantic had been chosen for his residence; because of its remote position Napoleon would enjoy much greater freedom than would be possible elsewhere. Napoleon protested eloquently: "I appeal to history!"

EXILE ON SAINT HELENA

On October 15, 1815, Napoleon disembarked in Saint Helena with those followers who were voluntarily accompanying him into exile: Gen. Henri-Gratien Bertrand, grand marshal of the palace, and his wife; the comte Charles de Montholon, aide-de-camp, and his wife; Gen. Gaspard Gourgaud; Emmanuel Las Cases, the former chamberlain; and several servants. After a short stay at the house of a wealthy English merchant, they moved to Longwood, originally built for the lieutenant governor.

Daily life at St. Helena

Napoleon settled down to a life of routine. He got up late, breakfasting about 10 AM, but seldom went out. He was free to go anywhere on the island so long as he was accompanied by an English officer, but he soon refused to comply with this condition and so shut himself up in the grounds of Longwood. He wrote and talked much. At first Las Cases acted as his secretary, compiling what was later to be the *Mémorial de Sainte-Hélène* (first published in 1823). From 7 to 8 PM Napoleon had dinner, after which a part of the evening was spent in reading aloud—Napoleon liked to hear the classics. Then they played cards. About midnight Napoleon went to bed. Some of his time was devoted to learning English, and he eventually began reading English newspapers; but he also had a large number of French books sent from Europe, which he read attentively and annotated.

Saint Helena has a healthful climate, and Napoleon's food was good, carefully prepared, and plentiful. His inactivity undoubtedly contributed to the deterioration of his health. The man who for 20 years had played so great a role in the world and who had marched north, south, east, and west across Europe could hardly be expected to endure the monotony of existence on a little island, aggravated by a self-imposed life of a recluse. He had also more intimate reasons for unhappiness: Marie-Louise sent no word to him, and he may have learned of her liaison with the Austrian officer appointed to watch over her, Graf Adam von Neipperg (whom she eventually married in secret without waiting for Napoleon's death); nor did he have any news of his son, the former king of Rome, who was now living in Vienna with the title of duke of Reichstadt. Finally, though the severity of Sir Hudson Lowe has been much exaggerated, it is certain that this "jailer," who arrived as governor of Saint Helena in April 1816, did nothing to make Napoleon's life easier. Napoleon from the start disliked him as the former commander of the Corsican rangers, a band of volunteers that had been recruited by the British and that was largely composed of enemies of the Bonaparte family. Obsessed by his responsibilities and always anxious to carry out his instructions exactly, Lowe came into conflict with Las Cases. He saw Las Cases as Napoleon's confidant and had him arrested and expelled. Thenceforward, relations between the governor and Napoleon were limited strictly to those stipulated by the regulations.

First signs of illness

Napoleon showed the first signs of illness at the end of 1817; he seems to have had an ulcer or a cancer of the stomach. The Irish doctor Barry O'Meara, having asked in vain for a change in the conditions under which Napoleon lived, was dismissed; so also was his successor John Stokoe, who was likewise thought to be well-disposed toward Napoleon. The undistinguished Corsican doctor who took their place, Francesco Antommarchi, prescribed a treatment that could do nothing to cure his patient. It is uncertain, however, whether Napoleon's disease was curable at all, even by 20th-century methods.

From the beginning of 1821, the illness became rapidly worse. From March, Napoleon was confined to bed. In April he dictated his last will:

> I wish my ashes to rest on the banks of the Seine, in the midst of that French people which I have loved so much . . . . I die before my time, killed by the English oligarchy and its hired assassins.

On May 5 he spoke a few coherent phrases: "My God . . . The French nation . . . my son . . . head of the army. . . ." He died at 5:49 PM on that day, not yet 52 years old. His body was dressed in his favourite uniform, that of the

Chasseurs de la Garde, covered by the gray overcoat that he had worn at Marengo. The funeral was conducted simply, but with due propriety, in the Rupert Valley, where Napoleon had sometimes walked, beside a stream in which two willows were reflected. The stone covering his tomb bore no name, only the words "*Ci-Gît*" ("Here Lies").

THE NAPOLEONIC LEGEND

Napoleon's fall had set loose a torrent of hostile books designed to sully his reputation. One of the least violent of these was the pamphlet *De Buonaparte, des Bourbons, et de la nécessité de se rallier à nos princes légitimes* (1814; *On Buonaparte and the Bourbons, and the Necessity of Rallying Around Our Legitimate Princes, for the Safety of France and of Europe*) by François de Chateaubriand, a well-known writer of royalist sympathies. But this anti-Napoleonic literature soon died down, while the task of defending Napoleon was taken up. Lord Byron had published his "Ode to Napoleon Buonaparte" as early as 1814; the German poet Heinrich Heine wrote his ballad "Die Grenadiere"; and in 1817 the French novelist Stendhal began his biography *Vie de Napoleon*. At the same time, the Emperor's most faithful supporters were working toward his rehabilitation, talking about him, and distributing reminders of him, including engravings. They idealized his life ("What a novel my life is!" he himself had said) and began to create the Napoleonic legend.

Early memoirs and chronicles

As soon as the Emperor was dead, the legend grew rapidly. Memoirs, notes, and narratives by those who had followed him into exile contributed substantially to it. In 1822 Dr. O'Meara, in London, had his *Napoleon in Exile, or a Voice from Saint Helena* published; in 1823 the publication of the *Mémoires pour servir à l'histoire de France sous Napoléon, écrits à Sainte-Hélène sous sa dictée (Memoirs of the History of France during the Reign of Napoleon, Dictated by the Emperor at St. Helena)* by Montholon and Gourgaud, began; Las Cases, in his famous *Mémorial*, presented the Emperor as a republican opposed to war who had fought only when Europe forced him to fight in defense of freedom; and in 1825 Antommarchi published his *Derniers moments de Napoléon*. Thereafter the number of books in Napoleon's honour increased continually; among them were Victor Hugo's "Ode à la Colonne," the 28 volumes of the *Victoires et conquêtes des Français*, and Sir Walter Scott's *Life of Napoleon Buonaparte, Emperor of the French*. Neither police action nor prosecutions could prevent books, pictures, and objects evoking the imperial saga from multiplying in France.

After the July Revolution of 1830, which created the bourgeois monarchy under Louis-Philippe, thousands of tricolour flags appeared in windows, and the government had not only to tolerate the growth of the legend but even to promote it. In 1833 the statue of Napoleon was put back on the top of the column in the Place Vendôme in Paris; and in 1840 the King's son François, prince de Joinville, was sent in a warship to fetch the Emperor's remains from Saint Helena to the banks of the Seine in accordance with his last wishes. A magnificent funeral was held in Paris in December 1840, and Napoleon's body was conveyed through the Arc de Triomphe in the Place de l'Étoile to entombment under the dome of the Invalides.

Napoleon's nephew Louis-Napoleon exploited the legend in order to seize power in France. Though his attempts at Strasbourg in 1836 and at Boulogne in 1840 were failures, it was chiefly because of the growth of the legend that he won election to the presidency of the Second Republic with an overwhelming majority in 1848 and was able to carry out the coup d'etat of December 1851 and make himself emperor in 1852.

The disastrous end of the Second Empire in 1870 damaged the Napoleonic legend and gave rise to a new anti-Napoleonic literature, best represented by Hippolyte Taine's *Origines de la France contemporaine* (1876–94). World Wars I and II, however, together with the experience of the 20th-century dictatorships, made it possible to judge Napoleon more fairly. Any comparison with Stalin or Hitler, for instance, can only be to Napoleon's advantage. He was tolerant, he released the Jews from the ghettoes, and he showed respect for human life. Brought up on the nationalist *Encyclopédie* and on the writings of the Philosophes of the Enlightenment, he remained above all a man of the 18th century, the last of the "enlightened despots." One of the gravest accusations made against Napoleon is that he was the "Corsican ogre" who sacrificed millions of men to his ambition. Precise calculations show that the Napoleonic Wars of 1800–15 cost France itself about 500,000 men; *i.e.*, about one-sixtieth of the population. The loss of these young men, furthermore, seems to have had a notably adverse effect on the birth rate.

Assessment and legacy

The social structure of France changed little under the First Empire. It remained roughly what the Revolution had made it: a great mass of peasants comprising three quarters of the population—about half of them working owners of their farms or sharecroppers and the other half with too little land for their own subsistence and hiring themselves out as labourers. Industry, stimulated by the war and the blockade of English goods, made remarkable progress in northern and eastern France, whence exports could be sent to central Europe; but it declined in the south and west because of the closing of the Mediterranean and the Atlantic. The great migrations from rural areas toward industry in the towns began only after 1815. The nobility would probably have declined more swiftly if Napoleon had not restored it; but it could never recover its former privileges.

Above all, Napoleon left durable institutions, the "granite masses" on which modern France has been built up: the administrative system of the prefects, the Code Napoléon, the judicial system, the Banque de France and the country's financial organization, the universities, and the military academies. Napoleon changed the history of France and of the world.

BIBLIOGRAPHY. Since the beginning of the 20th century, more than 200,000 volumes have been published on Napoleon and his times. It is, therefore, impossible to compile a complete bibliography; cited here are only the most important works.

Sources: An enormous mass of documents is dispersed throughout all the archives of Europe, but the essential source is the *Correspondance de Napoléon I*, 32 vol. (1858–69) published on command of Napoleon III, with the *Oeuvres de Napoléon à Sainte-Hélène*, 4 vol. (1870). In 1867, the *Oeuvres littéraires et écrits militaires* of Napoleon were published in 3 volumes. In English, one can read *The Bonaparte Letters and Dispatches . . . from the Originals in His Private Cabinet*, 2 vol. (1846); *The Confidential Correspondence of Napoleon Bonaparte with His Brother Joseph . . .*, 2 vol. (1855); and the *Unpublished Correspondence of Napoleon I, Preserved in the War Archives*, 3 vol. (1913). The principal ideas of the Emperor may be found in the following works: *The Corsican* (1910); J.M. THOMPSON, *Napoleon Self-Revealed* (1934); HEROLD J. CHRISTOPHER, *The Mind of Napoleon* (1955); ANDRE PALLUEL (ed.), *Dictionnaire de l'Empereur* (1969); and ADRIEN DANSETTE, *Napoléon, pensées politiques et sociales* (1969). For Napoleon's itinerary, see ALBERT SCHUERMANS, *Itinéraire général de Napoléon Ier* (1906); and LOUIS GARRES, *Itinéraire de Napoléon Bonaparte* (1947).

General biographies: PIERRE LANFREY, *Histoire de Napoléon Ier*, 5 vol. (1867–75; Eng. trans., *The History of Napoleon the First*, 5 vol., 1871–79), a work written at the end of the Second Empire—very hostile to Napoleon; AUGUST FOURNIER, *Napoleon I*, 3 vol. (1886; Eng. trans., 2 vol., 1911), an impartial study written by an Austrian historian; FREDERIC MASSON, *Napoléon et sa famille*, 13 vol. (1897–1919), furnishes numerous details on the everyday life of Napoleon and his relationships with his relatives; J. HOLLAND ROSE, *The Life of Napoleon I*, 2 vol. (1902), very apologetic; J.M. THOMPSON, *Napoleon Bonaparte: His Rise and Fall* (1952), excellent rectification; E.V. TARLE, *Bonaparte* (Eng. trans. 1937, reprinted 1961), the point of view of a Soviet historian; FELIX MARKHAM, *Napoleon* (1963), a very objective study; JEAN MISTLER, *Napoléon et l'Empire* (1968), a magnificently illustrated work, each chapter written by a specialist; ANDRE CASTELOT, *Napoléon* (1968), a vulgarized book that realized great success in France; JACQUES GODECHOT, *Napoléon* (1969), an essay and an empirical study (in French).

Specialized biographies: On Napoleon's youth, the basic work remains that of ARTHUR CHUQUET, *La Jeunesse de Napoléon*, 3 vol. (1897–99). On the more intimate life of Napoleon, ARTHUR LEVY, *Napoléon intime*, 7th ed. (1932); and FREDERIC MASSON, *Napoléon chez lui: la journée de l'Empereur aux Tuileries* (1894; Eng. trans., *Napoleon at Home*, 2 vol., 1894). On Napoleon's health, see JAMES KEMBLE, *Napoleon Immortal* (1959).

The Napoleonic legend and studies on Napoleon's captivity: MABEL BROOKES, *Saint Helena Story* (1960); JEAN LUCAS-DUBRETON, *Le Culte de Napoléon, 1815–1848* (1960), the only definitive study of the Napoleonic legend.

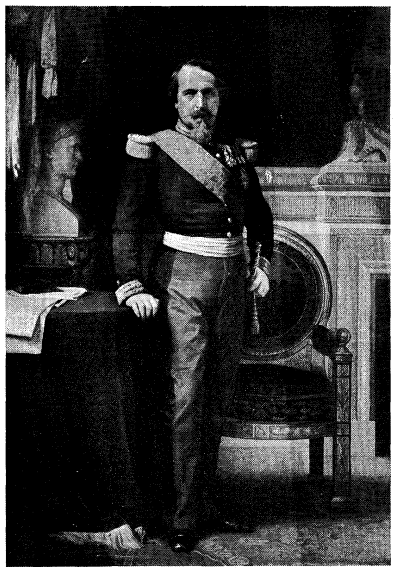
Films: Many films have been produced on the life of Napoleon. The best are by ABEL GANCE, *Napoléon* (1925) and *Austerlitz* (1960). The film *War and Peace* (1967), produced by Soviet director SERGEI BONDARTCHUK, gives a valid reconstruction of the imperial era. It was adapted from the novel by Tolstoy.

(J. Go.)

Napoleon III

Charles-Louis-Napoléon Bonaparte, the nephew of Napoleon I, was emperor of the French from 1852 to 1870. He successfully imposed two decades of stable, authoritarian government on France and encouraged industrial expansion. He also played a prominent role in European affairs, but finally led his country to defeat in the Franco-German War of 1870–71.

H. Roger-Viollet



Napoleon III, portrait by H. Flandrin (1809–64). In the Musée de Versailles.

He was born on April 20, 1808, in Paris, the third son of Napoleon I's brother Louis Bonaparte, who was king of Holland from 1806 to 1810, and his wife Hortense de Beauharnais Bonaparte, stepdaughter of Napoleon I. Other children born of this marriage were Napoléon-Charles, who died in infancy, and Napoléon-Louis.

Youth in exile. Louis-Napoléon's childhood and youth were spent largely in exile. His mother, like all the Bonapartes, was banished from France in 1815 after the fall of Napoleon I. Eventually, she found a new home in Switzerland, where, in 1817, she bought the castle of Arenenberg. Of romantic disposition herself, she inspired young Louis-Napoléon with a longing for his lost fatherland, as well as with enthusiastic admiration of the genius of Napoleon I. After attending a grammar school at Augsburg, Germany (1821–23), her "sweet stubborn boy" was taught by private tutors. During visits to relatives in southern Germany and Italy, he became acquainted not only with other exiled victims of the restoration of the Bourbon monarchy but also with the life of a suppressed people, such as those Italians who were living under Austrian and papal rule. He was, above all, interested in history and inspired by the idea of national liberty. Accordingly, he took part in an unsuccessful plot against the papal government in Rome in 1830 and in the rebellion in central Italy in 1831, in which his beloved brother perished. He himself was saved from the Austrian troops only by his mother's bold intervention.

Claim to the throne. After the death in 1832 of his cousin the Duke of Reichstadt (Napoleon I's only son), Louis-Napoléon considered himself his family's claimant to the French throne. To be better prepared for his task, he completed his military training and pursued his studies of economic and social problems. Soon after, he felt ready to publish his own writings on political and military subjects. In his pamphlet "Rêveries politiques" (1832), he asserted that only an emperor could give France both glory and liberty. He thus wanted to make his name known, propagate his ideas, and recruit adherents. Convinced that as Napoleon's nephew he would be popular with the French army, he vainly tried, on October 30, 1836, to win over the Strasbourg garrison for a coup d'etat. King Louis-Philippe exiled him to the United States, from which he was recalled early in 1837 by his mother's last illness. Expelled from Switzerland in 1838 as a result of French pressure, he settled in England, where he moved in fashionable circles.

Attempted coup d'état and exile

In 1839 he published "Des idées napoléoniennes." So far, Bonapartism had been nothing but a wistful reminiscing of former beneficiaries of the empire or a romantic legend created by those who were dissatisfied with the humdrum present. In his new booklet Louis-Napoléon tried to transform Bonapartism into a political ideology. In doing so, he obeyed mystical inspirations as well as rationalism. To him, ideology and politics were the result of rational reflection as well as of belief. The central exponent in history was, in his opinion, the great personality called by Providence and representing progress. Napoleon I had been such a man, even though he was not allowed to finish his work. But Napoleon, the "Messiah of the new ideas," was survived by the "Napoleonic idea," for the "political creed," like the religious creeds, had its martyrs and apostles. The Napoleonic idea was a "social and industrial one, humanitarian and encouraging trade," that would "reconcile order and freedom, the rights of the people and the principles of authority." Louis-Napoléon saw it as his task to accomplish this mission.

Landing with 56 followers, near Boulogne, on August 6, 1840, he was again unsuccessful. The town's garrison did not join him. He was arrested, brought to trial, and sentenced to "permanent confinement in a fortress." At his "university of Ham" (the castle in which he was held) he spent his time studying to fit himself for his imperial role. He corresponded with members of the French opposition and published articles in some of their newspapers. He also wrote several brochures, among them "Extinction du paupérisme" (1844), which won him some supporters on the left. It was not until May 25, 1846, that he succeeded in escaping and fleeing to Great Britain, where he waited for another chance to seize power.

Presidency. On hearing of the outbreak of the revolution, in February 1848, he travelled to Paris but was sent back by the provisional government. Some of his supporters, however, organized a small Bonapartist party and nominated him as their candidate for the Constituent Assembly. On June 4 he was elected in four *départements* but, awaiting more settled conditions, he refused to take his seat. Running again in September, he was elected in five *départements*, and after his arrival in Paris he lost no time in preparing to run for the presidency. He was now supported by the newly founded Party of Order, which consisted of adherents of the Bourbons, Louis-Philippe, and Catholics. Lacking a suitable candidate, they regarded Louis-Napoléon—not a skilled parliamentarian but a popular figure—as a useful and harmless tool.

He used, now on a large scale, the kind of propaganda that had won him elections before. Because of his name and his descent, the Emperor's nephew captivated the voters. Evoking the Napoleonic legend with its memories of national glory, Louis-Napoléon promised to bring back those days in time of peace. He succeeded also in recommending himself to every group of the population by promising to safeguard their particular interests. He

promised "order" and "prosperity" to the middle class and the farmers and assistance to the poor. In the elections in December 1848, he was the only candidate to obtain votes—totalling 5,434,226—from among all classes of the population.

He assumed office, determined to free himself from any dependence on the Party of Order, which had also won the parliamentary elections of May 1849. The new government sent a military expedition to help the pope reconquer Rome. At home it deprived active Republicans of their government positions and restricted their liberties, but the President could rely on only about a dozen members of the National Assembly who were Bonapartists. Prudently expanding his power by using every right the constitution granted him, Louis-Napoléon soon obtained key positions in the administration and in the army for his adherents. On October 31, he succeeded for the first time in appointing a Cabinet consisting of men depending more on him than on the National Assembly. By travelling through the country he gained wide popularity. Moreover, he used the disfranchisement of 3,000,000 electors of the poorer classes by the National Assembly in 1850 and an economic recession in 1851 as a pretext for agitating against the parties and for advertising himself as the "strong man" against the danger of a nonexistent revolution.

Marshalling his power

The constitution forbade the re-election of the president after expiration of his four-year term, and when Louis-Napoléon realized that he could not obtain the three-fourths majority necessary for a revision of the constitution he carried out a coup d'etat on December 2. Only the Republicans dared to resist him. On December 4 they were defeated in street fighting in Paris, just as they were in other towns and in some regions. Arrests and deportations numbered in the thousands. Louis-Napoleon dissolved the Legislative Assembly and decreed a new constitution, which among other provisions restored universal suffrage. A plebiscite approved the new constitution. Encouraged by his success, he held another plebiscite in November 1852 and was confirmed as emperor after the resolution of the Senate concerning the restitution of the empire. Failing to obtain the hand of a princess of equal birth, Napoleon III married the countess Eugénie de Montijo in January 1853.

Domestic policy as emperor. Napoleon III intended to be always ahead of public opinion so as to be able to understand the requirements of his time and to create laws and institutions accordingly. Hence, he took the greatest pains to study the public opinion and to influence it by means of propaganda. He tried to make his people believe in his mission: "I am not afraid of any attempts on my life. There are men who are instruments of the decisions of Providence. As long as I have not fulfilled my mission, there is no danger for me," he declared publicly on April 29, 1855, after an attempted assassination had failed. But he also made an appeal to his subjects' intelligence by emphasizing the usefulness of measures intended for the "moral and material improvement of man through education and work"—and calling himself "the one elected by the nation, the first citizen of the country and the representative of the interests of all." Although promising "reasonable freedom," for the time being he considered it necessary to use the methods of a police state.

Willing "to take the initiative to do everything useful for the prosperity and the greatness of France," he promoted public works, the construction of railroads, the establishment of institutions of credit, and other means of furthering industry and agriculture. An enthusiastic promoter of great technical projects, he supported inventors and took a personal interest in the rebuilding of modern Paris.

He did not, however, disavow what he called his "love of the diligent and needy." He ensured a lower price for bread, furthered the construction of hygienic dwellings for workers, and established boards of arbitration. In his societies of mutual assistance, employers and employees were to learn to understand each other. He hoped that his social-welfare institutions, to the endowment of which he frequently contributed, would be imitated by the citizens. The middle class, however, looked upon him only as its protector against Socialism and regarded his social ideas as mere utopianism.

Foreign policy as emperor. As in domestic policy, the Emperor immediately took the initiative in foreign affairs. "Louis-Philippe fell because he let France fall into disrepute. I must do something," he declared. He wanted to make France a great power once more by breaking up the European system created by the Congress of Vienna of 1815, which, incidentally, had imposed great humiliations on France. Convinced that in the present "epoch of civilisation the successes of armies were only temporary" and that it was "public opinion which always gained the final victory," he planned "to march at the head of generous and noble ideas," among which the principle of nationality was the most important. In accordance with this principle he wanted an international congress to reconstruct "the European balance of power on more durable and just foundations." And "if other countries gain anything France must gain something also." While advocating international solutions to European problems, he also followed traditions of French foreign policy because they corresponded "to the permanent interests" of France. "He has certain ideas and desires floating in his mind which turn up as circumstances seem favourable," was the comment of the English ambassador about Napoleon III's political activities.

Appeal to nationalism

The Crimean War offered him a chance of realizing one of his favourite ideas: the conclusion of an alliance with Great Britain that would succeed in checking Russian expansion toward the Mediterranean. After the Paris conference, at which the peace terms were settled, Napoleon seemed to become Europe's arbitrator. Ironically, it was an attempt on his life by Felice Orsini, an Italian revolutionary (January 1858), that reminded him of his wish "to do something for Italy." Together with Piedmont-Sardinia, he went to war against Austria in order to expel it from Italy. A promoter of technical warfare, he witnessed the success of his modernized artillery and of the military use of the captive balloon. The fact that at the victorious Battle of Solferino in June 1859 he had been in command convinced him of his military genius. Yet, frightened by the possibility of intervention by the German Confederation, he suddenly made peace. Outmanoeuvred by Count Cavour, who confronted him with a unified Italy instead of the weak federation he had intended, he received Nice and Savoy as a reward. His activities in Italy displeased the British. Despite the conclusion of an Anglo-French commercial treaty in 1860, they remained suspicious, and apprehensively watched his construction of armoured warships and his colonial and oriental policies.

Napoleon III dreamed of "opening new ways to commerce and new outlets to European products overseas," of accelerating "the progress of Christianity and civilization." He was therefore open to a colonial policy bent on furthering commercial interests and the establishment of bases. He intensified the extension of French power in Indochina and West Africa. In the Middle East the Emperor hoped that a better treatment of the Algerians would have a favourable influence on the Arabs from Tunisia to the Euphrates. He supported the construction of the Suez Canal. When the Roman Catholic Maronites who were under French protection in Lebanon were persecuted in 1860, he hoped to profit politically by dispatching an expeditionary force.

Colonial policy

Attempts at reform. In 1860 Napoleon III believed his regime to be sufficiently stable to grant some reasonable freedoms. The commercial treaty with Great Britain was to be the beginning of a new economic policy based on free-trade principles, with the aim of increasing prosperity and decreasing the cost of living. Dissatisfied with the functioning of the legislature, the Emperor decided to give "the great bodies of the state a more direct part in the formation of the general policy of our government."

His hopes were not fulfilled to the extent he had expected. A deterioration in the economy caused dissatisfaction among the middle class and the working people, who joined the Catholics, angered by his antipapal Italian

policy, to become a steadily growing opposition. In the elections of 1857 only five members of the opposition had gained seats in the National Assembly; six years later there were 32, and they demanded more freedom.

At this very time, repeated bladder-stone attacks temporarily incapacitated the Emperor, who had been in poor health since 1856. He had always insisted on exercising control over all decisions of government; in his ministers he had seen nothing but tools. Now, because of his illness he became dependent on persons in his entourage who formed groups and intrigued against each other. In 1863 the authoritarian Eugène Rouher, nicknamed the "Vice Emperor," became prime minister; on the other hand, Napoleon III took the advice of his cousin the Duke of Morny to continue his policy of liberalization. With the help of another cousin, Prince Napoléon, who preached a democratic Bonapartism, he tried to win over the workers. But his concessions (freedom of coalition in 1864, freedom of assembly in 1868, extension of the rights of members of parliament, liberalization of the press laws) were restricted by too many reservations and came too late. He allowed Victor Duruy, his minister of education since 1863, to fight clerical influence in education, yet on the other hand he tried to reconciliate French Catholics by working for a compromise settlement in disputes between the papacy and the new Italian Kingdom.

Foreign adventures

In 1861, by proposing to make the Austrian archduke Maximilian emperor of Mexico and by negotiating with the President of Ecuador about a projected "Kingdom of the Andes," he had begun his Latin American venture. He had expected material rewards for France and also hoped that the planned kingdom would check the growing influence of the United States in Latin America. Yet as soon as the United States had concluded its Civil War it forced the French to withdraw. In Europe when the Polish insurrection broke out in 1863, he did not, in spite of his sympathy, dare to support Poland against Russia. Nevertheless, such sympathies led to an estrangement from Russia. Moreover, the great powers refused Napoleon's proposal of a conference for the reorganization of Europe. Regarding Bismarck's policy with a certain benevolence, he kept aloof when Prussia settled the Schleswig-Holstein question by a war on Denmark. He had always sympathized with Prussia and the idea of the extension of Prussia's power in North Germany. He did not, however, openly tell Bismarck what price he demanded for his help. When in 1866, after routing Denmark, Prussia turned on its former ally, Austria, and defeated it more quickly than Napoleon had expected, he refused any armed intervention in its favour and only acted as mediator. Bismarck, however, was not willing to pay for Napoleon's neutrality by the cession of German territories. The Emperor's plans to obtain compensation in Belgium failed, as did his attempt to gain Luxembourg in 1867. The retreat of Prussian troops from the fortress Luxemburg (in Luxembourg) was no satisfactory reward: "Bismarck tried to cheat me. A French emperor cannot be cheated," grumbled Napoleon III, not willing to allow the Prussians to cross the Main River line and extend their power into southern Germany, which was Bismarck's obvious aim.

Last years. The Emperor's failures in foreign affairs strengthened the opposition. When in the 1869 elections the government received 4,438,000 votes against the opposition's 3,355,000, Napoleon came to recognize that a genuine change of the regime was now inevitable. In January 1870 he appointed Olivier-Émile Ollivier, whom Morny had recommended as the most appropriate prime minister for a liberal empire. The new cabinet informed Great Britain and Prussia that France was ready to disarm, but Bismarck refused to cooperate.

Drift toward war

On July 2 it became known that a Hohenzollern prince, a relative of the King of Prussia, was a candidate for the Spanish throne. In Paris this was regarded as Prussian interference in a French sphere of interest and a threat to its security. Using his favourite means of secret diplomacy, Napoleon played a major part in causing the Hohenzollern prince to renounce his candidature. But then the sick Emperor, influenced by the advocates of a belligerent policy, set out to humiliate Prussia by demanding that the candidature of the Hohenzollern prince would never be revived. "Never was war so popular, and the head of the state could not have stopped the nation's war spirit without risking his crown," he excused himself later. As a result, war broke out on July 19. At the Battle of Sedan the sick Emperor tried in vain to meet his death in the midst of his troops, but on September 2 he surrendered. He was at once deposed, and on September 4 the Third Republic was proclaimed.

Defeat and death

After the conclusion of peace, Napoleon was released by the Germans, and he went to live in England. He studied technical and social problems, defended his politics in various publications, and even thought of landing in France to regain his throne. After undergoing an operation for the removal of bladder stones, he died on January 9, 1873.

His life and work have been variously interpreted. He has been called a revolutionary as well as a reactionary, a precursor of the League of Nations as well as Fascism. He himself believed that he had fulfilled a providential mission. After he was dethroned he confessed: "I may sometimes have been mistaken in my choice of means and men," but he never doubted that his idea of giving France prosperity at home and glory abroad was "an historical necessity."

Narcotic

Narcotics, which constitute one of the oldest classifications of drugs known to man, produce several effects, primarily analgesia (the relief of pain), but also narcosis (a state of stupor or sleep), addiction (physical dependence), and side effects. The term narcotic is often restricted to the addictive pain-killers.

The narcotics, or narcotic analgesics, as they are more properly called, are the most effective drugs available for the relief of pain during the conscious state. Some types of pain are more amenable to the effects of narcotic analgesics than others. Characteristically, colicky pain originating in hollow viscera, as, for example, the gastrointestinal tract, or ureter, is more affected by narcotic than by non-narcotic analgesics (such as aspirin, acetaminophen, and similar compounds). Narcotic analgesics are useful following major wounds acquired in battles or in civilian accidents. It must be borne in mind, however, that the psychological context in which a wound occurs is of major importance to the perception of pain. For example, four-fifths of a group of male, civilian patients requested pain medication following major surgery, while only one-third of a group of wounded soldiers did so, although the latter had in most instances suffered far greater tissue damage. This difference in response might be explained by the fact that the soldier feels relief at having escaped from the battlefield alive, while the civilian is still concerned with the threat to his well-being posed by major

surgery. Thus there is, generally speaking, no direct relationship found between wound severity and the degree of pain perceived.

General characteristics of narcotics. Narcotic analgesics may be classified as natural, semisynthetic, or synthetic.

Natural narcotics. Opium is the source of natural narcotics. The pharmacologically active constituents of opium are members of a class of chemical compounds known as alkaloids (for a discussion of their biochemistry, see ALKALOIDS); they constitute about 25 percent by weight of opium. Although numerous alkaloids are present in opium, only a few of them—morphine, codeine, papaverine, and noscapine—have wide clinical use. Morphine, the most important alkaloid of opium, is predominantly responsible for its pharmacological properties and remains the standard against which new analgesic narcotics are measured.

Opium

Opium is obtained as a milky juice of unripe seed capsules of a poppy plant (*Papaver somniferum*) native to Asia Minor. The juice, dried in air to form a brownish, gummy mass, is further dried and powdered to provide the final product. Since opium is a source of natural alkaloids, narcotics with actions similar to those of morphine are sometimes called opiates.

Semisynthetic and synthetic narcotics. A number of semisynthetic narcotic analgesics (*e.g.*, heroin), obtained by relatively simple structural modifications of the morphine or codeine molecules, find use; these compounds are listed in Table 1. Fully synthetic compounds, sometimes called opioids, with structural resemblance to the whole, or to a part, of the morphine molecule also are employed as narcotic analgesics. The chemical and generic names of these compounds appear in Table 2.

Table 1: Semisynthetic Narcotic Analgesics

generic name	relative analgesic effect*	relative effect in addicts*	duration of action of average dose (hours)
Morphine†	100	100	3–4
Codeine	8–15	20	3–4
Ethylmorphine	10–20	—	3–4
Heterocodeine	100–200	100–200	2–3
Heroin	200–330	280	2–4
Dihydromorphine	120	333	2–4
Dihydrocodeine	30	30	2–3
Desomorphine	500–1,000	500	2–3
Hydromorphone	200–500	700	2–4
Metopon	200–300	700	3–5
Hydrocodone	70	100	2–3
Oxymorphone	500–1,000	800–1,000	4–6
Oxycodone	100	76	2–3

*The analgesic effect of morphine sulfate and its ability to suppress abstinence syndrome in addicts is rated 100.
†Morphine included for the sake of comparison.

Table 2: Synthetic Narcotic Analgesics

generic name	relative analgesic effect*	relative effect in addicts*	duration of action of average dose (hours)
Morphinan derivatives			
Morphinan	negligible	negligible	—
Levorphan (Levorphanol)	330–500	200–500	4–5
Pentazocine	500	200–300	—
Methadone derivatives			
Methadone	100–130	420	3–4
Isomethadone	40–80	140	3–4
Dipipanone	40	100	2–3
Phenadoxone	15	80	2–4
Dextromoramide	200	300–400	3
Meperidine derivatives			
Meperidine (Pethidine)	10	40	1–2
Alphaprodine	25	60	1–2
Ketobemidone	70–100	100	2–4
Anileridine	25	35	2–3
Phenoperidine	700–1,500	—	1–2
Fentanyl	5,000–10,000	—	1–5

*The analgesic effect of morphine sulfate and its ability to suppress abstinence syndrome in addicts is rated 100.

Relationship between chemical structure and narcotic action. The mechanism and the site of action of narcotic analgesics have not been clearly delineated. In all potent narcotics, it is possible to recognize three molecular characteristics that are believed to be related to the mode of action of the drugs. These consist of (1) a tertiary basic nitrogen; (2) a quaternary carbon separated from the basic nitrogen by an ethylene ($-CH_2\ CH_2-$) chain; and (3) a phenolic hydroxyl or a ketone. A phenyl group, or a group with a similar shape, attached to the quaternary carbon atom is also thought to be an important constituent of the narcotic analgesic molecule.

The primary sites of action of morphine in the body probably consist of the sensory cortex of the frontal lobes and the diencephalon (the posterior portion of the forebrain). Morphine has been shown to depress the pain responses travelling from the brain centres that initially perceive them to those responsible for the subjective reaction of pain. It may be said, therefore, that the analgesic effects of narcotics resemble the effects of transecting the thalamocortical tracts, a surgical procedure known as prefrontal lobotomy. While the precise mechanism of action of the narcotics has not been elucidated, there is general agreement the drugs act on the central nervous system rather than upon peripheral pain receptors.

Biological disposition of narcotics. *Absorption.* Narcotics are absorbed well by all species following hypodermic or intramuscular administration. Absorption from the gastrointestinal tract and other mucous membranes is good but less reliable; codeine is absorbed in this way better than is morphine. Following hypodermic or intramuscular administration of narcotics, results appear within 15 to 30 minutes, with peak effect occurring in 45 to 90 minutes. After intravenous administration, the onset of action is noticeable within one minute and, depending upon the type of narcotic used, reaches its peak in three to six minutes.

Distribution. Free morphine leaves the blood rapidly and, as is the case with other narcotics, accumulates in the parenchymatous organs (the kidney, lung, liver, and spleen), with only a small fraction of the total amount being found in the central nervous system. Narcotics readily cross the placental barrier; concentrations of meperidine, for example, in fetal blood are comparable to those of maternal blood.

Metabolism. The liver is primarily responsible for the metabolic transformation of narcotics. Known and postulated metabolic pathways for morphine include conjugation, dimerization, removal of the methyl group from nitrogen, and addition of a methyl to the 3-oxygen. Narcotics of the ester type, such as meperidine, anileridine, and heroin, are hydrolyzed in the body and excreted as acids. Compounds such as codeine, with an ether linkage in the 3-position, undergo dealkylation. Only the first of these—conjugation with glucuronic acid—has been established for morphine *in vivo*.

Physical dependence. The condition popularly known as drug addiction is more appropriately described as physical dependence upon a narcotic drug. Physical dependence is closely related to drug tolerance, a condition in which standard doses of the drug produce progressively less effect. Dependence has been attributed to various factors, including delayed or incomplete absorption, altered tissue distribution in the central nervous system, or increased rate of metabolism or excretion; it is generally agreed that physiologic dependence develops initially at the cellular level. This has been demonstrated for morphine in cell cultures of several types. Cells of the central nervous system that initially acquire the ability to function in the presence of relatively high levels of narcotics soon become unable to function normally in their absence. (The plasma levels of narcotics that prevent the onset of withdrawal symptoms, however, may be substantially below the peak levels that follow intravenous injection.) Because of tolerance, the euphoria initially produced by the drug diminishes with chronic exposure and progressive physical dependence. The resulting paradox in established addiction is the absence of euphoria and the need for increasing dosage.

Withdrawal symptoms

Upon withdrawal, the following signs and symptoms of physiological dependence in man appear: yawning, tearing, perspiration, running of the nose, dilation of the pupils, tremors, restlessness, abdominal cramps, gooseflesh, defecation, vomiting, and increases in systolic pressure, rectal temperature, and respiratory rate. Subjects who are excessively dependent may experience convulsions, respiratory failure, and death. Dependence develops more rapidly to heroin than to morphine, and more rapidly to morphine than to anileridine, oxymorphone, or meperidine. The administration of a narcotic antagonist can precipitate signs of physiological dependence (see below).

A new approach to the rehabilitation of heroin and other opiate addicts is termed "methadone therapy." Methadone is a narcotic with analgesic and other effects similar to morphine. Unlike most other narcotics, it is effective upon oral administration. It is used in the management of heroin addicts because of its ability to block the euphorogenic effects and cravings for heroin without, apparently, duplicating the physical and mental debilitation produced by that drug. Because of its relatively long duration of effect, a single, daily oral dose of methadone may suffice in most cases of heroin dependence. Methadone itself is addicting, though less so than heroin. In methadone therapy, methadone addiction is substituted for heroin addiction because it is believed that the former allows the patient to function more normally in a social matrix (see also DRUG PROBLEMS).

The clinical use of narcotic analgesics. *General considerations.* It is generally accepted that there is an optimum dose of narcotic analgesics, below which there is insufficient effect and above which there is little gain in analgesia but an exponential increase in undesirable side effects. The side effects include: respiratory and circulatory depression, nausea, vomiting, pruritis, and dysphoria. The optimal therapeutic dose of morphine in a 150-pound man is 15 milligrams. Although all narcotic analgesics share certain common chemical characteristics, there are marked chemical differences between the naturally occurring compounds, typified by morphine, and such synthetic analgesics as meperidine, alphaprodine, or fentanyl. Nevertheless, the pharmacological characteristics of the narcotics as a general class are so similar that specific drugs are selected primarily for differences in duration of effect, degree of sedation, and absorbability from the gastrointestinal tract. The few pharmacological differences creating relative indications for specific drugs are mentioned below, as appropriate.

Circulatory effects

The circulatory effects of narcotics are probably a result of both narcotic influence in the brain stem, where regulatory centres for circulation exist, and a direct action upon the peripheral blood vessels themselves. Since narcotics can cause the liberation from tissues of histamine, a known blood-vessel dilatator, it is likely that dilatation in the peripheral blood vessels following the administration of a narcotic is secondary to the liberation of histamine. (Morphine and most other narcotics cause histamine release although, as yet, this property has not been demonstrated with fentanyl.) Narcotics in general, and morphine in particular, are drugs used in the treatment of pulmonary edema. This condition may occur during congestive heart failure when the flow of blood returning to the heart from the lungs cannot be adequately handled by the left atrium and ventricle. The resulting decrease in available oxygen produces restlessness and apprehension. Morphine, in addition to tranquillizing such a patient, may dilate the peripheral vascular bed and cause the sequestration of sufficient blood to reduce the work load upon the heart, thus improving the clinical situation. Narcotics such as meperidine, which cause an increase in heart rate, would be avoided in such instances.

The crushing chest pain that may accompany coronary occlusion is a prime indication for narcotic analgesics. A given dose of narcotic produces less respiratory depression in a patient with pain than in a patient without pain.

Preoperative. Claude Bernard, the renowned physiologist of the late 19th century, was the first to administer morphine to animals prior to the induction of ether anesthesia. Narcotics are commonly included in preanesthetic medications today; they enhance sedation and amnesia and reduce apprehension and anxiety. In addition, the total dose of anesthetics required is reduced. Narcotics may be especially useful when the patient is in pain prior to surgery, when he suffers from chronic alcoholism or barbiturate or narcotic addiction, and when he should not be exposed to postoperative restlessness and excitement.

Postoperative. The relief of postoperative pain is one of the most frequent indications for administering narcotic analgesics. Sex and nationality have been listed among the factors that may alter the postoperative response to pain (and therefore the need for narcotics), but little documentation exists to substantiate their inclusion. On the other hand, fear, anxiety, and concern have definitely been shown to increase the postoperative need for narcotics. Additionally, such sociological factors as income bracket seem to have an effect: the average number of doses of morphine were tabulated following gallbladder removal in ward patients, semiprivate patients (two beds to a room), private patients, and patients in the most luxurious rooms. The respective numbers of doses of morphine required by these four groups were 3, 5, 9 and 12. Another, more obvious, factor is the site of operation. The most severe pain is likely to occur when the wound is in an area where unavoidable movements (such as breathing) occur. Generally, operations involving the upper abdomen are associated with moderate to severe pain and require narcotic analgesics. When a patient is educated before surgery about the pain he is likely to encounter, the reasons for it, and the means by which he may avoid the movements that will enhance it, there is usually a marked reduction in the need for postoperative narcotics.

During childbirth. Morphine has been used for many years to relieve the pain of childbirth. R. von Steinbüchel was the first to describe the combination of morphine and scopolamine for the relief of labour pain. The combined effect was referred to as "twilight sleep," a translation of the German word *Dämmerschlaf*. While no increase in maternal mortality could be attributed to this combination of drugs, the frequent occurrence of the depressed "blue baby" following its use led many obstetricians to condemn it.

Twilight sleep

Fetal depression attributed to the use of morphine in childbirth has led to many attempts to replace the drug with less depressant narcotic analgesics. Most of the narcotics in Tables 1 and 2 have been used in attempts to combine pain relief for the mother with less respiratory depression for the newborn. It has become almost axiomatic, however, that the degree of respiratory depression parallels the degree of pain relief. There is some evidence that meperidine and alphaprodine are exceptions to this rule; this is probably due to the fact that the immature liver of the newborn is better able to detoxify these drugs than it is morphine and other opioids.

In general anesthesia. Narcotics also are used during general anesthesia. After the production of sleep with a short-acting barbiturate, such as thiopental, one common technique of inducing general anesthesia consists of the administration of nitrous oxide plus oxygen. In many instances, however, nitrous oxide is not sufficiently potent to provide the depth of anesthesia required; intermittent increments of narcotic are then given intravenously for reinforcement. In the recent past, morphine has been used in this fashion with great success, especially in extreme poor-risk patients, such as those undergoing cardiac surgery. The exceedingly high doses of morphine used successfully in such cases attests to the general safety of narcotics when respiratory support is maintained.

The most potent narcotic in current clinical use is fentanyl. This drug is approximately 50 to 100 times more potent than morphine and has recently been employed along with a potent tranquilizer, droperidol. The administration of this combination of drugs produces a state that has been called neuroleptanalgesia (indicating that both the autonomic and the central nervous systems are affected). When nitrous oxide and oxygen are also administered, the state induced is referred to as neuroleptanesthesia.

Narcotic antagonists. Chemically, the narcotic antagonists are usually N-allyl derivatives of narcotic analgesics.

There is a close correlation between the analgesic and respiratory effects of the narcotics themselves and the pharmacological effects of the antagonists derived from them. The mechanism of action of the antagonists is most probably a competition between the narcotic and the antagonist for a single receptor site. When they are administered to human subjects, the narcotic antagonists show some pharmacological effects similar to those of the narcotics. For example, the analgesic activity of nalorphine is as great, milligram per milligram, as that of morphine. On the other hand, the antagonists levallorphan and naloxone have insignificant analgesic effects in doses capable of counteracting narcotic-induced respiratory depression. A significant characteristic of a narcotic antagonist is its inability to produce physiological dependence; this is probably related to the fact that these drugs do not produce the euphoria that results in addiction. Pentazocine, a synthetic agent, was discovered as the result of a search for a narcotic antagonist that could be employed primarily as an analgesic.

Treatment of overdosage

The primary use of narcotic antagonists is in the treatment of accidental or purposeful overdosage with narcotics. They also may be administered to newborns who manifest respiratory depression attributed to the narcotic administered to the mother for purpose of pain relief during labour and delivery. Physical dependence on narcotics can be demonstrated by administering a narcotic antagonist; this so-called "allyl test" precipitates the symtoms of withdrawal in addicts.

(E.S.S.)

Nasser, Gamal Abdel

No other Arab leader in modern times has succeeded in winning the sometimes hysterical support of Arab masses throughout the Middle East as did Gamal Abdel Nasser during the last 15 years of his life. Even the loss of two wars, with disastrous results for Egypt, did not dim the popularity of this charismatic, almost mythogenic, army officer who became the first true Egyptian to rule the country in several millennia, giving his people the dignity denied them under foreign rule. Yet, he failed in his ambition to create a unified Arab world, and before his death he was forced to sacrifice some of Egypt's political independence for the military support of the Soviet Union.

© Karsh—Rapho Guillumette

Nasser.

Although complex and revolutionary in his public life, privately Nasser was conservative and simple. He knew the loneliness of power. He was more than six feet tall, weighed 200 pounds, had close-cropped graying hair, a swarthy complexion, the physique of an athlete, and a warm, pleasant personality.

Early life

He was born on January 15, 1918, in a mud-brick house on an unpaved street in the Bacos section of Alexandria, Egypt, where his father was in charge of the local post office. In an effort to identify him with the fellahin (peasants), Egyptian government publications for years gave his birthplace as Banī Murr, the primitive Upper Egypt village of his ancestors. From Alexandria, Nasser's father was transferred to al-Khaṭāṭibah, a squalid delta village, where the boy got his first schooling. Then he went to live in Cairo with an uncle who had just been released from a British prison and had rooms in a building occupied by nine Jewish families.

Constantly in trouble with schoolteachers, some of them British, Nasser took part in many anti-British street demonstrations. In one he received a blow on the forehead that left a lifetime scar. After secondary school he went to a law college for several months, then entered the Royal Military Academy, graduating as a second lieutenant.

While serving in the Egyptian Army in The Sudan, he met three fellow officers—Zakaria Mohieddine, later vice president of the United Arab Republic; Abdel Hakim Amer, later field marshal; and Anwar Sadat, who succeeded Nasser as president. Together, they planned a secret revolutionary organization, the Free Officers, whose composition would be known only to Nasser; their aim was to oust the British and the Egyptian royal family.

In the 1948 Arab war against the newly created state of Israel, Nasser was an officer in one of three battalions surrounded for weeks by the Israelis in a group of Arab villages called the Faluja Pocket.

On July 23, 1952, Nasser and 89 other Free Officers staged an almost bloodless coup d'état, ousting the monarchy. Sadat favoured the immediate public execution of King Farouk and some members of the establishment, but Nasser vetoed the idea and permitted Farouk and others to go into exile. The country was taken over by a Revolutionary Command Council of 11 officers controlled by Nasser, with Maj. Gen. Mohammad Naguib as the puppet head of state. For more than a year Nasser kept his real role so well hidden that astute foreign correspondents were unaware of his existence; but in the spring of 1954, in a complicated series of intrigues, Naguib was deposed and placed under house arrest; Nasser emerged from the shadows and named himself prime minister.

Attainment of power

That same year an Egyptian fanatic tried to assassinate Nasser at a mass meeting in Alexandria. When he confessed that he had been given the assignment by the Muslim Brotherhood, Nasser cracked down on this extremist Arab religious organization.

In January 1956 Nasser announced the promulgation of a constitution under which Egypt became an Islāmic, Arab, welfare state with a one-party political system. In June, 99.948 percent of the 5,000,000 Egyptians voting marked their ballots for Nasser, the only candidate, for president. The constitution was approved by 99.8 percent.

As Nasser took titular as well as actual control, Egypt's prospects looked bright. A secret contract had been signed with Czechoslovakia for war material, and Great Britain and the United States had agreed to put up $270,000,000 to finance the first stage of the Aswān High Dam project. But on July 20, 1956, the U.S. secretary of state John Foster Dulles cancelled America's offer; the next day Britain followed suit. Five days later, addressing a mass meeting in Alexandria, Nasser announced nationalization of the Suez Canal, promising that the tolls Egypt collected in five years would build the dam. On October 29, while attending a birthday party for one of his children, Nasser received news that the Israeli Army had invaded the Sinai Peninsula. Two days later, French and British planes attacked Egyptian airfields. Although the Israelis occupied the Sinai Peninsula to Sharm ash-Shaykh and the Egyptian Air Force was virtually de-

stroyed, Nasser emerged from the brief war with undiminished prestige throughout the Arab world.

In *Philosophy of the Revolution*, which he wrote in 1954, Nasser told of "heroic and glorious roles which never found heroes to perform them" and outlined his aspiration to be the leader of the 55,000,000 Arabs, then of the 224,000,000 Africans, then of the 420,000,000 followers of Islām. In 1958 Syria and Egypt formed the United Arab Republic, which Nasser hoped would someday include the entire Arab world. Syria withdrew in 1961, but Egypt continued to be known as the United Arab Republic. That was as close as Nasser ever came to realizing his tripartite dream.

Nasser's accomplishments

But there were other accomplishments. The Aswān High Dam, built with the help of the Soviet Union, began operating in 1968; 20th-century life was introduced into many villages; industrialization was accelerated; land reforms forbade any individual to own more than 100 feddans (104 acres); a partially successful campaign was conducted against corruption; and women were accorded more rights than they had ever had. A new middle class began to occupy the political and economic positions once held in Egypt by Italians, Greeks, Frenchmen, Britons, and other foreigners, whom Nasser now encouraged —sometimes not gently—to leave the country. Nasser's outstanding accomplishment was his survival for 18 years as Egypt's political leader, despite the strength of his opponents: Communists, Copts, Jews, old political parties, rival military cliques, dispossessed landowners, supporters of Naguib, and what was left of the foreign colony.

On the negative side, Nasser made Egypt a police state, in which mail was opened, the communications media were strictly censored, the chief newspapers nationalized, telephones tapped, and visitors' rooms searched. Political democracy in the Western sense was nonexistent. One-party candidates for office were handpicked by Nasser and his close associates. Political enemies were herded into concentration camps in the desert. Life was little changed for most fellahin. The birth rate remained so high as to defeat attempts to increase the living standard.

In foreign affairs Nasser joined Tito of Yugoslavia and Jawaharlal Nehru of India as an advocate of nonalignment, or "positive neutrality." At the Bandung conferences of Asian and African nations in 1955, he emerged as a world figure. His refusal to recognize Israel and Egypt's defeat by Israel in 1956 forced him to divert vast sums into military channels that might have gone to implement his social revolution.

Egyptian troops supported the Republican Army in Yemen's civil war starting in 1962. But they were withdrawn in 1967, when war broke out again between Egypt and Israel after Nasser had requested the United Nations to remove its peace-keeping troops from the Gaza Strip and Sharm ash-Shaykh, then closed the Gulf of Aqaba to Israeli shipping. After the Egyptian Air Force was destroyed on the ground and the Egyptian Army forced to retreat across the Suez, Nasser attempted to resign, but massive street demonstrations and a vote of confidence by the National Assembly induced him to remain in office. The Soviet Union immediately began replacing all the destroyed war equipment and installed surface-to-air missiles along the Suez as a cover for Egypt's artillery emplacements. Nasser had tentatively accepted an American plan leading to peace negotiations with Israel when he died on September 28, 1970, from a heart attack.

Natal

Natal, the smallest of the four provinces of the Republic of South Africa, is bounded on the east by the Indian Ocean, on the south by Cape Province, on the west by Lesotho, the Orange Free State, and Transvaal, and on the north by Swaziland and Mozambique. Its area, which includes Zululand and Tongaland, is 33,578 square miles (86,967 square kilometres), and its population, in 1970, was about 4,250,000. It was given its name by Vasco da Gama, who, on Christmas Day 1497, sighted the entrance to the harbour of Port Natal, today called Durban. Its capital is Pietermaritzburg. The province attained its present extent by 1902.

History. The area was occupied centuries ago by the Nguni branch of the Bantu, who entered in strength from the north. The first European settlers established the trading post, called Port Natal, in 1824, but little attempt was made to develop the interior, whose inhabitants had been decimated by the Zulu chief Shaka by 1820. This apparently empty land was entered by the Voortrekkers, Afrikaners who left Cape Colony, via the Drakensberg (see below) passes in 1837. After the defeat of the Zulus by the Afrikaners at Blood River in 1838, the Afrikaners established the Republic of Natal. When Natal was annexed by the British in 1843, many of the Afrikaner inhabitants left for the interior and were replaced by immigrants, mainly from Britain. From 1860 onward, increasing numbers of Indians entered to work as labourers in the sugar plantations on the coast. The colony was extended by successive acquisitions—notably that of Zululand (the area north of the Tugela River), which was added after the Zulu War of 1879, fought between the Zulu and the British. The lands north of the Buffalo River were added in 1902. During the South African War (1899 to 1902), when the British fought the Boers, the Afrikaner descendants of Dutch settlers, Natal was invaded by the Boer forces who were checked by the British defense at Ladysmith. In 1910 the colony became a province of the Union of South Africa and in 1961 of the republic.

European settlement

The natural landscape. Natal is generally hilly or mountainous, especially along its western border, and rises from the coast to over 11,000 feet at the Drakensberg Escarpment (the edge of the interior plateau of South Africa and of Lesotho). The slope, however, is not gradual and is converted by various outcrops into steps of undulating land separated by escarpments. The lowest step is the coastal plain, less than 500 feet above sea level, widening to the north; then follow surfaces at 2,000 to 2,500 feet and at 3,500 to 4,500 feet (parts of which are referred to as the Midlands). Beyond the province, to the west, lies the Highveld, or high plateau. The continuity of these steps is often interrupted by spurs extending from the Drakensberg and by rivers—notably the Tugela—that cross the province in troughs hundreds of feet below the surrounding countryside.

Relief and drainage

Climate. The climate is generally related to major relief features. Rainfall decreases from more than 50 inches annually along parts of the coast to 30 to 40 inches inland, and then increases to well over 60 inches in the Drakensberg. About 60 percent of the coastal rainfall and 85 percent in the west falls in the summer months, October to March, often as heavy afternoon showers associated with thunderstorms. Temperatures decrease with altitude from the frost-free coast (January 70° to 75° F [21° to 24° C], July 60° to 65° F [16° to 18° C]) to the west (January 60° to 65° F [16° to 18° C], July 40° to 45° F [4° to 7° C]). There are significant day-to-day changes in weather and innumerable local climates due to minor differences in relief. In sheltered valleys or basins annual rainfall is often below 25 inches, and temperature inversions occur in winter (April to September); sea-facing slopes receive higher rainfall, while in the Midlands, mist belts often form in summer along escarpments and hot mountain winds blow from the interior occasionally. In general, summers are hot with occasional rain, and the humidity is high near the coast; hence, the Drakensberg mountain resorts are well patronized at this season. The warm, dry, and sunny winters have made the coast the principal holiday playground of southern Africa.

Vegetation and animal life. The natural vegetation, where it has not been modified or destroyed, falls into several belts according to altitude and climate. Tropical forest or bush, mangrove-fringed in the north, occurs in patches on the more open land along the coast. Farther inland in the north is bushveld, or savanna (grassy parkland), while farther south, in the river basins and valleys, cactus-like euphorbias (spurges) are characteristic. The Midlands and southwest sustain temperate forests, but these now exist only in relict patches. Open country, studded with thorn trees, covers the western half of the province; with true grassland occurring only at the high altitudes.

The province, especially its coastal margin, is regarded as a transitional corridor along which tropical and more temperate animal life and vegetation have spread and intermingled. Measures for conservation are taken. The Natal Parks Board controls 34 parks or game and nature reserves, with a total extent of 527,000 acres, which provide facilities for wilderness trail hiking. The larger reserves are situated in two different environments—along and behind the Zululand coast and in the Drakensberg. In Zululand, rhinoceros, buffalo, hippopotamus, and crocodile are characteristic varieties of animals. Fishing owls and fish eagles are also found, while vegetation includes the fever tree and the crane flower. In the Drakensberg are found the eland (a large African antelope) and the baboon, the martial eagle, and the lammergeier (bearded vulture). Vegetation includes tree ferns and ground orchids. Trout are found in the rivers of the interior, while along the coast, fish catches range from shad to sharks; in winter, sardine or pilchard shoals attract many game fish.

Game and nature reserves

Population. The people of Natal form a mosaic of different ethnic groups living together within a complex social structure. As elsewhere in South Africa, the main distinction is between two composite groups, white and black, who, in accordance with the government's policy of apartheid (separate development), live in different but coexistent worlds. The whites are mainly of British or Dutch descent, while the nonwhites include a Bantu majority (*i.e.*, Africans speaking Bantu languages), a number of Asians (Indians), and a group of Coloured people who are the product of interbreeding. In the early 1970s the Bantu people had the highest rate of increase, followed by the Coloureds, Indians, and Europeans. In 1970, out of a total of about 4,250,000, there were 3,210,000 Bantu, 500,000 Indians, 450,000 Europeans, and 70,000 Coloureds. Most of Natal's people live along and behind the coast (except in the north) or in the centre of the province; the extreme west and northeast is lightly populated. The Bantu are especially concentrated in many fragmented areas (now referred to as homelands), which, in 1970, were designated as the Zulu Territorial Authority and granted some autonomy. These homelands cover about a third of the province, and—except in the northeast—consist of broken rugged country. About half the Bantu live in them; the remainder live in the European rural areas or towns. Two-thirds of Natal is European-owned, and most Europeans live in or near Durban, in the towns along the route running west to the Witwatersrand ridge on South Africa's central plateau, or along the coast. More than 80 percent of South Africa's Indians live in Natal, and these and the Coloured people have a distribution similar to the Europeans.

Bantu homelands

Urban–rural distribution. Urbanization is proceeding apace. In 1970, out of the total population, a little over one-third (38 percent) was urbanized. About 90 percent of the Europeans, 89 percent of the Coloureds, 85 percent of the Indians, and 22 percent of the Bantu are urbanized. The towns are a European innovation, superimposed upon a previous Bantu rural settlement pattern, but they have proved increasingly attractive to the other population groups who live in separate residential areas within them, and few towns now have a majority of Europeans. Durban (population 1,000,000) and to a lesser extent Pietermaritzburg (170,000) dominate the urban scene. The other towns are few in number and are considered small in size.

Customs, language, and religion. Each population group has a cultural identity reflected in its religion, language, and customs. Some 70 percent of the Europeans have English as their basic language, most of the remainder speak Afrikaans, and many Europeans speak both languages. The Europeans are mainly Christians; the Coloured people have a close affinity to the Europeans and have a similar culture. The Indians, on the other hand, have adopted many elements of the Western culture, but they retain an identity and a diversity by maintaining much of their own cultures. Some 70 percent profess Hinduism, 20 percent are Muslims, and the remainder are largely Christians. Most are fluent in English, but about 85 percent speak various Indian languages at home. The Bantu have not been culturally assimilated to the same extent as the other non-Europeans. They have retained their identity through their use of Zulu, which is the language of some 90 percent of the Bantu, and through a rich heritage of folklore, ceremony, and customs that reflect the diversity of tribal allegiances. The rest of the Bantu speak cognate languages.

Administration. The constitution of the republic provides for provincial administration from Pietermaritzburg, through an administrator (chief executive officer), a provincial council, and its executive committee. The province has powers in such matters as taxation, education, hospitals, charitable institutions, and local works. The local administrative unit is the magisterial district. The province, under the aegis of the central government, imposes duties and grants certain rights to local government authorities functioning through municipal and borough councils or town boards—normally under the chairmanship of mayors.

Social conditions. *Public health.* The provincial administration, local authorities, voluntary bodies, and a range of welfare authorities cooperate with the South African Department of Health in caring for health and welfare. The province controls hospital services, which, in 1965, included some 19,000 beds in 20 provincial and many private institutions, some 30 of which were in the Bantu homelands. Medical facilities are largely concentrated in the towns but are supplemented by many outlying clinics and health centres. Medical training for doctors is available for nonwhites at Natal University, Durban. There are about 900 doctors in the province. Diseases that especially affect the Bantu include tuberculosis, bilharzia (a parasitic disease of the blood), and kwashiorkor (malnutrition resulting from severe protein deficiency).

Education. Education below the university level is provided for whites at some 360 schools, two technical colleges, and three teacher training colleges; and for nonwhites at about 1,200 schools, nine technical colleges, and ten teacher training colleges. The University of Natal, which was founded in 1909 as a constituent college of the University of South Africa and assumed university status in 1949, is the chief institution of higher education. It is located partly in Pietermaritzburg and partly in Durban. Higher education for Indians is available at the University of Durban-Westville—established in 1960—and for Bantu at the University of Zululand, located at Kwa Dlangezwa, near Empangeni, established in 1957.

Universities

Economy. Natal has two coexistent economies. One is the subsistence economy of the Bantu homelands based upon pastoralism (largely cattle raising) and cultivation (mainly of corn [maize] grown in small plots) and supplemented by migrant labour. The homelands have poor resources, although considerable effort is being directed toward their development; their economy is supplemented by the earnings of Bantu who work elsewhere in South Africa. The other is the advanced commercial economy pursued by the whites, with the assistance of nonwhites, elsewhere in the province. It is through this economy that most of the considerable and varied resources of the province are being developed.

Minerals. The mineral wealth of Natal consists essentially of coal, which is mined in the Newcastle-Vryheid-Dundee-Utrecht area of the northwest; 85 percent of the output is high-grade bituminous coal, much of it of cok-

ing grade. This coalfield is South Africa's chief source of coking and semi-anthracite coal. Annual production is about 10,000,000 tons.

Agriculture and forestry. The most important agricultural area lies along the coast, where sugarcane is the major crop. Production amounts to some 1,500,000 tons of sugar, grown on 700,000 acres and processed by 18 mills. Sugar growing is now of increasing importance in the Midlands. Refining for domestic and export requirements is mainly carried out at Durban. Plantations of pine and eucalyptus provide raw materials for sawmills and for paper, hard and soft board, and rayon pulp mills. Subtropical fruits, especially pineapples and bananas, are also grown. Durban is also the base for an important whaling industry. In the Midlands, plantations of pine, eucalyptus, poplar, and especially black wattle cover large areas. A tanning agent, of which South Africa is the largest world producer, is made from the wattle bark.

Dairying is important. Milk is produced near Durban and Pietermaritzburg; butter and cheese are produced inland. The northwest is largely devoted to cattle raising and maize cultivation, although the Drakensberg Escarpment cannot be used for agriculture because of its rough terrain. The northeast coastal plain is also unproductive, but projected irrigation schemes may provide the impetus for a final movement of the economic frontier of the province to the Mozambique border.

Industry. The products of mining, farming, forestry, and fishing, together with imported materials, support important manufacturing industries. Most are established in the towns, with the number of factories and output values roughly proportional to urban populations. Rural industries are generally restricted to those where processing takes place on the spot, although since 1960 decentralization in the form of the establishment of border industry (industry located just outside the Bantu homelands) has been in progress, notably at Elangeni (Hammarsdale), between Durban and Pietermaritzburg.

Rural and border industries

Durban, with nearby Pinetown, is the economic heart of the province and its industrial centre. It possesses over 80 percent of Natal's factories, and—with more than 10 percent of those of the republic—is South Africa's second or third most important industrial region. Its factories are associated primarily with shipping, food processing, chemicals, sugar, and oil refining. An oil pipeline connects Durban with the southern Transvaal. Pietermaritzburg has a number of industries, including an aluminum plant, several footwear factories, and food processing establishments. The northern coalfield has not yet developed industrially, but plans for the development of the Tugela Basin and a recent decision to establish a large steel plant at Newcastle may engender considerable industrial growth. Production was due to begin on a reduced scale in 1974.

Transportation and communications. A railway network consists of a main electrified axis from Durban, northwest through Pietermaritzburg to the Witwatersrand, a line along the coast, and various branch lines. The roads parallel the railways and also serve more remote areas; main roads are tarred, country roads have gravel or earth surfaces. Aircraft fly from Durban's airport to South African cities, and to Mozambique and Rhodesia, and—via Jan Smuts Airport (Johannesburg/Pretoria)—to world centres; other towns have smaller airfields.

A completely new port and industrial growth point is being developed at Richard's Bay, 100 miles north of Durban; dredging began in 1972, and the port was expected to open in 1976. An aluminum smelter was already in production in the early 1970s. In the meantime, however, Durban remains Natal's only port. It serves much of the interior of southern Africa and is South Africa's main cargo port. It has shipping links with the world, and its importance was considerably increased by the closure of the Suez Canal.

Cultural life. The people of Natal have a rich cultural heritage drawn from their differing backgrounds. Generally speaking, that of the Europeans and Coloureds is of the West, the Indians of the East, and the Bantu of Africa, although non-Europeans are becoming increasingly westernized. Cultural institutions include botanic gardens, parks, museums, libraries, art galleries, cinemas, theatres, music societies, and agricultural and industrial exhibitions in many centres, notably Durban and Pietermaritzburg. Of particular importance is the recently established Natal Performing Arts Council.

(O.W.)

National Income Accounting

The purpose of national income accounting, often called simply national accounting, is to furnish measures of the income and production of a nation.

National production, or output, is the total of final, or end, products produced by the nation during a specified period. That is to say, it is the sum of products available for consumption or for additions to the stock of capital. It does not include raw materials and semifinished products used up in production. For instance, if flour is baked into bread, only the bread is counted. The totals are expressed in monetary values, since these provide a common unit for summing the wide variety of goods and services produced. In Communist countries, it should be pointed out, the concept of national product includes only material goods and "productive" services; other services, such as those of government workers, soldiers, musicians, and household help are not counted.

Measures of national output. One commonly used measure of output is gross national product (GNP), which is the country's total output of goods and services valued at market prices. It includes also output produced abroad to which residents of the country have a claim. For some purposes it is desirable to count only the output produced within the country; the resulting total is called gross domestic product. Both of these measures of output are referred to as "gross" because they make no allowance for the amount of fixed capital (buildings, equipment, and inventories) used up in the process of production. It is logically inconsistent not to allow for the using up of fixed capital, since it cannot be considered output, and therefore statisticians try to estimate net national product by deducting an allowance for capital depreciation.

The three foregoing concepts of national output measure it in terms of market prices. The prices at which goods and services are sold include a substantial amount of indirect taxes (sales and turnover taxes, payroll taxes, and some property taxes). These may be subtracted from net national product to arrive at a figure that reflects the actual costs of production, called net national product at factor prices (or factor costs). This is generally known as national income, since it is the sum of wages, salaries, profits, and other incomes received by the population of the country.

Relationship between national product and national income

The relationship between national product and national income is basic to the understanding of national accounting statistics. It resembles on a larger scale the operations of double-entry bookkeeping in a business enterprise. It may in fact be seen as the summation of the operations of all the business enterprises in the country, if one also includes the government and the activities of paid household help. The typical business enterprise produces goods that it either sells or adds to its inventories. Chargeable to this production are purchases of raw materials and other intermediate products from other enterprises (but not purchases of fixed plant and equipment); wages, salaries, and other incomes paid out in production; indirect business taxes, such as sales, excise, and property taxes; and depreciation and kindred allowances for fixed capital used up. A residual item of profit or loss equalizes the expenses chargeable to production with its value.

If a balance sheet is prepared for the business system as

Table 1: Expenditure on Gross National Product at Market Prices* (1968)

	Argentina	Japan	United Kingdom	United States	Federal Republic of Germany
Private consumption	4,208.7	26,682	27,020	538.9	297.3
General government consumption	657.9	4,288	7,747	184.6	83.5
Gross domestic fixed capital formation	1,245.5	17,242	7,798	146.2	121.3
Increase in stocks	3.1	2,425	204	8.5	10.2
Exports of goods and services	547.6	5,353	8,610	43.6	121.7
Less imports of goods and services	501.9	4,763	9,038	45.8	103.4
Gross domestic product	6,161.0	51,223	42,341	876.0	530.7
Net factor income from the rest of the world	−50.8	−150	558	4.7	0.1
Gross national product	6,110.2	51,077	42,899	880.8	530.8
Less indirect taxes	—	3,833	6,960	80.2	72.4
Plus subsidies	—	551	886	0.8	5.8
Less provisions for the consumption of fixed capital	—	6,574	3,375	84.1	59.3
Statistical discrepancy	—	−405	—	2.5	—
National income (net national product at factor cost)	—	40,817	33,450	719.8	404.9

*In 000,000,000 Argentine pesos, 000,000,000 Japanese yen, 000,000 British pounds, 000,000,000 U.S. dollars, and 000,000,000 deutsche marks.
Source: United Nations Statistical Office, *Yearbook of National Accounts Statistics 1969.*

a whole, those sales of enterprises that represent purchases of intermediate products by other enterprises cancel one another. Thus, purchases of intermediate products disappear from the left-hand side of the statement, and sales on the right-hand side are correspondingly reduced. Matching the noncancelling final products there remains a numerically equivalent total consisting of income streams (including profits), indirect taxes, and capital-consumption allowances. (Inasmuch as the income aggregate reflects current production, capital gains and losses are not included.)

Non-market activities

National product as defined for statistical purposes does not include all the goods and services produced in the country. The bulk of the production covered by most measures of national output consists of items that are intended for sale in the market. Goods provided outside the marketplace are usually excluded, even though they may resemble items that are included. For instance, the services of housewives are usually excluded, while services rendered by domestics are included. On the other hand, some goods and services that do not enter the market are included in the statistics. Monetary values are generally imputed to wages paid in kind, to food and fuel produced on farms for home consumption, to the services owner-occupants derive from their homes, and sometimes also to certain services, such as the handling of bank deposits, which financial institutions render free of charge to individuals. The treatment of nonmonetary items raises difficult problems in the measurement of the output of the less developed countries, where many types of productive activity that are channelled through the market in Western countries are performed within the confines of the individual household.

For some purposes it is useful to have a measure of the actual incomes received by individuals. One such measure is personal income, or the sum of the incomes received by individuals. It is derived by subtracting from national income all earnings of corporations not paid in dividends and adding to it government payments such as welfare, social security, and interest on the national debt. A related concept, disposable income, subtracts all taxes in order to arrive at an estimate of the income available to private individuals for spending.

Methods of presentation. Statistics of national output can be broken down in a number of ways according to the purposes for which they are to be used. One way, as shown in Table 1, is according to the character of the products—that is, whether goods are used for consumption (both private and governmental), investment, or export. Each category can, of course, be broken down into further detail to show sales of products to various groups of consumers, businesses, and foreign purchasers. Table 1 also shows the relationship between national income and gross national product: the former is equal to the latter, minus indirect taxes on business, plus subsidies to business, and minus an allowance for the depreciation of fixed capital.

The national output may also be analyzed according to the industries in which it is created. Table 2 does this for five countries in terms of broad categories such as manufacturing, construction, and wholesale and retail trade. As one would expect, the proportion of the national product originating in the manufacturing sector is relatively large in countries such as the United States and the United Kingdom, whereas the importance of the agricultural sector is relatively greater in less industrialized countries such as Turkey.

Table 2: Industrial Origin of Gross Domestic Product at Factor Cost* (1968)

	Argentina	Turkey	United Kingdom	Italy	United States
Agriculture, forestry, hunting, and fishing	782.1	33.7	1,127	4,591	25.3
Mining and quarrying	97.8	1.7	687	309	14.2
Manufacturing	1,683.8	16.3	12,527	11,290	246.4
Construction	305.5	7.5	2,455	3,341	39.5

The value of national output may be broken down according to the various types of incomes—wages and salaries, interest, rents, profits, and others—originating in production. Table 3 shows how the importance of the different categories varies among five countries.

Another useful form of national income account shows the financial relationships among various groups in the economy. This makes it possible to analyze the sources of savings and the channels by which they find their way into investment. Table 4 is a simplified presentation of the financing of capital investment. It shows that the largest single source of investment is saving (in the customary meaning of the term) by government and business as well as by private households. A very large part of investment, however, shows up in the accounts as the using up of

capital that is already in existence; it is written off the books in annual depreciation allowances.

More elaborate breakdowns of the financial relationships in the national economy, known as flow-of-funds accounts, are made in some countries. These show in considerable detail the amount of borrowing and lending in various sectors of the economy by various kinds of institutions.

Input–output statistics

Two other ways of presenting statistical information on an aggregate basis may also be mentioned. Input–output statistics show the flows of products between industries —for example, the quantities of coal and iron ore used by the steel industry or the amounts of steel, rubber, glass, and other materials needed in the production of automobiles. Input–output statistics are used for such purposes as estimating the total effect on the economy of changes occurring in a single industry or the effects on different industries of a change in the supply of a particular material.

Statistics of national wealth have been developed in close relation to national income statistics. The difference between income and wealth is that the latter consists of stocks, or assets, whereas the former consists of flows. National wealth is the sum of domestic tangible assets and the net foreign balance. Changes in tangible assets can be estimated on the basis of changes in flows of national income, primarily saving and investment.

Uses of national income statistics. The concepts of national product and national income provide a means of appraising the performance of the economy as a whole. By reducing the great complexity of economic activity to a single unit of measurement, they make it possible to compare one year's level of output with another's or to measure changes in the distribution of income and product among different groups or sectors. To give only a few examples, the gross domestic product of Japan grew by more than 10 percent annually during the 1960s, as compared with less than 5 percent annually in the case of West Germany and the United States and around 3 percent for Great Britain—a comparison that sheds some light on the economic problems of those countries. The relative importance of agriculture, hunting, forestry, and fishing to total production has declined in recent decades in the industrialized countries: in the United States it declined from about 5 percent of the domestic product in 1953 to less than 3 percent in 1968; in Japan, from about 21 percent in 1953 to about 10 percent in 1968; and, in West Germany, from just over 9 percent in 1953 to under 4 percent in 1968. (Agricultural production, it should be noted, did not decline but increased; the production of other sectors, however, particularly of manufacturing, increased much more rapidly.)

The best known uses of national income and product estimates are for public-policy purposes. Economic planning in the non-Communist industrial countries is nowadays based upon projections of national income. The effects of an increase in business investment or in government spending or of a tax reduction upon national income are widely discussed, and these statistics have even crept into the speeches of presidents and prime ministers (see FISCAL AND MONETARY POLICY). Elaborate forecasting techniques have been developed for predicting the consequences of such changes upon the GNP and upon its various components (see ECONOMIC FORECASTING and ECONOMETRICS).

Limitations of national income statistics

The wide use of national income statistics does not mean that those who employ them are able to predict the future. Such estimates provide only an indication of what has already happened, and there is no guarantee that the regularities disclosed in them will persist. The behaviour of savers and investors is notably irregular, even when taken in the aggregate; no one can be certain how the general public will respond to a change in the income tax or whether the stated plans of businessmen will bear fruit in the capital market.

Sources and methods. The creation of reliable statistics of national income and product require large staffs of skilled researchers. The components of national output must be estimated on the basis of data that have been prepared largely for other purposes. These data include census enumerations, sample surveys, and statistics that are by-products of various governmental activities such as the administration of social security systems, tax laws, and expenditure programs. Many other sources, too varied to summarize, are also used. The basic data often depart definitionally and in coverage from the items in the national income accounts. Estimation of these items involves, accordingly, the integration of all the available —and sometimes conflicting—information and the filling of gaps by resorting to partial and indirect evidence.

National income figures are thus subject to error not only because of inaccuracies in the basic data but also because of imperfections in the estimating methods. Moreover, their margin of error cannot be precisely quantified because the usual mathematical techniques for measuring error are not applicable to this complex case. Estimates of the margin of error that are occasionally given with national income figures fall short of definitional precision and incorporate a great deal of subjective judgment.

The reliability of national income statistics varies greatly from country to country and within each country among the several entries in the accounts and according to the time period covered. Reliability is likely to be vastly higher for advanced industrial countries than for countries in which industrial processes have not de-

veloped. This is so mainly because industrial economies are characterized by transactions that lend themselves to registration in statistical form and because the problems confronting such economies lead to extensive data collection.

Relative errors are likely to be smaller in broad aggregates than in separately estimated components because of offsetting errors. For any given series, estimates referring to the remote past and to very recent periods are likely to be less accurate than estimates for intervening dates. This is because the quantity of primary data diminishes rapidly as one moves into the past and because estimates for recent periods are usually made before all the source material is at hand. Quarterly and monthly series are likely to be less accurate than annual estimates for similar reasons.

Skill is required not only in the preparation of national income statistics but also in their use. For some purposes it may be necessary to go beyond the published estimates and examine the methodology underlying them in order to form a judgment as to their reliability for a particular purpose.

National income estimates were prepared in England as early as the 17th century. But workmanlike estimates covering a span of years and built up from detailed components are largely a product of the 20th century. The economic problems associated with the depression of the 1930s and World War II gave impetus to the development of the statistics, largely under governmental aegis. National income estimates are now available for a large number of countries, but they reflect the wide differences among them in technologies, institutions, and statistical methods. The United Nations Statistical Office has been active in promoting international comparability, both by developing standard accounting systems and by preparing compilations in which reported series are adjusted to uniform definitions.

Difficulties of international comparisons

Comparability. Because countries differ greatly in their economies and patterns of life, comparisons of their GNP or income are apt to be misleading. If, for instance, the output of radios in one country is double that in another while the output of television sets is one-half, it is not possible to make an unambiguous comparison of the outputs of radio and TV sets combined. The result will vary according to the relative value attached to each. Thus if one country values its TV sets at three times its radio sets, while the other country values its TV sets at two times its radio sets, their statistics of total output may show one country's national product as being 40 percent greater than the other's or only 25 percent greater, depending upon which country's values are used. In reality the problem is much more complex because of the multitude of items making up each country's national output. For this reason, tables showing national income per capita for a number of different countries expressed in U.S. dollars cannot be considered very precise, even when there is no question as to the relative values of currencies and the accuracy of population estimates.

A similar difficulty arises in making comparisons over time. If in one time period the output of transportation equipment consists of horse-drawn carriages and in another of automobiles, it is not really possible to make a quantitative comparison between the two.

Another kind of difficulty arises when countries use different definitions of their national product. The national output statistics of the Soviet Union and other Communist countries cannot be directly compared with those of the United States and other Western industrial countries because of the broad difference in what is included.

Problems of design. Several unsolved problems have to do with the design of national income statistics.

As noted earlier, measures of national output are confined largely to output intended for sale, but a few departures from this rule are made by imputing values to certain nonmarket items. These imputations are a source of irritation logically because they do not flow from any general definition of output that can be specified. Moreover, the treatment of nonmarket production constitutes an acute practical problem in the analysis of economic conditions in countries whose market economies are undeveloped and also in international comparisons. Accordingly, much thought has been devoted to nonmarket output. Some progress has been made through the proposal of international conventions for its treatment, and ad hoc solutions may be found to serve the needs of specific analyses. But it seems doubtful whether an operational definition of national output not anchored to the market criterion can ever be devised.

Intermediate and final products

Questions have been raised as to the proper distinction between final output and intermediate products. Specifically, it has been urged that not all of the output purchased by government be considered final, as is commonly done. Some of it should be excluded from the national output total, it is said, as are intermediate products. Somewhat more tentatively it has been suggested that not all output bought by consumers be regarded as final either. No clear-cut proposals have been made, but the general idea appears to be to distinguish purchases that are direct causes of final human satisfaction from those that are only indirect conditions of it and to exclude the latter. Opponents of the idea have argued that the proposed distinction cannot in fact be drawn; and they have not been refuted, either in logic or through the presentation of a viable alternative to the concept in use.

For some purposes it would be desirable to extend the definition of capital formation (investment) beyond that of tangible capital formation by business to intangible items, such as expenditures for industrial research, and to capital formation by government and consumers. Little has been done to recognize intangible capital, but capital expenditures by government have increasingly been taken into account instead of being treated as current consumption.

The acquisition of residences is the only consumer purchase that is generally recognized as capital formation. There are sound reasons for extending this treatment to other consumer durables, inasmuch as these also outlast the normal accounting period and thus constitute additions to wealth.

Measurement of capital formation on a gross basis (*i.e.*, before deduction of capital consumption allowances) raises problems because it is difficult to frame a uniform definition. It is hard to draw a systematic line, for instance, that will either exclude or include repair and maintenance expenditures. In addition, the gross measure is insufficient because it does not show net additions to the capital stock. But it appears difficult also to obtain a net capital formation measure that is meaningful for output measurement.

The conventional capital consumption allowances made by business are inadequate. To an increasing extent they are made noncomparable over time by changes in tax laws. In addition, they are usually stated in terms of the original cost of the capital goods and hence cannot be deducted from gross capital formation, which is expressed in current prices, to obtain a meaningful indication of the net change in capital stock. The realism of the methods used to allocate capital consumption charges over the lifetime of the assets is also often in doubt. It is not easy, however, to devise alternative, more meaningful measures of capital consumption.

BIBLIOGRAPHY. Most contemporary textbooks of economics contain discussions of the methods and purposes of national income accounting. Basic introductory works are J.R. HICKS, *The Social Framework of the American Economy*, 2nd ed. (1955); JAMES E. MEADE and RICHARD STONE, *National Income and Expenditure*, 8th ed. (1966); RICHARD and NANCY RUGGLES, *National Income Accounts and Income Analysis*, 2nd ed. (1956); and PAUL STUDENSKI, *The Income of Nations (with Corrections and Emendations)*, 2 vol. (1961). The UNITED NATIONS STATISTICAL OFFICE publishes uniform national income data for many of the member countries of the UN in its *Yearbook of National Accounts Statistics*. It has also published a survey of the methods used in various countries in *National Accounting Practices in Sixty Countries* (1964). The UNITED STATES DEPARTMENT OF COMMERCE, OFFICE OF BUSINESS ECONOMICS, publishes regular accounts for the United States in its monthly *Survey of Current Business*. See also its *National Income and Product Accounts of the United States, 1929–1965: Statistical Tables* (1966).

Nationalism

Nationalism may be defined as a state of mind in which the individual feels that everyone owes his supreme secular loyalty to the nation-state. Nationalism is a modern movement. Throughout history men have been attached to their native soil, to the traditions of their parents, and to established territorial authorities; but it was not until the end of the 18th century that nationalism began to be a generally recognized sentiment molding public and private life and one of the great, if not the greatest, single determining factors of modern history. Because of its dynamic vitality and its all-pervading character, nationalism is often thought to be very old; sometimes it is mistakenly regarded as a permanent factor in political behaviour. Actually, the American and French revolutions may be regarded as its first powerful manifestations. After penetrating the new countries of Latin America, it spread in the early 19th century to central Europe and from there, toward the middle of the century, to eastern and southeastern Europe. At the beginning of the 20th century, nationalism flowered in the ancient lands of Asia and Africa. Thus the 19th century has been called the age of nationalism in Europe, while the 20th century has witnessed the rise and struggle of powerful national movements throughout Asia and Africa.

Nationalism, translated into world politics, implies the identification of the state or nation with the people—or at least the desirability of determining the extent of the state according to ethnographic principles. In the age of nationalism, but only in the age of nationalism, the principle was generally recognized that each nationality should form a state—its state—and that the state should include all members of that nationality. Formerly states, or territories under one administration, were not delineated by nationality. Men did not give their loyalty to the nation-state, but to other, different forms of political organization: the city-state, the feudal fief and its lord, the dynastic state, the religious group, or the sect. The nation-state was nonexistent during the greater part of history, and for a very long time it was not even regarded as an ideal. In the first 15 centuries of the Christian Era, the ideal was the universal world-state, not loyalty to any separate political entity. The Roman Empire had set the great example, which survived not only in the Holy Roman Empire of the Middle Ages, but also in the concept of the *res publica christiana* ("Christian republic" or community) and in its later secularized form of a united world civilization and in world policy as it appeared in the writings of the 17th century.

As political allegiance, before the age of nationalism, was not determined by nationality, so civilization was not thought of as nationally determined. During the Middle Ages, civilization was looked upon as determined religiously; for all the different nationalities of Christendom as well as for those of Islam there was but one civilization —Christian or Muslim—and but one language of culture —Latin (or Greek) or Arabic (or Persian). Later, in the periods of the Renaissance and of Classicism, it was the ancient Greek and Roman civilizations that became a universal norm, valid for all peoples and all times. Still later, French civilization was accepted throughout Europe as the valid civilization for educated people of all nationalities. It was only at the end of the 18th century that, for the first time, civilization was considered to be determined by nationality. It was then that the principle was put forward that a man could be educated only in his own mother tongue, not in languages of other civilizations and other times, whether they were classical languages or the literary creations of other peoples who had reached a high degree of civilization.

From the end of the 18th century on, the nationalization of education and public life went hand in hand with the nationalization of states and political loyalties. Poets and scholars began to emphasize cultural nationalism first. They reformed the mother tongue, elevated it to the rank of a literary language, and delved deep into the national past. Thus they prepared the foundations for the political claims for national statehood soon to be raised by the people in whom they had kindled the spirit.

Cultural nationalism

Before the 18th century there had been evidences of national feeling among certain groups at certain periods, especially in times of stress and conflict. The rise of national feeling to major political importance was encouraged by a number of complex developments: the creation of large, centralized states ruled by absolute monarchs who destroyed the old feudal allegiances; the secularization of life and of education, which fostered the vernacular languages and weakened the ties of church and sect; the growth of commerce, which demanded larger territorial units to allow scope for the dynamic spirit of the rising middle classes and their capitalistic enterprise. This large, 18th-century, unified territorial state with its political and economic centralization became imbued with a new spirit—an emotional fervour similar to that of religious movements in earlier periods. Under the influence of the new theories of the sovereignty of the people and the rights of man, the people replaced the king as the centre of the nation. No longer was the king the nation or the state; the state had become the people's state, a national state, a fatherland. State became identified with nation, as civilization became identified with national civilization.

The roots of national feeling

That development ran counter to the conceptions that had dominated political thought for the preceding 2,000 years. Hitherto man had commonly stressed the general and the universal and had regarded unity as the desirable goal. Nationalism stressed the particular and parochial, the differences, and the national individualities. Those tendencies became more pronounced as nationalism developed. Its less attractive characteristics were not at first apparent. In the 17th and 18th centuries, the common standards of Western civilization, the regard for the universally human, the faith in reason (one and the same everywhere) as well as in common sense, the survival of Christian and Stoic traditions—all of these were still too strong to allow nationalism to develop fully and to disrupt society. Thus nationalism in its beginning was thought to be compatible with cosmopolitan convictions and with a general love of mankind, especially in western Europe and North America.

EUROPEAN NATIONALISM

The first full manifestation of modern nationalism occurred in 17th-century England, in the Puritan revolution. England had become the leading nation in scientific spirit, in commercial enterprise, in political thought and activity. Swelled by an immense confidence in the new age, the English people felt upon their shoulders the mission of history, a sense that they were at a great turning point from which a new true reformation and a new liberty would start. In the English revolution an optimistic humanism merged with Calvinist ethics; the influence of the Old Testament gave form to the new nationalism by identifying the English people with ancient Israel.

The new message, carried by the new people not only for England but for all mankind, was expressed in the writings of John Milton in whose famous vision the idea of liberty was seen spreading from Britain, "celebrated for endless ages as a soil most genial to the growth of liberty" to all the corners of the earth.

> Surrounded by congregated multitudes, I now imagine that . . . I behold the nations of the earth recovering that liberty which they so long had lost; and that the people of this island are . . . disseminating the blessings of civilization and freedom among cities, kingdoms and nations.

English nationalism then was thus much nearer to its religious matrix than later nationalisms that rose after secularization had made greater progress. The nationalism of the 18th century shared with it, however, its enthusiasm for liberty, its humanitarian character, its emphasis upon the individual and his rights and upon the human community as above all national divisions. The rise of English nationalism coincided with the rise of the English trading middle classes. It found its final expression in John Locke's political philosophy, and it was in that form that it influenced American and French nationalism in the following century.

American nationalism was a typical product of the 18th

century. British settlers in North America were influenced partly by the traditions of the Puritan revolution and the ideas of Locke and partly by the new rational interpretation given to English liberty by contemporary French philosophers. American settlers became a nation engaged in a fight for liberty and individual rights. They based that fight on current political thought, especially as expressed by Thomas Jefferson and Thomas Paine. It was a liberal and humanitarian nationalism that regarded America as in the vanguard of mankind on its march to greater liberty, equality, and happiness for all. The ideas of the 18th century found their first political realization in the Declaration of Independence and in the birth of the American nation. Their deep influence was felt in the French Revolution.

Jean-Jacques Rousseau had prepared the soil for the growth of French nationalism by his stress on popular sovereignty and the general cooperation of all in forming the national will, and also by his regard for the common people as the true depository of civilization.

The nationalism of the French Revolution was more than that: it was the triumphant expression of a rational faith in common humanity and liberal progress. The famous slogan "liberty, equality, fraternity" and the Declaration of the Rights of Man and of the Citizen were thought valid not only for the French people but for all peoples. Individual liberty, human equality, fraternity of all peoples: these were the common cornerstones of all liberal and democratic nationalism. Under their inspiration new rituals were developed that partly took the place of the old religious feast days, rites and ceremonies: festivals and flags, music and poetry, national holidays and patriotic sermons. In the most varied forms, nationalism permeated all manifestations of life. Like the rise of American nationalism, the rise of the French produced a new phenomenon in the art of warfare: the nation in arms. In America and in France, citizen armies, untrained but filled with a new fervour, proved superior to highly trained professional armies that fought without the incentive of nationalism. The revolutionary French nationalism stressed free individual decision—in the formation of nations. Nations were constituted by an act of self-determination of their members. The plebiscite became the instrument whereby the will of the nation was expressed. In America as well as in revolutionary France, nationalism meant the adherence to a universal progressive idea, looking toward a common future of freedom and equality, not toward a past characterized by authoritarianism and inequality.

Napoleon's armies spread the spirit of nationalism throughout Europe and even into the Near East; while at the same time, across the Atlantic, it aroused the Latin Americans. But Napoleon's yoke of conquest turned the nationalism of the Europeans against France. In Germany the struggle was led by writers and intellectuals, who rejected all the principles upon which the American and the French revolutions had been based as well as the liberal and humanitarian aspects of nationalism.

German nationalism began to stress instinct against reason; the power of historical tradition against rational attempts at progress and a more just order; the historical differences between nations rather than their common aspirations. The French Revolution, liberalism, and equality were regarded as a brief aberration, against which the eternal foundations of societal order would prevail.

That German interpretation was shown to be false by the developments of the 19th century. Liberal nationalism reasserted itself; it permeated more and more peoples: the rising middle class and the new proletariat. The revolutionary wave of 1848, the year of "the spring of the peoples," seemed to realize the hopes of nationalists such as Giuseppe Mazzini, who had devoted his life to the unification of the Italian nation by democratic means and to the brotherhood of all free nations. Though his immediate hopes were disappointed, the 12 years from 1859 to 1871 brought the unification of Italy and Romania, both with the help of Napoleon III, and of Germany; at the same time the 1860s saw great progress in liberalism, even in Russia and Spain. The victorious trend of liberal nationalism, however, was reversed in Germany by Bismarck. He unified Germany on a conservative and authoritarian basis and defeated German liberalism. The German annexation of Alsace-Lorraine against the will of the inhabitants was contrary to the idea of nationalism as based upon the free will of man. The people of Alsace-Lorraine were held to be German by objective factors, by race, independent of their will or of their allegiance to any nationality of their choice.

The 1848 revolutionary wave

In the second half of the 19th century, nationalism disintegrated the supranational states of the Habsburgs and the Ottoman sultans, both of which were based upon prenational loyalties. In Russia, the penetration of nationalism produced two opposing schools of thought. Some nationalists proposed a westernized Russia, associated with the progressive, liberal forces of the rest of Europe. Others stressed the distinctive character of Russia and Russianism, its independent and different destiny based upon its autocratic and orthodox past. These Slavophiles, similar to and influenced by German romantic thinkers, saw Russia as a future saviour of a West undermined by liberalism and the heritage of the American and French revolutions.

Central and eastern Europe

One of the consequences of World War I was the triumph of nationalism in central and eastern Europe. From the ruins of the Habsburg and Romanov empires, emerged the new nation-states of Austria, Hungary, Czechoslovakia, Poland, Yugoslavia and Romania. Those states in turn, however, were to be strained and ravaged by their own internal nationality conflicts and by nationalistic disputes over territory with their neighbours.

Russian nationalism was in part suppressed after Lenin's victory in 1917, when the Bolsheviks took over the old empire of the Tsars. But the Bolsheviks also claimed the leadership of the world Communist movement, which was to become an instrument of the national policies of the Russians. During World War II Stalin appealed to nationalism and patriotism in rallying the Russians against foreign invaders. After the war he found nationalism one of the strongest obstacles to the expansion of Soviet power in eastern Europe. National communism, as it was called, became a divisive force in the Soviet bloc. In 1948 Tito, the Communist leader of Yugoslavia, was denounced by Moscow as a nationalist and a renegade; nationalism was a strong factor in the rebellious movements in Poland and Hungary in the fall of 1956; and subsequently its influence was also felt in Romania and Czechoslovakia.

ASIAN AND AFRICAN NATIONALISM

Nationalism began to appear in Asia and Africa after World War I. It produced such leaders as Kemal Atatürk in Turkey, Sa'd Pasha Zaghūl in Egypt, Ibn Sa'ūd in the Arabian peninsula, Mahatma Gandhi in India, and Sun Yat-sen in China. Atatürk succeeded in replacing the medieval structure of the Islāmic monarchy with a revitalized and modernized secular republic in 1923. Demands for Arab unity were frustrated in Africa and Asia by British imperialism and in Africa by French imperialism. Yet Britain may have showed a gift for accommodation with the new forces by helping to create an independent Egypt (1922; completely, 1936) and Iraq (1932), and displayed a similar spirit in India, where the Indian National Congress, founded in 1885 to promote a liberal nationalism inspired by the British model, became more radical after 1918. Japan, influenced by Germany, used modern industrial techniques in the service of a more authoritarian nationalism.

The new nations

The progress of nationalism in Asia and Africa is reflected in the histories of the League of Nations after World War I and of the United Nations after World War II. The Treaty of Versailles, which provided for the constitution of the League of Nations, also reduced the empires of the defeated Central Powers, mainly Germany and Turkey. The league distributed Germany's African colonies as mandates to Great Britain, France, Belgium, and South Africa, and its Pacific possessions to Japan, Australia, and New Zealand under various classifications according to their expectations of achieving independence. Among the League's original members, there were only five Asian countries (China, India, Japan, Thailand,

and Iran) and two African countries (Liberia and the Union of South Africa), and it added only three Asian countries (Afghanistan, Iraq, and Turkey) and two African countries (Egypt and Ethiopia) before it was dissolved in 1946. Of the mandated territories under the League's control, only Iraq, Lebanon, and Syria achieved independence during its lifetime.

Of the original 51 members of the United Nations in 1945, eight were Asian (China, India, Iraq, Iran, Lebanon, Saudi Arabia, Syria, and Turkey) and four were African (the same as in the League). But less than a quarter of a century after its founding, the United Nations had added 66 member nations, 55 of them Asian and African. Whereas Asian and African nations had never totaled one-third of the membership in the League, they came to represent nearly half of the United Nations. Of these new Asian and African nations, four in Asia and seven in Africa were in part or in whole created from mandated territories.

After World War II, India, Pakistan, Ceylon, Burma, and Malaya in Asia, and Ghana in Africa achieved independence peacefully from the British Commonwealth, as did the Philippines from the United States. Others had to fight hard for their independence in bitter colonial wars, as in French Indochina (Vietnam, Laos, Cambodia) and French North Africa (Tunisia, Algeria). Communism had sought to recruit supporters from within the ranks of the new nationalist movements in Asia and Africa, first, by helping them in their struggle against Western capitalist powers, and later after independence was achieved, by competing with Western capitalism in extending financial and technical aid. Chinese nationalism under Chiang Kai-shek during World War II was diminished with the take over of the Chinese Communists. But Chinese communism soon began to drift away from supranational communism, as the European Communist countries had earlier. By the late 1960s, Russian and Chinese mutual recriminations revealed a Chinese nationalism in which Mao Tse-tung had risen to share the place of honour with Lenin. As Chinese communism turned further and further inward, its influence on newborn Asian and African nations apparently waned.

Political and religious differences

Ambitions among new Asian and African nations clashed. The complex politics of the United Nations illustrated the problems of the new nationalism. The struggle with Dutch colonialism that brought the establishment of Indonesia continued with the UN mediating the dispute over West Irian (West New Guinea) well into the late 1960s. In the Suez crisis of 1956, UN forces intervened between those of Egypt and Israel. Continuing troubles in the Middle East beginning with the establishment of Israel and including inter-Arab state disputes brought on by the establishment of the United Arab Republic, concerned the UN. Other crises involving the UN included: the India-Pakistan dispute over Jammu and Kashmir; the Korean partition and subsequent war; the four-year intervention in the Congo; the struggle of Greece and Turkey over newly independent Cyprus; Indonesian and Philippine objection to the inclusion of Sarawak and Sabah (North Borneo) in the newly formed Malaysia.

Many new nations, all sharing the same pride in independence, faced difficulties. As a result of inadequate preparation for self-rule, the first five years of independence in the Peoples' Republic of the Congo passed with no semblance of a stable government. The problem of varying peoples and languages was exemplified in the Federal Republic of Nigeria, where an uncounted population including an uncounted number of tribes (at least 150, with three major divisions) used an uncounted number of languages that included at least a hundred language and dialect clusters. Religious differences kept alive the question of whether the predominantly Muslim state of Jammu and Kashmir should go with Muslim Pakistan or Hindu India for more than 20 years after the India Independence Act became effective in 1949. Desperate economic competition caused trouble, as in Israel where the needed life-giving water of the Jordan River kept it in constant dispute with its water hungry Arab neighbours.

In Europe the spirit of nationalism seemed to have waned after World War II with the establishment of international economic, military and political organizations such as NATO, the European Coal and Steel Community, Euratom, the Common Market, and others. But the policies pursued by France under Pres. Charles de Gaulle, and the problem of a divided Germany, showed that the appeal of the nation-state was still very much alive.

BIBLIOGRAPHY. The origins and development of nationalism as a political idea are discussed in detail in HANS KOHN, *The Idea of Nationalism* (1944, reprinted 1967). The various interpretations of nationalism in modern times will be found analyzed in LOUIS L. SNYDER, *The Meaning of Nationalism* (1954). The most important attempts at solving the nationality problem within a supranational framework were made in the 19th century in Austria; on this topic, see ROBERT A. KANN, *The Multinational Empire: Nationalism and National Reform in the Habsburg Monarchy, 1848–1918*, 2 vol. (1950). A new approach to the problem of nationalism was opened up by KARL W. DEUTSCH, *Nationalism and Social Communication* (1953). On nationalism in the Third World, see RUPERT EMERSON, *From Empire to Nation: The Rise to Self-Assertion of Asian and African Peoples* (1960). There are two valuable bibliographies: KOPPEL S. PINSON, *A Bibliographical Introduction to Nationalism* (1935); and KARL W. DEUTSCH, *Interdisciplinary Bibliography on Nationalism* (1956).

(H.K./Ed.)

Native Elements

Excluding the free gases of the atmosphere, there are 20 elements that occur in nature in pure or nearly pure form; these are called the native elements. Of the 20 native elements, only eight have historic or major commercial significance. The remaining elements are not abundant, and a few are considered to be mineralogical curiosities.

Although most elements in native form are rare, from ancient times several have been known, used, and cherished by man. It is generally agreed that the first metals known to man were those found in the native state. The earliest of these probably were nuggets of gold from alluvial sand and gravel deposits. Too soft for tools or weapons, this gold was used in jewelry or other decorative objects; native silver was probably used in the same way. Native copper, though soft, hardens when it is hammered and could have been used for sickles and daggers capable of cutting corn or flesh. Iron and nickel-iron, although less widely distributed, were known and were fashioned into implements by early man. The nonmetals, carbon (both as graphite and diamond) and sulfur also have been known throughout historic time.

Native gold and silver are important commercially as principal ores of these metals. Native copper is used as an ore but is not of great commercial importance. Native iron and nickel-iron are relatively rare and are of no commercial importance. Platinum in the native state, on the other hand, is practically the exclusive source of this precious metal. Platinum was unknown to the ancients, and man's first knowledge of it dates from its discovery in 1735, in the form of nuggets found in a Colombia stream bed. Early in the 20th century graphite was synthesized, but the natural product remains an important source of the substance. Diamonds have been man-made, but synthetic stones are small and are used only for industrial purposes. Not until the mid-20th century have other sources of sulfur challenged the dominant position of that native element as a basic raw material of the chemical industry.

CLASSIFICATION AND PROPERTIES

Native elements are classified as metals, semimetals, or nonmetals. In the mineralogical classification below, naturally occurring solid solutions or compounds of two or more metals are included with the metals.

Metals. The native metals of mineralogical significance are in the gold group, the platinum group, and the iron group; the others are of only minor importance.

Gold, silver, and copper

The gold group comprises three important metals; namely, gold, silver, and copper. These elements fall in the same family in the periodic classification (classification by atomic weight and number) of elements and, hence, have somewhat similar crystallographic, chemical, and physi-

cal properties. They are alike in crystal structure: the atoms, held together by metallic bonds, are arranged in a configuration known as cubic closest packing, in which array each atom lies on a point of a face-centred cubic lattice (cubic arrangement with atoms in centres of faces) and is coordinated with 12 others. The unit of structure is a cubic unit cell containing four atoms. The three metals crystallize in the isometric system, hexoctahedral class, space group Fm3m (see MINERALS; CRYSTALLOGRAPHY). The length of the edge of the unit cell is dependent on the radius of the atom and differs for each metal. The cell dimensions and some of the physical constants of the pure elements are given in Table 2.

The common structure of these metals gives rise to similar properties. All are soft, malleable, and ductile (can be drawn into wire). This plastic deformation is the result of four possible directions of translation of the atoms in the structures. Of all known elements, these metals are the best conductors of heat and electricity in the order of silver first, followed by copper and gold.

Table 2: Properties of the Gold Group Metals
(Angstrom, Å = 10^{-8} cm)

property	gold	silver	copper
Atomic radius	1.44 Å	1.44 Å	1.28 Å
Cell dimensions	4.0786 Å	4.0862 Å	3.6150 Å
Mohs hardness	2½–3	2½–3	2½–3
Specific gravity	19.32	10.50	8.96
Melting point	1,063° C	961° C	1,083° C

The differences in properties of the metals of this group arise from individual properties of the atoms. The yellow of gold, the white of silver, and the red of copper are a manifestation of atomic properties, as are the specific gravities.

The solubility of the gold group metals in the solid state is largely dependent on atomic size. Gold and silver have essentially the same atomic radii and can substitute for one another in all proportions (to 100 percent). Most gold contains some silver and its rich yellow colour becomes progressively lighter as more silver enters the structure. When silver is present in amounts 20 percent or more, the natural alloy is called electrum. Much gold also may be present in native silver. Although traces of copper occur in gold and silver and vice versa, there is only limited substitution because the radius of the copper atom is significantly smaller. In addition to the impure nature of these metals from mutual substitution, other elements may be present in trace amounts. Among the most common are iron in gold; mercury in silver; and arsenic, iron, or bismuth in copper.

The metals of the gold group most commonly occur in nature as irregular masses, plates, and scales. All have been found, however, in beautifully crystallized arborescent groups, frequently with dendritic (branching or tree-like) shapes. Single crystals, particularly of gold and silver, are found as plates flattened parallel to octahedron faces or as wires elongated perpendicular to such a plane. Octahedral crystals of gold with equal-area faces are rare. Crystal groups of copper may show faces of the cube, dodecahedron, and octahedron.

Mercury and zinc

The metals of the mercury group are rare. Above −39° C, mercury is a silvery-white liquid with a density of 13.6; below this temperature it crystallizes in the form of rhombohedral crystals. Natural alloys with other metals include moschellandsbergite, Ag_2Hg_3; gold-amalgam, Au_2Hg_3; and potarite, Pd_3Hg_2. These minerals, extremely rare and poorly defined, are believed to be isometric in crystallization.

The properties of native zinc are those for man-made

Table 3: Properties of the Platinum Group Metals
(Angstrom, Å = 10^{-8} cm)

properties	ruthenium	rhodium	palladium	osmium	iridium	platinum
Crystal system	hex	iso	iso	hex	iso	iso
Atomic radius	1.32 Å	1.34 Å	1.37 Å	1.34 Å	1.35 Å	1.38 Å
Cell dimensions	a=2.706 Å c=4.282 Å	3.803 Å	a=3.882 Å	a=2.714 Å c=4.314 Å	a=3.831 Å	a=3.916 Å
Mohs hardness	6.5		4.8	7.0	6.5	4.3
Specific gravity	12.41	12.41	12.02	22.57	22.42	21.45
Melting point	2,250° C	1,960° C	1,552° C	3,000° C	2,443° C	1,769° C

zinc. Its structure is hexagonal closest packing, with unit cell dimensions: $a = 2.66$Å and $c = 4.94$Å. It is a bluish-white metal with hardness of 2 and specific gravity of 7.14. Although native zinc has been reported from Australia, New Zealand, and the United States, no occurrence is well authenticated.

Platinum group metals

Of the six platinum group metals, only platinum and palladium occur in sufficient purity to be considered native elements. Platinum is the only common element in the group and the other metals generally are found alloyed with it. The atoms of both platinum and palladium are arranged in cubic closest packing, and these metals have structures that are analogous to those of the gold group. The cell dimensions and physical properties of the pure platinum group elements are given in Table 3.

Chemical analyses rarely report more than 90 percent purity for native platinum. The remainder is made up of varying percentages of the other platinum group metals plus gold, copper, and nickel. The principal impurity, however, is iron, which in some analyses exceeds 10 percent and makes much native platinum magnetic. The specific gravity of pure platinum is reduced by impurities to a range of 14 to 19. The colour is silver-white to steel-gray. Platinum is malleable and ductile but less so than the metals of the gold group. Although distorted cubes and octahedrons of platinum have been reported, crystals are rare.

Natural alloys of the platinum group metals are found associated with native platinum but are very rare. Platiniridium (Ir,Pt) and aurosmiridium (Ir,Os,Au) are silver-white minerals with isometric crystallization and high hardness (6–7); their specific gravity, also high, varies with composition. Iridosmine (Ir,Os) and siserskite (Os,Ir) have hexagonal crystallization; they form a solid solution series (metal–metal solution) containing from about 77 percent Ir to 80 percent Os and sometimes ruthenium, rhodium, or platinum.

Iron and nickel-iron

Iron with 2 to 7 percent nickel, and nickel-iron with 30 to 75 percent nickel are found in terrestrial deposits and in meteorites. Ordinary iron (α iron) has a body-centred cubic structure (cubic arrangement of atoms with one atom at centre of cube). The unit cell with dimensions $a = 2.86$Å, contains 2 (Fe,Ni). Iron is malleable and has cubic cleavage (tends to cleave along planes at right angles), a Mohs hardness of 4, and a specific gravity of 7.3 to 7.87. Crystals are rare, and terrestrial material is in small to large regular masses. In meteorites known as kamacite it occurs in platy masses and in irregular intergrowths with nickel-iron.

Nickel-iron, like the metals of the gold group, has a face-centred cubic lattice. Its unit cell ($a = 3.59$Å) contains 4 (Fe,Ni). Nickel-iron's colour is silver-white to grayish-white, its hardness is 5, and its specific gravity 7.8 to 8.2; it is strongly magnetic. Terrestrial nickel-iron occurs in small grains and fine scales; in meteorites it is called taenite and it forms regular intergrowths with kamacite.

Tin, lead, and tantalum

Tin is very rare as a native metal. It is tetragonal in crystallization, and its unit cell ($a = 5.82$Å, $c = 3.18$Å) contains 4 Sn. Tin is malleable and ductile, its colour is tin-white, its hardness is 2, and its specific gravity is 7.3. It has been found in small, rounded grains associated with gold, platinum, and cassiterite in sands from New South Wales, Australia.

Lead is very rare as the native metal and authenticated occurrences are few, but large crystal groups have been found at Långban, Sweden. Native lead crystallizes in the isometric crystal system and has a face-centred cubic lattice; its crystals are octahedral with subordinate dodecahedron and cube faces. The unit cell ($a = 4.94$Å) contains 4 Pb. Native lead is relatively pure, usually containing over 99 percent Pb; small amounts of silver and antimony may be present. It is quite malleable and has a lead-gray colour, a hardness of 1½, and a specific gravity of 11.37.

Native tantalum is isometric and crystallizes in minute cubic crystals. It has a body-centred cubic lattice with the edge of the unit cell $a = 3.30$Å. Its colour is grayish-yellow, its Mohs hardness is 6 to 7, and its specific gravity is 11.2 (measured), 16.6 (calculated). Tantalum is the rarest of the native metals. It reportedly has been found in placer deposits (stream-laid gravels) in the Ural and Altai mountains, U.S.S.R., but the latter occurrence has been questioned.

Arsenic, antimony, and bismuth

Semimetals. The native semimetals (arsenic, antimony, bismuth) fall in the same family in the periodic table of the elements and thus have many similar chemical and physical properties. They crystallize in the hexagonal system, scalenohedral class, and have one direction of good cleavage; they are brittle and are poorer conductors of heat and electricity than the native metals. These properties result from a bonding mechanism intermediate to true metallic and covalent bonding (see MINERALS). Each atom is bonded to six neighbours but is more closely held to three of these than to the other three. The resulting structure has sheets of atoms that are strongly held to one adjacent sheet but weakly bonded to the other. Cleavage takes place by breaking the weak bond between sets of double sheets. Cell dimensions and physical properties for the native semimetals are given in Table 4.

Table 4: Properties of the Arsenic Group Native Elements
(Angstrom, Å = 10^{-8} cm)

property	arsenic	antimony	bismuth
Atomic radius	1.25 Å	1.45 Å	1.55 Å
Cell dimensions	a=3.76 Å c=10.55 Å	a=4.31 Å c=11.27 Å	a=4.55 Å c=11.86 Å
Mohs hardness	3.5	3–3.5	2–2.5
Specific gravity	5.7	6.7	9.7–9.8
Melting point	—	630.5° C	271.3° C

Native arsenic and antimony occur most commonly in tin-white, massive, botryoidal (globular) or lamellar (platelike) aggregates. They rarely are found in well-formed pseudocubic crystals. Native bismuth occurs usually in silver-white reticulated or arborescent shapes or in veinlets showing well-defined cleavage. These elements occur in a relatively pure state in nature, but each of them may contain traces of the other two. In addition, arsenic may contain iron, nickel, silver, and sulfur; antimony may contain iron and silver; and bismuth may contain tellurium and sulfur.

Native sulfur

Nonmetals. Sulfur has three modifications (forms), designated α, and β, and γ. Although β and γ sulfur (monoclinic forms) have been reported from a fumarole (gaseous emanation) at Vulcano, Lipari Islands, they are extremely rare in nature. Sulfur as a native element essentially occurs in the α modification. It crystallizes in the orthorhombic system, dipyramidal class, with space group Fddd (see CRYSTALLOGRAPHY). The unit cell contains 128 atoms and has the dimensions: $a = 10.44$Å, $b = 12.84$Å, $c = 24.37$Å.

Figure 2: (Left) Bismuth crystals from Utah. (Centre) Sulfur crystals (greatly enlarged) from Sicily. (Right) Iron meteorite found at Springwater, Sask. in 1931.
By courtesy of the Illinois State Museum; photographs, John H. Gerard—EB Inc.

The yellow colour of sulfur is characteristic. The fracture is conchoidal, but imperfect cleavages parallel to {001}, {110}, and {111} are sometimes observed. The Mohs hardness is 1½ to 2½, the specific gravity 2.07, and the melting point 112.8° C (235° F). Sulfur is an electrical nonconductor and an extremely poor thermal conductor.

Native sulfur commonly contains small amounts of clay, bitumen, and other mechanically held impurities. Some sulfur contains selenium, rarely more than one percent, which renders it orange-red or reddish-brown. Most commonly, native sulfur is massive or in spherical and reniform (rounded, kidney-like mass) shapes, or it occurs as incrustations. In some places, notably at Girgenti, Sicily, it is found in beautiful, symmetrically developed crystals that usually display a pyramidal habit.

Carbon Group. Native carbon has only two forms, diamond and graphite, and the only similarity between them is that both are composed of carbon atoms. No other polymorphic minerals present a greater contrast in physical properties: diamond is isometric, transparent, and the hardest of natural substances, whereas graphite is hexagonal, opaque, and one of the softest minerals. These differences arise from the manner in which the atoms are bonded together in the crystal structures.

Diamond

Diamond is the high-temperature, high-pressure form of carbon that crystallizes in the isometric system. Although the crystal class has been in doubt, most crystallographers assign it to the hexoctahedral class, space group Fd3m. The unit cell contains eight carbon atoms, the length of the cell edge is $a = 3.567$Å. In the diamond structure each carbon atom is linked equidistantly to four neighbouring carbon atoms by covalent bonds so that a tetrahedral linkage occurs throughout. This close-knit, strongly bonded structure gives rise to the high Mohs hardness as well as the high (for a nonmetallic mineral) specific gravity.

The scratch hardness of diamond is usually given as 10 on the Mohs' scale, with the next hardest mineral being corundum at 9. Actually, diamond is very much harder than corundum; its true proportional value on the Mohs' scale would be about 42. Diamond's hardness varies significantly in different directions; this makes some facets of a cut diamond easier to polish than others. Diamond has been found to be as much as 200 times more effective in abrasion than the synthetic abrasives silicon carbide (Mohs hardness 13) and boron carbide (Mohs hardness 14).

Diamond has a perfect cleavage (referred to as grain by diamond cutters) in four directions parallel to its octahedral crystal faces. This property is used by diamond cutters to split a big stone. Diamond has a specific gravity of 3.51, an adamantine to greasy lustre, and a high dispersion. Its index of refraction (change in direction of propagation of entering light) under sodium light is 2.4175. Diamonds have many colours. Although as a gem it is usually colourless to blue-white, more commonly it is yellow or brown; rarely, it is orange, pink, green, blue, red, or black.

Two types of diamond are known, termed Type I and Type II. Type II diamond shows a normal X-ray diffraction pattern, but patterns of Type I show extra spots and streaks. The photoconductivity of Type I diamond is poor, of Type II good; Type I diamonds are birefringent (show double refraction), and Type II are not. The two types also differ in their infrared and ultraviolet absorption characteristics. Diamonds intermediate between the two types have been noted, as well as two varieties of Type II. Large diamonds of gem quality have always been Type I.

Diamond characteristically is found in crystals, many well formed. They are predominantly octahedral, less commonly dodecahedral or cubic. Some crystals are flattened parallel to octahedron faces; others have a spherical form with radiated structure. Twinning on the octahedron is common with the twinned pair flattened parallel to the twin plane.

Diamonds were synthesized in 1955 by the General Electric Company, Schenectady, New York. They were made by subjecting carbonaceous material simultaneously to pressures over 1,500,000 pounds per square inch and temperatures over 5,000° F (2,800° C), thus simulating pressure-temperature conditions 240 miles deep within the earth. The diamonds made were of industrial quality and by 1960 were being marketed on a large scale at prices comparable to natural stones of the same quality. Continued experimentation produced (1967) a hexagonal polymorph with properties similar to those of normal (isometric) diamond. Almost simultaneously, small crystals of the hexagonal diamond were found in a meteorite and named lonsdaleite.

Bort is granular microcrystalline diamond, usually without cleavage and coloured gray to black by inclusions of other elements in the structure. The term also applies to poorly coloured or flawed diamond without gem value. Specimens of bort may contain as much as 20 percent mechanically held impurities; spectroscopic analyses reveal traces of barium, strontium, and chromium. Carbonado or carbon is black, massive diamond without cleavage and is less brittle than crystals.

Graphite

Graphite crystallizes in the dihexagonal-dipyramidal class of the hexagonal system; space group C6/mmc. It has a layered structure in which strongly bonded carbon atoms are arranged in six-membered rings in individual sheets. Adjacent sheets are widely spaced and are held together by the weak van der Waals bond. This arrangement results in graphite's characteristics of low hardness, low specific gravity, and good cleavage. The unit cell contains four carbon atoms and has the dimensions $a = 2.461$Å, $c = 6.708$Å.

The physical properties of graphite are distinctive: one perfect cleavage; hardness, 1 to 2 (it soils the fingers); specific gravity, 2.2; lustre, metallic; colour, black. It is often impure due to admixed clay and other minerals. Graphite crystals are rare but when found are usually six-sided tablets with triangular marking. The mineral most commonly occurs as foliated masses and as isolated scales.

The tellurium group comprises the rare native elements tellurium and selenium, which crystallize in the hexagonal

Tellurium and selenium

system, trigonal trapezohedral class, space group $P3_121$ or $P3_221$. Cell dimensions and physical properties of these native elements are given in Table 5.

Table 5: Properties of the Tellurium Group Elements
(Angstrom, Å = 10^{-8} cm)

property	tellurium	selenium
Cell dimensions	a=4.46 Å c=5.93 Å	a=4.36 Å c=4.96 Å
Mohs hardness	2–2.5	2
Specific gravity	6.1–6.3	4.8
Melting point	449.5° C	217° C

Tellurium has a metallic lustre, a tin-white colour, and a perfect cleavage parallel to $\{10\bar{1}1\}$. Selenium has a metallic lustre, gray colour, and a good cleavage parallel to $\{01\bar{1}2\}$. Both elements may contain small amounts of the other in the native form. In addition, tellurium sometimes contains admixed gold, silver, and iron.

Crystals of both are usually acicular (needlelike) elongated on the c crystal axis. Tellurium is commonly massive or granular; selenium may occur in sheets or glassy droplets. The formation of selenium as a native element has resulted chiefly from mine fires that produce artificial fumarolic conditions. Tellurium, on the other hand, is found in hydrothermal veins associated with sulfide and telluride minerals as at Kalgoorlie, Western Australia; Balia, Asia Minor; Hokkaido, Japan; and Cripple Creek, Colorado.

OCCURRENCE OF THE NATIVE ELEMENTS

One can make no generalization as to the occurrence of the native elements. They form under greatly contrasting physicochemical conditions and in all types of rocks. Even a single native element can occur in widely diverse environments.

Metals. *Gold.* Most gold is found in the earth's crust in the native state. Although a rare element, it occurs in two types of widely distributed deposits: hydrothermal veins (deposits produced by the reaction of high-temperature solutions and the invaded rocks) and placers. As a primary hydrothermal mineral, gold is found in all types of rocks of all geologic ages, but most commonly it occurs in quartz veins associated with pyrite and other sulfide minerals. Gold is recovered as a valuable by-product in some vein deposits mined essentially for other metals.

Gold placer deposits

Gold is liberated by weathering from the enclosing matrix of vein deposits and, if washed into neighbouring streams, accumulates to form placer deposits. Throughout history it has been free gold, located in the unconsolidated gravels of a placer, that has led to the discovery of major gold deposits. By tracing the gold upstream to its source, prospectors have located the vein deposits from which it came. Ancient placers, former stream gravel deposits that have been consolidated into conglomerates, are actively mined today. More than 60 percent of the world's gold is derived from such "fossil placers" in the Transvaal and Orange Free State, Republic of South Africa. The U.S.S.R. is believed to be the second-ranking country in gold production. Some gold is recovered from vein deposits in the Ural Mountains, but placers in Siberia are reported to be the major source. Elsewhere, gold is won chiefly from vein deposits. Canada ranks third in production, followed by the United States, Ghana, Australia, and the Philippines.

Silver. Unlike gold, native silver is not the principal source of the metal, but it is widely distributed in small amounts in the upper portions of ore deposits, where it has formed by oxidation of other silver minerals. Native silver has been mined in larger deposits formed from hydrothermal solutions. In the primary deposits it has three types of association: with sulfide minerals (*q.v.*), zeolites, calcite, barite, and quartz (such a deposit was worked for several hundred years at Kongsberg, Norway and produced many excellent, crystallized specimens of silver); with arsenides and sulfides of cobalt, nickel, and silver, and with native bismuth (the deposits at Freiberg and Schneeberg in Saxony, actively mined in the 16th century, and at Cobalt, Ontario, discovered early in the 20th century, were of this type); and with uraninite and cobalt-nickel minerals (such are the old deposits at Jáchymov, Bohemia, and those more recently discovered at Great Bear Lake, Northwest Territories, Canada).

Copper. Small amounts of native copper have been found in many localities in the shallow oxidized zones overlying copper sulfide deposits. Such occurrences of native copper are commercially unimportant because most of the metal is derived from natural compounds, particularly chalcopyrite, $CuFeS_2$. At a number of localities native copper is a primary mineral associated with basaltic lavas; the reaction of hydrothermal solutions with iron minerals results in the deposition of native copper rather than the normal copper sulfides. The only important deposit of this type is on the Keweenaw peninsula, Michigan; but for 70 years, commencing in 1845, this district was a leading world copper producer. Here, dipping lavas interbedded with conglomerates are exposed for 100 miles along the peninsula. The copper occurs principally as fillings in cavities in the lavas and as replacement for pebbles or filling space between them in the conglomerates.

Platinum. Native platinum, palladium, and natural alloys of platinum group metals usually occur together, in association with olivine, chromite, pyroxene, and magnetite in ultrabasic rocks (those with high percentages of iron and magnesium) (especially dunites, which are nearly pure olivine rocks). Because platinum is chemically inert and has a high specific gravity, it tends to collect in placers. It was found in Colombia in 1735 and in the Ural Mountains in 1822 in such deposits. Placers were the chief source of platinum until 1934, when large amounts were recovered from sperrylite, $PtAs_2$, a mineral associated with copper-nickel ores at Sudbury, Ontario. In 1924, platinum was discovered in the "Merensky Reef" of the Bushveld Igneous Complex, Republic of South Africa. By 1953, mining of this narrow but extensive layer of ultrabasic rock placed South Africa first in world platinum production. More recently, the U.S.S.R. has assumed first place; the recovery of platinum from placer deposits and more particularly from copper-nickel ores enabled that country to account for about 60 percent of the world production of platinum metals in 1969.

Iron and nickel-iron. Although terrestrial native iron is a great rarity, it has been found in igneous rocks (basalts), in carbonaceous sedimentary rocks, and in petrified wood. Some iron in basalts is considered to be a primary or original constituent, but most of it is believed to have formed from iron compounds by the reducing action of later incorporated carbonaceous material. Likewise, in sedimentary rocks and petrified wood, native iron has resulted from the reduction of iron compounds by organic material. Small amounts of native iron have been reported from Ireland, France, Poland, U.S.S.R., and in the United States from Cameron, Missouri, and New Brunswick, New Jersey. The most important occurrence is on Disko Island, Greenland, where it is found in a basalt in the form of small grains and as large masses, some weighing 20 tons.

Terrestrial nickel-iron is less common than native iron. It has been found sparingly as small plates and grains with gold in placer deposits of New Zealand, U.S.S.R., and Canada. The largest masses, some exceeding 100 pounds, have been found in Josephine and Jackson counties, Oregon.

Both native iron (kamacite) and nickel-iron (taenite) are found in meteorites. The iron meteorites called hexahedrites are almost completely composed of kamacite, and in those called octahedrites it is the principal constituent.

Semimetals. The native semimetals arsenic, antimony, and bismuth are found in hydrothermal veins formed under similar conditions. Consequently, all three elements may be found at the same locality with native silver and ore minerals containing arsenic and antimony. Common associated minerals are sphalerite, pyrite, galena, and quartz. In addition, native arsenic and native bismuth frequently accompany ores of nickel and cobalt. In this

association they are found in the old Saxon mining districts of Schneeberg and Annaberg, and in Bohemia at Jáchymov. Other noted localities for arsenic are Romania, Italy, Borneo, and Chile. The most productive deposits of native bismuth are in Bolivia; other important localities are Australia, where it is found in pegmatites (intrusive igneous rocks with exceptionally large crystals), and at Cobalt, Ontario, where it is associated with silver ores. Fine specimens of native antimony have come from France, Borneo, Australia, and Chile.

Nonmetals. *Native sulfur.* Native sulfur occurs at the crater rims of active or extinct volcanoes, where it forms from gases given off by fumaroles either as a sublimation product or by the incomplete oxidation of hydrogen sulfide. Less commonly, sulfur is found in veins associated with sulfide ore minerals where it is formed by their oxidation.

The largest deposits are found in sedimentary rocks associated with sulfate minerals (anhydrite and gypsum) and with limestone. In this type of deposit the sulfur is believed to have been derived from the sulfates by the action of sulfur-forming bacteria. Sulfur associated with gypsum and anhydrite near Agrigento, Sicily, has been mined since 1250, and for several hundred years this locality was the principal source of the element. Sulfur, associated with the same minerals, occurs several hundred feet below the surface in the cap rock of salt domes (*q.v.*) in Texas, Louisiana, and elsewhere. Production from such deposits by the Frasch process began in 1894. In this method, superheated water is pumped into the sulfur-bearing rock; the sulfur is melted and brought to the surface in molten form.

Over half of the 1969 world production of sulfur was produced as the native element. Although large tonnages of volcanic sulfur were mined in Chile and similar deposits were worked in Japan and Italy, over 75 percent of the native sulfur in that year was produced by the Frasch process in the United States and Mexico.

Carbon: diamond and graphite. Diamond occurs in two types of deposits: embedded in the rock in which it crystallized and in alluvium and placers as loose crystals washed from their primary source. All early diamonds were alluvial. Stream gravels in India were their only source until about 1725, when diamonds were discovered in similar deposits in Brazil and later, 1866, in the gravels of the Vaal River, South Africa.

Diamonds in South Africa

Only in diamond pipes, especially well exemplified by those discovered in 1871 in the Kimberley district, South Africa, are diamonds known to occur in the original rock matrix in which they formed. These pipes are funnels, more or less oval in section and narrowing with increasing depth. They extend to unknown depths (some have been mined to depths of more than 4,000 feet) and are evidently the result of eruptive action. The rock filling the pipes is an altered and brecciated (broken, angular fragments) basic rock known as kimberlite or blue ground. This must have been forced up from great depths, because it is entirely unrelated to the country rock surrounding the pipes. There is no evidence to indicate that the blue ground was extremely hot when forced into its present position. Therefore, it is concluded that the diamonds were formed in the depths of the earth under conditions of great heat and pressure and reached the surface by extrusion. Diamonds in alluvial deposits originally must have been formed in kimberlite, later released by erosion from their mother rock and redeposited in rivers and streams.

Over 700 kimberlite pipes, dikes, and sills have been located in South Africa; although many are barren, these are the principal source of diamonds mined in that country. The Premier Mine near Pretoria is most productive and since its discovery in 1903 has produced nearly 30 million carats (six tons) of diamonds. In Tanzania, production from a large diamond pipe discovered in 1940 makes that country an important producer. South West Africa is the major producer of gem-quality diamonds. These stones come from terrace deposits along the coast north of the Orange River. Other important African alluvial deposits are in the Democratic Republic of the Congo, Angola, Ghana, and Sierra Leone. More than half of the world's diamonds today come from placers in the Democratic Republic of the Congo, but this large production accounts for only 13 percent of the total value because about 95 percent are industrial grade. Diamonds are produced in the U.S.S.R. from both pipes and placers.

Metamorphic origin of graphite

Graphite is widely distributed, occurring most commonly in metamorphic rocks such as schist, gneiss, and marble, where it may be in disseminated flakes or layers and lenses forming an appreciable proportion of the rock. Such graphite is believed to be the metamorphic product of carbonaceous or bituminous material present in the original sedimentary rocks. In some places, either regional or contact metamorphism has converted coal beds to graphite; the graphitic coal of Rhode Island and Sonora, Mexico, is of this type. Graphite also occurs in veins as typical fracture fillings. Important economic vein deposits are found in Ceylon, Korea, Malagasy Republic, and India. As a minor constituent, graphite is found in some igneous rocks, pegmatites, and iron meteorites.

Natural Gas

Natural gas is an ideal fuel product and a raw material for the chemical industry. It usually occurs in association with petroleum because geological conditions favourable for the presence of oil generally are favourable for natural-gas occurrence as well. Although many natural gases can be used directly from the well without treatment, some must be processed to remove such undesirable constituents, as carbon dioxide, hydrogen sulfide, and other sulfur components.

Bitumen and asphalt, the oldest known petroleum products, and evidence of natural-gas leaks were first found between 6000 and 2000 BC in Iran. The use of natural gas is mentioned in China about 900 BC; around AD 900–1100 wells were drilled and gas was piped through bamboo tubes.

In Europe these achievements were unknown, and natural gas was not discovered until 1659 in England. Gas distilled from coal was discovered in 1670 and began to be used in 1790 because it was easier to transport, store, and process for use in internal-combustion engines and lighting of streets and houses. In 1821 the town of Fredonia, New York, was lit by natural gas. But natural-gas uses remained localized because there was no way to transport gas over long distances, and for a century natural gas remained on the sidelines of industrial development, which was based on coal, oil, and electricity.

Methods of pipeline transportation developed in the 1920s marked a significant stage in the use of gas. After World War II, there occurred a period of tremendous expansion that has continued until today. In 1950 the worldwide output of natural gas was 200,000,000,000 cubic metres (7,100,000,000,000 cubic feet), and the

United States was the leading producer. In 1960 world output was 470,000,000,000 cubic metres (16,590,000,000,000 cubic feet), and forecasts called for 1,000,000,000,000 in 1970 and for 1,630,000,000,000 in 1980. In 1950 gas accounted for 12 percent of the energy consumed in the world, a rate that increased to 14.6 percent in 1960 and is expected to be around 18.5 percent in 1980.

This article includes treatment of the properties, origin, and occurrence of natural gas and of some aspects of gas production. For additional details of gas technology see GASES, INDUSTRIAL AND DOMESTIC; for treatment of related resources, see PETROLEUM; COALS; and OIL SHALES.

PHYSICAL AND CHEMICAL PROPERTIES

Composition

Natural gas is usually a mixture consisting primarily of methane and ethane, both of which are gaseous under atmospheric conditions. It may also contain such hydrocarbons as propane, butane, pentane, and various liquids, and heavier hydrocarbons, all of which are in liquid form under atmospheric conditions but in gaseous form inside the reservoir; and other gases such as nitrogen, carbon dioxide, hydrogen, hydrogen sulfide, and rare gases. Because gas and water occur together in a reservoir, natural gas also contains water vapour, which is partially condensed during transmission from the reservoir to the processing plant. The composition of gas in selected fields in Algeria, the United States, and The Netherlands is given in Table 1.

Table 1: Characteristics of Selected Gas Fields

	Hassi R'Mel Algeria	Handle-Hugoton Texas	Groningen Netherlands
Depth	2,100 m 6,900 ft	820 m 2,700 ft	2,800 m 9,200 ft
Pressure	309 bars 4,482 psi	34 bars 493 psi	350 bars 5,080 psi
Reserves	2,200 × 10^9 cu m 77,600 × 10^9 cu ft	2,000 × 10^9 cu m 70,600 × 10^9 cu ft	1,600 × 10^9 cu m 56,500 × 10^9 cu ft
Composition of gas (%)			
Nitrogen	5.11	12.8	14.32
Oxygen		2	0.01
Carbon dioxide	0.19	0.5	0.87
Methane	79.6	76.2	81.30
Ethane	7.4	4	2.84
Propane	2.7	2.6	0.43
Butane	5	1.3	0.14
Pentane		0.6	0.08
Hexane			0.02

Behaviour of gas with pressure and temperature. The amounts of gas accumulated in a reservoir and the recoverable reserves, as well as outputs, are expressed in standard volumes (the volume at a temperature of 15° C [59° F] and a pressure of 750 millimetres of mercury). In order to obtain this standard volume from the actual reservoir pressure, temperature, and flow conditions, and to study reservoir behaviour, it is necessary to know the so-called equation of state of the gas (a relation between the pressure and volume and the temperature and gas amount). The simplest way of expressing this relationship is

$$PV = Z\frac{m}{M}RT,$$

in which P is absolute pressure (as read on a pressure meter, plus one atmosphere of pressure); V equals the volume occupied, at pressure P and temperature T, by a mass (m) of the gas under consideration, assuming it to have a molecular mass (M); Z equals a compressibility factor; T equals absolute temperature (°K = °C + 273, or °R = °F + 460); and R equals a universal gas constant.

This equation differs from the law governing the behaviour of perfect gas (a hypothetical gas that obeys the equation PV = (m/M) RT under all of the conditions) by the introduction of the compressibility factor Z, which depends on the composition of the gas and on its temperature and pressure. As Z diminishes, the effect of molecular interactions decreases. As Z reaches a minimum and then approaches 1, the gas tends to behave like a perfect gas. Variation of Z with pressure and temperature for ethane is shown in Figure 1. The value of Z is determined either experimentally or by calculation, using the properties of the gas under consideration.

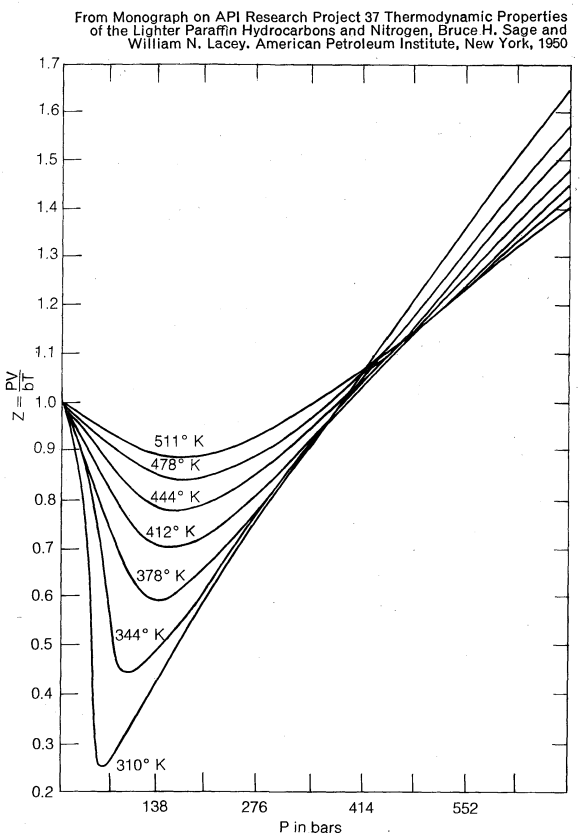

Figure 1: Compressibility factor for ethane (see text).

Condensable products

Some types of natural gas are always in a gaseous state in the reservoir and produce no liquid deposit (other than water) under atmospheric conditions at the surface; these are dry gases. Others, on the contrary, are gaseous in the reservoir and contain condensable products; these are wet gases. Such gases are ordinarily characterized by the volume or weight of the condensables contained in a given standard volume of total gas produced—*i.e.*, including both the gas and the gaseous equivalent of the condensables, expressed either in gallons per thousand cubic feet or in grams per cubic metre. The gas produced at the Hassi R'Mel gas field, Algeria, for example, contains approximately 200 grams of condensables per cubic metre (0.2 ounce per cubic foot). Some recovered condensables are of economic value: propane and butane, for example, are bottled under slight pressure, and heavier hydrocarbons are made into gasoline.

Under some pressure and temperature conditions, four paraffins—methane, ethane, propane, and butane—and carbon dioxide and hydrogen sulfide form solid hydrates in the presence of liquid water. Such hydrates may be formed during the transportation of the gas through boreholes or flow lines, whenever expansion causes cooling. Although this process sometimes results in the plugging up of pipes, there are various prevention methods.

Viscosity is an important property with respect to gas flow. The viscosity of a natural gas varies between 100 and several hundred micropoises, increases with pressure, and decreases when the temperature increases except at low pressures.

Heating power of gas. When natural gas burns completely, carbon dioxide and water are normally formed. The heating power of a gas is measured with calorimeters in which the combustion products are cooled to their initial temperature so that the measurement then indicated corresponds to the amount of heat absorbed by the cooling fluid. Because heat is given off during the condensation of water, the definition "lower heating value" can be used if all of the vapour is assumed not to condense

during cooling, and "gross heating value" if the water vapour is assumed to be condensed. The gas industry mainly uses the first definition. The values that can be found for the first paraffins, that is, methane, CH_4, and successively heavier compounds are given in Table 2.

Table 2: Heating Values of the First Paraffins

paraffins	heating power kcal/m³ (32° F 14.7 psia)	kcal/kg
Methane	9,494	13,300
Ethane	16,634	12,380
Propane	23,673	12,030
Normal butane	30,695	11,830
Isobutane	30,622	11,800
Normal pentane	37,714	11,700

The commercial gas from Hassi R'Mel, Algeria, in 1962 (83.5% methane, 7% ethane, 2.1% propane, 1.4% butane and heavier hydrocarbons, 6% carbon dioxide and nitrogen), has a heating power of approximately 9,400 kilocalories (39,330,000 joules) per cubic metre (60° F [16° C], 14.51 pounds per square inch).

ORIGIN OF NATURAL GAS

The accumulation of gas, like that of petroleum, in reservoirs is the result of successive transformation stages of the basic raw materials, followed by accumulation and trapping in reservoirs. The diversity of composition of natural gas reflects the various origins of its constituents. Most of them come from the organic matter in sedimentary rocks during long time periods. Other constituents, however, are of purely inorganic origin.

Adapted from *Revue de l'Association Française des Techniciens du Petrol* (November-December 1969)

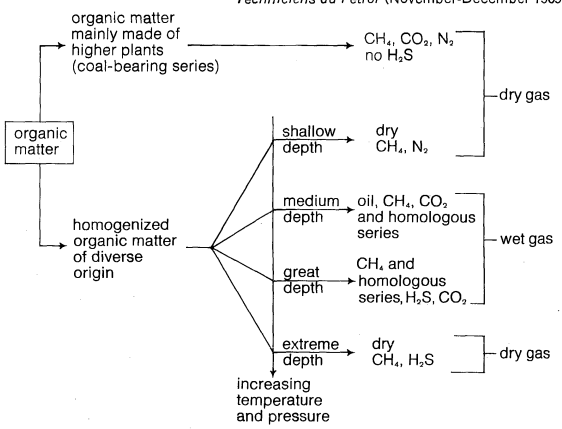

Figure 2: Derivation of natural gas from organic matter.

Organic origin. Freshly deposited sediments at the bottom of seas and lakes are the site of intensive bacterial activity capable of producing methane, carbon dioxide, nitrogen, and nitrogen oxide (NO) from the organic matter incorporated in the sediment. Although methane is formed in abundance (marsh gas, peat gas), ethane and heavier hydrocarbons are almost entirely missing. Some families of bacteria (sulfate-reducing bacteria) also form hydrogen sulfide (H_2S).

With burial of the sediment beneath succeeding deposits, bacterial activity ceases and the organic matter is transformed into kerogen, an insoluble product with a complex macromolecular structure. Through thermal degradations kerogen supplies most oil and natural gas (Figure 2). In an initial phase, at a depth of between 1,000 and 3,000 metres (3,300 and 9,800 feet), the most important occurrence is the formation of crude oil, accompanied by methane and carbon dioxide. Farther down, as the thickness and temperature of the sediment increase, the formation of light, and especially gaseous, hydrocarbons is favoured over that of oil. At very great depths (more than 5,000 metres, or 16,400 feet), molecule cracking leaves only dry methane and kerogen residue with a high carbon content.

Kerogen

This outline of how organic matter evolves covers the most general case, in which this matter has a mean composition resulting from the existence of natural associations and from being stirred by streams and currents. Nevertheless, in individual depressions located in the middle or on the edge of continents, the organic deposits may be made up mainly of lignite coming from higher plants and are then coal bearing. In this case the organic matter produces almost no oil by thermal degradation but only methane (CH_4), carbon dioxide (CO_2), nitrogen (N_2), and carbonaceous matter. The natural gas produced in The Netherlands appears to originate from such processes.

The origin of the hydrogen sulfide sometimes found at great depths raises a special problem. Apart from bacterial activity, it may be derived by a reduction of the sulfates contained in the sediments by hydrocarbons or organic matter, as well as from the action of sulfur on naphthenic hydrocarbons.

Inorganic origin. Helium and some of the argon found in natural gas are products of radioactive disintegration. Helium comes from radioisotopes of thorium and the uranium family, and argon is derived from potassium. As might be expected, the oldest gas accumulations (Paleozoic) are the richest in helium because these geological formations have been the scene of greatest radioactivity. Volcanism may act as a source of carbon dioxide and hydrogen.

Accumulation and entrapment. The sediments containing the organic matter that produces gas are clays or fine limestones—*i.e.*, rocks that are mainly compact and relatively impermeable. The gas is expelled and migrates to reservoir levels, which are porous and permeable and are made up of sands, sandstones, or even vug (or fissure) containing carbonate rocks such as limestones and dolomites. This expulsion occurs under the influence of the pressure difference that exists between porous reservoirs (in which the pressure is about the same as hydrostatic, or equal-sided, pressure) and compact source-rocks (those compressed by the weight of overlying formations).

Gas inside the reservoir circulates in the porous space, for example, between sand grains. Normally the pores, usually less than one millimetre (0.04 inch) in diameter, are filled by water, but gas, because of its very much lower specific gravity, tends to occupy the upper parts of the reservoir level, whereas water remains in the lower parts. For a gas accumulation to exist, the gas must be trapped; that is, the reservoir must be sealed off at the top —*i.e.*, covered by an impermeable stratum or cap rock (clay, salt), with the entire reservoir-cover structure being shaped in such a way as to prevent gas from leaking up to structurally higher zones, in particular to the surface.

Traps for natural gas (Figure 3) are the same as those

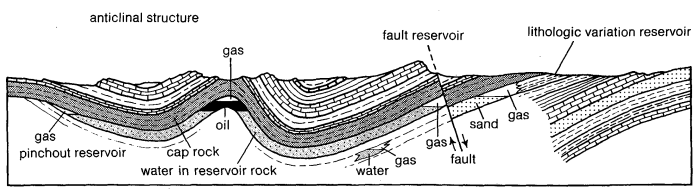

Figure 3: Principal types of natural-gas traps.

for oil accumulations and may be of several kinds. Original sedimentary deposition may form a trap by lateral lithological variation, as in a sand lens or a reef; subsequent sedimentation may form a trap by pinching or wedging out, and structural conditions after deposition may lead to folding or faulting and, hence, to the formation of anticlines and fault traps. Inside traps all of the three fluids (gas, crude oil, and water) may coexist. From the top to the bottom, they are encountered in that order, which is the same as that of their specific gravities.

OCCURRENCE AND PRODUCTION OF NATURAL GAS

World distribution. The annual production and known reserves of the world's leading countries are given in

Table 3. Among the largest accumulations are those of Urengoiskoye in Siberia (reserves of 4,000,000,000,000 cubic metres), the Texas Panhandle in the United States

(2,000,000,000,000 cubic metres), Slochteren–Groningen area in The Netherlands (1,600,000,000,000 cubic metres), and Hassi R'Mel in Algeria (2,200,000,000,000 cubic metres).

The fact that in all of the hydrocarbon accumulations the percentage of gas fields increases with the depth explains why gas accumulations are mostly encountered in the deeper parts of sedimentary basins. On the Gulf Coast of the United States more than 70 percent of the accumulations discovered at depths greater than 3,600 metres (11,800 feet) are gas fields. In France the extremely deep southwestern part of the Aquitaine Basin contains only gas. Hence, deeper drilling in the future is likely to mean that new discoveries will more often be of gas than of oil.

Flow of natural gas

Gas reservoirs. The laws governing gas flow in a porous medium are complex, and nonlinear terms must be introduced into the equation of movement. The total pressure drop in a circular reservoir with a radius (R), into which is drilled a well with a radius (a), with the well having a rate of flow (Qm), is written as

$$P^2_{(R)} - P^2_{(a)} = AQm + BQm^2,$$

in which $P_{(R)}$ is the mean pressure of the layer, and $P_{(a)}$ is the pressure in the well, and A and B are coefficients that depend on the characteristics of both the gas and the reservoir layer. This formula is used for well testing because it gives the relation between steady state pressure and flow. Its graphic expression is called the back pressure curve of a well. Because production from gas reservoirs began prior to theoretical research on flow, most back pressure curves are usually plotted from the following empirical relation:

$$Q_m = \alpha [P^2_{(R)} - P^2_{(a)}]^n,$$

in which the exponent (n) and coefficient (α) are empirically derived.

Although the theoretical and empirical expressions are not the same, they may be used interchangeably because the differences between them are usually less than the errors of measurement. When flow rates are quite slow, as in parts of the reservoir far from boreholes, it is possible to use simpler flow laws for liquids.

Gas wells and recovery

The outputs from gas wells are often more than 1,000,000 cubic metres (35,000,000 cubic feet) per day. The back pressure curves deduced from flow tests give the relation between flow and pressure. The aim of well tests is to evaluate the qualities of the reservoir and to determine flow with regard to the wellhead pressure for various possible types of well completion (sealing, casing, etc.). The search for the most effective completion equipment is of great importance because gas flows are sometimes enormous, and the influence of tubing diameter on pressure drops (and hence flow rates) is very great. In addition, the gas arriving at the wellhead must be under sufficient pressure to enable it to be piped off to processing installations.

The quality of the producing reservoir and of the downhole equipment is sometimes measured from the flow obtained by applying atmospheric pressure at the bottom of the well. This quality is called absolute open flow potential.

Production from gas reservoirs is facilitated by gas expansion. The recovery factor may attain 50 to 80 percent of the original gas in place, which is much higher than that for primary recovery from oil reservoirs. As a result, complex recovery methods are unnecessary. When gas pressure decreases during production to a nonprofitable level, production is stopped.

In studying the production balance of a reservoir, expansion of the gas itself is the most important factor. The high compressibility of gas practically cancels out variations in volume as the result of interstitial water expansion and reservoir contraction. Therefore, the production balance equation is relatively simple. It shows that cumulative production varies linearly with P/Z, where Z is the compressibility factor and P is pressure.

The slope of the plotted straight line gives the amount of gas initially in place. The line can be extrapolated to forecast cumulative production up to the time the wells are abandoned. Production cannot be continued until total exhaustion because of the drop in the flow through boreholes.

Water may rise into gas reservoirs associated with an aquifer (a water-bearing stratum of rock, sand, or gravel). The expression P/Z is then no longer linear, depending on cumulative production. The extent to which pressure is maintained by inflows of water is never very great because of the great compressibility of gas. Thus, expansion remains the fundamental phenomenon.

Production from condensate gas reservoirs gives rise to phenomena that are quite comparable to those observed for dry- or wet-gas reservoirs. The difference lies in the fact that condensation inside the reservoir may possibly cause the loss of a large proportion of the heavy hydrocarbons initially present in the gas. The condensate deposit is larger where pressure is lower; consequently, it is low in the most outlying parts of the field. It increases as the gas approaches the borehole where sharp pressure drops occur. The gasoline that accumulates around the borehole considerably reduces well productivity.

Depending on the region and on market conditions, condensate is often of greater value than gas itself. Therefore, when the condensate has been extracted on the surface, the dry gas is frequently reinjected into the reservoir so as to maintain pressure and push the wet gas *in situ* toward the boreholes. This process is called dry-gas recycling.

Gas injection and nuclear methods of fracturing

The oil from some reservoirs normally contains natural gas in solution. When this gas is present in large proportions, it is often used on the spot to assist oil production. It may be injected back into the reservoir to maintain pressure or improve oil recovery, or it may help increase the flow in wells by gas lift. Gas reservoirs located near an oil reservoir are sometimes made to produce for these reasons.

Some gas reservoirs located within thick and relatively impermeable reservoir formations cannot be economically exploited by standard methods. In the 1970s, plans were being drawn up to set off confined underground

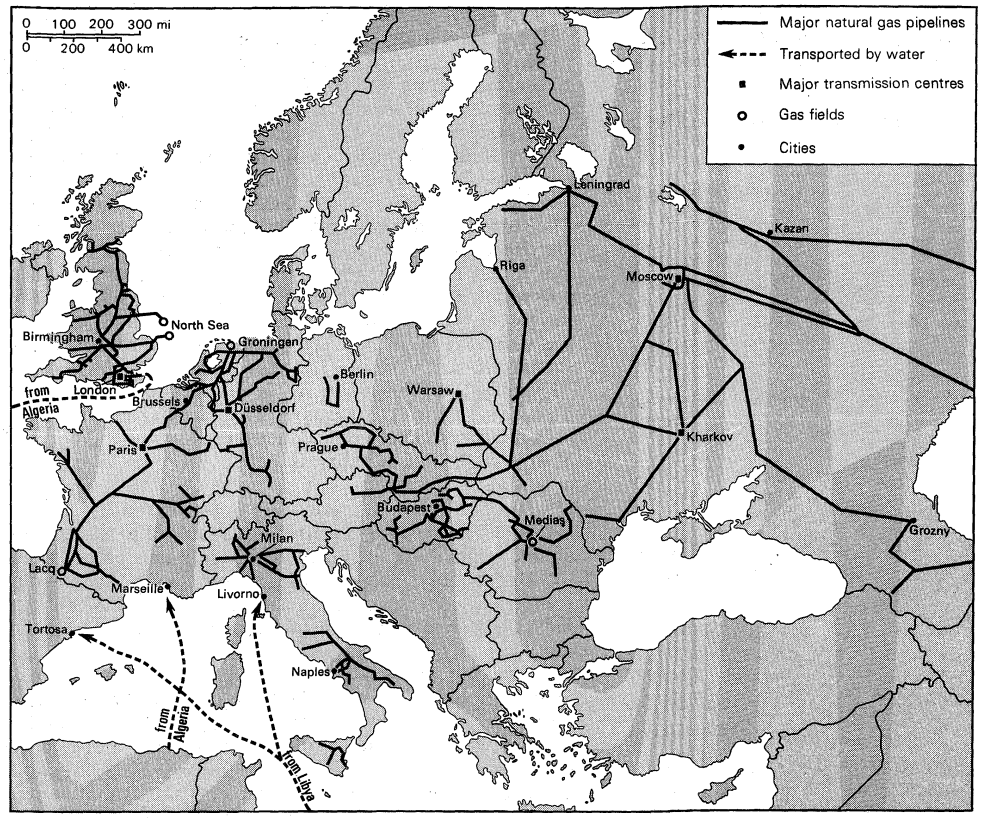

Figure 4: European gas transportation network.

nuclear explosions in the expectation that the zone fractured by the explosion and made to cave in could possibly be used to drain the reservoir. Tests were made in 1967 and in 1969, and initial results were fairly encouraging.

GAS PROCESSING

Natural gas is not directly usable when it comes from the well. Often it is extremely rich in methane and contains heavy hydrocarbons; in addition, it contains varying proportions of nitrogen and carbon dioxide, hydrogen sulfide, mercaptans, and other sulfur compounds. The aim of gas processing is to make the gas conform to standards of use and to recover the liquid or solid components, which are often of greater commercial value than the gas itself.

Treatment and purification

After its arrival at the central plant, the gas must undergo the following series of treatments: (1) expansion at processing pressure, which causes the formation of condensates; these are removed, and the gas is then dehydrated by contact with glycol, which is regenerated; (2) sweetening, which removes the hydrogen sulfide and carbon dioxide by diethanolamine treatment, and fixes them in an absorber; (3) elimination of the mercaptans by soda fixation; (4) stripping (either by cooling or by absorption in an oil), which extracts the hydrocarbons with longer chains than methane and produces a gas conforming to commercial specifications. The rich absorption oil and the purified condensate are fractionated by distillation to produce propane, butane, stabilized gasoline, and residues. These successive operations are performed continuously and require an extremely sophisticated control system. For further details, see GASES, INDUSTRIAL AND DOMESTIC.

TRANSPORTATION AND STORAGE

Transportation of gas. Natural gas is both a fuel (it accounts for more than one-third of the energy consumed in the United States) and a raw material for the chemical industry. Gas fields are often located far from major consumption centres; consequently, the gas has to be transported, although chemical industry transformation plants are frequently installed in the vicinity of production fields. Transportation of natural gas depends upon its form—in a gaseous form it is transported by pipeline under high pressure, and in a liquid form it is transported by boat.

Overland transport by pipeline

Large gas pipelines enable gas to be transported over thousands of miles. Examples are the North American pipelines, which extend from Texas and Louisiana to the northeast coast, and from the Alberta fields to the Atlantic Seaboard. Pipelines extend from Siberia to central Europe, and in the near future they will extend on to western Europe. Lengths of the world's gas pipelines are given in Table 4.

Table 4: Lengths of National Gas Main Transmission Pipelines in the World

	miles	kilometres
United States	223,700	360,000
Soviet Union	34,800	56,000
France	5,590	9,000
Netherlands, The	4,100	6,600
Italy	4,040	6,500
Germany	2,980	4,800
Great Britain	620	1,000
Algeria	500	800
Belgium	375	600

In the early 1970s transportation pressure was 70 bars (1,000 pounds per square inch) because economic studies, in keeping with technological advances, showed that transportation costs are at a minimum for pressures of this magnitude. Pipeline diameters for such long-distance transportation have tended to increase from an average of about 60 to 70 centimetres (24 to 29 inches) in 1960 to a size of 1.20 metres (about four feet) by 1970; some Soviet projects involve diameters of more than two metres (6½ feet) and pressures of about 40 bars (580 pounds per square inch).

Because of pressure losses, the pressure has to be boosted at regular intervals to keep a constant flow rate in the pipeline, and economic surveys show that a compression station should be located every 80 or 100 kilometres (50 or 60 miles) in order to obtain maximum flow under the most economically advantageous conditions. At greater

intervals, the pipeline is doubled in size if the gas flow is to be increased.

Pipelines of this sort are extremely expensive, costing approximately $90,000 per kilometre with a diameter of 70 centimetres (28 inches) and a capacity of about 1,000,000,000 cubic metres (35,000,000,000 cubic feet) per year. The cost of transportation accounts for 75 to 80 percent of the fixed charges, and the operational costs, which vary little with the output, account for the other 20 to 25 percent. Consequently, it is important for such a transportation artery to be used at peak capacity.

Despite the high pressure and circulation rates of 10 to 15 metres (33 to 49 feet) per second for gas, the energy carried by a gas pipeline is still one-third or one-half as much as that carried by an oil pipeline because one cubic metre of oil contains as much energy as 1,000 cubic metres of natural gas.

Marine transport

Petroleum prospecting has revealed the presence of large gas fields in Africa, the Middle East, Alaska, and elsewhere. Transportation from such areas is now effected by boat. The gas is liquefied to −160° C (−256° F) and transported as oil in tankers designed especially for this purpose. One cubic metre of liquid natural gas is equivalent to 600 cubic metres of gas at atmospheric pressure, with the specific gravity of the liquid being relatively low (about 0.55).

This technique has developed very quickly since the first industrial operations involving it began in 1965 from Africa to Great Britain and France. Two other lines opened up in 1970, the first from Libya to Spain and Italy, and the second from Alaska to Japan. Other large-scale projects were under way in the early 1970s from African, South American, and Indonesian fields to the United States, Europe, and Japan. There were 18 liquid natural gas, or methane, tankers in use or being built, compared with only three in 1965.

After 1965, when methane tankers with a capacity of 20,000 cubic metres began to be used, the size of these ships rose to 90,000 and even 120,000 cubic metres, an increase that enabled them to carry from 50,000,000 to 70,000,000 cubic metres (1,800,000,000 to 2,500,000,000 cubic feet) of gas per trip. The cost of a methane tanker was about $40,000,000 or $50,000,000 for the largest.

Gas storage. In the course of marine transport, necessary land storage requires double-walled tanks with special insulation. Such tanks may have unit volumes of as much as 50,000 cubic metres. The low temperatures attained require the use of special steels with a high nickel content or aluminum-base alloys. Other solutions using prestressed concrete were also being tried in the early 1970s. Because the problem of heat loss is less important at ports of arrival, where the liquid gas has to be vaporized, frozen-earth tanks, consisting of enormous holes dug in the ground and made leakproof by freezing the ground water, are used.

Storage facilities on a more extensive scale have been created by using depleted oil or gas reservoirs near consumption centres (northeastern United States, northern Italy), or by the creation of artificial gas fields in aquifer layers. The latter technique developed very rapidly and the number of storage facilities of this type in the United States increased from 125 in 1950 to more than 300 in 1968, with the storage volume being more than 130,000,000,000 cubic metres. In Europe, there are six such underground storage areas in France, five in Germany, and about ten in the Soviet Union.

Natural Law

"Natural law," or "law of nature," is the term used by philosophers and jurists, not always precisely in the same sense, to refer in general to a system of right or justice held to be common to all mankind. As a body of generally recognized principles of right conduct, it is often contrasted with "positive law," the legal rules formally promulgated by the state and enforced by definite sanctions. Throughout the history of the concept, from Greek antiquity, there have been disagreements over the meaning of natural law and over its relation to positive law.

The Greek and Roman period. The development of the Greek city-states was accompanied by much reflection on the part of philosophers on the nature of the order that governed the relations of men. In the 5th and 4th centuries BC, a group of such thinkers known as the Sophists distinguished between *physis* ("nature") and *nomos* ("law"), the former being wise and eternal, the latter arbitrary and born of expediency. Law was thus taken to be utilitarian, designed to serve the interests of the strong, according to one variant of this view, or of the weak, according to another. This kind of relativism, though it seems now to have been an anticipation of some modern theories, was not at that date conducive to social stability. In an alternative approach, some Sophists appealed to the law of nature, which was thought to govern the evolution of natural phenomena. Man, by his faculties of reason and will, in this view has insight into goodness and badness and can develop in either direction; but he ought to devote his powers to developing according to a natural morality. Socrates, Plato, and, after them, Aristotle asserted the discoverability of immutable standards with reference to which positive law—that is, the law as actually formulated—might be evaluated.

Sophist view of natural and positive law

Neither Socrates nor Plato concerned themselves explicitly with natural law. But Socrates did initiate the search for definitions of things and qualities. And Plato held that if this search succeeded, man should know what justice, courage, and so forth really were. Since the word know implied that what is known is independent of the individual mind of the knower, he held that there must be such independent realities as justice and courage, and he concluded that such realities as justice and courage (which he called "Forms" or "Ideas") were permanent and unchanging entities, existing independently of particular things and actions. He held that these realities could not be apprehended by perception or empirical observation but must be pursued by pure reason, by the special activity that he called "philosophy," the goal of which was certain, final, and infallible knowledge. Since the "Forms" alone are real, he held that man's reason, which leads him to knowledge of them, is the highest side of his nature and most akin to the eternal and the divine. Since such knowledge is the only firm guide to action, reason must be trained and directed to achieve it; and, in the state, philosophers must be kings.

In *The Republic*, Plato asserted that insight into justice (or natural law) is confined to philosophers, an elite to whom legislation and government should thus be exclusively entrusted. In the real rather than the ideal world, however, such politics risk the dangers of dictatorial rule. In his last work, *Laws*, he thus dropped the idea of the philosophers' rule and advocated instead a mixed constitution combining monarchy and democracy.

Aristotelian concept of perfect natural law

Aristotle held that there is a natural law or justice that "everywhere possesses the same authority and is no mere matter of opinion" and that is discoverable by the use of reason. This perfect natural law, he said, embraced citizens and their life in society, though slaves could not share in it but could receive only its blessings, more or less second-hand, in the form of good treatment from their masters. Barbarians, too, were excluded. Like Plato, Aristotle supported the tendency to restrict perception of high principles and enjoyment of the good life to a few people

especially favoured by talents, birth, wealth, and education. The education that aided the understanding of justice and natural law was not a literary, technical, or intellectual education but the character training of a man brought up in a good family and a good city.

The Stoic school of philosophy, founded at the beginning of the 3rd century BC, introduced a new attitude and conceived an egalitarian law of nature. Previous thinkers had made familiar the part played by reason in molding behaviour. The Stoics in their turn asserted that reason is an attribute of all men and not of citizens alone. The state of nature, they said, is one of harmony, regulated by reason. This had been perverted by selfishness, and the task confronting mankind was to fashion its laws in such a way as to recover the antique ideal. To live according to reason was to live naturally. The laws of nature and morality were considered identical. Reason, moreover, was common to men in all countries, and natural law was therefore all-pervading.

The era of Roman ascendancy, which superseded the Greek, contributed hardly at all to natural law theory. A significant development, however, was the evolution of the *jus gentium*, or law of nations, applicable to both Romans and non-Romans (see ROMAN LAW). Although the *jus gentium*, as a gradual synthesis of practical rules and precepts, was not deduced from any general presupposition, it was applied to persons of all races, and there was a tendency in later times to identify it, to some extent, with natural law. Another significant development of the Roman period was the work of the Christian Fathers, notably St. Augustine of Hippo, who developed the idea that man had lived freely under the natural law before his fall and had since lived in bondage under sin and the positive law.

The medieval period. In Europe during the Middle Ages, the church was the main centre of learning, and it fell to the churchmen to propound a theory of law to suit the needs of the times. The classical philosophy was clearly adaptable, but to have followed the teachings of the pagan philosophers would have detracted from the authority of the church. The solution was to identify the law of nature of the ancients with the law of God, and this was the method in the 12th century of Gratian, the so-called father of the science of Canon Law, who equated the natural law with the revealed law of the Old and the New Testaments, particularly the Christian version of the Golden Rule, "So whatever you wish that men would do to you, do so to them."

Combining the law of God and the law of nature

In the 13th century St. Thomas Aquinas worked out a highly systematized interrelation between the eternal law of God, natural law, and human law. The eternal law of the divine reason, he maintained, though it is unknowable to man in its perfection because it is in God's mind, is yet known in part not only by revelation but also by the operations of human reason. The law of nature, which is "nothing else than the participation of the eternal law in the rational creature," comprises those precepts that mankind is thus able to formulate—namely, the preservation of one's own good, the fulfillment of "those inclinations that nature has taught to all animals," and the pursuit of the knowledge of God. Human law must be the particular application of the natural law. The Thomist system thus combines the philosophy of the Greeks, the law of the Romans, the teachings of the Christian Fathers, and contemporary Pragmatism with consummate power and skill. What is most striking in it, however, is its uncompromising appeal to reason, the law of God itself being declared to be "nothing else than the reason of divine wisdom."

Thomistic groups of principles

St. Thomas distinguished three groups of principles of natural law. The supreme group of principles called for love of God, love of neighbour according to the Golden Rule, and, generally, the performance of good and the avoidance of evil. The secondary principles, derived from the first, were contained in the Ten Commandments, involving obedience toward parents and authority, protection of the person and life of another and of his property, truthfulness, and faithfulness to one's pledged word. The third group of principles consisted of concrete rules of justice that were formed by applying the first two groups of principles to individual situations. St. Thomas believed that in every man there is a natural disposition to recognize the first two groups of principles. For him, this disposition could not err and was incorruptible, though the application of those principles to a given situation, made by the conscience, was far from infallible. The mistake was thought to occur always in the minor premise of a moral syllogism; *i.e.*, everyone knows that murder is wrong, but it is not always easy to say whether a particular act is murder.

Other Scholastic philosophers—for instance, John Duns Scotus, William of Ockham, and Francisco Suárez—emphasized the divine will instead of the divine reason as the source of natural law. Duns Scotus' view is illustrative. He asserted that God can will whatever does not imply a contradiction; hence he could have created another universe in which morality might differ somewhat from the morality of this universe; but once granted that he has created man in this particular universe, it would imply a contradiction in God if he ordered men to hate one another. What gives the natural law stability is the nature of God and of the creatures to whom it applies, even though there is an arbitrary element consisting of God's free choice of this world as the object of his creative activity. Phrased another way, God has two distinct powers—his absolute power and his regulatory power—and there is no necessary connection between the one and the other. Thus, for instance, the eternal law of God (involving his absolute power) may not be reflected precisely in the natural law of the Ten Commandments (involving his regulatory power); and this is evident because he has occasionally exempted certain men from observing certain commandments, and he would not do so if they were a part of eternal law. This so-called voluntarism of Duns Scotus and others influenced Catholic jurisprudence of the Counter-Reformation, but the Thomistic doctrine was later revived and reinforced to become the main philosophical ground for the papal exposition of natural rights in the 19th and 20th centuries.

The Renaissance and the Age of Reason. The intellectual atmosphere in which the Middle Ages ended was dominated by three factors: the growth of rival Christian sects, the birth of the nation-state, and the rise of science. Each of these affected the concept of natural law. The breakup of Christendom stimulated such a variety of selection, application, and interpretation of ideas and laws as almost to involve a principle of private moral judgment. There arose a demand for a moral standard independent both of ecclesiastical authority and of biblical texts. The rise of independent nation-states posed new questions regarding not only relations between the ruled and their rulers but also relations between the states, such as the question of whether they were to be governed by naked power politics. Finally, science had begun its work of subjecting all natural phenomena to free rational inquiry. It was inevitable that social and moral phenomena should be subject to the same critical review, and the result was a demand for a rational basis for natural law.

The man who first met these demands in a way that could be called "modern" was Hugo Grotius, a 17th-century Dutch jurist. Echoing the Stoics, he saw the universe as dominated by a rational law of nature. For man, the law of nature was the collection of those rules that followed inevitably from his essential nature. Natural law was therefore intelligible and immutable. Man was distinguished from the animals by his "appetite" for tranquil association with his fellows and by his power to act on general principles. If men were to live at peace with their fellows there were certain rules that must be observed: the keeping of promises, the recognition of human equality, the principles of equity and justice, of parental responsibility, and of marital fidelity. Here then was that set of moral standards, independent of church and of Scripture, that the new Europe demanded. Here were rules not tied to narrow national tradition but based on the universal nature of man, rules to which princes and governments no less than private individuals should be subject.

The law of nature had long ago been identified with the *jus gentium*. In one sense this had meant that these rules could be discovered not only by deduction from the nature of man but also inductively by noting their universal acceptance in all human societies. But, for Grotius, *jus gentium* had a deeper meaning as a rule governing the relations between peoples considered as moral agents. Some of the natural laws cited above (marital fidelity, parental responsibility) could not apply to the behaviour of sovereign states; and indeed Grotius was inclined to emphasize one single rule as relevant here—the rule that promises are to be kept. Men—and nations—as essentially social beings, desired a peaceful social order.

Natural law and the social contract

A concept that was to become important at this time (a version of which Hugo Grotius himself propounded) was the social contract. The individual, it was said, was born into a state of nature, which was happy or unhappy according to the particular version of the theory; he then, by the exercise of natural reason, formed a society by means of a contract or compact with other individuals. The Englishman Thomas Hobbes, who lived through the instability of the English Civil Wars of the mid-17th century, took the social contract theory and made it a vehicle for authoritarianism. According to him, men in the state of nature were selfish and cruel and, in order to inhibit their brutality and give themselves any kind of future, needed to come under the governance of an absolute authority. They thus entered into a social contract. The resultant sovereign, whose actions had been authorized by the subjects, became absolute, a social leviathan, whose power guaranteed stability, safety, and contentment. All that Hobbes was prepared to concede was that the sovereign (who was responsible only to God) should act according to natural law, which consisted of moral injunctions that sovereigns were expected to observe. Apart from this, the individual had no guarantees. Positive law was thus distinguished from natural law, its distinctive feature being the fact that it emanated from sovereign authority. Hobbes made the form of promulgation, rather than its content, the determining feature of law.

A milder version was forthcoming a generation later from John Locke. The reign of the Stuarts in England had revealed the danger of absolutism to the individual. Accordingly, Locke maintained that individuals had not surrendered all their rights to the sovereign but only the powers appurtenant to the preservation of law and security. Other "natural" rights relating to the integrity of the person and property were retained because they were fundamental. What Locke was seeking to do was to protect the individual from the arbitrary acts of a sovereign.

In France the continuing need to protect the individual against an oppressive monarchy found expression in the 18th century in the theories of Montesquieu and Jean-Jacques Rousseau. Montesquieu argued that natural laws predated society and were superior to those of religion and of the state. Rousseau went on to assert that early man or the savage had been virtuous in isolation and was actuated by two principles "prior to reason"—namely, self-preservation and compassion (innate repugnance against the sufferings of others), or freedom and equality. In forming a social contract, individuals did not surrender their natural rights to any single sovereign but to society as a whole, and this was their guarantee of continued freedom and equality. Society, having come into being for this purpose, was expected to confirm these rights as civil liberties. Society and law were thus dependent upon general will, on popular, as distinct from parliamentary, sovereignty. Little wonder that this theory was utilized as the philosophy of the French Revolution.

19th and 20th centuries. By the beginning of the 19th century a reaction against the natural law theories had developed for many reasons. First, and chief among them, was the critical spirit of a new scientific age that looked askance at unproved hypotheses. The social contract, in particular, was said to be palpably false, historically untrue. Second, it was asserted that deductive reasoning from a priori assumptions was incapable of yielding solutions to the problems of complex societies. Third, pure reason had been a slogan of the French Revolution with all its attendant excesses, and the reaction against the Revolution caused a reaction against using reason as the exclusive guide to social reform. Fourth, there was a growing conviction that improvement of the law would be more fruitfully approached on a practical basis, and not by appealing to reason. It was thought needful, above all, to understand existing institutions by means of a thorough analysis of them in order to bring about their improvement.

Waning of natural law theory

If there was a diminution of theorizing about natural law, such theorizing never disappeared altogether. Particularly in the 20th century, when there was a search for new values amid the instabilities of wars and mass society, there was a revival of natural law theory among some writers. This interest was stimulated by the need for guidance amid the conflicting ideologies that had sundered the world, so that the legality of regimes such as that of Nazi Germany might be opposed from the outset, before they could unleash terrible suffering. The collectivist tendencies of the age were reflected in certain new emphases. Léon Duguit, professor of law at the University of Bordeaux, preached that social solidarity and interdependence was the all-important fact of society. Human activity should be directed at ensuring the fulfillment of this social solidarity. Men owed duties to help to promote it, but no one had any right unless it were the right to do his duty within the social organism. The validity of laws was to be judged according to social solidarity as the criterion. All this was very far removed from those theories that insisted on fundamental rights.

An interesting feature of modern natural law was the endeavour to establish evaluative criteria empirically—that is, to derive them from general social experience. Critics contended that this kind of empirical search for common values—such as the United Nations' attempts to define human rights—is not the same as the explication of an immutable natural law. But proponents assert that, although their criteria had to be expressions of value judgments, they did not stem from ideologies or emotions. A dispassionate judgment founded on a study of all the available data and opposing considerations was far removed from confessions of faith or spontaneous reactions. In any event, the task that still confronts proponents of the search for common values is twofold: to evolve the values and to win for them a measure of acceptance.

Nature, Philosophy of

The discipline here entitled "the philosophy of nature" consists in the investigation of substantive issues regarding the actual features of nature as a reality and is divided into two parts: the philosophy of physics and the philosophy of biology. In this discipline, the most fundamental, broad, and seminal features of natural reality as such are explored and assessments are made of their implications for man's metaphysics, or theory of reality; for his *Weltanschauung,* or "world view"; for his anthropology, or doctrine of man; and for his ethics, or theory and manner of moral action. These implications are explored on the assumption that man's understanding of the natural setting in which his life is staged strongly conditions his beliefs and attitudes in many fields.

In its German form, *Naturphilosophie,* the term is chiefly identified with Friedrich Schelling and G.W.F. Hegel, early 19th-century German Idealists who opposed it to *Logik* and to the *Phänomenologie des Geistes* ("of

the spirit or mind"). Employment of the term spread, in due time, beyond its narrower historical context in German Idealism and came to be used, particularly in Roman Catholic parlance, in the sense that it bears in this article (*e.g.*, the philosophies of physics and biology). Despite a notable decline in its usage in more recent years, the term is here employed, in the interest of the clear delineation of topics, as a complement to the philosophy of science (see SCIENCE, PHILOSOPHY OF), the discipline to which its subject matter has been allocated by recent philosophers. Thus in this work, the article on the philosophy of science is largely restricted to man's approach to nature, and thus to epistemological (theory of knowledge) and methodological issues, while that on the philosophy of nature encompasses the more substantive issues about nature as it is in itself.

I. Philosophy of physics

PHYSICS AS A FIELD OF INQUIRY

Essential features. Physics is concerned with the simplest inorganic objects and processes in nature and with the measurement and mathematical description of them. Inasmuch as the binding forces of chemistry can now, at least in principle, be reduced to the well-known laws of physics, or calculated from quantum mechanics (the theory that all energy is radiated or absorbed in small unitary packets), chemistry can henceforth be considered as a part of physics in theory if not in practice. Moreover, it has become clear, through the general theory of relativity (which formulates nature's laws as viewed from various accelerating perspectives), that there is an aspect of geometry, too, that can be regarded as a part of physics. The fact that, over a wide range of circumstances, Euclidean, or ordinary uncurved, geometry presents a good approximation to reality is considered today not as a fact stipulated by a necessity of thought, nor a derivative from such a necessity, but as a fact to be established empirically; *i.e.*, by observation. In their application, the laws of Euclidean geometry refer to those experiences that arise with measurements of length and angle and optical sightings as well as with surface and volume measurements. The possibility—already extensively elucidated in antiquity—of deriving geometrical propositions by deduction from a few axioms, assumed without proof to be correct, had given rise in earlier philosophy to the opinion that the truth of these axioms must and could be guaranteed by a kind of knowledge that is independent of experience. The recognition of such a priori knowledge, however, has been superseded by the modern development of physics. While it is granted that a pure geometry is free to posit any axioms that it pleases, a geometry purporting to describe the real world must have true axioms. Today it is considered that, if Euclidean geometry is true of the world, this truth must be established empirically; the axioms would be true because the conclusions drawn from them correspond to experience. Actually, the world appears Euclidean, however, only when this experience is limited to cases in which the distances are not too great (not much greater than 10^9 light-years) and in which gravitational fields are not too strong (as they are in the vicinity of a neutron star).

Axiomatic versus empirical geometry

The possibility of deducing all known laws or regularities as logical inferences from a few axioms, which was discovered in Euclidean geometry, became a model for the construction also of another chapter in the history of physics. The classical physics of Newton, the 17th–18th-century father of modern physics, had employed Euclidean geometry as a foundation and had portrayed the solar system as a system of mass points subject to his mechanical axioms. The laws for falling bodies framed by the 16th–17th-century Italian physicist Galileo are the simplest logical consequences of Newton's axioms, and the laws framed by Johannes Kepler, a 16th–17th-century German astronomer, which precisely describe the motions of the planets, follow from them.

In addition to the laws of mechanics there are those of the broad sphere of electromagnetic phenomena as summarized in the equations of James Clerk Maxwell, a 19th-century Scottish physicist, which describe both the electric and magnetic fields and the laws of their mutual changes, equations that may thus be considered as the axioms of electrodynamics. Because they assume the mathematical form of partial differential equations—which express the rates at which differentials (small or infinitesimal distances or quantities) in several dimensions change with respect to their neighbours—electrodynamics is a local-action theory rather than an action-at-a-distance theory as in older formulations modelled after Newton's law of gravitation. The principle of local action states that the variations of electromagnetic magnitudes at a point in space can be influenced only by the electromagnetic conditions in the immediate vicinity of this point. The finite velocity of propagation for electromagnetic disturbances, which follows from this principle, leads on the one hand to the existence of electromagnetic wave events and on the other hand to conformity with the requirements of special relativity (a theory that formulates nature's laws as viewed from the perspectives of various velocities), which demand a maximum finite velocity for signals—the velocity of light in a vacuum.

Macroscopic versus microscopic physics

The most important division of physics today is one that replaces the traditional distinctions between mechanics, acoustics, and other classical branches of physics with that between macroscopic and microscopic physics, in which the latter investigates the conformity of atoms to law and their reactions in discrete quantum jumps, whereas the former extends from the level of ordinary human experience into astronomy to a total comprehension of the universe, attained through theoretical endeavours in the field of cosmology. Because it is now possible to observe especially bright objects (quasars) that are located perhaps 10^{10} light-years from the Earth, the possibility of empirically testing cosmological models is beginning to arise. In particular, the application of non-Euclidean, or curved, geometries to the cosmos has suggested the conception of a finite, yet boundless, world space (positively curved), in which the maximum possible distance between two points would no longer be much greater than 10^{10} light-years.

Historical sketch. In the historical development of physics before the 17th century, geometry was the only field in which extensive advances were made; besides geometry, only the rudiments of statics (the laws of levers, the principle of hydrostatics of the 3rd-century BC scientist Archimedes) were clarified. After Galileo had discovered the laws of falling bodies, Kepler's laws describing the motions of the planets and Newton's reduction of them to a set of dynamical axioms established the science of classical mechanics, to which was annexed the investigation of electromagnetism. These developments culminated in the discovery of induction by Michael Faraday, an English physical scientist, the knowledge of local action by Faraday and Maxwell, and the discovery of electromagnetic waves by a German physicist, Heinrich Hertz. It was not until the 19th century that the law of the conservation of energy was first recognized as a general law of nature, through the work of two physicists, Julius von Mayer in Germany and James Joule in England, and that the concept of entropy (see below *Entropy and the direction of time*) was formulated by Rudolf Clausius, a mathematical physicist. At the beginning of the 20th century, the German physicist Max Planck introduced the so-called quantum of action, $h = 6.626 \times 10^{-27}$ erg-seconds, which, when multiplied by the vibration frequency, symbolized by the Greek letter nu, ν, demarcates a basic packet of energy. Albert Einstein then extended the quantum theory to light. The real existence of atoms was proved by him and other investigators, and the science of microphysics thus arose. The researches of Niels Bohr on the quantum-theoretical significance of atomic spectra paved the way for broader search into the fine details of quantum laws, the final comprehension of which was introduced by Werner Heisenberg in 1924 and then systematically developed by Max Born, Heisenberg, and Pascual Jordan, of Germany, and by P.A.M. Dirac, of England. Moreover, Erwin Schrödinger, an Austrian physicist, pursuing a line of thought pointed out by Einstein and Louis de Broglie, arrived at results that were

outwardly quite different from those of Heisenberg *et al.*, but were mathematically equivalent. The quantum mechanics, or wave mechanics, created by these men, which formulated quantum phenomena, were later extended to quantum electrodynamics.

General and special theories of relativity

Einstein's theory of relativity, first formulated in 1905, which was eventually extended from a special to a general formulation, brought about a revolutionary transformation in physics similar to that induced by quantum theory. The Newtonian mechanics of mass points turned out to have been merely an approximation to the more exact relativistic mechanics. The most important consequence of the special theory of relativity, the equivalence of mass (m) and energy (E),

$$E = mc^2, \qquad (1)$$

in which c is the velocity of light, was formulated by Einstein himself.

After 1916 Einstein strove to extend the theory of relativity to the so-called general theory, a formulation that includes gravitation, which was still being expressed in the form imparted to it by Newton; *i.e.*, that of a theory of action at a distance. Einstein did succeed in the case of gravitation in reducing it to a local-action theory, but, in so doing, he increased the mathematical complexity considerably, as Maxwell, too, had done when he transformed electrodynamics from a theory of action at a distance to a local-action theory.

The great importance of physics for the technology that depends upon it—which has become a leading factor in the rapidly increasing development in the conditions of human existence—is shown historically in the close connection of decisive technical developments with basic advances in physical knowledge. Einstein's equivalence of mass and energy—to cite but one example—pointed to the atomic nucleus as an energy source that could be opened up through the study of nuclear physics. Moreover, the intellectual influence proceeding from physics and affecting the development of modern thought has become especially strong through the deepened grasp of the concept of causality that has followed from quantum theory (see below *Modalities of the natural order*).

BASIC CHARACTERISTICS AND PARAMETERS OF THE NATURAL ORDER

Framework of the natural order. Earlier mathematicians and particularly Richard Dedekind, a pre-World War I number theorist, have precisely defined the concept of real numbers, which include both rational numbers,

Measurements in $t; x, y;$ and x, y, z

such as $\frac{277}{931}$, expressible as ratios of any two whole numbers (integers), and irrational numbers, such as $\sqrt{27}$, π, or e, which lie between the rationals. By reference to these numbers, the Newtonian concept of space and time, which presupposes a Euclidean geometry of space, may be made precise: the values of the time t, ordered according to the ideas of earlier and later, can be made to correspond to the single real numbers, ordered according to those of smaller and larger. Also, the points on a straight line can be brought into correspondence with the real numbers in such a manner that the location of a point P between two other points P_1 and P_2 corresponds to a number assigned to P that lies between those assigned to P_1 and P_2.

Cartesian analytic geometry. Guided by the wish to find a method that allows the systematic proof of all philosophical truths, René Descartes, often called the founder of modern philosophy, established in the 17th century the analytic geometry of Euclidean planes. In it the points of a plane can be designated by two numbers x, y, their coordinates. One chooses two orthogonal coordinate axes, $x = 0$ and $y = 0$, like those of a graph, and, with any point P, associates its two projections, one upon each coordinate axis, which define the location of P. A curve in the x–y plane is then expressed by an equation $f(x,y) = 0$, shorthand for any equation ("function") containing x's and y's. In the context of analytic geometry, every theorem of plane Euclidean geometry may be expressed by equations and thus be analytically proved.

This procedure can also be extended to three-dimensional Euclidean space by introducing three mutually perpendicular axes x,y,z. In this case, there are two different axis systems—either congruent or mirror reflections—analogous to right-handed and left-handed screws.

Metrology in modern physics. The simple space–time relationships of Newtonian physics, which was brought to completion in Maxwell's electrodynamics, have been changed in many ways by modern developments. The concept of simultaneity has been made relative by the special theory of relativity; every time measurement t is thus tied to a definite inertial system or moving frame of reference. It is accordingly appropriate to speak not primarily of points in time but of events, which are defined in each case by giving both a point in space and a point in time.

More specifically, an inertial system is a coordinate system that, relative to the fixed stars, is in uniform, straight-line motion (or at rest) with no rotation. In all inertial systems, Newton's principle of inertia, which states that all mass points not acted upon by some force persist in uniform motion with a constant velocity, is valid.

Hyperspherical space–time: x,y,z,u

Moreover, cosmological theories make it probable that space in the real astronomical universe corresponds only approximately to the relationships of Euclidean geometry and that the approximation can be improved by replacing Euclidean space with a space of constant positive curvature. Such a space can be mathematically defined as a three-dimensional hyperspherical "surface"

$$R^2 = x^2 + y^2 + z^2 + u^2 \qquad (2)$$

in a hypothetical Euclidean space of four dimensions with mutually perpendicular x,y,z, and u coordinate axes.

The assertion that the foregoing statement has no operationally comprehensible content—*i.e.*, no content provable by performable measurements—is designated conventionalism, a view that is based on a remark by a French mathematician, Henri Poincaré, who was also a philosopher of science, that a fixed non-Euclidean space can be mapped point by point on a Euclidean space so that both are suitable for the description of the astronomical reality. The range of this remark is limited, however, in that this mapping, though it can indeed carry over points into points, can in no way carry over straight lines into straight lines. Hence, many philosophers of science have held that, as long as astronomical light rays are held to be straight lines, the question of a possible curvature of space (*i.e.*, a deviation from Euclidean conditions) will by no means be solved by some arbitrary convention; that it signifies, instead, a problem to be solved empirically. If the universe in fact has a positive constant curvature, then every straight line has a length that is only finite, and its points no longer correspond, as in the Euclidean case, to the set of all real numbers.

In a very definite manner, cosmological facts have further indicated that time is by no means unlimited both forward and backward. Rather, it seems that time as such had a beginning about 10^9 or 1.2×10^9 years ago; thus, with an explosive beginning, the cosmic development began as an expansion.

The foregoing discussion has considered only the replacement of Euclidean spatial concepts by an elementary non-Euclidean geometry corresponding to a space with a constant curvature. According to Einstein, however, the fundamental idea of a still more generalized Riemannian geometry, so-called after Bernhard Riemann, a geometer and function theorist, must be brought into play in order to produce a local-action theory of gravitation.

Riemannian space: g_{kl}

Riemannian geometry is a further development of the theory of surfaces created by the 18th- and 19th-century German mathematician and astronomer Carl Friedrich Gauss, often called the founder of modern mathematics, a theory that aimed to investigate the curved surfaces of three-dimensional (Euclidean) spaces with exclusive regard to their own inner dimensions and no consideration of their being imbedded in a three-dimensional space.

Gauss thought that the points on such a surface could be

specified by reference to two arbitrary coordinates u and v defined with the help of two single-parameter families of curves, u = constant and v = constant. The square of the infinitesimal distance between two adjacent points of the surface, ds^2, is then a quadratic form of the differentials du and dv, belonging to the pair of points, namely,

$$ds^2 = g_{11}du^2 + 2g_{12}dudv + g_{22}dv^2, \qquad (3)$$

in which the coefficients g_{kl} are functions of position. One can then calculate the curvature corresponding to the location of the pair of points according to a prescription given by Gauss, a curvature that measures the deviation from Euclidean behaviour that exists at this point. The curvature is a definite function of the g_{kl} and their derivatives.

Riemann has extended Gauss's considerations to the case of a three-dimensional space that can have different curvature properties from place to place (expressed by several functions of position that are collectively called the curvature tensor); and Einstein has generalized these ideas still further, applying them to the four-dimensional space–time continuum, and has thereby attained a reduction of the Newtonian action-at-a-distance theory of gravitation to a local-action theory.

Contents of the natural order. Among the most basic constituents of the physical world are symmetries, fields, matter, and action.

Symmetries. Symmetry is one of the chief concepts of modern mathematics, which combines the different symmetries belonging to an object or a concept into groups of relevant symmetries. The a priori investigation of the totality of possible groups, defined with respect to some operation (such as multiplication), comprises a division of modern mathematics called group theory.

Three-dimensional Euclidean space displays several important symmetry properties. It is homogeneous; *i.e.*, arbitrary shifts in the origin or zero point of the coordinate system produce no change in the analytic expression of the geometrical laws. It is also isotropic; that is, rotations of the coordinate system leave all geometrical laws in effect. Further, it is symmetric with regard to mirror reflections. It is tempting to suppose that these symmetry properties of space are also valid for the physical processes that occur in space, and this is indeed true over a wide range of cases, but not in all cases (for exceptions, see below *Charge/parity/time symmetry*).

Vector fields: directional quantities. That Newtonian mechanics and Maxwellian electrodynamics display in fact all of the symmetries of Euclidean space is revealed by the fact that they can be formulated in the language of vector analysis (see ANALYSIS, VECTOR AND TENSOR). Passing over the more familiar Newtonian mechanics (see MECHANICS, CLASSICAL), a few points about Maxwell's theory may be mentioned. This theory can be made to satisfy the requirements of operational thinking by ascribing to the electric and magnetic field strengths the significance of measurable physical realities, which makes it unnecessary to interpret them as states of a mysterious, hypothetical substance or ether, for which, in any case, the special theory of relativity (with the equivalence of all inertial systems) has no place.

Field; line integral; gradient

Mathematically interpreted, a vector $\boldsymbol{a}$ represents a quantity with both magnitude and direction, which preserves its length or value and its direction when displaced. The vector field—*i.e.*, the association of a vector with every point in space (*e.g.*, electric field strength, or electric current density)—and the line integral (or summation) of a vector field V along a curve K leading from a point P to a point P' are basic concepts in vector analysis. To obtain the line integral, the curve K is divided into infinitesimal elements $\boldsymbol{ds}$, the scalar (numerical or nonvector) product of ds with the value of V at that point is taken, and the results are summed with an integration.

A small surface area envisioned with a given sense of rotation around its boundary curve can also be described by a vector. In this instance, the vector, $\boldsymbol{dF}$ is perpendicular to the surface and forms, with the sense of rotation about the boundary, a right-handed system. Its magnitude is the area of the surface. The flux of the vector field V through the surface dF is called the scalar product $V \cdot dF$.

If $\mathbf{V}$ has the property that the line integral along every closed curve K is equal to zero, then $\mathbf{V}$ is said to be irrotational. This property is equivalent to the requirement that the vector field be a so-called gradient field; *i.e.*, that there exist a scalar field quantity W with the property that the difference in the value of W at two points P and P' is equal to the line integral of the vector field $\mathbf{V}$ from P to P' (along any arbitrary curve K). If $\mathbf{V}$ is, for example, an electrostatic (charged) field, the significance of being irrotational is that one can gain no mechanical work in leading a small test charge around any closed curve; the work involved is equal to zero. For an unclosed curve K, however, the movement of the test charge yields an amount of mechanical work that is proportional to the potential difference between the endpoints of the curve. The components of the gradient of W, expressed in partial derivatives ∂, are

$$\text{grad } W = \frac{\partial W}{\partial x}, \frac{\partial W}{\partial y}, \text{ and } \frac{\partial W}{\partial z}. \qquad (4)$$

Curl; divergence; charge; and current density

If the vector field is not irrotational, there can then be constructed from it an adjunct rotational field, called curl V, by considering a small (infinitesimal) surface area dF located at a point P and forming the line integral of $\mathbf{V}$ along the boundary curve of dF. Then, when this line integral is divided by the magnitude of the surface area, the component of the curl $\mathbf{V}$ parallel to the vector dF is obtained.

On the other hand, the flux of a vector field $\mathbf{V}$ out of a closed surface can be formed by integration. If this flux is always zero (for every choice of a closed surface), $\mathbf{V}$ is called source-free. Otherwise, there is a so-called divergence of $\mathbf{V}$ at a point P, which is defined as follows: one divides the net flux of $\mathbf{V}$ out of a small surface that surrounds P by the volume enclosed by the surface. The limit of this quotient for infinitesimally small surfaces is called the divergence of $\mathbf{V}$ at P or the source field div $\mathbf{V}$.

The formulation of the basic laws of electrodynamics given by Maxwell is called the Maxwell equations. These equations contain, for example, the statement that, in a vacuum, the source field of the electric field strength is proportional to the spatial electric charge density, symbolized by the Greek letter rho, ρ, and that the magnetic field strength is source-free (divergence equal to zero). Thus, magnetic monopoles having no correlate of opposite sign do not exist. Remembering that every source-free vector field may be expressed mathematically as a rotation field (and vice versa), it is possible to derive the magnetic field strength $\boldsymbol{H}$ as a rotation field from a vector field $\boldsymbol{A}$, which is usually called the vector potential of $\boldsymbol{H}$

$$\boldsymbol{H} = c \cdot \text{curl } \boldsymbol{A}. \qquad (5)$$

The fundamental law of the conservation of charge results from Maxwell's equations in the form of the continuity equation

$$\dot{\rho} + \text{div } \boldsymbol{i} = 0, \qquad (6)$$

in which ρ is the time derivative of the charge density, and the vector field $\boldsymbol{i}$ is the electric current density.

In the case of a vacuum, the Maxwell equation that expresses Faraday's law of induction takes the form of a proportionality between the rotation field of the electric field strength and the time derivative of the magnetic field strength.

$$\dot{\boldsymbol{H}} = c \cdot \text{curl } \boldsymbol{E}. \qquad (7)$$

Matter and action. It is a significant fact that Maxwell's theory leads to a localization of energy, which in electromagnetic fields is propagated somewhat in the manner of a substance, with a density that, for the vacuum case, is

$$W = (\boldsymbol{E}^2 + \boldsymbol{H}^2)8\pi. \qquad (8)$$

There remains also the unsolved problem of clarifying the relation of gravitation to quantum theory, which is

much aggravated by the fact that gravitational energy allows of no similar localization.

In both mechanics and electrodynamics, the fundamental equations have such a form that they can be understood as the conditions for a variational or an extremal principle: that, through the fulfillment of these conditions, a certain integral receives an extreme value. This integral, which has the dimensions of action—*i.e.*, of energy times time—is one of the most fundamental quantities of nature. Although the concept of action is less obvious to man's physical intuition than that of energy, it is of even greater significance, as it appears also in connection with the quantum laws. For the basic constant of all of quantum physics, which always occurs in the laws of this domain, is likewise of this dimension: namely, Planck's quantum of action

$$h = 6.626 \times 10^{-27} \text{ erg-seconds.} \quad (9)$$

Modalities of the natural order. In a purely phenomenalist theory of matter—*i.e.*, a theory that does not go into the details of atomic physics but considers matter only in a first approximation as a spatially extended continuum—numerous material properties are ascribed to every type of matter, properties such as density, electrical conductivity, magnetizability, dielectric constant, thermal conductivity, and specific heat. To be complete, a theory must provide a means of deriving all of these material properties theoretically from the laws of atomic physics.

Causality and statistical approach

The hiatus-free causality envisioned throughout the science of physics before the rise of quantum theory cannot be separated conceptually from the far-reaching assumption that all physical processes are continuous. It had been supposed that continuous changes in antecedent causal processes would issue in continuous changes in the sequence of processes that are causally dependent upon them. Quantum physics, however, has expressly breached the old philosophical axiom that *natura non facit saltūs* ("nature does not make leaps") and has introduced a granularity not only in the matter filling space, but also in the finest processes of nature. It is therefore only logical that, with respect to causality, the quantum theory would arrive at new and modified ideas as well. Renouncing unbroken causality, it speaks only of a probability that is statistical and a predetermination for the discrete saltatory events of which physical processes consist—a view that must now, in spite of Einstein, be regarded as irrevocable.

The special theory of relativity demands that the fundamental validity of the local-action principle be acknowledged: all actions have only finite velocities of propagation, which cannot exceed the velocity of light. Thus, in relativistic cosmology it is quite possible that two partial regions of the total spatial manifold may exist between which no causal interaction can occur: causal influences could then assert themselves only inside the so-called interdependent regions in the space–time manifold. These remarks also apply to the quantum theory, in which, however, instead of a causal dependence of physical processes upon each other, there is only an induction of statistical probabilities for possible quantum transitions.

Levels of the natural order. Moving in quite different directions, the theory of relativity on the one hand and the quantum theory on the other have diverged far from the earlier basic ideas of classical physics, which were considered unalterable. There are also some physical problems, however, that can be thought through only by appealing to both the relativistic and the quantum-theoretical modifications. A so-called joint relativistic and quantum-mechanical theory suitable for such problems is quantum electrodynamics, the development of which, however, is not yet complete. Its development was greatly hindered at first by certain mathematical difficulties (so-called divergences), which it later became possible to mitigate by renormalization; *i.e.*, by a technique of correcting the calculated results. The more generally conceived quantum theory of wave fields finds a broad area of possible application in the physics of the different kinds of elementary, though short-lived, particles produced by the huge high-energy accelerators. In its final form, the theory of elementary particles should not only formulate, in general, the laws valid for all known elementary particles but should also allow a deductive derivation for all possible kinds of elementary particles—analogous to the derivations of elements in the periodic table. Heisenberg has endeavoured to set up this far-reaching problem, which has been called the world formula, for a solution. Imposing mathematical difficulties, however, have arisen in the attempt to clarify its consequences for a quantitative comparison with experience, and considerable further work may still be required.

SPECIAL PROBLEMS IN THE PHILOSOPHY OF PHYSICS

Special topological properties

Problems at the formal level. Euclidean space, in contrast to imaginable spatial structures that deviate from it, is distinguished by the simplicity of the topological properties (those preserved through rubberlike distortions) that arise from its unusually simple continuity relationships. One may ask, then, whether the empirical knowledge of modern physics gives any cause to consider deviations from the topological relations of Euclidean space. The U.S. physicist John A. Wheeler, author of a new theory of physics called geometrodynamics, has speculated about this question. In particular, he has pointed to the possibility of so-called worm holes in space, analogous to the way in which the cylindrical surface of a smooth tree trunk is changed topologically if a worm bores a hole into the trunk and emerges from it again elsewhere: the surface of the trunk has thus obtained a "handle." Similarly, one can envision certain handles being added to three-dimensional Euclidean space. Whether this hypothesis can be fruitful for the theory of elementary particles is yet to be determined. From the methodological and epistemological standpoints, it is obvious that a geometrical structure is here being assumed, the measurement of which is fundamentally hindered by the lack of rulers with calibrations smaller than the structure itself. Presumably, the practical possibility of appealing to such topological modifications of the ordinary notion of space is to be found in astrophysics rather than in elementary particle physics. Viktor A. Ambartsumian, a Soviet astrophysicist, is convinced that the processes involved in the origins of galaxies are connected with explosions in which the matter of new stellar systems arises from prestellar material; and it has been found tempting to suppose that this prestellar material exists in regions with unusual topological properties.

Lorentz transformations

The basic idea of the special theory of relativity can also be understood as a statement about the symmetry properties of the four-dimensional space–time manifold. The special principle of relativity states, in fact, that the same physical laws are valid in all of the various inertial coordinate systems—in particular the law that the velocity of light in a vacuum always has the value c. This equivalence of the space–time coordinates x,y,z,t with other coordinates x', y', z', t' that are linear, homogeneous functions of the unprimed coordinates can be expressed by the equation

$$x^2 + y^2 + z^2 - c^2t^2 = x'^2 + y'^2 + z'^2 - c^2t'^2. \quad (10)$$

In this formulation, the isotropy of space—its sameness in all directions—appears as a special case of a more comprehensive symmetry property of the space–time manifold. When $t = t'$, the special case of a purely spatial rotation of coordinates is obtained; and in the general case, in which the primed coordinates are moving with velocity u with respect to the unprimed, the famous Lorentz transformations are obtained, which, to adjust to the finiteness of c, add a factor, symbolized by the Greek letter gamma, $\gamma = \sqrt{1 - \frac{u^2}{c^2}}$, to the ordinary Galilean transformation, $x = x' + ut'$, thus yielding

$$x = (x' + ut')\gamma \quad (11)$$

(see RELATIVITY: *Relativity of space and time*). The groups of symmetries of the four-dimensional space–time manifold thus produced are called Poincaré groups.

Problems at the quantum level. Problems of particle theory, complementarity, and symmetry have arisen in studies at the quantum level.

Elementary particle theory. Whereas the atomic nuclei beyond hydrogen-1 (the proton) are compounded structures, consisting of neutrons and protons, modern physics also deals with numerous elementary particles—neutrinos; π (pi), μ (mu), and K mesons; hyperons; etc.—that are thought of as uncompounded. The elementary particles of each particular kind show no individual differences. Except for the case of light quanta, for each kind of particle a corresponding antiparticle has come to light (which, for charged particles, always carries a charge of opposite sign). For instance, to each of the two known forms of neutrino there corresponds an antineutrino with charge zero and zero rest mass; *i.e.*, with a mass that would be zero were it not moving at a velocity of the order of (in fact, at) that of light. Whether Heisenberg's world formula can provide a complete framework for all possible kinds of elementary particles is still undecided.

Every type of elementary particle has a definite value for its spin, which is either integral (*e.g.*, light quanta) or half-integral (*e.g.*, electrons, protons, neutrinos). Particles with half-integral spin obey Fermi–Dirac statistics; those with integral spin obey Bose–Einstein statistics, which differ in form as $u/(1+u)$ differs from $u/(1-u)$—u being any function. The conformity to law that underlies the Fermi–Dirac statistics for electrons was first recognized by Wolfgang Pauli, an Austrian-Swiss physicist, and formulated as the Pauli exclusion principle, which played a decisive role in settling upon the shell structure in the periodic system of the elements.

Waves and corpuscles

Heisenberg's uncertainty principle. The basic duality of waves and corpuscles is of universal significance for all kinds of elementary particles, even for composite particles in those experiments that cannot lead to a breakup of the particles into their component parts.

An electron (and analogously any other elementary particle or even, for example, an alpha particle) can appear just as well in the form of a wave as in that of a localized corpuscle. In an idealized thought experiment, one can imagine that the position of an electron can be ascertained with a gamma-ray microscope. If the electron is described in terms of wave processes in the sense of Schrödinger's wave mechanics, a very sharply concentrated wave packet appears at the stated position. In an investigation of this packet by Fourier analysis—a technique that analyzes a function into its sinusoidal components—wave components of quite different wavelengths occur; thus an electron in this condition has no definite value for its de Broglie wavelength and consequently none also for its translational momentum. Then, as stated in the so-called de Broglie relation,

$$\lambda = h/mv, \qquad (12)$$

there is for an electron moving free from impinging forces a corresponding wavelength, symbolized by the Greek letter lambda, λ, that is inversely proportional to its momentum mv. And conversely, an electron moving inertially with a definite momentum (which in the limiting case of small velocities is equal to the product of the mass and the velocity vector) has no definite position. If an electron that is moving inertially (especially an electron at rest) is constrained by the use of a gamma-ray microscope to "make up its mind," as it were, on a location, then the probability of its appearance at a point in space is the same for all locations. More precisely stated, the probability of the appearance of the electron in a definite volume is proportional to the magnitude of this volume.

In particular, it will be helpful to consider an electron moving in the x-direction and to suppose that it has a wave amplitude that depends only upon x, an electron in which the most representative wavelengths are confined to a narrow interval while the amplitudes that are discernibly different from zero are likewise confined to a certain interval Δx. If, on the other hand, Δp is the range of discernible momentum values—computed from the discernible wavelengths that represent them according to the de Broglie relation (12)—then the product of the uncertainties Δx and Δp cannot be smaller than Planck's fundamental quantum of action h. This statement comprises the famous Heisenberg uncertainty relation, which expresses the "complementarity" of position and momentum—as Niels Bohr characterized it.

If one assumes, as above, that all physically possible states of an electron can be represented by Schrödinger's wave mechanics, then the complementarity of the position coordinate x and its corresponding conjugate momentum p_x is a simple mathematical fact. When one thinks primarily of physical-measurement experiments, it should be emphasized that stringent limitations are imposed on the simultaneous measurement of the position and momentum of a particle that, according to the uncertainty principle, make it impossible to measure simultaneously both of these complementary quantities with unlimited precision. In an experiment that measures its position, the electron is forced into a sharper localization; and its particle nature comes to light. By contrast, in an experiment that measures its momentum, an interference experiment is involved; the electron must be able to display a certain wavelength, which requires an adequately extended region in space for its reacting. These two complementary and opposing demands can only be brought into harmony in the sense of a compromise; and the Heisenberg uncertainty relation formulates the best possible compromise.

Thus, it becomes at the same time clear that the state of the electron given in the wave-mechanical description before carrying out a new measurement experiment can establish only a statistical prediction for the result. The probability density for the appearance of an electron at a point in space is given by the square of the absolute value of the (complex) Schrödinger wave amplitude; for a definite result in measuring a wavelength or a momentum, the square of the absolute value of the (complex) Fourier coefficient belonging to it provides the standard. The general statistical transformation theory of quantum mechanics (as developed by Dirac and Jordan) gives a complete review of the measurable physical quantities for a microscopic mass point (or a system of such points). According to this theory, two different measurable quantities A and B can be simultaneously determined with unlimited precision only if the operators or matrices that describe A and B commute; *i.e.*, if $AB = BA$.

Charge/parity/time symmetry. A transformation in which the nucleus emits an electron and a neutrino is called beta decay, an example of nuclear radioactivity (*q.v.*). The forces that thus come to light are those of the so-called weak interactions. It has been experimentally determined that for these forces the symmetry associated with reflections in a mirror does not hold. At least in certain circumstances, however, a remnant of this symmetry continues to hold, in which the so-called CPT (for the initials in charge/parity/time) theorem applies. This theorem states that basic physical laws remain of unaltered validity when a reflection of the space coordinates as in a mirror is combined with an interchange of positive and negative charge (which is largely synonymous with the interchange of particles and antiparticles) and with a reversal of the direction of time. Whether or not this symmetry law is valid without exception is by no means fully clarified at present (see CONSERVATION LAW AND SYMMETRY.)

Weak interactions

Problems at the macrophysical level. Proceeding from the properties of atoms and molecules that are described in terms of quantum theory, a theory of macrophysical substance aggregates has been built using statistical mechanics. The theories of heat, of gases, and of solid-state aggregates (crystal lattices) have been extensively clarified. Only the liquid state still poses certain unsolved problems for the statistical theory of heat.

Mach's principle of cosmic influence. In any case, Newtonian mechanics may be derived as a macroscopic consequence of the laws of the mechanics of atoms, and its validity for the motions of astronomical bodies presents no problem. It is not so simple to prove, however, that the statements of Newtonian mechanics for rotating bodies (*i.e.*, the mechanical laws of centrifugal force and the Coriolis force) may be established from Einstein's general theory of relativity. Ernst Mach, a physicist and

philosopher of science whose train of thought has substantially fertilized the modern development of physics from the point of view of the theory of knowledge, raised objections against Newton's idea that centrifugal force is a consequence of the absolute rotation of a body; he asserted instead that the rotation of a body relative to the very distant giant mass of the universe was the true cause of centrifugal force. This idea, often referred to as Mach's principle, has been corroborated, though in a different form, within the conceptual framework of Einstein's general theory. An irrotational coordinate system —specifically, a system not rotating with respect to the fixed stars (or, better, to the spiral nebulae)—is distinguished from a rotating system by the difference in the metric field for the two cases (*i.e.*, in the properties of their respective space–times as expressed by the equation —(3) above—for the interval between two events). It is true that the local metric field (in the vicinity of the solar system) is influenced by the distant masses of the universe, but of course only in the sense of a local-action principle and therefore in no way such that the metric in the solar system is directly given as a function of these distant masses and of their motions.

The question of the precise circumstances in which Mach's principle can still be defended on the basis of Einstein's theory is somewhat complicated and thus remains obscure. In any case, it is certain that a deduction of this principle from Einstein's theory can only be given in conjunction with a complete solution of the cosmological problem; *i.e.*, of the problem of what are the overall geometric and dynamic properties of the universe considered in its totality. The remaining problems involved in justifying the application of classical Newtonian mechanics in astronomy by means of Einstein's theory contain, however, no additional fundamental difficulties.

Entropy and the direction of time. There is one more influence of cosmological relationships upon macroscopic physics, which arises in connection with thermodynamics. The existence of irreversible processes in thermodynamics indicates a distinction between the positive and negative directions in time. As Clausius recognized in the 19th century, this irreversibility reflects a quantity, first defined by him, called entropy, which measures the degree of randomness evolving from all physical processes by which their energies tend to degrade into heat. Entropy can only increase in the positive direction of time. In fact, the increase in entropy during a process is a measure of the irreversibility of that process. In contrast, it is true of the quantum theory of the atom that the positive and negative directions in time are equally justifiable (in the sense of the principle of CPT symmetry). Consequently, it is difficult to understand how statistical mechanics can make possible a thermodynamics in which the entropy grows with time.

It is true that there are fluctuating thermodynamic phenomena, even in a system in overall thermodynamic equilibrium—and here theory and experiment agree. Thus, the states that arise within any small partial volume of the system may be not only those that are thermodynamically most probable but also transitory deviations from the most probable state. The mention of these fluctuations, however, does not help to remove the above paradox.

Most physicists now hold that, until recently, this problem was treated erroneously in the usual textbook presentations. In the statistical theory of heat, entropy was regarded as proportional to the logarithm of the thermodynamic probability, and students came to regard it as a necessity of thought that nature progresses from states of lower probability to states of higher probability. In truth, however, the increase of entropy is a real physical property of the positive direction in time. Nonetheless, it was supposed that shaking a vessel containing red and white balls (or even grains of sand) in an originally ordered condition with the two colours neatly separated must result in a condition of extreme intermixing of balls. This result does not correspond, however, to some necessity of thought but to an empirical property of the real universe in which men live and experiment.

Boltzmann's theorem

This interpretation, which was held for a long time and has only quite recently been recognized as erroneous, was allegedly supported by a famous mathematical theorem of Boltzmann, which seemed to show that, in an ideal gas for which the entropy—measured by its number of particles and its total energy—was not yet at its maximum value, the entropy must increase. If collisions of gas molecules are characterized by velocity vectors that are mechanically allowable (both before and after the collision), and if these vectors must satisfy both energy and momentum conservation, then what Boltzmann actually proved is that the entropy increase follows only when a correct count of the collision rate is made, according to which every kind of collision of gas molecules has a frequency of occurrence proportional to the product of the number of collision pairs that were present and the velocities that existed before the impact.

As one can subsequently see, the positive direction in time is already marked out by the collision rate count in a manner that no longer corresponds to the CPT principle. Although it is in fact possible to reason out the continuous increase in entropy on this basis, the paradox is not overcome. The question then remains of how it is physically justifiable—*i.e.*, how it can correspond to reality—to regard this principle of collision rates as valid even though it fundamentally contradicts the CPT principle.

An answer to this paradox can now be given, thanks to the insight of modern theoreticians—among them Hermann Bondi, a mathematician and cosmologist—who have shown that the entropy principle must be understood in the sense that in the universe as a whole, one definite time direction is singled out, namely, the one for which the universe expands. The thermodynamic distinction of a positive direction in time—with increasing entropy on the macroscopic level and with collision rate counts on the microscopic level—results from an expansion of the universe. Surprisingly, the Hubble expansion of the system of all the galaxies—so named after Edwin Hubble, an extragalactic astronomer—thus displays physical effects right down to the level of everyday physics; specifically, when two bodies at different temperatures are brought into thermal contact, the temperature equalization that results is an irreversible process corresponding to an asymmetry of the positive and negative directions in time that depends upon the expansion of the universe.

Problems at the cosmological level. A mathematical discovery by Alexander Friedmann, a Russian meteorologist, has become of great significance for the mathematical derivation of cosmological models from Einstein's general theory of relativity. According to Friedmann, if the average mass density is constant throughout space, the gravitational field equations can be satisfied by a metric that embraces a three-dimensional space of constant curvature together with a time coordinate t such that the radius of curvature $R(t)$ is a definite function of time; and these cosmologies turn out differently depending upon whether the curvature of space is positive, negative, or zero. Among the models of the universe that are mathematically allowable are models in which the time coordinate may run through all values from zero to infinity, models in which the time is limited to a finite interval, and models in which it may run from minus infinity to plus infinity.

The steady-state theory

For a time, many specialists working in the field of cosmology found the so-called steady-state theory, first projected by an astronomer, Sir Fred Hoyle, especially convincing. In a modified version, this theory was adapted to the Friedmann model by Bondi. By adopting the so-called perfect cosmological principle, which holds that the broadest features of the universe are the same at all times as well as at all places, the theory then satisfied the unusually high symmetry or homogeneity requirements not only of a three-dimensional space with constant time but also of the entire space–time manifold. This high-degree homogeneity was so convincing to many authors that, in deference to it, a fundamental deviation from Einstein's field equations was tolerated: Bondi and Hoyle supposed that a small but constant creation of hydrogen

occurs in the intergalactic vacuum. This hypothesis was introduced in order to achieve, in spite of the Hubble expansion of space, a mass density that remained constant in the universe.

This theory, which in spite of its deviation from Einstein's field equations certainly advocates an allowable hypothesis worthy of consideration, no longer seems tenable, however, because of the discovery of background radiation with a present temperature of 3° Kelvin, which is interpreted as a remnant of an original "big-bang" beginning of the universe. It thus appears that it is no longer possible to uphold the steady-state theory or the perfect cosmological principle upon which it is based. Instead, one must favour either a Friedmann model, which has a beginning, from which it expands monotonically and without limit; or a Lemaître model, in which a quantity lambda, λ, called the cosmical constant, arises that is, mathematically, a constant of integration, and physically, a force of cosmic repulsion that partially neutralizes that of gravitational attraction, and which lends a curvature to space even in its empty regions. For both of these models the time coordinate increases without limit from some initial value, which would naturally be called zero. For the beginning of time, one thinks, moreover, of a singularity $R(0) = 0$ and thus of a space that at the null point of time is still a mass point. Cyclical models that alternately expand and contract in an endless sequence have also been discussed.

The empirical cosmological data, some of which, indeed, are more estimated than ascertained, seem to suggest that, in the present-day universe, the positive energy corresponding to the total rest mass of all the material existing in the universe may be exactly equal to the negative gravitational energy existing in the universe; thus, the total energy would then be equal to zero. This interesting singularity, however, needs further support. At one time, Dirac advocated the speculation that the total mass of the universe is not constant in time but is increasing—at a rate somewhat slower, however, than that in the steady-state theory. Ambartsumian's notion concerning prestellar material, which was mentioned above (see *Problems at the formal level*), could perhaps be considered support for this idea, which Dirac himself pursued only temporarily. Many further discussions have followed another conjecture by Dirac, according to which the gravitational constant G should be liable to change in the course of cosmic development. This constant would thus have to be considered a scalar field quantity, which in a Friedmann universe is approximately independent of the three space variables but dependent on the time variable. In spite of extensive theoretical deliberations on this theme, no decision has yet been reached.

The way has been opened for some fundamental conjectures on certain emerging themes by the fact that the product of the mean mass density in the universe and the gravitational constant has the same order of magnitude as the square of the reciprocal of the radius of curvature of the universe. The aforementioned relation between the mass and gravitational energy in the universe presents a different expression for this ratio. The total mass of the universe divided by the proton mass probably has approximately the order of magnitude 10^{80}, according to present cosmological notions. The order of magnitude of the radius of curvature of the universe is approximately 10^{40}, when expressed as a multiple of an elementary length of which the order of magnitude is approximately that of the nuclear radius. Whether it is justifiable to presume that there is here a functional dependence—*i.e.*, a proportionality of M to R squared—is a question for the present still undecidable. The speculative attempt of Dirac to find an answer, however, is still—at least provisionally—judged with skepticism by the majority of physicists. (P.W.J.)

II. Philosophy of biology

The sharp increase in man's understanding of biological processes that has occurred in recent years has stimulated philosophical interest in biology to an extent unprecedented since the development of evolutionary theory in the 19th century. Biologists and philosophers alike have devoted much attention to a variety of issues regarding the subject matter and the methodology of biology, resulting in a sizable output of written material, formulating philosophical questions that are still arising and framing answers to acknowledged difficulties. Most of the problems of the philosophy of biology are old questions now being investigated afresh in the light of biological advances and new standards of philosophical rigour. In this account contemporary questions will be stressed (for historical background, see BIOLOGICAL SCIENCES: *The philosophy of biology*).

THE RANGE OF TOPICS

An investigation of recent writings in biophilosophy reveals a continued preoccupation with unanswered—some say unanswerable—questions about evolutionary theory and a growing concern for a critical reappraisal of the question of whether biology is an autonomous discipline unamenable to reduction to mere physical and chemical underpinnings. Until the mid-20th century the biological sciences suffered from a lack of attention by philosophers; the principles that were generated were far less rigorously examined than were those of the physical sciences. There is now renewed hope, however, for a fresh approach to the age-old puzzles regarding life and its raison d'être. This hope rests on the recrudescence of interest in all biological matters as a direct result of an increased understanding of biological processes, of the changing quality of life, of the growing awareness of man's stewardship of the Earth, and of the exploration of space. Biology has just begun to make the sort of impact that the physical sciences have already made. It has generated a life technology with genetic engineering, organ transplants, and artificial organs. Each innovation, each technical masterstroke, each conceptual knot untied emphasizes the need for a definitive philosophy of biology, and developments toward this goal are now under way. Good biological work has been accomplished by investigators with varied philosophical outlooks ranging from Neo-Thomism to skeptical naturalism. No inevitable metaphysics evolves from the study of biology or any other natural science; nevertheless, some of the general conclusions of biology have a philosophical interest, defining the limits of reasonable belief about the nature of the living world.

Natural distinctions

Categorical discontinuities that are recognized for the purpose of scientific methodology often seem impossible to justify as "natural" distinctions. Many biologists have noted, for example, that it is easier to study life than it is to define it. Properties such as metabolism and reproduction undeniably characterize organisms and might be said to define them, yet such a definition is arbitrary to the extent that such properties are logically independent. What is true of all life forms today may not have been true of the very earliest ones and, what is more, might not be true of extra-terrestrial ones that might be encountered in the future. There is not as yet a set of nonarbitrary characteristics that mark the distinction between living and nonliving systems. Moreover, in the course of analysis, it becomes necessary to arrange all of the phenomena of nature in a more or less linear, continuous sequence of classes and then to describe events occurring in the class of more complex phenomena in terms of events in the classes of less complex phenomena (principle of hierarchical continuity). Within each class, however, there are numerous interrelations observed between events of the same order of complexity. It is thus possible to recognize a number of more or less autonomous disciplines, each permitting generalization, but ordered so that the more complex events treated by one discipline can also be analyzed in terms of less complex events treated by another discipline. It is possible, for example, to establish a body of generalizations about human society independent of the behaviour of individual persons; a number of generalizations about individual behaviour without consideration of the physiology of the sensory, conductor, and effector mechanisms involved; and a large body of generalizations about muscle or nerve physiology

Living and nonliving systems

without considering the molecular mechanisms involved. A particularly striking feature of the hierarchy is that an increase in complexity is coupled with the emergence of new characteristics. The origin and development of life from small systems that synthesized biochemicals to organisms that perform highly complicated functions suggests that the hierarchical arrangement of nature and the sciences is correlated with the temporal order of evolution. The maintenance of a steady state by metabolism, reproduction, responsiveness, modification of response by experience, tradition, and social phenomena are just some of the more dramatic examples of emergent phenomena. The emergence of new qualities as evolution proceeds might generally characterize the universe.

Moreover, photosynthesis, on the one hand, and reproduction followed by natural selection, on the other, provide a mechanism by which physically less probable systems can emerge locally from physically more probable ones. Though it frequently has been supposed that physical evolution is at an end, there is no reason to suppose that this is true of social development, for which Sir Julian Huxley, a biologist, philosopher, and educator, provided an evolutionary context. In his Romanes Lectures, published in 1943, Huxley wrote:

> It is only through social evolution that the world-stuff can now realize radically new possibilities. Mechanical interaction and natural selection still operate, but have become of secondary importance. For good or evil, the mechanism of evolution has in the main been transferred [in man] onto the social or conscious level. . . . The slow methods of variation and heredity are outstripped by the speedier processes of acquiring and transmitting experience. . . .
>
> And in so far as the mechanism of evolution ceases to be blind and automatic and becomes conscious, ethics can be injected into the evolutionary process. Before man that process was merely amoral. After his emergence onto life's stage it became possible to introduce faith, courage, love of truth, goodness—in a word moral purpose—into evolution. It became possible, but the possibility has been and is often unrealized.

It may well be that social evolution is only in its early stages. These stages, moreover, have for the most part taken place in a period during which systematic knowledge was undeveloped. A Russian mineralogist, Vladimir Vernadsky, the founder of biogeochemistry, regarded the envelope of the Earth as passing from a stage determined primarily by biological processes to one determined by conscious human effort. He called this layer of consciousness the noösphere. The concept was later extended, notably by Pierre Teilhard de Chardin, a French paleontologist, who began the building of a new philosophic bridge between biology and religion.

THE NATURE OF BIOLOGICAL SYSTEMS

Questions about the character of biological systems and of the biological world merge with those about the concepts and methods required for their understanding. Although the two cannot be wholly separated, in this account those matters most clearly related to the substantive philosophical aspects of biology will be stressed. Methodological issues will be touched on in respect to the concepts being elucidated.

Origin and definition of life. Space exploration has directly influenced the development of life-detecting devices. This technological need spurred intensive study regarding the kinds of evidence living things display reflecting their aliveness. In his *Chance and Necessity* (1972) Jacques Monod, a biologist, deals with the invariance of genetic endowment, morphological autonomy, reproductive invariance, and teleonomy (the tendency to have a purpose or project written into their molecules) as the major properties of living systems; he considers that they involve the chance and necessity that determine the course and character of the entire biological world.

Philosophic views

Philosophers have long deliberated over the definitive features of living systems. The distinction between living and nonliving, which was widely discussed at the turn of the 20th century, has lost much of its interest for current biology. A growing conviction, intuitively felt by many biologists, is that no clear line can be drawn between the living and the nonliving. The bridge between what is and is not obviously alive consists of a range of problematic agents, including viruses and genes, which appear to be living at times and nonliving at other times.

Viewpoints on the nature of life. Basically and traditionally, there are three distinct philosophical stands regarding the biological nature of life: vitalism, mechanism, and organicism.

Vitalism. Essentially, vitalism holds that there exists in all living things an intrinsic factor—elusive, inestimable, and unmeasurable—that activates life. In its classic form, as espoused by many biologists at the turn of the 20th century—in particular, by Hans Driesch, a German biologist and philosopher—it has suffered severe criticism. Ernest Nagel, a philosopher of science, rang its death knell in 1951, when he wrote in *Philosophy and Phenomenological Research* (11:327 ff.):

> Vitalism of the substantival type . . . is now a dead issue . . . less, perhaps, because of the methodological and philosophical criticism that has been leveled against the doctrine than because of the infertility of vitalism as a guide in biological research and because of the superior heuristic value of alternative approaches.

And whereas most biologists concur in renouncing this so-called naïve vitalism, some continue to espouse a so-called critical vitalism, perhaps indistinguishable from organicism (see below).

Mechanism. Simply stated, the view of the mechanists is that organisms are no different from subtle machines: the whole is the sum of its parts, which are arranged in such a way that an internal energy source can move them in accordance with a built-in program of purposeful action. In the mechanist's view, advances in molecular biology corroborate this claim and demonstrate that in principle organisms are no more than complicated physical systems. This is, in essence, the reductionist position, which states that biological principles can be reduced to physical and chemical laws. Antireductionists, of course, contend that molecular biology cannot explain all aspects of living forms.

It has often been said that, whereas biologists may think as vitalists—and hold the conviction that organisms are more than just complex machines—they perforce become practicing mechanists in the laboratory, required by the demands of scientific inquiry to view their experiments in terms of the measurable parameters of physics and chemistry. K.F. Schaffner, an American philosopher, suggested in 1967 that, even though reductionism may be correct, a better strategy may be to strive toward an independent biology.

Organicism. The basic claim of organicism is that organisms must be interpreted as functioning wholes and cannot be understood by means of physics and chemistry alone. Few scientists today call themselves organismic biologists or endorse the doctrines put forward by such organismic theorists as Ludwig von Bertalanffy and Edward Stuart Russell. Nevertheless, most antireductionists subscribe at least to part of the organismic doctrine, in particular to its wholistic claim. Russell, a foremost proponent of organicism, stated in his work *The Interpretation of Development and Heredity* (1930):

The views of E.S. Russell

> Any action of the whole organism would appear then to be susceptible of analysis to an indefinite degree—and this is in general the aim of the physiologist, to analyze, to decompose into their elementary processes the broad activities and functions of the organism. But . . . by such a procedure something is lost, for the action of the whole has a certain unifiedness and completeness which is left out of account in the process of analysis. . . . In our conception of the organism we must . . . take account of the unifiedness and wholeness of its activities . . . since . . . the activities of the organism all have reference to one or other of three great ends, and that both the past and the future enter into their determination. . . . Bio-chemistry studies essentially the *conditions* of action of cells and organisms, while organismal biology attempts to study the actual modes of action of whole organisms, regarded as conditioned by, but irreducible to, the modes of action of lower unities.

In some special sense, then, an organism is regarded as being more than a simple sum of its parts; an additional

"something" has accrued to it as a result of the unique arrangement of its components. As Morton Beckner, a philosopher of biology, asserted in an article in the *Encyclopedia of Philosophy* (5:549):

> In the history of biology it is difficult to disentangle vitalistic and organismic strands, since both schools are concerned with the same sorts of problems and speak the same sort of language. The distinction between them was drawn clearly only in the twentieth century. Organismic biology may be described as an attempt to achieve the aims of the murky organismic-vitalistic tradition, without appeal to vital entities.

Further (p. 551):

> Organismic biology is to be interpreted as a series of methodological proposals, based on certain very general features of the organism—namely, the existence in the organism of levels of organization with the biological ends of maintenance and reproduction. These features are sufficient to justify "a free, autonomous biology, with concepts and laws of its own," whether or not the higher levels are ultimately reducible to the lower ones.

Organisms as systems. The concept of an organism as a cybernetic, or automatic-control, system is currently influential in biology.

Holism and emergence. The holistic concept of an organism—*i.e.*, the theory that the determining factors in biology are its irreducible wholes—owes its success primarily to the existence of control and regulation mechanisms operating at the molecular level that determine development and behaviour. The character of such systems at all levels of analysis—molecular through total organism—is nothing other than a sophisticated kind of cybernetics. Holism and reductionism are similar in this respect. Closely allied to organicism is the old problem of emergent properties dealt with earlier: at each successive level of organization, qualities emerge that cannot be anticipated by the components and that confer an added dimension to each hierarchical level in the biological world.

General systems theory. A theoretical and methodological program called general systems theory—presented in its fullest and most persuasive form by Bertalanffy—is an extension of the tenets of organismic biology. It is an attempt to provide a common methodological approach for all of the sciences, based upon the idea that systems of any kind—physical, biological, psychological, and social—operate in accordance with the same fundamental principles. Ideally, it should be possible to deduce the principles applying to a particular sort of system from the more general ones. This approach is one still very much in need of development.

Function and purpose in biological systems. Attributions of purpose (teleology) appear frequently in biological writing. Not only do biologists say that parts of organisms have a purpose with respect to the whole, but some hold that life itself is inherently purposive. But the term purpose is both vague and ambiguous. That every biological system—from self-replicating molecules (DNA) to biotic communities—involves specific and identifiable functions is undeniable. But whether, or in what way, functional ends like the reproduction of a cell resemble human intentions or purposes is a matter of some controversy. Even if this matter were settled, a larger question would still remain, viz., whether a biological system as a whole can have a goal that is in some way similar to a human goal—*i.e.*, whether it is programmed with an utlimate purpose. Although resolution of this matter has long been and will continue to be a critical point in the philosophy of biology, much has been done in the last few years to clarify the issues involved.

PHILOSOPHY IN EVOLUTION

Teleology and determinism. Vitalists and those who subscribe to a Lamarckian view of evolution involving the inheritance of acquired characteristics claim that evolution involves a deterministic finalism, or directedness toward an end. Most evolutionary biologists—among them George Gaylord Simpson—reject that claim and hold that natural selection is the non-random element in evolution, that which gives evolution direction. Other evolutionists—among them Theodosius Dobzhansky—argue that the chance factors in mutation and selection, in addition to the unpredictability of environmental change, make it impossible to formulate deterministic laws even in experimental populations, let alone in natural populations. Similar considerations by others have led to the claim that evolutionary biology is a paradigm of an after-the-fact exploratory science and that the course of evolution can never be predicted.

The species problem. Whether biological species can be said to have a real existence in the world is a question that has received much consideration in recent years. The issue may be posed in the words of Benjamin Burma, a paleontologist, who, writing in *Evolution* (3:369), asked:

> What, then, is a species? It would seem thus far to be the whole of any one series of breeding populations. . . . [But the] definition as it stands unfortunately puts all living and fossil animals in one species, since there is a continuity of germ-plasm back from John [an individual animal] to the original primordial cell, and from it forward to every living animal (not to mention plant). Thus, if we ignore time, we end up with only one species. . . .

The temporal difficulty, however, is not the only stumbling block to the question of species reality; for, if the species is redefined as the whole of any one series of breeding populations as it exists at any one time, then there is an infinity of species, since time itself is infinitely divisible. On the basis of these and other objections, some biologists have concluded that species have only a subjective existence merely as convenient labels for arbitrary assemblages and have only a minimum of biological significance. On the other hand, there are proponents of the idea that species have an objective reality. Ernst Mayr, a U.S. evolutionist representing the latter group, has written—also in *Evolution* (3:372):

> In all multidimensional situations an inference has to be made (Simpson, 1943) on the basis of the objective species of the non-dimensional system. The subjectivity of this exmade (Simpson, 1943) on the basis of the objective species concept per se. The species of the local naturalist or of the paleontologist within a given horizon is clearly delimited against other species and can thus be considered as having objective reality.

Although the controversy is confused by semantic difficulties, one of the chief contributions of the philosophy of biology has, in fact, been to separate mere linguistic puzzles from matters of substance. Many taxonomists are guilty of ambiguity of reference; they often fail to distinguish their entities clearly, with the result that there is widespread befuddlement over just what stand is held by whom. The problems are now clearer than they have ever been, and with few exceptions biologists and philosophers tend to agree about the nature of biological species and the definition of the species category (see also SPECIES AND SPECIATION).

Evolutionary theory. Although most of the issues connected with evolution as a theory are methodological ones, two issues go beyond the limits of logic. Some philosophers have tried to demonstrate, for example, that evolutionary theory is circular and offers no real understanding of the process of evolution. Others have argued that the notions of types of organisms must be used to understand evolution and that evolutionary change takes place when a new type emerges.

The views of Simpson and Schindewolf

Two clear viewpoints regarding evolutionary theory have come to the fore since 1950. One is expressed in detail by George Gaylord Simpson, in his work *The Major Features of Evolution* (1953), and the other is put forward by a paleontologist, Otto Schindewolf, in his *Grundfragen der Paläontologie* (1950). In 1959, Marjorie Grene, a philosopher of biology, writing in the *British Journal of the Philosophy of Science* (9:11 ff.), summarized their positions as follows:

> Professor Simpson is the principal American spokesman of neo-Darwinism. . . . He sees evolution as a continuous series of minute changes in innumerable directions, in which all alterations of any significance, larger as well as smaller, quicker as well as slower, are determined by the great cooperating "pressures" of mutation, geographical isolation, and

selection, with adaptation as the universal effect, and criterion, of systematic change. The basic concept, ultimately is variation in the occurrence of genes; out of such variations all the systematic relations of living things have been gradually evolved.

Schindewolf's principles are simpler. He sees typical shapes, and sees again and again what appear to be new shapes. Therefore he assumes that living things are able to originate novel types. Mutation, he agrees, must have been the mechanism by which they originated; but the adaptive control of mutation occurs only within, not between types. The basic pattern is of change from type to type, and always, as we have seen, with the more general appearing before its specialised subdivisions.

The controversy between these two opposing viewpoints is a complex one filled with both philosophical and scientific issues. In the opinion of most biologists, Schindewolf's view is persuasive only with respect to the paleontological evidence and is not supported by the experimental study of evolution in current organisms. Most of them thus tend to accept the synthetic theory in more or less the form expressed by Simpson. It remains possible, however, that the process that Schindewolf is talking about is fundamentally different from that explored in population genetics and that typostrophic mutations are so rare, on the time scale of man, as to be beyond hope of detection in the laboratory.

EVOLUTION AS A WORLD VIEW

Very few attempts have been made in recent years to employ the concept of evolution as a scheme for viewing all knowledge and experience. Sir Julian Huxley, who remains one of the best representatives of such an effort, continues to claim that the entire universe is in a process of evolution, which, however, has different aspects, viz., physical, biological, and social. Life and nonlife alike must be understood as part of the process of cosmic evolution, and from this follows a host of metaphysical and ethical implications. The other chief representative of this viewpoint is the evolutionist priest Teilhard de Chardin, who has woven into the fabric of cosmic evolution the panoply of a Christocentric religion that sees the perfection of all things in an "Omega" point toward which evolution is moving.

Metaphysics of the more piecemeal kind—exploring the implications that biological knowledge has on beliefs and attitudes—is fostered by Simpson, a consistent antagonist of Huxley and Chardin. Simpson suggests, for instance, that knowledge of man's origins and of the process that has brought him to his current state in no way threatens belief in his own uniqueness. Man is an animal, but a very special sort of animal. Other matters of a similar kind—purpose in nature and man's evolutionary future—are considerations that constitute the implications of biology in general and of evolutionary biology in particular.

BIOLOGY AND ETHICS

The question of innate aggressiveness. One of the best known issues threatening accepted beliefs about moral responsibility is probably that raised by the proponents of the theory of innate aggression, in particular by such spokesmen as Konrad Lorenz, an Austrian student of animal behaviour, and Robert Ardrey, a U.S. writer. If there is an instinct for aggressiveness, then the notion that it is acceptable to blame individuals and society for outbreaks of violence or war loses its validity. The thrust must then be elsewhere: not in faultfinding but in shoring up against what is felt to be pedestrian and inevitable. As Ardrey puts the theory in his *African Genesis* (1961):

Views of the ethologists

> But we were born of risen apes, not fallen angels, and the apes were armed killers besides. And so what shall we wonder at? Our murders and massacres and missiles, and our irreconcilable regiments? Or our treaties whatever they may be worth; our symphonies however seldom they may be played; our peaceful acres, however frequently they may be converted into battlefields; our dreams however rarely they may be accomplished. The miracle of man is not how far he has sunk but how magnificently he has risen. We are known among the stars by our poems, not our corpses.

Raymond Dart, a South African anatomist and anthropologist, in an article entitled "The Predatory Transition from Ape to Man," published in the *International Anthropological and Linguistic Review* (1:201–208), expressed the thesis of innate depravity on which Ardrey's more popular presentation is based.

Another aspect of the innate aggression inherited from man's primate forebears is militant enthusiasm, which Lorenz described in *Das sogenannte Böse: zur Naturgeschichte der Aggression* (1963; Eng. trans., *On Aggression*, 1966):

> In reality, militant enthusiasm is a specialized form of communal aggression, clearly distinct from and yet functionally related to the more primitive forms of petty individual aggression. Every man of normally strong emotions knows, from his own experience, the subjective phenomena that go hand in hand with the response of militant enthusiasm. A shiver runs down the back and, as more exact observation shows, along the outside of both arms. One soars elated, above all the ties of everyday life, one is ready to abandon all for the call of what, in the moment of this specific emotion, seems to be a sacred duty. All obstacles in its path become unimportant; the instinctive inhibitions against hurting or killing one's fellows lose, unfortunately, much of their power. Rational considerations, criticism, and all reasonable arguments against the behavior dictated by militant enthusiasm are silenced by an amazing reversal of all values, making them appear not only untenable but base and dishonorable. Men may enjoy the feeling of absolute righteousness even while they commit atrocities. Conceptual thought and moral responsibility are at their lowest ebb. As a Ukrainian proverb says: "When the banner is unfurled, all reason is in the trumpet."

Montagu's view

Equally notable opponents of the theory of innate aggression see it much as M.F. Ashley Montagu, a British–U.S. anthropologist, does, as "original sin revisited," and deplore the tendency to neglect authoritative studies in favour of simplistic popularization. In *Man and Aggression* (1968), he writes:

> While the findings of these disciplines [anthropology and the behavioral sciences] are wholly opposed to the deeply entrenched view that man is an innately aggressive creature, most people tend to dismiss these findings out of hand or ridicule them as a rather eccentric idealistic heterodoxy, which do not deserve to become generally known. In preference to examining the scientific findings they choose to cast their lot with such "authorities" as William Golding who, in his novel *Lord of the Flies*, offers a colorful account of the allegedly innate nastiness of human nature, and Robert Ardrey who, in *African Genesis* and more recently in *The Territorial Imperative*, similarly seeks to show that man is an innately aggressive creature. . . .
>
> . . . when through the distorting glass of his prejudgments he looks at a tool it becomes not simply a scraper but a weapon, a knife becomes a dagger, and even a large canine tooth becomes "the natural dagger that is the hallmark of all hunting animals," while in "the armed hunting primate" it becomes "a redundant instrument." "With the advent of the lethal weapon natural selection turned from the armament of the jaw to the armament of the hand." But the teeth are no more an armament than is the hand, and it is entirely to beg the question to call them so. Virtually all the members of the order of primates, other than man, have large canine teeth, and these animals, with the exception of the baboons, are predominantly vegetarians, . . . that such teeth may, on occasion, serve a protective purpose is entirely secondary to their main function, which is to rip and shred the hard outer coverings of plant foods.

Further responses to Ardrey's and Lorenz' thesis are the interpretations of field studies of primate groups, such as those of George Schaller on the gorilla, of Jane van Lawick-Goodall on the chimpanzee, and of Barbara Harrison on the orangutan. These researches suggest that the majority of such groups are singularly free of belligerence. According to Montagu,

> The myth of the ferocity of "wild animals" constitutes one of Western man's supreme rationalizations, for it not only has served to "explain" to him the origins of his own aggressiveness, but also to relieve him of the responsibility for it—for since it is "innate," derived from his early apelike ancestors, he can hardly, so he rationalizes, be blamed for it! And some have gone so far as to add that nothing can be done about it, and that therefore wars and juvenile delinquents, as Mr. Ardrey among others tells us, will always be with us! From one not-so-minor error to another Mr. Ardrey sweeps on to the grand fallacy.

The matter remains moot; but there appears to be a growing consensus that, given a certain genetic constitution—and within the bounds of that endowment—whatever man is, he learns to be, especially in respect to values, morality, and customs. Baser appetitive needs, however, may have a genetic component that is greater than an environmental one.

New understanding of environmental factors and the consequences of man's actions with respect to them has made it clear that man has acquired responsibilities that he did not recognize before. It has become increasingly accepted that standards and values with respect to the environment must be established; this is perhaps the most dramatic case in which recent biological knowledge has generated a crisis of a moral kind. The classic work *Science and Survival* (1966) by a biologist, Barry Commoner, is particularly noteworthy in connecting theoretical and philosophical issues about reductionism and holism to practical matters of environmental understanding and problem solving.

The metaphysical issue of man's place in nature is now being construed as one that requires that man make value decisions, assign responsibilities, and plan for the future of his planet. Environmental problems have become intertwined with problems of social planning, racial tension, transportation and housing crises, genetic engineering, and a host of other current concerns.

Evolutionary ethics. The question of whether nature provides guides to the actions of humankind has held a fascination for many biologists. Those who call themselves evolutionary ethicists say that it does. The defenders of evolutionary ethics contend that external moral standards exist in the facts and process of evolution.

Social Darwinism

Toward the end of the 19th century, Herbert Spencer, in England, and others advanced a series of principles that came to be called Social Darwinism. It espoused such ideas as the inevitability of progress, survival of the fittest, and the struggle for existence, expressions that have become bywords even though they have since been discredited in their original sense, as applied to social phenomena. Social Darwinism as C.H. Waddington, a biologist, explains in his book *The Ethical Animal* (1960), has been superseded by

> . . . the more recent phase of evolutionary ethical thought beginning in the early 1940s, [which] comprises a number of rather different methods of approach. At one extreme we have discussions framed in terms of extremely wide scope, which treat of evolution not only in the animal world but throughout the cosmos, and attempt to relate such broad concepts to man's religious and spiritual life. The pre-eminent example of this tendency in recent years is Teilhard de Chardin, but a rather similar approach can be found in the works of several biologists, such as Conklin, Holmes, and Huxley. The opposite tendency, which of course is also found expressed to various extents in these authors, particularly in Julian Huxley, is the attempt to demonstrate, in a logically coherent argument, a real connection between evolutionary processes and man's ethical feelings.

Some biologists continue to insist, therefore, that biological facts can provide a yardstick by which to measure the morality of a given course of action. Julian Huxley, for one, has long claimed that moral principles can be found in nature and in the evolutionary process in particular:

> When we look at evolution as a whole, we find, among the many directions which it has taken, one which is characterized by introducing the evolving world-stuff to progressively higher levels of organization and so to new possibilities of being, action, and experience. This direction has culminated in the attainment of a state where the world-stuff (now moulded into human shape) finds that it experiences some of the new possibilities as having value in or for themselves; and further that among these it assigns higher and lower degrees of value, the higher values being those which are more intrinsically or more permanently satisfying, or involve a greater degree of perfection.

Huxley further asserts that, although the Golden Rule, the policy of action based on sympathy—doing as you would be done by—may be an immediate good, it ultimately leads to the suppression of those qualities most needed for survival and the continuation of a species. Rather, he argues:

> The facts of nature, as demonstrated in evolution, give us assurance that knowledge, love, beauty, selfless morality, and firm purpose are ethically good. . . . In the broadest possible terms evolutionary ethics must be based on a combination of a few main principles: that it is right to realize ever new possibilities in evolution, notably those which are valued for their own sake; that it is right both to respect human individuality and to encourage its fullest development; that it is right to construct a mechanism for further social evolution which shall satisfy these prior conditions as fully, efficiently, and as rapidly as possible.

Simpson, however, contends, in the article "Biological Sciences," in *The Great Ideas Today* (1965):

> The facts and the processes of evolution are neither ethical nor unethical. The questions of good or bad are simply irrelevant to this field, with the important reservation that evolution has produced a species, *Homo sapiens*, concerned with ethics. Denial of man's naturalistic origin and animal nature is flatly false, and any ethic based on such denial is invalid. Evolution controverts primitive creation myths, but it is consistent with higher values in the Judeo-Christian tradition and those in most now-current religions and philosophical systems. One need only think of the brotherhood of mankind—a biological fact, not only an ethical idea.
>
> Beyond such considerations as those, efforts to combine science and religion may be noble in intention but usually end up distorting or stultifying both. One of the most striking examples at present is the cult, as it may fairly be called, of Pierre Teilhard de Chardin. He preaches necessarily posthumously, for the Roman Catholic Church suppressed his views during his life—a mystical Christianity ostensibly derived from evolutionary principles. But since the mysticism is primary, the evolutionary principles are distorted and downright falsified for seeming coherence with the nonscientific, nonnaturalistic premises. In turn, the mystical views advanced as having that false basis are thereby vitiated. The result (in my opinion) has been a disservice to true religion and to true science.
>
> At the same time, no one can deny the purity of Father Teilhard's intentions or the correctness of his view that evolution and religious feeling should be considered congruent aspects of the nature of man. It is almost as irrational to deny evolution as to deny gravity. The management of life and the goals of aspiration, to be sane, must take account of all such truths of nature. They need not thereby become brutal or earthbound.

POTTER, *Bioethics* (1971), a collection of articles dealing with the influence of biology on practical moral problems; BERNHARD RENSCH, *Biophilosophie auf erkenntnistheoretischer Grundlage* (1968; Eng. trans., *Biophilosophy*, 1971), emphasizes the rise and nature of consciousness within the framework of the evolutionary process; M.A. SIMON, *The Matter of Life* (1971), a good review of the current approaches to the philosophy of biology; GEORGE GAYLORD SIMPSON, *This View of Life: The World of an Evolutionist* (1964), a collection of essays by a renowned scholar, some of which have shaped the direction of philosophical biology today, and the especially pertinent chapter, "Man's Place in Nature," in his *Meaning of Evolution*, pp. 281–294, rev. ed. (1967); PIERRE TEILHARD DE CHARDIN, *Le Phénomène humain* (1956; Eng. trans., *The Phenomenon of Man*, 1959), a controversial attempt to meld science and religion by presenting a mystical viewpoint of cosmic evolution; C.H. WADDINGTON, *The Ethical Animal* (1960), a defense of the claim that biological facts can provide grounds for moral principles.

(P.W.J./R.C.Y.)

Nature Worship

In the history of religions and cultures, nature worship as a definite and complex system of belief or as a predominant form of religion has not been well documented. Among nonliterate or primitive peoples the concept of nature as a totality is unknown; only individual natural phenomena—*e.g.*, stars, rain, animals, plants, water, and fire—are comprehended as natural objects or forces that influence them and are thus in some way worthy of being venerated or placated. The concept of nature as an entity in itself, in contrast with man, human society and culture, or even God, is a philosophical or poetic conception that has been developed among advanced civilizations. Nature worship, therefore, is a working concept limited primarily to scholars involved in or influenced by the modern (especially Western) study of religion.

NATURE AS A SACRED TOTALITY

To students of religion, the closest example of what may be termed the worship of nature as a sacred totality, or an entity in itself, is perhaps most apparent in cultures—*e.g.*, ancient or primitive—in which there is a high god as the lord in heaven who has withdrawn from the immediate details of the governing of the world. This kind of high god—the *Deus otiosus*, or hidden god—is one who has delegated all work on earth to what are called "nature spirits" (*i.e.*, the forces or personifications of the forces of nature). High gods exist, for example, in such indigenous religions on Africa's west coast as that of the Diola of Guinea. In such religions the spiritual environment of man is functionally structured by means of personified natural powers; *i.e.*, the nature spirits.

Pantheism (a belief system in which God is equated with the forces of the universe) or deism (a belief system based on a non-intervening creator of the universe), as was advocated in the rationalistic philosophy of religion of western Europe of the 16th to 18th centuries, is not appropriate in studies of concepts of nature in preliterate cultures. Worship of nature as an omnipotent entity, in the pantheistic sense, has not as yet been documented anywhere.

The concepts of mana, orenda, wakan, and manitou

The power or force within nature that has most often been venerated, worshipped, or held in holy awe is mana. Mana, often designated as "impersonal power" or "supernatural power," is a term used by Polynesians and Melanesians that 19th-century Western anthropologists appropriated to apply to that which affected the common processes of nature. Mana was conceptually linked to North American Indian terms that conveyed the same or similar notions—*e.g.*, orenda of the Iroquois, wakan of the Dakotas, and manitou of the Algonkin. Neither the designation "impersonal power" nor "supernatural power" implies what mana really means, however, because mana usually issues from persons or is used by them, and the concept of a supernatural sphere as distinct or separate from a natural sphere is seldom recognized by preliterate peoples.

Thus, a better designation for mana is "super force" or "extraordinary efficiency." A person has mana when he is successful, fortunate, and demonstrates extraordinary skill; *e.g.*, as an artisan, warrior, or chief. Mana can also be obtained from the *atuas* (gods), providing that they themselves possess it. Derived from a root term that has aristocratic connotations, mana corresponds to Polynesian social classifications. The ariki, the nobility of Polynesia, have more power (mana), and the area that belongs to them and even the insignia associated with them have mana. Besides areas and symbolic elements associated with the ariki, many objects and animals having special relationships with chiefs, warriors, or priests have mana.

The concept of *hasina* of the Indonesian Hova (or Meri-

na) on Madagascar is very similar to mana; it demonstrates the same aristocratic root character as mana in that it indicates that the word mana is derived from the Indonesian *manang* ("to be influential, superior").

The Iroquoian term orenda, similar to mana, designates a power that is inherent in numerous objects of nature but that does not have essential personification or animistic (soul) elements. Orenda, however, is not a collective omnipotence. Powerful hunters, priests, and shamans have orenda to some degree. The *wakanda*, or wakan, of the Sioux Indians is described similarly, but as Wakan-Tanka it may refer to a collective unity of gods with great power (wakan). The manitou of the Algonkin is not merely an impersonal power, comparable to the wakan, that is inherent in all things of nature but is also the personification of numerous manitous (powers), with a Great Manitou (Kitchi-Manitou) at the head. These manitous may even be designated as protective spirits that are akin to those of other North American Indians, such as the *digi* of the Apaches, *boha* of the Shoshones, *tamanoas* of the Chinook, and *maxpe* of the Crow, as well as the *sila* of the Eskimos.

The super forces (such as Mulungu, Imana, Jok, and others in Africa) that Western scholars have noted outside of the Austronesian–American circles of peoples are often wrongly interpreted as concepts of God. Only the *barakah* (derived from the pre-Islāmic thought world of the Berbers and Arabs), the contagious superpower (or holiness) of the saints, and the power Nyama in western Sudan that works as a force within large wild animals, certain bush spirits, and physically handicapped people —appearing especially as a contagious power of revenge —may be added with a certain justification to that force of nature that is designated by mana. A striking similarity with mana may also be noted in the concepts of *heil* (good omen), *saell* (fortunate), and *hamingja* (luck) of the Germanic and Scandinavian peoples.

HEAVEN AND EARTH AS SACRED SPACES, FORCES, OR PROCESSES

Heaven and earth as personified powers of nature

Heaven and earth, as personified powers of nature and thus worthy of worship, are evidently not of equal age. Though from earliest times heaven was believed to be the residence of a high being or a prominent god, the earth as a personified entity is much rarer; it probably first occurred among archaic agrarian civilizations, as it still does in some primitive societies in which agriculture is practiced. Gods of heaven, however, are characteristic spiritual beings of early and contemporary hunter and collector cultures and are found in almost all cultures.

Primitive world views generally assume the earth to be simply given (*i.e.*, as continuously existing). Sometimes it is believed to have emerged out of chaos or a primal sea or to have come into existence by the act of a heavenly god, transformer, or demiurge (creator). Even in such world views, however, the earth usually remains without a divine owner, unless through agriculture and the cult of the dead the earth is conceived as the underworld or as the source of the renewing powers of nature. The fact that heaven is animated by rain-giving clouds (with lightning and thunder) and by a regular chorus of warming and illuminating celestial bodies (sun, moon, and stars) led to concepts of the personification of heaven from earliest times.

Heaven. Heavenly deities, as the personification of the physical aspects of the sky, appear in variations that are adapted to the types of cultures concerned. The listing offered below does not represent a unilinear development that is applicable everywhere.

The father of the family. The god of heaven is often viewed as an ever-active father of the family, often called upon but rarely the recipient of sacrifices. He is able to intervene in human and natural affairs without the aid of an intermediary (*e.g.*, priest, medicine man, or ancestors). As a numinous (spiritual) being, he is closer to man than other spiritual powers. He sends lightning and rain and rules the stars that are at most essential aspects of himself or are members of his family subject to him. He is the creator and the receiver of the dead. Modern scholars have designated such a being as the "high god," "supreme god," the "highest being" of the "original monotheism" (according to the theories of a German scholar, P.W. Schmidt), the idealized god of heaven (according to the views of an Italian historian of religion, Raffaele Pettazzoni), or the familiar father deity (according to the views of a British anthropologist, Andrew Lang). Very human, often comical, or even unethical and repulsive traits of such deities are often represented in myths that also sometimes include legends of animal or human ancestors.

Relationship of the "high god" to men

This type of deity is generally found in its most developed form among the old hunter and collector peoples of the temperate and arid areas (*e.g.*, forest Indians of North America, Indians of California and of Tierra del Fuego in South America, Australian Aborigines, and African Bushmen) and of the tropic primeval forests, where he is usually conceived as a storm and thunder being (*e.g.*, Tore of the Ituri Pygmies or Karei of the Semang of the Andaman Islands). He is also worshipped among the pastoral peoples as the "blue" or "white" sky of the wide pastures in the steppes of northeastern Africa (*e.g.*, Waka of the Galla) and of Central and North Asia (*e.g.*, Torem, Num, and Tengri of the Ugrians, Samoyeds, and Mongols).

Among such peoples, heaven is often merged with an old hunting deity, the Lord of the Animals, or it allows the latter to exist as a hypostasis by his side.

The withdrawn god. The god of heaven also may be a *Deus otiosus*, who has, after completing the creation, withdrawn into heaven. He has abandoned the government of the world to the ancestors of men or to nature spirits that are dependent on him and act as mediators between him and men. This type of the god of heaven, who is able to intervene directly only when there are widespread existential necessities or needs (*e.g.*, drought, pestilence, or war), can be found primarily where worship of the dead or worship of individual local "earth spirits"—not yet integrated into an all-inclusive earth deity—obscures everything else. This type of god occurs especially in areas of so-called primitive agriculture (*e.g.*, large parts of Africa, Melanesia, and South America).

Relationships of the "high god" to other deities

The first among equals. The god of heaven also may be the head of a pantheon of gods, the first among equals, or the absolute ruler in a hierarchy of gods. This occurs in polytheism (belief in many gods) in its purest form. The deities associated with him are often related to him by family ties (genealogies of gods). Occasionally, the heavenly phenomena are distributed among members of the clan of gods, the god of heaven himself thus becoming rather vague. The divine pair heaven–earth represents only one among many possible combinations—*e.g.*, Dyaus-pitṛi (= heaven, male) and Pṛthivī (= earth, female) in Vedic India or, with an unusual distribution of the sexes, Nut (= heaven, woman) and Geb (= earth, man) in ancient Egypt.

Occasionally, generations of gods succeed each other (*e.g.*, Greece, western Asia). In such instances, the more universal god of heaven is often replaced by the younger god of thunderstorms (*e.g.*, Zeus of the Greeks, Teshub of the Hittites, or Hadad of the Semites) or is even relegated to the background by a goddess, such as Inanna-Ishtar (the love or fertility goddess) in Babylonia or Amaterasu, the sun goddess of Japan.

In ancient China, Heaven (T'ien, or Shang Ti, the highest lord) ruled over the many more popular gods and was even closely related to the representatives of the Imperial household. Deification of the celestial emperor is a cultic practice that extends from Korea to Annam (part of Vietnam). The roots of the worship of heaven in Asia are probably the beliefs of central and northern Asiatic nomadic peoples in a solitary god of heaven. Gods of heaven, above or behind a pantheon (grouping of gods), probably originated in areas in which a theocratic stratified bureaucracy existed or in which sacral kingdoms exist or have existed—*e.g.*, in The Sudan or northeastern Africa (Akan-Baule, Dahomey, Yoruba-Benin, Jukun, Buganda, and neighbouring states), western Indo-

nesia, Polynesia and Micronesia, and in the advanced civilizations of pre-Columbian Meso-America and South America (see also SACRED KINGSHIP; POLYTHEISM).

Heaven and earth deities as partners. The god of heaven in many areas is a partner of an earth deity. In such cases, other numina (spirits) are missing or are subject to one of the two as spirits of nature or ancestors. Myths depicting the heaven–earth partnership usually describe the foundations or origins of the partnership in terms of a separation of a primeval chaos into heaven and earth or in terms of a later separation of heaven and earth that originally lay close together, and they describe the impregnation of the earth by the seed of the god (*e.g.*, *Hieros gamos*, or the sacred marriage).

This type of god of heaven (plus goddess of earth) may be found in areas of Africa that have been influenced by advanced civilizations (especially The Sudan and northeastern Africa), in eastern Indonesia, and in some areas of America under influence of advanced civilizations.

The god of heaven viewed dualistically. In several religions the god of heaven has an antagonistic evil adversary who delights in destroying completely or partially the good creative deeds of the god of heaven. This helps to explain the insecurity of existence and concepts of ethical dualism. In most such cases, the contrasts experienced in the relationship between heaven and earth deities have been re-evaluated along ethical lines by exalting the heavenly elements at the expense of the earthly ones (especially in Jewish, Christian, and Islāmic sects in Europe, west central and northern Asia, and certain areas in the northern half of Africa). The figure of an antagonistic trickster or demiurge with a somewhat ethical component may be the result of diffusion and is rather rare in primitive cultures—*e.g.*, African Bushmen, Australian Aborigines, and North American Indians (see also DUALISM, RELIGIOUS).

Exaltation of heavenly elements over earthly elements

The god of heaven viewed monotheistically. The god of heaven, viewed in his ethical aspect, is always an active, single god—*e.g.*, Christian, Jewish, and Islāmic monotheism (see also MONOTHEISM).

Earth. Although in almost all polytheistic religions earth is usually represented as a goddess and associated with the god of heaven as her spouse, only rarely is there an elaborate or intensive cult of earth worship. There are in many religions mother goddesses who have elaborate cults and who have assumed the function of fertility for land and man, but they hardly have a chthonic (earth) basis. Some mother goddesses, such as Inanna-Ishtar, instead have a heavenly, astral origin. There are, however, subordinate figures of various pantheons, such as Nerthus (Jord) in Germanic religion or Demeter and Persephone (earth mother and corn girl) in Greek religion, who have played greater roles than the world mother (Gaea). Among Indo-Europeans, western Asiatics (despite their various fertility deities), Chinese, and Japanese, the gods of heaven, sun, and thunderstorms have held a paramount interest.

"Mother earth"

When the common people have displayed intensive attention to "mother earth" (such as the practice of laying down newborn babies on the earth and many other rites), this partially reflects older cults that have remained relatively free from warrior and nation-building peoples with their emphasis on war (as in western Sudan, pre-Aryan India, and the Indian agrarian area of northern Mexico). The Andean earth-mother figure, Pacha-Mama, worshipped by the Peruvians, stands in sharp contrast to the sun religion of the Inca (the conquering lord of the Andes region). Earth deities are most actively venerated in areas in which people are closely bound to ancestors and to the cultivation of grain.

Mountains. Especially prominent mountains are favourite places for cults of high places, particularly when they are isolated as island mountains, mountains with snowcaps, or uninhabited high mountain ranges. The psychological roots of the cults of high places lie in the belief that mountains are close to the sky (as heavenly ladders), that clouds surrounding the top of mountains are givers of rain, and that mountains with volcanoes form approaches to the fiery insides of the earth.

Mountains, therefore, serve as the abodes of the gods, as the centres of the dead who live underground, as burial places for rainmakers (medicine men), and as places of oracles for soothsayers. In cosmogenic (origin of the world) myths, mountains are the first land to emerge from the primeval water. They frequently become the cosmic mountain (*i.e.*, the world conceived as a mountain) that is symbolically represented by a small hill on which a king stands at the inauguration. Pilgrimages to mountain altars or shrines are favourite practices of cults of high places.

The larger mountain ranges and canyons between volcanic mountains—especially in Eurasia from the Pyrenees to the Alps, the Carpathian Mountains, the Caucasus Mountains, the Himalayas, the mountainous areas of northern China and Japan, and the mountainous areas of North and South America (the Rocky Mountains, the Andes)—are most often centres of cults of high places. Elevations of the East African Rift Valley (Kenya, Tanzania, Uganda), volcanic islands of the Pacific Ocean (*e.g.*, Hawaii), and the mountains of the Indian Deccan have also served as centres of the cult of high places.

The high places as the abodes of the gods

In the early civilizations, the cult of high places was closely combined with that of the earth (*e.g.*, Olympus of the Greeks, the mountains of Enlil or of the Mountain Mother Cybele in western Asia, and the Meru mountain of India) were believed to bring heaven and earth into a close relationship and were often viewed as the middle pillar of the world pillars upholding the sky. Bush and wild spirits (Lord of the Animals) of the cultures of the hunters and collectors were often believed to reside in inaccessible mountainous areas (*e.g.*, Caucasus).

In addition to other mountain deities of a more recent date (*e.g.*, God of the Twelve Mountains and the One-Legged Mountain God), the mountain deity Yama-no-kami has been demonstrated to be a deity of the hunt (*i.e.*, god of the forest, Lord of the Animals) of ancient Japan. Through the worship of farmers, Yama-no-kami assumed the elements of a goddess of vegetation and agriculture. The mountain goddesses (earth mothers) of non-Aryan India still incorporate numerous features of hunt deities, and, because of indigenous influences, the Vedic (early Aryan scriptural) gods and their wives (*e.g.*, Pārvatī, Umā, and Durgā) have their abodes on mountains. The isolated mountains of East Africa, surrounded by clouds, are believed to be the dwelling places of the heaven and rain gods, and in the area of Zimbabwe (Rhodesia) there are pilgrimages to mountain sanctuaries that are viewed as the seats of the gods.

Pre-Islāmic peoples of North Africa and the extinct inhabitants of the Canary Islands (Guanches) associated mountain worship with a cult of goats (and sheep), which, when practiced in rituals, was believed to secure rain and thunderstorms in the often arid landscape. Similar cults are also found on the Balkans and in the valleys of the southern Alps.

Beliefs about the causes of earthquakes

Earthquakes. According to the beliefs of many peoples, earthquakes originate in mountains. In areas of Africa, where the concept of mana is particularly strong, many believe that the dead in the underworld are the causes of earthquakes, though in the Upper Nile, The Sudan, and East Africa, an earth deity is sometimes blamed. In some areas, a bearer who holds the world up—a concept that probably came from Arabia, Persia, India—is believed to cause an earthquake when he changes his position or when he moves his burden from one shoulder to the other. In the Arab world, on the east coast of Africa and in North Africa, an ox generally is viewed as the bearer, sometimes standing on a fish in the water. World bearers often are giants or heroes, such as Atlas, but they also may be animals: an elephant (India), a boar (Indonesia), a buffalo (Indonesia), a fish (Arabia, Georgian S.S.R., and Japan), a turtle (America), or the serpent god Ndengei (Fiji). Generators of earthquakes also may be the gods of the underworld, such as Tuil, the earthquake god of the inhabitants of Kamchatka (a peninsula in eastern Siberia), who rides on a sleigh under the earth. The earthquake is driven away by noise, loud shouting, or

poking with the pestle of a mortar. Among peoples with eschatological (last times) views, earthquakes announce the end of the world (Europe, western Asia).

Tides. The view that the tides are caused by the moon can be found over almost all the earth. This regular natural phenomenon seldom gives rise to cults, but the ebb and flow of the coastal waters has stimulated mythological concepts. Not infrequently the moon acquires the status of a water deity because of this phenomenon. The Tlingit (of northwestern America) view the moon as an old woman, the mistress of the tides. The animal hero and trickster Yetl, the raven, is successful in conquering (with the aid of the mink) the seashore from the moon at low tide, and thus an extended area is gained for nourishment with small sea animals.

CELESTIAL PHENOMENA AS OBJECTS OF WORSHIP OR VENERATION

The sun. Generally, the sun is worshipped more in colder regions and the moon in warm regions. Also, the sun is usually considered as male and the moon as female. Exceptions to these generalizations, however, are notable: the prevalent worship of the sun in hot, arid ancient Egypt and in parts of western Asia; the conception of the moon as a man (who frequently is believed to be the cause of menstruation) among primitive hunter peoples (African Bushmen, Australian Aborigines, and hunters of South America) and among certain pastoral and royal cultures of Africa (*e.g.*, the Masai and the Hottentots); and the conception of the female sun ruling northern Eurasia from the Northern Sea to Japan and parts of North America.

In many state cults of ancient civilizations, the sun plays a special role, particularly where it has replaced an old god of heaven (*e.g.*, Egypt, Ethiopia, South India, and the Andes) and especially where it is viewed as a marker of time.

Solar religions in Africa and the Orient

The sun as the centre of a state religion. In Africa, ancient Egypt was the main centre from which solar deity concepts emanated. The solar religion, promoted by the state, was concerned with the sun god Re (Atum-Re, Amon-Re, Chnum-Re), the sun falcon Horus, the scarab (Chepre), and a divine kingdom that was determined by the sun (*e.g.*, pharaoh Akhenaton's solar monotheism *c.* 1350 BC). The sun religion reached, by way of Meroe (a sun sanctuary until the 6th century AD) and the Upper Nile, as far as western Ethiopia (*e.g.*, the Hego cult in Kefa and the sun kings in Limmu) and Nigeria (*e.g.*, Jukun). In the Orient, the sun cult culminated in the religion of Mithra of Persia. Mithra was transported by Roman legionaires to western Europe and became the Unconquerable Sun of the Roman military emperors. In Japan, the Imperial deity in state Shintō is Amaterasu, the sun goddess from whom Jimmu Tennō, the first human emperor, descended. In Indonesia, where the descent of the princes from the sun also is a feature, the sun often replaces the deity of heaven as a partner of the earth. In Peru, the ruling Inca was believed to be the sun incarnate (Inti) and his wife the moon. A sun temple in Cuzco contains a representation of Inti as the oldest son of the creator god. The Natchez Indians of southeastern United States, who are culturally connected with Central America, called their king "Great Sun," and the noblemen were called "the Suns."

The sun as a subordinate deity. The sun, within a polytheistic pantheon, often is revered as a special deity who is subordinate to the highest deity, usually the god of heaven. This may be observed in the great civilizations of ancient Europe and Asia: Helios (Greece); Sol (Rome); Mithra (Persia); Sūrya, Savitṛ, and Mitra (India); Utu (Sumer); and Shamash (Babylonian and other Semitic areas).

The sun not infrequently is considered female (Shams of some Arabs, Shaph of ancient Ugarit in Palestine, Sun of Arinna of the Hittites, as well as the female Sun of the Germans). Siberian people such as the Taimyr Samoyed (whose women pray in spring to the sun goddess in order to receive fertility or a rich calving of the reindeer) or the Tungus worship sun goddesses. They sacrifice to the sun goddess, and her symbols are embroidered on women's clothes.

The sun and moon as a divine pair. A sun god is often related to a moon goddess as one member of a divine pair (in the place of heaven and earth as "world parents"). A sun-moon god exists among the Munda-Dravida in India (Singbonga); a sun-moon (earth) pair, partially seen as bisexual, exists in eastern Indonesia; and Nyambe (the sun) among the Rotse in Zambia is represented as united with the moon goddess as the ruling pair.

The sun as an attribute of the highest being. The sun sometimes is viewed as a coordinated or subordinate attribute, or hypostasis, of the highest being. This may possibly occur because of a partially weakened influence of a stronger solarism in areas of older primitive peoples, such as in The Sudan, Upper Volta, Nigeria, northern East Africa, and Australia.

The sun as a mythical being. The sun, in some religions, is conceived as a purely mythical being, who is cultically recognized in sun dances (*e.g.*, prairie Indians) and in celebrations of the solstice, with jumps over fires, sports festivals, and other events. These rites may be either survivals of an earlier local cult of a sun deity or influences of such a cult.

The moon. The moon is often personified in different ways and worshipped with ritual customs; nevertheless, in contrast to the sun, the moon is less frequently viewed as a powerful deity. It appears to be of great importance as the basis of a lunar calendar but not in the higher agrarian civilizations. The moon, infrequently associated with the highest god, is usually placed below heaven and the sun. When the moon with the sun together (instead of "heaven and earth") constitute an important pair of gods (world parents), it frequently assumes the features of an earth deity. In tropical South America, the sun and moon are usually purely mythical figures.

The moon as a female or a male deity

Between the Tropic of Capricorn and the Tropic of Cancer, the moon is predominantly female. Only some remainders of ancient peoples (hunter peoples) view the moon as a male being (*e.g.*, African Bushmen, Australian Aborigines, Congo Pygmies, Semang, Andamans, Chaco Indians, Ona, and some Brazilian tribes). In the few significant moon gods of the Oriental civilizations (Chonsu in Egypt, Sin-Nanna in Babylonia, Candra in India)—in contrast with the female Selene and Luna in the Greek–Roman culture, a more ancient substratum may possibly be present. Where the moon is considered as male, he often determines the sexual life of the woman, especially among the Aborigines of Australia.

The phenomenon of the moon that attracts all people is the sequence of its phases. The waxing and waning of the moon crescent is often interpreted as gaining or losing weight (eating, dieting). Thus, the Taulipang in Guayaná believe that the moon is first nourished well and then inadequately by his two wives, Venus and Jupiter. Where the moon is viewed as female, the phases represent pregnancy and delivery. Elsewhere, people see childhood, maturity, and dying as the phases of the moon: the first crescent is thus the rebirth or the replacement of the old by a new moon.

The appearance of the crescent or the full moon is sometimes celebrated by a rest from work, and some attempt to participate in the waxing and waning of the moon by analogous magical rites. Girls with small breasts stand in the full moonlight (in the Salzburg, Austria, area); persons who desire a tumor to decrease point to the waning moon; and newborn children often are exposed to the waning moonlight, or they and everything else that is desired to be healthy and permanent are dyed white; *i.e.*, they are made "moonlike." Nearly everywhere, connections between the moon phases and the rhythm of nature (the tides) and humans (menstruation) are recognized.

Significance of the phases and signs of the moon

The three dark days of the "death" of the moon are believed by many to be dangerous. During this period the moon is believed to be defeated in a battle with monsters who eat and later regurgitate the moon; or the moon is viewed as having been killed by other heavenly beings

and later revived. The period is a time in which people, if possible, do not engage in a new enterprise.

The halo of the moon is also viewed as a bad omen among many peoples. Moon spots are regarded as testimonies of a battle with heavenly opponents. In addition to the popular Man in the Moon, there are also other figures represented: "the woman with the basket on her back," "the spinning woman," or "the weaving woman" (in Polynesia the woman who pounds tapa). The most popular animal figure recognized in the features of the moon, the rabbit (from Europe to America), presumably earned this role because of its fertility.

Beliefs and practices centring on eclipses

Eclipses of the sun and moon. Eclipses of the sun or the moon—usually interpreted as a battle, as the dying, or the devouring of one of the two heavenly bodies—in many religions are met with anxiety, shouting, drum beating, shooting, and other noises. Many North American Indian tribes, Hottentots in Africa, Ainu in Japan, and the Minangkabau in Sumatra interpret the eclipses as fainting, sickness, or the death of the darkened heavenly body. In Arctic America, Eskimos, Aleuts, and Tlingits believe that the sun and moon have moved from their places in order to see that things are going right on earth. The explanation that heavenly monsters and beasts pursue the stars and attempt to injure and to kill them, however, is a view found over a larger area. Noise and shooting are believed to deter the monsters from their pursuit or to force them to return the celestial bodies if they have already been captured. In China and Thailand the monster is the heavenly dragon; in China, among the Germanic tribes, and among northern American Indians, dogs and wolves (coyotes) are the culprits; in Africa and Indonesia, they are snakes; in South America, the beast is the jaguar; and in India they are the star monsters Rāhu and Ketu. The belief in the darkening of one star by the other in a battle—*e.g.*, between the sun god Lisa and the moon goddess Gleti in Dahomey—is about as widespread. An eclipse may also be interpreted (as in Tahiti) as the lovemaking of sun and moon, who thus beget the stars and obscure each other in the process.

Stars and constellations. Worship of the stars and constellations in the modern world survives only in a very corrupt or hidden manner. True star worship existed only among some ancient civilizations associated with Mesopotamia, where star worship was practiced. Mesopotamia, where both astronomy and astrology reached a high degree of refinement—especially after a Hellenizing renaissance of astronomy—was the origin of astral religions and myths that affected religions all over the world. Though the view is controversial, Mesopotamian astral worship and influence may have reached as far as Central and Andean America (by way of China or Polynesia). Sumerian, Elamite, and Hurrian contemplation of the stars influenced not only Mesopotamia, Asia Minor, Egypt, Iran, and India but also other areas. Knowledge of the zodiac, the planets, and observation of precession extended from the West to south Asia—*e.g.*, the Pythagoreans and Orphics (mystical philosophers) in the Mediterranean area and astrological mystical thinkers in India, Indonesia, China, and Polynesia. West Sudan, for example, was deeply influenced by the spirit of ancient Mediterranean and Oriental knowledge of the stars.

The influence of Mesopotamian astral worship

Apart from areas in The Sudan, northeast Africa, and Rhodesia (Monomotapa), not much of Africa has had any considerable knowledge of the stars. That knowledge of the stars is relatively limited among forest peoples, unless old hunting cultures survived, is explained by an Ekoi tribesman in southeast Nigeria, as follows: "Ekoi people do not trouble themselves about the stars, because the trees always hide them." Hunting pygmies likewise have never achieved any significant knowledge of the stars, which the Bushmen on the steppe have.

Knowledge of the stars in the areas of the true primitive peoples rarely leads to a worship of the stars. True star gods are rare, for example, in large parts of Africa. In Polynesia, where significant knowledge of the stars by the seafaring people and fishermen was learned in regular schools of astronomy, there seldom occurred what can be called true religious worship of the stars. Knowledge of the stars, however, is still relatively significant among the hunting peoples in the Southern Hemisphere, especially among the African Bushmen and Australian Aborigines, who were formerly untouched by the high civilizations. Economic considerations connected with the rising and setting of the stars, however, surpasses their mythological significance by far. The stars are usually considered to be living beings, particularly animals that have been transferred to the sky. They evidently are taken seriously primarily because they indicate by their rising and setting the appearance of game to be hunted or fruits to be collected.

Widespread beliefs in the constellation Orion and the planet Venus

The widespread African interpretation of the constellation Orion as a hunter, as game, or as a dog (from East Africa to the lower Congo and in the area of the Niger) is most likely a vestige from an earlier hunting period that has survived in agricultural civilizations. In a different form, the constellation Orion is still known in Europe as a hunter, in north Asia as a hunter of reindeer and elk, and in North America as a hunter of bears. In South America—outside the Andean empires—a whole series of astral beliefs of the ancient hunting culture has been preserved: the concepts of stars and constellations as Lords of the Animals, as helpers of the hunter, or as animals themselves.

Venus, the best known planet, has probably experienced its most significant personification in the figure of the Mesopotamian goddess Inanna-Ishtar. She was viewed as a being, sometimes female and at other times bisexual. Through her identification with the Greek Aphrodite and the Roman Venus, Inanna-Ishtar, the queen of heaven, still survives in Roman Catholic iconography—*e.g.*, as the Virgin Mary standing on the moon. African cultures also have been significantly impressed by this planet, not only in the rare figure of a Zulu heavenly goddess who determines the agricultural work of the women but even more as the evening and morning star, who are the wives of the moon. In the royal culture of Monomotapa (Rhodesia) and its influences in Buganda and southern Congo, the king is related to the moon, and his wedding with the Venus women is a type of *hieros gamos* ("sacred wedding"). In large areas of Africa the concept of "Venus wives of the moon" is preserved, although the moon is usually considered as the wife (or sister) of the sun. This concept was most likely prevalent at a time when the moon-king ideology was widespread in the eastern half of Africa from the Nile to South Africa, perhaps indicating south Arabian influences.

The Pleiades, Polaris, and the Milky Way

The Pleiades, a group in the constellation of Taurus (six to seven adjacent stars), are viewed in many parts of the world as maidens who are pursued by men (*e.g.*, hunters). The Pleiades are also interpreted as a mother hen with her chickens, especially in Eurasia, where the star Aldebaran, which is located close to the Pleiades, is often included as a part of the constellation. In Africa the Pleiades designate the beginning of the agricultural year. Therefore, in many Bantu languages the verb *kulima* ("to hoe") furnishes the basis for their designation *kilimia*, the Pleiades. In addition to East and South Africa there is still a smaller area in the western Sudan that retains this belief.

Polaris (the north star) enjoys a central significance among the Finno-Ugric and Turkish Tatars as "nail of the world" or "pillar of heaven." Among Altai Tatars Polaris is viewed as the negotiator of the god of heaven Ülgan; in Japan, Polaris is a god of heaven above the ninth layer of clouds.

The Milky Way, depending on a group's economy and life style, is often simply named after hunting or domestic animals: way of the tapir, the donkey, or the camel. It also is called the seam of the heavenly tent or a water stream. As the footsteps of God or the way of God, as the way of the dead, or as a deserted way of the gods, the Milky Way reveals older mythical conceptions, among which is that of the world (cosmic) tree.

Aurora borealis, the northern lights of the polar regions, is frequently interpreted by Arctic and sub-Arctic peoples (*e.g.*, Eskimo, Athapascan, Tlingit) as the reflection of the dance fire of the ghosts or of the peoples further in

the north, as the "cooking of meat," or the ball game of these peoples. Northern Germanic tribes saw in it the splendor of the shields of Valkyrie (warrior women).

FORCES OF NATURE

The natural forces of fire and water, which evidently exclude each other, are brought together in a unity of opposites in the worldviews of early archaic civilizations. Both forces are purifying as well as protective, and are viewed by many as being connected with the cosmic powers of the sun and moon. Where they are truly combined, often genetically, fire (as the sun) is usually male, and water (as the moon), female. Where the fire is included more into the chthonic (earthly) sphere it may also receive a feminine character (*e.g.*, fire in the earth, preserved in the womb); where rain is viewed as the semen of heaven, which is usually personified as male, it takes on a male character.

The "living" qualities of water

Water. Many of the qualities of water make it appear to be animated; on this basis it is psychologically understandable that water (*e.g.*, rain, sea, lakes, and rivers) might become a natural phenomenon worthy of worship. Water is always in motion, changes color in the light of the stars, reflects the world and man, "speaks" with murmuring and roaring, brings new life to dried out vegetation, refreshes men and animals, the tired and the ill, and heals. Because it dissolves dirt it is also most suitable for purifying the soul (*e.g.*, after the violation or the commission of a sin of any kind). Under certain circumstances, even pictures (icons) of gods have to be washed. Water also demonstrates destructive forces (seaquakes, floods, and storms). The most important mythical-religious facts symbolized by water are the following: the primal matter; the instrument of the purification and expiation; a vivifying force, a fructifying force; and a revealing and judging instrument.

Water as primal matter. The conception of a primal body of water from which everything is derived is especially prevalent among peoples living close to coasts or in river areas—*e.g.*, the Egyptian Nu (the primordial ocean) and the Mesopotamian Apsu (the primeval watery abyss) and Tiamat (the primeval chaos dragon). The earth may be fished out or emerges from the primeval water; heavenly beings (*e.g.*, Ataentsik, ancestress of the North American Iroquois) appear on the emerged earth; and birds lay an egg that is later divided into two halves (heaven and earth) on the chaotic sea. Thus, water is viewed as the foundation of all things. A survival of the original primeval sea, in such myths, is the water that flows around the earth's disk (*e.g.*, Oceanus).

Water as an instrument for purification and expiation. Water is viewed as an instrument for purification and expiation, especially in arid areas. Cultic acts, in such areas, generally take place only after lustrations, sprinkling, or immersion in water. The same view holds true for entry into new communities or into life (*e.g.*, baptism). Water lustration is especially necessary after touching the dead, and as a purificatory washing for priests and kings. Pictures of the gods also have had water poured over them.

Myths of a great flood (the Deluge) are widespread over Eurasia and America. This flood, which destroys with a few exceptions a disobedient original population, is an expiation by the water, after which a new type of world is created.

Water equated with life forces in the body

Water as a vivifying force. Water is viewed as vivifying, like the heavenly rainwater that moistens the earth. Water also is equated with the flowing life forces of the body (*e.g.*, blood, sweat, and semen). In order to replace the lost liquids, water was added to the mummified dead in Egypt. The African Ashanti designate their patrilinear groups as *ntoro*, which means water, river, and semen, and the Wogeo of Papua call their patrilinear clans *dan*; *i.e.*, both water and semen. The myth of the Kasuar ancestress of the But of Papua related how Kasuar's blood became sea (and salt).

Water as fructifying. Wherever early archaic culture spread the myth of the world parents heaven and earth, there also was a belief that heaven fructifies the earth with heaven's seed. The springs, pools, and rivers on the earth, therefore, may bring not only healing and expiation, but also fertility. The river Skamandros in ancient Greece evidently was so personified; according to Aeschines, a 4th century BC Greek orator, girls bathed in it before marrying and said: "Skamandros, accept my virginity." Magical rites in which water serves as a substitute for semen or the fertility of men are numerous.

At the corn festival Nsiä of the Bamessing (in Cameroon), which is celebrated in the dry season, the festival begins with the mourning of the dead vegetation. Reminiscent of the Egyptian Osiris and the Mesopotamian Tammuz festivals, the Nsiä festival emphasizes that the god who gave the nourishment has died and is being mourned like a chieftain. The chief, dying symbolically with the god, has to be strengthened with a miraculous "chieftain water," which has to be fetched by virgins of the chieftain's clan. For two weeks the chieftain drinks from the gourds of all the maidens after the women of the tribe have drunk from the holy water place.

Battles of gods and heroes with mythical beings, beasts, and monsters that hold back the fructifying water are widespread in mythology. The liberation of water during the mythical battle is equivalent to the end of the dry season or a drought, to the reviving of vegetation. In Indian mythology Indra slays Urtra; in Syrian and Palestinian mythology Baal battles with Leviathan; and in Huron (North American Indian) mythology Joskeha, the spring hero, kills the frog that attempted to restrain the water from flowing freely.

Water as a revealing or judging instrument. Water also serves as an instrument that reveals and judges. Reflections in the water led to a whole series of oracles originating from an alleged prophetic or divinatory power of water. A visionary look into the water surface was believed to reveal the future as well as past misdeeds. This ancient custom may have been preserved in the use of crystal balls by modern fortune tellers. The custom of water divination is found in ancient Europe, North Africa, the Near East (*e.g.*, Babylonian fortune telling by means of cups), eastern and northern Asia (where the use of metal mirrors by the shamans often replaces the water as a divining means), and in Southeast Asia and Polynesia. Where such means of divination were severely repressed, such as in sub-Saharan Africa, these methods of mirror and water gazing were changed into manipulated water ordeals.

Water is also used as a judging element: in ordeals believed to demonstrate the judgment of the gods, water ordeals (*e.g.*, immersion in water), as well as the more frequent fire ordeals, appear. Here also the purifying character of the water plays a role.

Fire. Worship of fire is widespread, especially in areas where the earthly fire is believed to be the image of the heavenly fire.

Fire as a living force or power

Because of various psychological reasons, fire is considered to be a personified animated or living power: it moves vehemently, devours, and becomes hungrier; it spreads fast into a giant blaze and is red like human blood and warm like the human body. It makes the plants that it has devoured suitable for fertilizing the earth; it shines brightly in the night and, by transference, may have "eternal life" or by constant rekindling can be made into a "perpetual fire." In cremation it separates the body from the soul; it drives away predatory animals and insects that cause pestilence.

Its chief functions are similar to those of its main adversary, water: to purify and to ward off evil, especially from home and hearth. Fire magically drives away rain, but with its smoke it also attracts rain clouds during a period of drought. Fire is believed to have both heavenly and earthly origins: it is brought by lightning, and it lives in the volcano of the underworld.

Stories are told of ancestors, heroes, or animals of primeval times who purloined the fire from the higher numina (spiritual powers). Bringers of civilization, similar to the Greek god Prometheus, fetch it—often together with fruits of the field, iron, or musical instruments—from heaven. Like Prometheus, Nommo, the primal being among the Dogon in Mali, brings fire and the first fruits

of the field down to the earth. Prometheus steals the fire from the blacksmith Hephaestus, but Nommo himself is the first blacksmith. In both areas this cultural achievement is celebrated with annual torchlight parades (in Greece, called Promethea festivals). Elsewhere, birds, or animals, such as the dog (especially in Africa), who is closely allied to the hearth fire of man, are the bringers of fire. Animals often fetch the fire from the Lord of the Animals in the bush.

Where geysers and volcanos indicate that the oldest fire is beneath the surface of the earth, fire is brought forth by animals and heroes. The Maori hero Maui seizes it from his ancestress Mahuike in the depth of the earth and puts it into a tree. Since that time it has been possible to get fire from the wood of the trees (*e.g.*, the fire borer). In areas practicing a definite ancestor worship, hunters obtained the fire from the subterranean world of the dead (as in East Africa). Previous to the Iron Age (15th century–2nd century BC), the generating of fire with the aid of fire borers, or fire saws, was viewed as a sexual act (male and female fire wood), especially in East and South Africa, India, Indonesia, and Mexico. In the creation myths of the Dayak of Borneo, fire is produced by rubbing a liana (male) on a tree (female) and is interpreted as coitus. The Tlingit (of northwest America) tell a story of the magical conception of a girl by the sawdust of the fire borer. The boring for the new state fire in the Loango empire (West Africa) coincides with the public coitus of a young couple.

The generating of fire as a sexual act

This conceptual framework seems to be a late consequence of earlier ideas of fire in the body of humans, especially of women, as a centre of sexual life. Such views are probably most pronounced among the Aborigines of Papua and Australia. The Marind in New Guinea, who, in their myth of the origin of fire view it as being derived from the sexual act, undertake the new boring of fire in connection with a cultic act in which the raping of a girl is the central rite. Elsewhere in New Guinea, there is a concept that fire lies in the genitals of women, especially of the first woman.

When iron-smelting techniques by means of fire became common among Neolithic (New Stone Age) peoples of similar mentality, as in Indonesia and Africa, the making of iron in shaft furnaces (considered as female) and bellows (male) has been interpreted as coitus with a subsequent birth (especially among the Bantu).

In archaic civilizations with sacral kings, the sacred perpetual fire (*i.e.*, the state fire) of the residences and temples of the royal ancestors was believed to have a phallic element. It was cared for by virgins, who were viewed as wives of the fire. Vestal virgins of this kind are documented in ancient Rome, Monomotapa (Africa), and pre-Columbian America. Among the Maya of Central America, an order of fire caretakers was founded by a deified "virgin of the fire." Extinguishing and rekindling of fire at the inauguration of a prince points to the idea of a spirit of the princes in the state fire and also to the cyclical renewal of the state in the purifying fire, which signifies the beginning of a new era.

Fire gods are found less frequently in primitive cultures than in archaic civilizations. That fire gods are not yet known in some ancient Oriental areas is probably because of the advanced development of a sun deity.

Iranian fire worship was derived from the cult of the god Ātar, but it was made a central act in Zoroastrianism (a religion founded by the 6th century BC Iranian prophet Zoroaster). Fire worship continues to be practiced among the Parsiis (modern Zoroastrians) of India: in temples the sacred fire is maintained by a priest using sandalwood, while his mouth is bound with a purifying shawl; fire in new temples is kindled from the fire of the old temples; household fires are not permitted to go out and are greeted in the morning by the members of the household and offered sandalwood; and Aryan cremation practices are renounced because the fire would be contaminated, and the dead are thus deposited in the "temples of silence."

Weather. The worship of atmospheric powers can only with difficulty be separated from the worship of heaven. In most cases the high god in heaven is also the god of thunderstorms and rain. Specific gods of wind and storm are found especially in countries with tornadoes and hurricanes (*e.g.*, the Maya deity Huracan). People (*e.g.*, the Tuareg and Arabs) in arid countries and deserts, dried out by the wind, speak of sand funnel spirits or of a desert god, such as the "boneless Kon" of the Peruvians.

The worship of atmospheric powers

From northern Europe to the tropical forests, thunderstorm deities rule heaven and earth. The most famous group of these numina (spiritual beings) are the Indo-European thunder gods (Thor-Donar of the Germans, Taranis of the Celts, Perkunis of the Slavs, Indra of the Indians, Zeus-Jupiter of the Greeks and Romans), who throw their thunderbolts or bundles of lightning. The Finnish god Ukko and the Basque god Orko probably stem from the same root; these gods still continue in the popular beliefs of Eastern Europe or Latin America today, such as St. Elijah or Santiago. These deities are related to the west Asiatic gods Teshub and Hadad (associated with the steer and with lightning) but also to the thunder god Shango of the Nigerian Yoruba, who is accompanied by a ram (as Thor uses a he-goat for pulling his wagon). Shango, as Yakuta, throws thunderbolts (*i.e.*, stone axes) to the earth, as does the Chac Mol of the Maya.

The goat, the ram, or horses appear as companions of weather gods or as animals that pull the thundering sky vehicle. In other cultures thunderbirds are the companions of the thunder gods or are the lightning itself. The lightning bird Zu, or Imdugud, occurs in ancient Mesopotamia, and the Garuḍa (with Wadjra) in Vedic India. Thunderbirds are represented (sometimes with arrows or spears in their bill or fangs) on archaeological artifacts of the Bronze Age in Dodona, Minussinsk in Siberia, Dong Son in Vietnam, and on pots in north Peru; they are described in myths of the Pueblo and prairie Indians and among East and South Africans.

Where prayers or sacrifices to gods and ancestors in the religious cult are not effective in producing rain, rain magic, which is practiced universally in similar rites, is often able to accomplish it. Trained magicians usually perform such rites, but ancestral priests or "persons holding power" also may do so. In rain magic, sprinkling, spitting, or immersion of people or things is often used to call down heavenly moisture. Smoke clouds to attract the rain accomplish the same purpose. There also must be suitable vestments (fresh greens, skins or pelts of water animals), body painting (representing clouds), or adornment with bird down. The color black in the clothing or on a killed or exposed animal is believed to be especially effective. Animals held responsible for holding the rain or water back (frogs, snakes, or mythological dragons) must be challenged. The sound of rain or thunder is produced with "bull-roarers," whistling, noise pots, rattles, and chains. If excessive rain is to be stopped, the injunction to perform or refrain from certain acts (*e.g.*, the prohibition of washing, boiling water, burning objects, making noise, and whistling) must be observed.

Rain magic

The rainbow often is considered a being, generally in the form of an animal, who swallows and holds back rain or water. The rainbow serpent (as a double bow also conceived as bisexual) is a figure that is found especially in the tropics of Africa, south Asia, north Australia ("ungud" snake), and Brazil. Elsewhere, the rainbow is viewed as a heavenly bridge that connects the worlds of gods and men: the Bifröst bridge in the Edda (a Norse saga); the bridge of the soul boats in Indonesia or of the creator god in Africa; and the path of the Greek goddess Iris. In Christian iconography, the rainbow is the throne of Christ; among Arabs and some Bantu of Central Africa it is the bow of god, and among the Nandi, Masai, and the Californian Yuki it is the robe of god.

WORSHIP OF ANIMALS, ANIMALISM, AND TOTEMISM

Animalism. Among the numerous animals that are prominent in religion and magic, the wild animals of the forests, the sea, and the air that are most important for the hunter are the most significant. Hunters and collec-

tors, rooted in the earliest cultures of man, believed that they not only had to kill animals—which were important for their economy as nourishment and raw materials—but also that they had to avoid their revenge. The feeling of a close connection between men and animals that has been lost to the highly civilized people (broadly speaking) led to an anthropomorphizing of animals. They were not only considered as living beings but were humanized to such an extent that the borderline between man and animal became virtually nonexistent and animals were held responsible for crises.

The religious magical attitude by which primitive peoples confront animals may be called animalism, regardless of whether the animal is thought to have life (animatism) or to have a soul (animism).

Totemism. The best known form of what may be called animal worship is totemism. An anthropologist, Sir James Frazer, defined totemism as "an intimate relation which is supposed to exist between a group of kindred people on one side and a species of natural or artificial objects on the other side, which objects are called the totems of the human group" (*Totemism and Exogamy*, 1910, IV, 3ff.). Frazer added that the mentioned "species" generally is more "natural" than "artificial." In this "intimate relation" the animal has the prerogative and in true totemism this relationship represents a more or less reverent attitude of man toward his animal partner. In totemism the relationship with the animal has not only merged into the realm of religion but has at the same time become a phenomenon of social life.

Man's relationship to animals

The Algonkin Indian word totem actually refers to one's own group, or family, thus indicating that totemism is a group phenomenon. It has also become customary among scholars, however, to include here "individual totemism" (that is, the personal permanent intimate relationship of an individual with an animal) and also "sex totemism," found mainly in Australia, where the women and men of a tribe separately are associated with an animal as totem. In Southeast Australia the totem is most commonly a species of small birds or male or female lizards.

True totemism, however, is always "group totemism," and that only when the totemic group is a so-called "unilinear association," such as a clan, which may be either matrilinear or patrilinear. Neither individual nor sex totemism belong to group totemism. In tribal totemism, one animal is significant for the whole tribe, thus indicating a kind of worship of a tribal animal. The Kwena tribe of the Tswana (South Africa) has the crocodile as such a tribal animal; they call it their "father." Sex and tribal totemism would better be associated with the general worship of animals; *i.e.*, the animal cults within the framework of "animalism." The same is true of the individual "totems," which are better designated as guardian animals.

The main features of group totemism are: unilinear groups of a tribe (clan, phratries) that are named after an animal (more rarely plant or sky phenomena) and avoidance of the totem, by not killing or eating it. The totem is inherited in the paternal or maternal lines. The group also believes, through its clan legend, in a descent from an ancestor who took up the association with this animal.

In "cult totemism," which shows a stronger religio-magical relationship to the animal but is rarer than the more profane form, the following features may be added: sacrifices and nourishment for the animal (a clan on Samoa gives to the eel as the totem the first fruits of the taro), and the idea of descent may be expanded to a belief in an animal ancestor. Some clans (particularly in Australia) specialize in the fact that they care magically for the proliferation of their totem animals. (For additional information see also ANIMISM; TOTEMISM; PRIMITIVE RELIGION.)

BIBLIOGRAPHY. Apart from some older works about particular forms of nature worship, the most important discussions of this form of religion and the related nature mythology appear in journals. JAMES G. FRAZER, *The Worship of Nature* (1926), is a classic work mainly concerned with the worship of the heavens, the sun, and the earth; and *The Golden Bough*, 3rd ed. rev., 12 vol. (1907–15; abridged ed., 1922 and 1959), contains an important discussion of nature gods, especially vegetation gods, and their cults. Important references to the worship of nature may be found under various headings in *The Mythology of All Races*, ed. by LOUIS H. GRAY, 13 vol. (1916–32); and *The Encyclopaedia of Religion and Ethics*, ed. by JAMES HASTINGS, 13 vol. (1908–26, reprinted 1955).

The heavens and earth: HERMANN BAUMANN, *Schöpfung und Urzeit des Menschen im Mythus der afrikanischen Völker*, 2nd ed. (1964), and *Das Doppelte Geschlecht* (1955); MIRCEA ELIADE, "La Terre-Mère et les hiérogamies cosmiques," *Eranos-Jahrbuch*, 22:57–95 (1954); JURGEN ZWERNEMANN, *Die Erde in Vorstellungswelt und Kultpraktiken der sudanischen Völker* (1968).

Sun and moon: The solar mythology that originated with the development of Indo-European linguistic studies places the sun at the centre of religion and myth: see G. ELLIOT SMITH, *The Migrations of Early Culture* (1929); and WILLIAM J. PERRY, *The Children of the Sun* (1923). (*General material concerning sun-worship*): FRANZ J. BOLL, *Die Sonne im Glauben und in der Weltanschauung der alten Völker* (1922). (*The sun in the cults and myths of African peoples*): HERMANN BAUMANN, "Die Sonne in Mythus und Religion der Afrikaner," in *Afrikanistische Studien* (1955). (Ed.)

Naval Ships and Craft

The first craft fitted purposely to make war were undoubtedly conversions of the dugouts, inflatable bladders, papyrus rafts, or hide boats used in everyday transport. It is probable that the conversion at first consisted simply of a concentration of weapons in the hands of a raiding party. In time conversions added offensive and defensive powers to the craft itself.

As vessels became more seaworthy and more numerous, warships designed as such developed both as marauders and as defenses against marauders. In succeeding millennia the warship went through many changes, some with revolutionary impact upon civilization. Though many ships are designed for a warlike purpose, the practice of converting peaceful ships to wartime uses has also survived. Any major war demands far more fighting ships than a nation can economically maintain during peace, and, even in World Wars I and II, merchant ships as large as passenger liners were converted into cruisers. The first craft designed and built especially for combat may have sailed in the fleets of Crete and Egypt 5,000 years ago. The word craft, it may be noted, has come increasingly to be applied to smaller vessels, with the term ship reserved for larger ones.

Naval vessels to World War I

THE ANCIENT WORLD

First warships

Early period. *Egypt.* The first recorded appearance of warships is on the Nile, where Egypt's history has centered since antiquity. Built of bundles of reeds lashed together to form a narrow, sharp-ended hull and coated with pitch, these were hardly suited for tempestuous seas; by 3000 BC larger wooden seagoing versions of the reed craft sailed for distant cruising, trade, and conquest.

Hieroglyphics recount the dispatch of 40 armed ships to Byblos on the Phoenician coast about 2900 BC to buy cedarwood (from the famous cedars of Lebanon) to build ships. These vessels had both oars and sails, being fitted with a bipod (inverted V) mast and a single, large, square sail. The whole mast could be lowered when under oars. Large Egyptian ships had over 20 oars to a side, with two or more steering oars. The war galley was built to the same pattern but was of stouter construction; modifications that could be easily incorporated in a merchant hull under construction included elevated decks fore and aft for archers and spearmen; in later Egyptian warships, a wider sail that could be furled; in the 12th century BC, planks fitted to the gunwales to protect the rowers, and a small fighting top high on the mast to accommodate several archers; and on some galleys a projecting ram, well above the waterline, which may have been designed to crash through the gunwale of a foe, ride up on deck, and swamp or capsize him.

Crete. By about 2000 BC Crete had evolved into a naval power exercising effective control of the sea in the eastern Mediterranean. Little record exists of Minoan seapower, yet these maritime people are known to have had an organized navy that cooperated with Egypt in suppressing piracy. They may also have been the first to build a warship designed as such from the keel up, rather than as a modification of a merchant ship. Sometime before their sudden and mysterious overthrow by the Mycenaeans from the Greek mainland in the 15th century BC, the Minoans began to differentiate between war craft and merchantmen and between the rowing galley and sailing vessel.

Sometime in this 2nd millennium BC, the commodious merchantman evolved as a beamy "round ship" powered by sails and emphasizing cargo capacity at the expense of speed. Fast fighting craft developed both as predator on and protector of maritime trade and coastal cities. This "long ship" was narrower, faster, and more agile than the tubby cargo ship. She hoisted her sails for cruising but depended on oars when in action.

The Cretan warship had a single mast and a single bank of oars. The sharply pointed or "beaked" bows suggest an emphasis on the tactical use of the ram. Relatively little else is known about the fighting craft, but the lack of defensive walls around Cretan cities may testify to the navy's effectiveness.

Phoenicia. Beginning about 1100 BC, the Phoenicians dominated the eastern Mediterranean for about three centuries and sailed beyond the Pillars of Hercules into the Atlantic. Information about Phoenician ships is fragmentary and somewhat inconclusive, though they appear to have been built primarily for trading, with a capacity to fight effectively if necessary. What little is known about their vessels comes from highly stereotyped representations.

These indicate that the Phoenician trading ships were galleys, mounting a single pole mast with a square sail and with steering oars to port and starboard. The war galleys show a Cretan influence: low in the bow, high in the stern, and with a heavy pointed ram at or below the waterline. Both these and the trading galleys are depicted as two-banked. The rowers of the upper bank may have sat on thwarts mounted on sponsons—*i.e.*, long platforms projecting outward above the waterline. This would have meant a narrow underwater hull with a high length to beam ratio, resulting in a slender and graceful vessel. Oars could be carried in a staggered, two-bank arrangement, allowing more oars to be mounted in a ship of a given length and increasing power and momentum.

Because the ram was the principal weapon, both the finer lines and greater rowing power were important in providing more speed for the decisive shock of battle. Coins of Sidon and Assyrian sculptures show the staggered-bank oar arrangement that the Phoenicians probably introduced.

Greece. Unlike the Egyptians, for whom wood was scarce and costly, the Aegean peoples had an abundance of timber for shipbuilding. Their earliest warships may have been large dugouts, perhaps 65 feet (20 metres) long, fitted with outriggers (timber frames built out from either side of the hull) for stability.

Tactically, they and their successors for centuries were used more to carry attack personnel than as fighting vessels. No mention is made in the *Iliad*, for instance, of sea warfare. Even the pirates of the time were sea raiders seeking their booty ashore, like the later Vikings, rather than in sea actions. The so-called long penteconter, mentioned by Herodotus, was employed in exploring, raiding, and communicating with outlying colonies. Light and fast, with 25 oars to a side, it even more than the "round-built" merchant ship, played an important role in the early spread of Grecian influence throughout the Mediterranean. As the Greek maritime city-states sped the growth of commerce and thus the need for protection at sea, there evolved a galley built primarily for fighting. The first galleys, called uniremes (Latin *remus*, "oar"), mounted their oars in a single bank and were undecked or only partially decked. They were fast and graceful with high, curving stem and stern. In Homeric times some carried an *embolon*—a beak or ram—that became standard in succeeding centuries.

Biremes and triremes. The bireme, probably adopted from the Phoenicians, followed and became the leading warship of the 8th century BC. Greek biremes were probably about 80 feet (24 metres) long with a maximum beam around ten feet (three metres). Within two or three generations the first triremes (ships with three banks of oars) appeared. This type gradually took over as the primary warship, particularly after the great sea victory of Salamis (480 BC).

The first triremes

Like its predecessors, the trireme mounted a single mast with a broad, rectangular sail that could be furled. The mast was lowered and stowed when rowing into the wind or in battle. Built on an entirely different system from the Egyptians—with keel, frames, and planking—these were truly seagoing warships.

The arrangement of oars has fed a scholarly controversy for generations. Two principal theories survive. One holds that there were, in fact, banks of benches for oarsmen—two for the bireme, three for the trireme—and that oarsmen of upper rows sat on thwarts slightly forward of the corresponding rower below. The other school argues that the thwarts ran at an angle obliquely from the galley's centre line. For a trireme, two oarsmen sat alongside each other on an upper thwart extending outward into a sponson with their oars projecting through ports in the sponson itself. The third oarsman in the group sat on a lower thwart with his oar projecting through a port in the hull.

After Salamis, the trireme continued as the backbone of the Greek fleet, with the ram continuing as the primary weapon. Its keel, like those of its predecessors, formed

the principal-strength member, running the length of the ship and curving upward at each end. The ram, usually shod in bronze, formed a forward prolongation that gained effectiveness from the heavy keel back of it. Additional longitudinal strength came from a storming bridge —*i.e.*, a gangway along the centre line from bow to stern along which the crew raced to board when a foe was rammed. Gradually, with ships becoming steadily heavier, boarding assumed greater importance and the ram lost some of its importance. Many war galleys also had full spar decks instead of the centre-line gangway.

A trireme of the 5th century BC may have had a length of 125 feet, a beam of 20 feet, and draft of three feet (about 38 × 6 × 1 metres). Her great length required extra longitudinal strength, which was provided by wales (belts) around the outside of the hull. Manned by about 200 officers, seamen, and oarsmen (perhaps 85 on a side), with a small band of heavily armed *epibatai* (marines), she could reach seven knots under oars and was a formidable foe.

Rowers in the ancient world, into early Roman times, were free crewmen rather than slaves. The captain of a Greek trireme was usually a wealthy man, a political appointee, who could afford to fit out and operate the warship for a year. The navigator was an experienced seaman.

With only scant room for provisions, such warships could not remain long at sea. A voyage usually consisted of short hops from island to island or headland to headland. Even the largest triremes put into shore and beached, stern first, for the night, resuming the passage in the morning, weather permitting. Light construction and little endurance made short distances between bases essential and frequent refits imperative.

Early Greek naval battle tactics were rudimentary. The basic tactical disposition was simply two opposing battle lines of galleys drawn up on line abreast, each trying to overwhelm the other by ramming and boarding. By the 5th century BC, however, skilled fleet commanders dared to essay the manoeuvre of "breaking through the line," or turning the foe's flank. Breaking through the enemy's battle line consisted of a sudden thrust at the centre of the opposing fleet. Piercing it, the attackers would then wheel to right and left behind the gap to take the rest of the line in the rear. For success, the manoeuvre required speed, surprise, and great coordination that only much training could achieve.

Evolution of naval tactics

Later developments. Athens employed quadriremes (four-bank rating) by the middle of the 4th century BC, with quinqueremes appearing soon thereafter. In the late 4th and early 3rd century BC an arms race developed in the eastern Mediterranean, producing even larger multibanked ships. Macedonia's rulers built 18-banked craft requiring crews of 1,800 men. Ptolemaic Egypt capped them with 20's and 30's. Ptolemy III even laid down a 40 (tesseraconter) with a design length of over 400 feet and calling for a crew of 4,000 rowers. The vessel was never actually used. The multiplicity of "banks," once a puzzle to historians, signifies the number of rowers on each oar rather than an almost unimaginable piling up of banks. While representations of biremes and triremes with staggered oars exist, nothing portrays any further superimposition of oars. The ratings were of "man-power" propulsion banks, similar to modern horsepower ratings.

This same arms race brought other changes of significance. Until the late 4th century BC, manoeuvre, marines, and the ram constituted a warship's offensive strength. Archers provided close-in fire, though perhaps not to the same extent as in the early Egyptian navy, in which the bow was favoured. Demetrius I Poliorcetes of Macedonia is credited with introducing heavy missile weapons on ships, at the end of the century, starting a trend that still has not ended.

Demetrius' ships mounted crossbow-like catapults for hurling heavy darts, and stone-throwing machines of the type the Romans later called ballistae. From this time on large warships carried these weapons enabling them to engage a foe at "standoff" ranges, though ramming and boarding also continued. Temporary wooden turrets—forecastles and sterncastles—were similarly fitted to provide elevated platforms for archers and slingers.

Following the fragmentation of the brief empire of Alexander the Great, sea power developed elsewhere. The city-state of Rhodes built a small but competent fleet to protect its vital shipping. Rhodian warships were reported to have made use, in at least one action, of firepots suspended on spars projecting from their bows, anticipating Greek fire by several centuries.

Meanwhile to the west, Carthage, a state with ancient maritime origins, rose to prominence on the north coast of Africa, and by about 300 BC had become the foremost Mediterranean naval power. Carthage's navy consisted probably of the same ram-galley types developed by its ancestral Phoenicians and by the Greeks.

Rome. Coincidentally, across the sea to the north the city-state of Rome expanded to include most of the southern Italian peninsula with its extensive seacoast and maritime heritage. Rome's growth southward collided with Carthage's ambitions in Sicily, leading to the First Punic War, which began in 264 BC. Unlike their seafaring opponents, the Romans were not a naval power. When in the fourth year of the war Carthage sent a fleet against Sicily, Rome realized her fatal disadvantage and moved to remedy it. The Greek city-states she had conquered had long seagoing experience. Employing their shipbuilders and learning also from the foe, Rome built a fleet of triremes and quinqueremes, the latter patterned after a Carthaginian warship that ran aground in Roman territory early in the war. While galleys were being built, oarsmen trained on dummy rowing benches ashore (an early ancestor of the training devices of modern navies). The first Roman battle fleet with effective crews soon put to sea.

Not content with copying the enemy's tactics, the Romans took land warfare to sea and forced the Carthaginians to fight on Roman terms. Each Roman galley had fitted in the bow a hinged gangplank with a grappling spike or hook (the *corvus*) in the forward end, thus providing a boarding ramp. They added to the crews many more marines than warships usually carried.

Roman techniques

The Phoenicians and Greeks had emphasized ramming, with boarding as a secondary tactic. A Roman captain rammed and then dropped the gangplank. Ram and *corvus* locked the galleys together, and the Roman marines boarded, overwhelming the opponent. The Roman fleet had extraordinary success in the great naval battle of Mylae off northeast Sicily destroying or capturing 44 ships and 10,000 men.

After other victories, and some defeats, by the end of the First Punic War, 241 BC, Rome had become the leading sea-power. A generation later, in 218 BC, Rome again engaged in war with Carthage. The genius of Hannibal almost overwhelmed Rome and probably would have had Carthage put forth major effort at sea and supported him in Italy. When the war ended in 201 BC, Carthage surrendered its navy and was never again to become a maritime power.

At the end of the Second Punic War Rome began a long effort to subdue the pirates of the eastern Mediterranean. After several generations of intermittent operations, in 67 BC Pompey was given a three-year commission to finish the task. The Mediterranean was divided into "naval districts"; regular patrols were established; the sea was systematically cleared and held. This operation helped convince Roman rulers of the need for a standing fleet.

As the Roman navy evolved, so did its warships. Though pictorial evidence is ambiguous, it seems clear that the gangplank and *corvus* disappeared as the Romans gained experience in sea warfare. Later Roman warships appear to have been conventional fully decked ram-galleys mounting one or two wooden turrets (probably dismountable) for archers. To the single mast with rectangular sail was added a bowsprit carrying a small sail, the artemon. Falces, or long spars tipped with blades, were used by Julius Caesar's fleet against the sailing vessels of the Veneti of northwest Gaul to cut their rigging and immobilize them. Catapults and ballistae served as "artillery," and it was under their fire that Caesar's legions landed in England.

The light liburnian

Early Roman warships were all large; to escort merchantmen and combat pirates Rome found need for a lighter type, the liburnian. Probably developed by the pirates themselves, this was originally a light, fast unireme; the Romans added a second bank of oars. In the Battle of Actium, 31 BC, Octavian's (later Augustus') skilled fleet commander, Agrippa, used his liburnians to good effect.

The Byzantine empire. Although polyremes continued to be built after Actium, the liburnian became the predominant Roman man-of-war. With the break-up of the western Roman Empire, naval organization and activity in the west decayed. In the eastern Roman Empire, however, the need for sea power was well appreciated. During the 11 centuries that the Roman Empire centred on Constantinople, the Byzantine rulers maintained a highly organized fleet. Their original type of warship was the liburnian, called in Greek the *dromōn*, or runner, a word that like liburnian, eventually came to denote any warship; it was built in several different sizes; the heavier designed to bear the weight of battle; the lighter single-bank dromons serving as cruisers and scouts.

Throughout the eastern Roman Empire's existence warships changed little except in rig and armament. An average large dromon measured up to 150 feet (45 metres) in length, with 100 oars and one or two fighting towers for marines. Other than some widening of the stern and its superstructure to provide more accommodation aft, the hull differed little from the Roman type. At some point early in the Christian Era, the lateen sail, three-cornered and suspended from an angled yard, probably adopted from the Arabs, came into general use. Eastern warships had two or three masts. In a departure from classical customs, these were left in place in battle. Contemporary pictures show rams above the waterline. Oars may have projected directly from the ship's side rather than from an overhanging sponson.

Missile-launching weapons grew in size, some hurling projectiles as large as 1,000 pounds (450 kilograms) up to 750 yards (700 metres). Greek fire, a combustible material for setting fire to enemy ships, was invented in the 7th century or earlier. The various compounds passing under the name used a blend of some of the following: pitch, oil, charcoal, sulfur, phosphorus, and salt. The pitch was inflammable resin, the oil, usually crude petroleum or naphtha, the salt probably crude nitrate of potash. As its composition improved, tubes shaped into the mouths of savage monsters were placed in the bows of war galleys and the flaming terror, which water merely spread, was hurled on the enemy. At close quarters marines also used a type of hand projector. In later tubes the charge was placed in a brass cup resembling a beer stein and inserted in the breech end of the tube. Significantly, the first guns (except handguns) followed the same practice.

Greek fire was an important factor in terrifying and repelling the Muslim fleet in sieges of Constantinople from the early 8th century on.

EARLY WAR VESSELS OF NORTHERN EUROPE

The earliest northern warships of which record exists were the sailing ships used against Julius Caesar by the Veneti of Gaul. During the Roman period, ships in European waters were of the Roman pattern—war galleys (mounting mast and sail but basically rowing vessels) and merchant ships. Like their Greek predecessors, the latter were slow, beamy sailing ships designed for cargo capacity rather than speed and manoeuvre. Like warships, the merchantmen mounted one mast with a single rectangular sail. They also hoisted two triangular topsails spread between the yard and masthead, as well as the artemon. Large Roman merchantmen were over 175 feet (50 metres) long, with a beam of perhaps 50 feet (15 metres).

Viking vessels. In addition to dugouts, early Scandinavian craft are believed to have included craft built of hides stretched over wood frames. These proved suitably strong and seaworthy for coastal operations. By the beginning of the Viking period, about AD 800, the early craft had evolved into the well-known Viking ship, a sturdy, double-ended, clinker-built (*i.e.*, with overlapping planks) galley put together with iron nails and caulked with tarred rope. It had a mast and square sail, which was lowered in battle; high bow and stern, with removable dragon heads; and a single side rudder on the starboard (steer-board) quarter. This method of construction had existed for about five centuries, though a keel providing strength for distant open-water operations and a rudder actually attached to the hull first appear in a recovered boat dating around AD 600; the mast and sail seem to have come into use later.

Viking vessels were essentially large open boats. Like the Homeric Greeks, the Vikings at first made no distinction between war and cargo ships, the same vessel serving either purpose as the occasion demanded. Later, however, they built larger ships specifically designed for war. By AD 1000 they sailed three categories of these: those with less than 20 thwarts (40 rowers); those with up to 30; and the "great ships" with more than 30, which might be considered the battleship of the time. Expensive and unhandy, though formidable in battle, the great ship was never numerous. The middle group, manoeuvrable and fast, proved most valuable.

These long ships played an important role in exploration (reaching Greenland and America before Columbus), in the consolidation of kingdoms in Scandinavia, and in far ranging raids and conquests. It was in them that the Norsemen early invaded the British Isles and established themselves in Normandy, whence their descendants under William I, the Conqueror crossed the Channel to win England in 1066.

English warships. English war vessels reflect developments that were going on elsewhere in western Europe. Early English warships resembled their Viking counterparts. Rather than being built specifically for fighting, most were called into national service only in time of emergency, though King Alfred built ships "full twice as long" as previous British craft, swifter and higher in the water, to battle the Danes at sea.

To about the end of the 13th century, the typical ship in northern waters remained a clinker-built, single-masted, square-rigged descendant of the long ship. In this century, and even more in the 14th, changes began that would bring an end to the long dominance of the oar in battle. Around AD 1200 came one of the great steps in the history of sail: the introduction, probably in The Netherlands, of the stern rudder. This rudder, along with the deep-draft hull, the bowsprit and, in time, additional masts, transformed the long ship into the true sailing ship that could beat into the wind as well as sail with it.

Thus the beamier round ship also became the warship. Fleets of this period, and indeed through the 16th century, were owned for the most part by feudal lords, merchants, and port cities, though some were royal ships. In time of peace the king's, as well as private, vessels were used as merchantmen and manned by civilian crews. When a need arose, the king mustered his own ships, called on vassals for theirs, and hired whatever others he needed. Temporary wooden castles added at bow and stern provided bulwarked platforms for archers and slingers. A complement of men-at-arms embarked, in addition to the ship's seamen. Tactics were usually simple and straightforward, opposing fleets closing and attempting to beat down each other's archers before grappling and boarding. At war's end, off came the castles, and the ships went back to trading.

Warships of feudal lords

THE AGE OF GUN AND SAIL

The trading vessel that could be promptly adapted to war did not, however, fulfill the need of a nation for a navy. The coming of gunpowder and the period of world exploration brought changes that were to cause the sailing man-of-war to become increasingly distinct from the merchantman.

Until the 15th century, northern ships probably continued to have single masts, though in the Mediterranean a two-mast rig carrying lateen (fore-and-aft) sails had existed for some time. Then change came rapidly in the

north, spurred on by Henry V's construction of large and strongly built warships for his cross-Channel French campaigns. The remains of one of these, "Grâce Dieu," reflected the clinker-built construction of the Viking long ship, but had a keel to beam ratio of about 2½:1 and now carried a second mast. The removable castles had become permanent parts of the ship, mounting many small guns.

Some historians believe that "Grâce Dieu" carried a third mast. At any rate, in a few decades ships had three and, by the end of the century, large vessels mounted four masts carrying eight or more sails. A three-master carried a large sail on each mast and in addition a main topsail and the spritsail under the bowsprit—the rig, in fact, of "Santa Maria" in 1492. Ships, no longer dependent on fair winds, could and did range the world.

Gun-armed warships. Employment of guns afloat, bringing a slow but progressive revolution in warship construction and naval tactics, had its first small beginnings by the 14th century. One of the compositions of Greek fire, given by Marcus Graecus in AD 846, was one part live sulfur, two of charcoal of willow, and six of saltpetre (potassium nitrate) ground into fine powder in a mortar and mixed. This recipe is a forerunner of black powder, the basic gun propellant until the late 1800s.

Gradually, saltpetre's properties became more widely known. In the 13th century, Mediterranean Muslims made hand grenades and fired small balls from hand tubes or lance heads. The first gun used at sea, undoubtedly a hand weapon, was probably in a Mediterranean galley in the 13th or early 14th century. It played a minor role. In fact, in the numerous sea battles of the Greeks, Genoese, Moors, Turks, and Venetians during this period there is no mention of guns. But by the middle of the 14th century, the English, French, Spanish, and other navies mounted guns. Most were relatively small "man-killers" located in the castles fore and aft. Later, heavier guns were added. The Mediterranean galleys of Turkey and Spain at first simply shackled a heavy gun on the forecastle to fire forward, supplementing the ram.

First guns used at sea

European guns were originally built up of wrought-iron bars welded together to form a tube, then banded with a thick iron hoop. Initially, they were breechloaders with an open trough at the rear of the barrel through which the ball was loaded and a cylindrical chamber filled with powder inserted and wedged tight. Inherently weak and low-powered, they were replaced in the British navy after 1500 by brass muzzle-loaders, cast in one piece with bores drilled out. Some of these attained great size for their day; by the mid-16th century even some 60-pounders (firing 60-pound solid shot) were mounted in the largest ships. In this century also, increasing knowledge of iron metallurgy led to the production of large cast-iron cannon that slowly replaced the bigger brass guns in ships, though brass remained predominant for the lighter calibre well into the 19th century.

Henry VII of England created the first true oceangoing battle fleet. The "king's ships" carried many guns but most of the impressively large numbers were small breechloaders. Following him, Henry VIII initiated gunports in English warships, a development that was to have a far-reaching effect on man-of-war design and, indeed, on world history. Neither stability nor structural strength favoured heavy guns in the high castles. Henry's introduction of gunports (perhaps following an earlier use across the Channel), at first low in the waist of the ship and afterward along the full broadside, made possible the true heavy-gun warship. The cutting of gunports in the hull must also have been a factor in causing the northern nations to shift from clinker-built ships to caravels with flush-fitting planks, a change that took place in the early 1500s.

The armament of an English man-of-war of the early 16th century consisted of four or five short-barrelled cannon, or curtals, a similar number of demicannon, and culverins. The average cannon, a short-range gun, hurled an iron ball of about 50 pounds, and the demicannon one of 32 pounds. The culverin, a longer and stronger gun, fired a smaller shot over a longer range and was likely to be more accurate at other than point-blank range. Supplementing these standoff "ship killers" were the smaller demiculverin, saker (quarter culverin), falcon (half saker), falconet, robinet, in descending size of ball fired, down to several ounces.

A great warship of the 16th century mounted a total of large and small pieces approximating the numbers mounted in battleships of World War II. Henry VIII's best known warship, "Henry Grâce à Dieu," had 186 guns for her original complement in 1514, mostly small, but a number of iron "great guns."

As the 17th century advanced, guns and powder improved and classification became standardized. The long gun (culverin type) ran 18 to 25 calibres (bore diameters) in length; the short cannon, 15 calibres. Gun carriages had heavy wooden sides called brackets, with sockets for the gun trunnions, joined by similar flat timbers called transoms, supported on wooden trucks and hauled out after recoil by heavy tackle.

Galleasses, galleons, and great gun battles. The coming of mighty men-of-war, like "Henry Grâce à Dieu," did not mean the immediate end of oared warships. In fact, some types of galleys and oared gunboats continued to serve well into the 19th century. Venice had galleys when conquered by Napoleon. Throughout the 18th century Russia and Sweden employed galleys and, later, oared gunboats. Indeed, Russian-oared gunboats were built in 1854 and engaged in action that year. The United States employed "row galleys" or oar-driven gunboats in the War of 1812 and the Mexican War (1846–48).

Survival of oared warships

Galleasses at Lepanto. The climactic action of the age of oar was Lepanto, fought off Greece in 1571, in which a combined European fleet defeated the Turkish fleet in an action that differed little from traditional galley warfare with two exceptions. First, galleys now carried guns, perhaps five heavy and medium guns forward to supplement the shock effect of the ram and more small breechloaders complementing bows, lances, and swords.

Second, the European line of battle included six Venetian galleasses, a compromise type developed in the transition from oar to sail. These huge vessels that depended on sail as well as oar, bristled with guns, including heavy ones in broadside. Although cumbersome to manoeuvre, their concentrated fire contributed importantly to victory.

Galleasses outside the Mediterranean differed somewhat from Venice's in that they were basically full-rigged sailing ships carrying broadsides of heavy guns and a bank of auxiliary oars for mobility. The hybrid existed only in small numbers and soon passed out of fashion to the north.

The galleon and the Spanish Armada. The "great ships" of Henry VII and Henry VIII were carracks: starting basically with the lines of beamy, seaworthy merchant ships, designers had added stronger timbers, masts, sailpower, broadside guns, and forecastles and aftercastles, with the forecastle triangular and overhanging. In the galleon, the successor to the carrack, the general principles of design of sailing men-of-war were established and ruled, without fundamental change, for three centuries. The galleon retained certain of the characteristics of the galley, such as its slender shape; it had a greater length to beam ratio than the carrack, standardizing in England for a time at about three to one but later increasing to considerably greater ratios. The triangular, overhanging forecastle of the carrack gave way to the long raised beak of the galley projecting beyond the stem and with a square-ended forecastle set back under the foremast. Like carracks, the larger galleons might carry a single mizzenmast or two relatively small masts, the second being called the bonaventure.

In the longer, leaner galleon, the number of heavy guns was increased until they ran the full length of the broadside in one or two tiers (and later three). This advance in firepower was incorporated in "Henry Grâce à Dieu" during its rebuilding in 1536, though it remained a carrack.

The galleon came into favour in the north during the following decades, leading to the first ships of the line. The far-ranging experience of mariners and improved construction techniques led to great fighting ships that

were both lower in the water and more seaworthy than their predecessors. They also carried comparatively large batteries of heavy guns, affecting the design of ships. The sides now sloped inward from the lowest gun deck up to the weather deck. This tumble home helped concentrate the weight of the big broadside guns toward the ship's centre line, improving stability. Sir Francis Drake's flagship, "Revenge," for example, displaced only 500 tons, yet she mounted a broadside of 34 guns ranging from 32-pounders to nine-pounders, plus smaller guns.

Heavy gun batteries

By that time it had become normal for northern warships to mount powerful broadsides of 28 or more ship-smashing guns, a much heavier armament, in proportion to their size, than their predecessors. For their handy, manoeuvrable ships, the British had also concentrated on the long-range-culverin type and by the time of the Armada most of their principal ships carried these in broadsides. Thus they were designed for off-fighting, permitting the English fleet to get the most out of its superior manoeuvring qualities. These early ships of the line began the true reign of the big gun at sea, maintained until World War II when the carrier and submarine became more formidable. Today the rocket missile (ballistic and guided) has taken the gun's leading role, except in amphibious warfare.

When the Spanish Armada arrived in 1588, the British sought and fought a sea battle with ship-killing guns, rather than the conventional fleet engagement of the past that concentrated on killing men, ramming, and boarding. With superior ability and long-range culverins, they punished the invading fleet outside the effective range of the heavy but shorter range cannon the Spanish favoured. This historic running battle of July 1588 closed one era and opened a greater one of big-gun sailing navies.

Ship of the line. The late Elizabethan galleon that began the true fighting ship of this type reached its culmination in England's "Prince Royal" of 1610 and the larger "Sovereign of the Seas," along with similar great ships in other European navies. These two English ships mounted broadside guns on three decks, "Sovereign of the Seas," most formidable ship afloat of its time, carrying 100 guns. This was the standard minimum armament for a first-rater long into the future.

In this mobile fortress of approximately 1,500 tons there was some reduction of height and the bonaventure mizzen disappeared, leaving the standard three masts that capital ships thereafter carried.

Soon ships began to be standardized into different categories. James I organized his ships into four ranks, and, by the mid-17th century, six rates existed as a general concept, though not yet a system. The number of guns carried determined rate, with a first-rater mounting 100 and a sixth-rater 18. An important improvement came in the standardization of batteries in the higher rates so that guns on the same deck were of the same weight and calibre rather than mixed, as originally in "Sovereign of the Seas." Near the end of the century, guns began to be described by their weight and calibre, with the 32-pounder long gun favoured as the standard lower deck weapon for British warships, though three-deckers might carry 42-pounders in the lowest tier.

Rates were periodically revised. By the middle of the 18th century, while the rate concept continued for some official purposes, ships were generally known by the number of guns they were rated to carry—*e.g.*, "Victory," 108. Similar developments took place in other navies. The French seemed to emphasize scientific shipbuilding more than the British, hence class for class their warships were often more efficient. The Dutch and Spanish also built excellent warships, the former favouring shallower draft vessels.

Tactics and guns. The frequent hard-fought sea battles of the 17th century between fleets closely matched in size and skill, particularly in the Anglo-Dutch wars, led to the column formation of heavy warships called line ahead. In 1653 the British Admiralty prescribed the line ahead as the principal combat formation, with the intention of enabling the commander to control the fleet and bring the entire force into action at the same time.

Anglo-Dutch formations

Two schools of British Navy thought existed as to the tactics of engaging the enemy. The formalists urged aligning the full line of battle from van to rear parallel with the foe before bearing down in a concerted manoeuvre that would engage all of the ships at the same time. The second school believed in prompt attack, closing the enemy quickly after a formal approach had brought the fleets near enough together, whether or not in exact alignment. They held that speed of onslaught more than compensated for lack of a completely concerted attack.

Both schools believed in fighting at close quarters where the fire of even the smallest guns could be effective. This shift from the tactics against the Spanish Armada did not do away with the long gun, but in time led to the introduction of larger bore, shorter range guns like the cannon of the early period. The change in viewpoint may have been strengthened in the world wars of the 18th century by the tendency of the French and Spanish to concentrate on damaging upperworks and rigging. They fired on the uproll, while the British, concentrating on the hull, fired on the downroll to smash the ship.

A large ball has greater crushing effect, but factors like those of recoil, weight, and metallurgy considerations required a short-bore gun. Late in the 18th century, the Scottish firm of Carron Company Ironworks brought out "The Smasher" of eight-inch (20-centimetre) bore, firing a close fitting 68-pound (31-kilogram) ball with only 5½ pounds (2½ kilograms) of powder. Carronades, as they came to be called, had a short bore. They gave ships massive close-range firepower without the weight and recoil problems of similar long guns. They could not replace the long gun and were valuable only because navies, in a sense, continued the tactics of the Romans—smashing with heavy artillery and boarding.

Ship design changes. Warships gradually improved in design through the 17th and 18th centuries. New types of sails, providing more canvas and more versatile combinations for varying weather conditions, such as staysails and the jib sail, came into use in the 17th century. Soon thereafter the steering wheel replaced the old whip staff, or tiller.

The adoption of line-ahead tactics made it necessary to standardize the battle line, which had consisted of ships of widely varying strength. Now only the more powerful warships were considered suitable "to lie in the line of battle." Hence the origin by the 1700s of the term line-of-battle ship, or the ship of the line, and, in the second half of the 19th century, the derived term battleship—ships that could hit the hardest and endure the most punishment.

Some first-raters were built to carry as many as 136 guns, but the biggest ships were often cumbersome, hence relatively few were built. The handier 74-gun third-rater proved particularly successful, combining sufficient hitting power with better speed and manoeuvrability. Most of the ships of the line of the late 18th and early 19th centuries were 74s. One of these might be approximately 175 feet (50 metres) long with two full gun decks, the lower mounting the heaviest guns, by the Napoleonic Wars usually 32-pounders. The upper gun deck customarily carried 24-pounders, while the forecastle and quarterdeck mounted lighter guns or carronades. The bigger ships were similar but had three covered gun decks instead of two. Viscount Nelson's "Victory," built in 1765 and preserved in dry dock as she was at Trafalgar in 1805, is a classic example of this powerful type.

The 74-gun third-rater

Frigates and other types. Ships of the line, first to fourth rates, had strong fast frigates as consorts. This ancestor of the modern cruiser evolved during the mid-18th century for scouting, patrol, and escort, as well as for attacking enemy merchantmen. The frigate carried its main battery on a single gun deck with other guns on forecastle and quarterdeck. Like the ship of the line, they varied in size and armament, ranging from about 24 guns in early small frigates to as many as 56 in some of the last. Two classic examples, still preserved, are the United States Navy's "Constitution," of 44 guns, and "Constellation," of 38.

Smaller vessels aided frigates in their blockade, escort, commerce raiding, and other duties. The single-masted cutter served as scout and coastal patrol craft. Brig and schooner-rigged types, generally called sloops of war, by the time of the American Revolution grew into the three-masted, square-rigged "ship sloop." Called a corvette on the Continent, the fast ship sloop complemented frigates on the fringes of the fleet. Smaller sloops, schooners, brigs, and luggers were widely used for special service. Fleets also needed ordnance and supply ships and other auxiliaries; these were usually merchantmen taken into service in war emergency. Converted merchantmen, such as John Paul Jones's "Bonhomme Richard," often played combat roles. Fleets also had various special types, such as fire ships and bomb ketches. The latter, with two large mortars hurling bombs of about 200 pounds, were developed by France in the late 1600s, and were used with devastating effect against Barbary pirate ports.

THE AGE OF STEAM AND IRON

As the Industrial Revolution unfolded in the 19th century, the age of wood and sail gave way to that of steam and iron. Phenomenal changes took place in nearly every aspect of warship design, operation, and tactics. These changes ended the reign of the majestic ship of the line by the mid-1800s, but another half century elapsed before it was clear what form her replacement as the backbone of fleets would take. The changes may be summarized under two headings: propulsion and ship construction and armament.

Propulsion. Steam for propulsion of vessels was tried with varying success in several countries during the late 18th century. Engines and supporting machinery were at first not adequate for this fundamental advance in ship capability, but useful steam craft appeared in the early 1800s, suitable for operation on inland and coastal waterways. The earliest steam warship was "Demologos" of the U.S. Navy (renamed "Fulton" after her designer). Built in the War of 1812, this well-gunned, double-hulled, low-powered ship cruised briefly in the New York Harbor area before the war ended and later was destroyed by an accidental fire.

First steam warship

The earliest steam warships in action were small paddle wheelers used by British and American navies against weak foes. USS "Sea Gull," a New York Harbor steam tug, operated against pirates in the West Indies during the 1820s.

As engines gradually improved, navies experimented with them in standard warships, first as auxiliaries to sail, which was then essential for endurance. The paddle-wheels were particularly vulnerable to enemy fire. In 1843, through the drive of Capt. Robert Field Stockton of the U.S. Navy and the inventive skill of John Ericsson, a Swede whom Stockton brought to America, the United States launched the world's first screw-driven steam man-of-war, USS "Princeton," a large 10-gun sloop.

The screw propeller was an old idea going back to Archimedes, but, with Stockton's assistance, Ericsson had made it effective for large warships, as Sir Francis Pettit Smith was doing at about the same time in England for large merchantmen. By the mid-1840s, boilers, engines, and machinery had improved to the point that thereafter practically all of the new warships had steam propulsion. The French Navy's "Napoléon" was a particularly successful application of steam to a great ship of the line. The U.S. Navy's experience in the Mexican War of the 1840s and the allied experience in the Crimean War of the 1850s demonstrated the outstanding advantages of steam warships for restricted-waters operations, as well as in adverse winds and tides.

Among the advances of this period were two other milestones. In 1834 Samuel Hall of England patented a type of steam condenser that made it possible to use fresh instead of corrosive salt water for boilers. In 1824 James Peter Allaire of the United States invented the compound-expansion steam engine, in which the steam was used in a second cylinder at a lower pressure after it had done its work in the first. Eventually it was made practical by progress in metallurgy and engineering; in 1854 John Elder, shipbuilder on the Clyde, installed a successful two-stage engine in the merchant steamer "Brandon." The higher efficiency was of great importance for ocean-keeping navies.

Ship construction and armament to the American Civil War. The change from wood to iron and armour that followed the introduction of steam propulsion came slowly, in considerable part because the new material required new techniques and experience in shipbuilding. By mid-century a handful of iron ships had appeared in various navies; the general use of iron for warships, however, awaited realization of the full value of the shell gun, the resulting development of armour, the employment of armoured batteries in the Crimean War, and the recognition of the significance of the battle between "Monitor" and "Virginia," better known as "Merrimack."

Slow change from wood to iron

Guns. "Princeton" not only set the course for propeller warships but exemplified the rapid development of armament that with steam and other factors brought navies increasing capabilities against each other and in operations against land defenses. She mounted 12-inch shell guns, which still had many unsolved manufacturing problems; in a gala demonstration for Pres. John Tyler one of the guns blew up, killing the Secretary of the Navy and several others.

Basic changes in armament that would advance rapidly throughout the 19th and 20th centuries had begun in the 18th century. In the British Navy steps to make possible heavier long-range guns began with the introduction of strong springs to take up the first shock of recoil, aided by inclined-plane wedges behind the trucks. Flintlocks pulled by a lanyard, instead of a match, fired the guns. Sights also improved. In the early 1800s navies began to employ mercury fulminate in caps to initiate firing. Efficient percussion locks came into use within a few years.

Smooth-bore guns were still inaccurate, and successful efforts were made to bring back the rifling, as well as breech-loading, of early guns, thus increasing speed and accuracy of fire. In the 1840s, Italian and Austrian inventors brought out sliding-wedge breechblocks. Later the French developed an interrupted screw system, originally an American invention. A British firm produced a rifled breech-loading gun that the British Navy used until 1864, when a number of accidents brought a temporary reversion to muzzle-loaders. But defects were eventually remedied, and breech-loading brought phenomenal increases in naval rates of fire.

French 6.5-inch (16.5-centimetre) cast-iron rifles in the Crimean War demonstrated superiority in range, destructive power, and accuracy. Along with the advent of armour, they helped impress all of the navies with the need for rifling. Slower burning powder was badly needed. Black powder was gradually improved during 600 years of use in firearms, but it still retained its primary defect, too rapid burning. This required keeping the charge down (and therefore the range) to prevent the bursting of even the best guns. Just before the American Civil War the U.S. Army developed large, perforated, dense grains of black powder that were a start toward the controlled burning ultimately achieved with smokeless powder.

Shell guns in warships' main batteries were preceded by bombs fired from mortars, small-shell guns, and solid hot shot heated to cherry red. A principal architect in bringing big-shell guns to sea was Henri-Joseph Paixhans, a general of French artillery. The first large-shell guns from Paixhans' design, chambered howitzers firing a 62½-pound shell (thicker walled than bombs to penetrate before exploding) was tested in 1824 against a moored frigate with remarkable accuracy and incendiary effect.

Big-shell guns at sea

The new guns began to come into use afloat in the 1830s, a French squadron firing them in bombardment of Vera Cruz, Mexico. The U.S. Navy began installation, including 16 eight-inch-shell guns in the three-decker "Pennsylvania," along with 104 32-pounder solid-shot guns. The British made similar installations. There was good reason for navies to proceed cautiously. Powder charges had to be limited, so shell guns had shorter range, and shell was

less accurate than shot. Improvements in metallurgy, gun construction, and fire control, along with the manoeuvrability of steam warships, at last were beginning to lead to an important extension of range that the big gun had promised from the beginning.

In 1853 the dramatic destruction of a weaker Turkish squadron by a Russian fleet in the harbour of Sinope of Turkey's Black Sea coast attracted world attention and increased interest in shell guns. England, the United States, and others built big-steam frigates (as they were misleadingly called) with large-shell guns. Their great striking power and manoeuvrability under steam made them the capital ships of the day, superseding the ship of the line for a brief time before the ironclads took over.

Larger guns, increased powder charges, and greater tube pressures were made possible by the replacement of cast iron by built-up wrought-iron guns (later, cast steel and, eventually, forged steel). Hoops were shrunk on over the powder chamber and breech end of the tube to give the strength required for the greater pressures.

Armour. The use of larger guns with more penetrating power and explosive shells made armour imperative. Among early experiments were floating armoured batteries built for the Crimean War. These flat-bottomed vessels could carry large-shell guns close inshore. Heavy wrought-iron plates over a thick wooden backing gave them outstanding protection. In October 1855 in a hard-fought duel, French floating batteries silenced a Russian fort at Kinburn, at the mouth of the Dnepr (Dnieper) River and forced its surrender, suffering little damage themselves from Russian shellfire and solid shot.

Other developments followed swiftly. The British soon built the first iron-hull floating batteries. The French followed with "Gloire," the first seagoing armoured warship, protected throughout her entire length by a wrought-iron belt of 4.3 to 4.7 inch armour backed by 26 inches (66 centimetres) of wood. Displacing 5,617 tons, she mounted 36 large-shell guns and could steam at 13.5 knots (one knot equals 1.15 miles per hour or 1.85 kilometres per hour); a three-masted sailing rig supplemented the engines. "Gloire" was the first of a series of ironclads laid down by Napoleon III; 13 similar ships soon followed, then two-decker armoured rams.

Great Britian countered with "Warrior," the first iron-hull, seagoing, armoured man-of-war. Much larger than "Gloire," she displaced 9,210 tons, mounted 28 seven-inch-shell guns, had slightly lighter armour, carried sails, and was one knot faster. These first ironclads were commissioned on the eve of the American Civil War in which ironclads were destined to take a decisive part. The war itself produced several spectacular developments, including pioneer submarines (see SUBMARINE), the first aircraft carriers (to handle balloons for observation), and the torpedo boat, one of several means the Confederates explored in trying to break the blockade. These little craft had weak steam engines and mounted a torpedo lashed to a spar projecting from the bow. Called Davids, they frightened the blockaders and might have sunk a wooden warship; but the one successful attack struck the armoured "New Ironsides." The explosion caused considerable damage, requiring shipyard repairs, but did not lift the blockade. The David was a weak but definite forerunner of the torpedo boat and then the versatile destroyer.

The ironclads

Ironclad warships were crucial, perhaps decisive in the North's victory. Partial ironclads appeared early on the western rivers, and, under Flag Officer Foote, spearheaded Ulysses Grant's victories in 1862. River and coastal ironclads (ultimately, mostly monitors) dominated the war against the South in attacks from the sea and in decisive support of land operations from the Mississippi system to the Chesapeake Bay and James River. Most memorable of the combats was the duel between "Monitor" and "Virginia" ("Merrimack"). When the Federal forces lost Norfolk Naval Shipyard, Portsmouth, Virginia, April 1861, they burned several warships, including the heavy steam frigate "Merrimack." The Confederates raised "Merrimack," installed a ram and slanting casemates made from railroad track over thick wooden backing, as had been done in "Gloire," and renamed her "Virginia." Mounting ten guns, including four rifles, "Virginia," with yard workmen still on board finishing up, sailed on March 8, 1862, for her trial run. Defying concentrated fire of ship and shore batteries, she sank two of the wooden blockading fleet before retiring with the ebbing tide. In this dramatic moment Ericsson's "Monitor" arrived from New York during the middle of the night. Displacing fewer than 1,000 tons, less than a third of "Virginia," "Monitor" had a boxlike iron hull supporting an iron-plated wooden raft on which revolved the turret. The 172-foot-long vessel had little freeboard except for the thickly armoured rotating turret that mounted two 11-inch smoothbores. (Although new on warships, the revolving turret was an old idea; a turreted warship was built in England at about the same time.)

"Monitor" had many deficiencies. Not really a seagoing warship, she had nearly sunk on her voyage down from New York and did sink on her next sea voyage. Yet she proved the equal of her rival in their duel on March 9. The battle ended in a draw with neither ship seriously injured, but repercussions swept the world.

On April 4, scarcely more time than required for a ship to cross the Atlantic, Great Britain ordered the 131-gun ship of the line, "Royal Sovereign," to be cut down, armoured, and fitted with turrets. Only three and a half weeks later she laid down "Prince Albert," the Royal Navy's first iron-hull turret ship, mounting four turrets.

Coastal and river monitors

The Union Navy ordered 66 coastal and river monitors, low freeboard ships not suitable for high-seas action and most not for long voyages. Many were not completed in time for war service. The North also laid down four double-turreted Kalamazoo-class monitors to carry 15-inch guns that would have been seagoing battleships; these, however, were not completed by the war's end and were scrapped.

Besides "Virginia," the Confederates began a number of other ironclads from Richmond south on the east coast and on the inland rivers. Several of these rendered valuable service and probably lengthened the war. But most had to be destroyed before completion; David Glasgow Farragut's decisive fleet dash into New Orleans, Louisiana, forestalled completion of two powerful ironclads that might have stopped him. Out of a combination of characteristics of the "Monitor" and "Virginia" types evolved the battleship that was next to rule the sea.

Underwater. The South developed innovative subsurface weapons, including mines (called torpedoes) that were detonated by contact or electrically, and a submarine armed with a torpedo attached to a spar. (For a detailed description, see SUBMARINE.)

Warship development to the end of the century. The later 19th century continued to be a time of great flux in warship design. European nations tried numerous arrangements of guns and armour, such as centre-line turrets, a central armoured citadel with large guns on turntables at each corner, lightly armoured big guns topsides in barbettes (open-top breastworks), torpedoes in even the largest vessels, and substitution of high speed for armour.

For a time even the ancient ram was revived. When the Austrians won the Battle of Lissa from the Italians in 1866 by ramming, its value for the future seemed confirmed. Hence for years most large ships carried rams, which proved to be more dangerous to friend than foe when ships were sunk in peacetime collisions.

Ships. The trend toward the centre-line-turret, all-big-gun battleship finally became clear. In it were combined the seagoing hull, armour, and habitability of "Virginia," "Gloire," and "Warrior" with the turret and massive big guns of "Monitor."

HMS "Monarch," 8,300 tons, mounting four 12-inch guns in two turrets, commissioned in 1869, was perhaps the first true seagoing turret warship. HMS "Devastation," 9,330 tons, four 12-inch guns in two turrets, and massively armoured, completed four years later without sail, was a next step toward the ultimate 20th-century battleship, a ship with an armoured citadel around the propulsion plant, powder magazines, and handling rooms. Rising out

of it, protecting big guns and crews, were barbettes and turrets. The main battery shrank to a few powerful guns, but these took the place of many in broadside because of their great size and ability to fire through a wide arc of bearings. The change was vividly illustrated by the "new navy" the United States began building in the 1880s, consisting not of improved monitors but of powerful seagoing capital ships with mixed-calibre main batteries. In 1891 the United States laid down "Indiana," "Massachusetts," and "Oregon." Displacing 11,700 tons, these sister vessels had 18-inch belt armour, a speed of 15 knots, and mounted four 13-inch guns in two turrets. They also mounted eight eight-inch guns in four turrets, smaller guns for defense against torpedo boats, and six torpedo tubes. The plan was, as in other navies, to employ the heavy guns against enemy machinery and magazines while the faster firing eight-inch guns attacked his superstructure.

Armoured cruisers

The armoured cruiser was developed in this period as a large, fast vessel armed with intermediate-calibre guns and protected by armoured deck and medium-weight belt armour. Designed for commerce protection and raiding, as well as to cooperate with the battle line in fleet action, it was considered powerful enough and sufficiently protected to fight any ship capable of catching it and able to outrun battleships. Some even held it should become the principal warship.

Less heavily armoured was the protected cruiser, the engines and magazines of which were shielded by an armoured deck, but which lacked an armour belt. Unprotected cruisers had little or no armour, carried fairly light guns, and were designed primarily for scouting, patrolling, and raiding.

In this period there were fundamental advances in underwater weapons. An Austrian naval captain and a Scottish engineer produced an underwater projectile driven by compressed air to strike the unprotected hull below the waterline. At first slow, inaccurate, and of short range, it was progressively improved. Advances included stabilizing devices, more powerful warheads (initially of dynamite), and, very importantly, alcohol-burning steam-turbine power instead of compressed air.

Carrying this new self-propelled weapon, the torpedo boat had great potential, particularly under conditions of low visibility. Small, unseaworthy, and useful only in restricted waters with the then short range, slow torpedoes, the new boats did not immediately live up to expectations; nevertheless, as craft and torpedo improved, they were soon regarded as a major menace. Torpedo-defense batteries of rapid-firing small guns joined the main batteries of larger warships. Heavy ships added searchlights and torpedo nets. The threat also brought a new type of warship. The torpedo-boat destroyer first appeared in Great Britain in 1893. It was essentially a larger torpedo boat, mounting quick-firing guns, as well as torpedoes, of high speed, and capable of operating on the open sea. It was intended to accompany a battle line at sea, screen it from torpedo boats, and attack the enemy line with torpedoes. HMS "Havock," of 240 tons, was the first of the new type.

General improvements in technology. Engines for all of the types of warships steadily improved. Stronger metals made possible higher steam pressures and weight reduction. With higher pressures the two-stage compound engine added a third and even a fourth stage; then as the century ended, the steam turbine appeared to provide a marked increase in the speed of ships.

Development of turbines

Early armour had been of wrought iron backed by wood. To increase resistance against ever more powerful rifled guns, compound armour of steel backed with iron was devised to combine steel's surface hardness with iron's resiliency. The firm Schneider & Cie in France invented an oil-tempering process to produce a homogeneous steel plate that had good resiliency and greater resistance than compound armour. The later addition of nickel further improved its resistance.

Steel-armour-piercing shells came into use in the late 1880s, again threatening the armoured ship. An American engineer, Hayward Augustus Harvey, perfected a face-hardening process, applying carbon to the face of the steel plate at very high temperatures for an extended period and tempering. Harvey nickel-steel armour superseded earlier types. Then, in 1894, the Krupp firm of Germany devised hot-gas tempering, based on Harvey's process, that in turn became standard with world navies. Later, the addition of chromium to nickel steel was found to be a further improvement.

The impact of developments in guns and powder exceeded even that of warship design in their effect upon navies. In the two decades after the American Civil War the main difficulties with breech mechanisms were resolved. Better guns, along with breech-loading, made possible both longer ranges and higher rates of fire.

New powders were equally important. About 1880 brown or cocoa powder appeared, employing incompletely charred wood. It burned slower than black powder, hence with a given maximum pressure the sustained pressure was much greater. To take advantage of this for longer-range firing, large gun calibres jumped to 30-35 times bore diameter.

Several nations began to achieve success with smokeless powder of nitrated cellulose and usually some nitroglycerin. Calibres of guns again advanced. With greater striking power available, armour-piercing projectiles became more formidable. These were originally solid shot designed simply to punch through armour plate. In the 1890s, better steel and fuses made it possible to add an explosive charge. The resulting semi-armour-piercing shells became highly destructive, and in time all of the armour-piercing projectiles carried explosive charges.

In 1881 the British Admiralty advertised for an anti-torpedo-boat gun to fire cased ammunition at a rate of 12 shots per minute. Benjamin Berkeley Hotchkiss, an American ordnance engineer with a factory in Paris, produced a series of one-, three-, and six-pounder rapid-fire guns that eventually went into nearly all of the navies, though he got his first order from the United States Navy. The rate of fire vastly increased for small guns. For larger ones, loading times also improved; in 1884 the average time to load a 12-inch gun was about four minutes. By World War I it had shrunk to about 20 seconds.

Increases in rate of fire

Other technical developments in these decades that had great impact on naval craft were the appearance of the internal-combustion engine and the electric motor, which at last made possible an effective submarine. Experiments in wireless telegraphy foreshadowed control of the operation of ships out of sight of the fleet commander.

Naval vessels of the World Wars

WORLD WAR I

The dreadnought battleship. By the 1890s the capital ship had evolved into what is known historically as pre-Dreadnought, characterized by its mixed main battery. Studies reinforced by battle experience in the Spanish-American (1898) and Russo-Japanese (1904–05) wars indicated that fire from large guns at longer ranges was more effective than mixed-battery fire closer in. Only big-gun shells had sufficient impact to do serious damage to well-armoured ships. Improved gunsights, new spotting techniques, and developing range finders made long ranges practicable.

Both the United States and Great Britain designed all-big-gun, centre-line-turret battleships, but the British "Dreadnought," completed in 1906, was the first to be commissioned. Equipped with ten 12-inch guns, turbine drive, 21-knot speed, she gave her name as a generic term to a new type. Other navies promptly sought to match and excel her.

Battle cruisers, essentially a further development of the armoured cruiser but with battleship guns, were designed to run down and destroy hostile cruisers and to protect friendly shipping. The battle cruiser was several knots faster than contemporary battleships, speed being achieved by reducing armour. Germany's battle cruisers had slightly less speed but better protection than their British equivalents, both in armour and compartmentation. German crews were intensively trained in damage control.

As the naval race speeded up, progressively more powerful ships appeared. All of the navies quickly adopted turbine propulsion. The United States went to oil fuel even for its capital ships. With oil supply more of a problem, European nations nevertheless followed suit because of oil's superior efficiency. Newer battleships that could hit more and more accurately at ever increasing ranges rapidly made older ships obsolete. Guns increased in size and striking power with intensive research going into propellants, shell design, and detonating explosives. Improvements in range-finding and fire-control equipment rapidly extended the effective battle range. Director firing (control of several or all of a battery from a single station) made for better coordination of fire, as well as more precise spotting and salvo shooting. World War I speeded up these developments, especially in range keepers and other fire-control equipment that made possible rapid and accurate calculation of target course and speed. The complex elements of the fire-control problem were so well-handled that early hitting became possible, sometimes on the first salvo—no mean feat when the target is many miles away racing through the sea.

This extension in range was a factor in the adoption of larger guns. Because accuracy, range, and the destructive power of guns all increase with calibre, given the same initial velocity and accuracy of fire control, it is evident that as soon as range-finding and spotting can determine the fall of shot beyond the effective range of existing guns, a larger calibre is demanded. "New York" and "Texas" of the United States Navy, commissioned in early 1914, mounted 14-inch guns. Great Britain's Queen Elizabeth class, joining the fleet in 1915–16, mounted 15-inch guns and sped through the water at 25 knots, virtually outmoding the battle cruiser. The United States' Colorado class mounted 16-inch batteries.

Steady increase in gun calibre

The battleship saw little combat in World War I as compared to the heavy service of its ship-of-the line predecessor and the role it was destined to play in World War II. Yet World War I was in many ways the zenith of the battleship's influence. Despite submarines, aircraft, and destroyers, the outcome of the war still hinged upon control of the sea by the battleship. Had superiority in battleships passed to Germany, Great Britain would have been lost, and the Allies would have lost the war. The one moment when this might have happened was the one large-scale clash of battleships, the Battle of Jutland. Fought in May 1916 in mist, fog, and darkness, the combat revealed the strengths and weaknesses of the battleships and battle cruisers; superb seamanship on both sides demonstrated that miles-long battle lines lost in the mist could be effectively controlled. Three British battle cruisers were lost. Several German battleships, thanks to watertight subdivision and efficient damage-control systems, survived despite more hits. But the British advantage in numbers of battleships was decisive. Germany turned to the submarine as a means of countering the Allied blockade.

Cruisers and destroyers. On the eve of World War I, Britain had 145 cruisers in commission or building, almost as many as the other major naval powers combined; Germany had 57, the United States 32. Cruisers of the first part of the 20th century did not show the phenomenal changes in size and power of the battleship. They benefited from the same advances in propulsion, gunnery, and materials that made all of the warships more effective. Cruisers had only a modest speed advantage over battleships until the Omaha class of the United States Navy, designed late in World War I and built afterward. Small tube boilers and superheated steam gave them a speed of 35 knots, about a 50 percent increase over other United States cruisers.

Destroyers experienced radical development. HMS "Havock" that started the type in 1893 soon had an outstanding successor. HMS "Viper," powered by improved turbines, on trials in 1899, achieved the then unprecedented speed of 34 knots. The destroyer grew in size, power, habitability, and functions into World War I, when the submarine gave it enormous importance. In August 1914 Britain had nearly 300 destroyers, Germany about half as many, the United States about 50. When Germany adopted unrestricted submarine warfare in February 1917, Great Britain felt an acute shortage of destroyers. Shipping losses soon forced diversion of destroyers from fleet duty to convoy protection and antisubmarine warfare.

When the United States entered the conflict it brought 67 destroyers in commission, with a few on the ways, and began a massive naval shipbuilding effort primarily in destroyers and smaller antisubmarine vessels and the host of merchant ships needed to sustain the vast overseas logistic flow into France and Britain. Most of the 247 United States destroyers laid down were completed after the Armistice; but these 35-knot ships of 1,200 tons, or more, a generation later played an important role in World War II. The U.S. and other Allied destroyers of 1917–18, equipped with hydrophones and depth charges, as well as guns and torpedoes, overcame the submarine threat and had a large share in the safe convoy of 2,000,000 American troops to Europe without loss of a single soldier.

Submarines. The last half of the 19th century brought the many technical advances that made possible undersea craft. Paradoxically, most of the development was carried out in France, Great Britain, and the U.S., though the craft were to be used primarily by these nations' adversary, Germany, in World War I.

Germany started building undersea craft later than other countries. In 1914 it had 38 in commission when war broke out—fewer than Britain, France, Russia, or the United States, counting those nearing completion. Despite the number in existence, since the submarine was unproven in war, its true potential was not generally appreciated.

The World War I submarine

The submarine of World War I (and indeed of World War II) was still essentially a surface ship that could dive for brief periods. It could maintain moderate submerged speed for only a few hours until its batteries became exhausted, forcing it to surface to recharge with the engines. At night, and at other times whenever possible, the submarine cruised on the surface, rigged for quick diving, depending on its low profile to escape detection before it sighted the foe—an advantage that the airplane negated. Submarines would often make the first part of approach on a target surfaced at high speed to get in position to attack. Thus systematic ship and aircraft patrol severely restricted the U-boat's capabilities in the patrolled area. Of the 372 submarines the Germans had or commissioned during the war, over half were lost (see SUBMARINE).

Mines. Like most modern naval weapons, mines have long ancestry, including British and United States efforts in the 17th and 18th centuries. In the 19th century, the Confederates employed mines (called torpedoes) with considerable success in the American Civil War. Their versions included contact mines and percussion or electrically detonated mines fired from shore when the ship was in the right position. This controlled type sank USS "Cairo" on the Yazoo River in 1862, the first destruction of a warship by a mine in combat.

When Robert Whitehead's self-propelled underwater device appeared, it took the name torpedo whereas the term mine reverted to the underwater weapon that lies and waits (or drifts with the current) for its target.

During the latter part of the 19th century the Herzhorn, an improved method of firing contact mines that began to make this one of the most effective weapons in war, appeared. The horn, or tube, protruding from the mine contains a glass tube of acid. When struck by a ship, the glass breaks and releases the acid to form the electrolyte of a small battery that generates enough of an electrical charge to fire a detonator, which in turn sets off the mine.

Early moored mines were laid with a preselected length of mooring cable to suspend them at proper depth below the surface. Later mines of this type were fitted with automatic devices that paid out the cable from a reel in the anchor (or sinker) to position the mine.

Mines were used in the Spanish-American War without result, but in the Russo-Japanese War both sides em-

ployed them effectively, destroying three battleships, five cruisers, and eight other warships. During World War I the belligerents laid nearly 250,000 mines. Submarines joined surface ships as minelayers. During the last year of the war, mines began to be employed in large numbers against submarines. Allied minefields sank 44 U-boats, more than were sunk by any other means.

Naval aviation. The airplane had just begun to go to sea on the eve of World War I. In Chesapeake Bay in November 1910, the scout cruiser USS "Birmingham" launched the first airplane ever to take off from a ship. Two months later in San Francisco Bay, January 18, 1911, a plane was landed on an improvised flight deck built over a turret of the armoured cruiser USS "Pennsylvania." The next year the United States Navy bought its first plane, as did the British. Within a few years, larger warships were able to launch planes underway—thus navies were acquiring far-seeing "eyes of the fleet" greatly surpassing the scout cruiser and its frigate ancestor.

The first carriers

In 1914 the British Admiralty converted Channel steamers to carry seaplanes and converted a tanker hull for use as a seaplane carrier for ten planes. "Ark Royal" served in the Dardanelles campaign and in the North Sea in 1918, flying her planes against Zeppelin bases.

The British modified a number of other ships to take planes, including fighters with wheel landing gear that could be launched but could not land on board. A passenger liner was completed as HMS "Argus," the world's first true flush-deck carrier that could launch and land planes on a flight deck extending from bow to stern. But although scores of aircraft went to sea in warships during the war, most naval planes of this period, both sea and land types, operated from shore bases, principally against submarines. Nevertheless, navies put a substantial effort into pioneering air warfare. The United States Navy developed a flying bomb, a pilotless, remote-controlled airplane, an ancestor of the guided missile, and giant seaplanes for distant oyerwater cruising. In 1919 one of them, NC-4, completed the world's first crossing of the Atlantic by plane, arriving in Lisbon via the Azores on May 27.

Naval planes employed bombs against ships and shore bases. The Royal Navy also added torpedoes starting early in the war, and, by 1915, had seaplanes specially built for torpedo attack. In August of that year, operating from a seaplane tender, they sank two Turkish auxiliaries in the Dardanelles.

To counter the airplane, significant changes were made in warship armament. Early in the century, navies had standardized on two gun sizes for battleships—the centreline-turret main battery providing concentrated massive fire on most bearings and a secondary broadside battery of smaller calibre guns with the typical naval characteristics of high initial velocity, low trajectory, and short time of flight to combat high-speed targets—*i.e.*, destroyers and torpedo boats. The appearance of aircraft, smaller and even faster, demanded rapid-fire, high-angle guns and new fire control. Capital ships again used many types of guns on board with a third battery in U.S. battleships of 3″/50 calibre anti-aircraft guns. These and 0.30-calibre machine guns were a beginning of intensive developments in air defense.

WORLD WAR II

Naval limitations treaties. The end of World War I found Great Britain, France, and Japan building or planning large, new capital ships and the United States continued a major construction program that would have given it the world's leading navy. To end what was turning into an arms race among former allies, the Washington naval treaty of 1922, and later London naval treaty of 1930, prescribed limits for navies of signatory powers (5:5:3 for the United States, Great Britain, and Japan). Battleships could not be armed with guns larger than 16 inches (Britain had designed the battle cruiser "Furious" with 18-inch guns during the war, and a race for new super guns was feared), could not exceed 35,000 tons standard displacement, and could only be replaced when 20 years old. Any man-of-war over 10,000 tons was designated a capital ship, thus fixing this as the top limit for cruisers.

Arms limitations

Change in warships continued to accelerate, affecting every field of naval warfare, including aircraft and missiles, communications, the revolutionary introduction of radar, anti-aircraft gunnery, propulsion plants and other elements of surface ships, submarines, torpedoes, and mines.

Battleships. Battleship construction, halted for several years, began again in the late 1930s as the disarmament treaties expired. All of the major navies laid down battleships of superior size and quality to the earlier generation. The largest were two Japanese vessels, "Musashi" and "Yamato." Displacing 70,000 tons, mounting 18.1-inch guns, with armour capable of withstanding projectiles of equal calibre, these two giants were never surpassed in battleship construction. Four turbine engines gave each a speed of 27 knots, with fuel capacity for a cruising radius of 7,200 miles (11,600 kilometres) at 16 knots. Improvement in engineering plants, including higher steam pressures, added markedly to the speed and radius of the new capital ships; the United States Iowa class had a speed of 33 knots. All of the new battleships bristled with anti-aircraft guns.

In World War II, the new U.S. battleships served primarily with fast, carrier, task forces, protecting carriers from surface attack and providing anti-aircraft protection. They were also frequently used for bombardment of shore targets and occasionally fought surface action in traditional manner, as at Guadalcanal in 1942. Late in the war, United States battleships bombarded the coast of Japan. The newest ships survived hits by torpedoes, gunfire, and Japanese suicide planes (kamikaze) and continued to operate until they could be sent to port for repair.

Great Britain, Germany, and Japan lost new battleships to air attack, in which torpedoes from carrier-based aircraft were the primary weapon, or to a combination of air and submarine or, in the case of "Bismarck," to surface-ship gunfire and torpedoes. Had any of these battleships been given reasonable air protection, it would have survived. Even old United States battleships went through campaigns from Tarawa to North Africa, Normandy, and Okinawa without loss, though a number were hit.

Importance of air protection

At Pearl Harbor (December 7, 1941) several old battleships suffered fearfully in the peacetime surprise attack. This was inevitable for any ship not in a condition of maximum gun and watertight-door-closure readiness, employed at times of possible enemy contact and relaxed at other times for the sake of rest and habitability. Yet all but two were repaired—some quickly—and served valuably in amphibious assaults in both oceans.

Naval aviation. After World War I several nations built aircraft carriers, a new type of capital ship that Great Britain had pioneered during the war by converting warships and merchantmen. HMS "Hermes," laid down January 1918, was the first ship begun as an aircraft carrier. After its launch in 1919 the Japanese laid down the second carrier, "Hosho," and pushed it to completion ahead of "Hermes." The fundamental techniques of takeoff and landing were worked out on the "Hosho" and on British and United States ships in the early 1920s. A characteristic feature, the "island," or bridge for navigation and command, was added, though the Japanese continued to operate a few flush-deck carriers for several years. Following the limitations set by the Washington naval treaty of 1922, Japan, the United States, Great Britain, and France all converted capital ships then on the stocks into large carriers, most of which saw service in World War II.

Seaplane tenders were employed for patrol-plane operations. Battleships and cruisers were outfitted with aircraft for scouting and spotting. Techniques for these functions as well as torpedo-attack, dive-bombing, and fighter operations were refined into doctrine.

Among carrier planes in various navies, the United States SBD was probably the best dive bomber flying at the time of Pearl Harbor. The United States Navy's F4F was a rugged and dependable fighter. The lighter, faster Japanese "Zero" could outmanoeuvre it; but, in combat,

American pilots had a much higher rate of success, in considerable part because of armour, self-sealing fuel tanks, and heavier gunfire. Improved types of all of the planes were developed during the war.

Dominant role of attack aircraft carriers

Carriers played a dominant role in every aspect of the war at sea. The Pacific conflict began with the Japanese carrier strike against Pearl Harbor and ended with American and British carriers operating with impunity against the Japanese homeland. In between, the Battle of the Coral Sea, May 1942, was the first in history in which opposing fleets fought without ever coming in sight of each other. A month later off Midway atoll, carriers again played the decisive role.

The Battle of Midway reinforced a conviction already clear, especially from British operations in the Mediterranean with and without air support, that control of the sea now also meant control of the air over the sea. For the rest of the war this axiom ruled with increasing force. In the autumn of 1942 the Solomon Islands campaign underlined the importance of both aircraft and submarines in fleet operations, emphasized that modern sea power is a trident of air, surface, and undersea forces.

The powerful United States task forces of the war's later stages included three to four carriers, six to seven battleships and cruisers, and 13 to 14 destroyers. Improved fighters, guided by the carriers' combat-information centres, radar plots, and fighter direction, provided the basic air defense. Supported by aircraft, destroyers gave antisubmarine protection and set up an outer screen of anti-aircraft fire. Battleships and cruisers ensured protection from surface foes and massive anti-aircraft support closer in to the carriers. The introduction of radar fire control and the proximity fuze, which exploded the projectile in the vicinity of the target, for the 5-inch anti-aircraft batteries, made it almost impossible for enemy planes to penetrate the defense.

Use of radar

The phenomenon of radar had been observed in the 1920s. By the late 1930s, prototype sets with huge antennas were operating. A plane or ship as well as land reflected the transmitted beams, bouncing an echo back to the antenna on the ship's mast and thence to the receiving-set screen. Reaching ranges up to 200 miles, radar became invaluable for observation and control of a carrier's own planes and for detection and tracking of hostile planes. It also became a principal factor in antisubmarine warfare (especially for aircraft), for surface-ship formation-keeping and manoeuvring, and for navigation. Radar added markedly to the effectiveness of gunfire, especially anti-aircraft because at any range it could give distance measurements accurate to within a few yards.

Navies needed carriers for duties that did not require the high speed and complex fighting capability of the first-line, capital-ship attack carrier. A simpler type sufficed for the demands of convoy escort, antisubmarine duties, and amphibious assault. Conversions from merchant-ship hulls initially provided the ships that carried out these duties, thus continuing the time-honoured practice of using merchantmen as warships. Later these escort carriers, as they came to be called, were laid down as such. Most ranged around 8,000 tons, though some displaced over 11,000 tons, similar to the light attack carriers. They had a speed of 18 or 19 knots, carried 28–30 aircraft, and mounted one or two 5-inch guns, plus numerous smaller anti-aircraft batteries.

Seaplane tenders also served with the fleets. The largest could transport seaplanes. Any cove or inlet not controlled by the enemy could serve as an advanced seaplane base immediately upon the arrival of the tender. Seaplanes carried out valuable search, reconnaissance, patrol, and surveillance duties. Naval land-based patrol planes served similar functions; as their ranges increased they began to supplant the slower seaplane but did not do so completely until long after World War II.

Submarine warfare. Most major nations built submarines between the wars. The Soviet Union commissioned a very large fleet. Germany began the war with only 57, of which 49 were available for service, whereas the Soviet Union had 235. Germany was also very slow in building up production, losing more submarines than it commissioned in the first 15 months of the war—thus giving Britain time to develop defenses. The new submarines were larger, faster, could dive deeper, and had longer endurance than their World War I predecessors, and carried more powerful torpedoes. The fall of the Low Countries and France in May 1940, providing long, open coastline for submarine and air bases close to British shipping routes, enabled the handful of U-boats to become very effective, but although Germany belatedly put tremendous effort into building submarines, massive anti-submarine measures defeated them.

Improved anti-submarine measures

In addition to large numbers of escort vessels, there were improved weapons. Sonar gear became more efficient. New explosives increased the destructive effect of depth charges. The British produced the hedgehog, a multiple, mortar-like device, mounted forward, that threw a pattern of 24 contact depth charges ahead of the ship while sonar operators could still detect the target on their equipment. This eliminated the blank period unavoidable in a depth-charge attack astern. Patrol aircraft and radar also contributed; the range of patrol planes steadily expanded to permit covering more and more of the convoy ocean routes where submarines might surface to recharge batteries. The extension of range together with the installation of radar on ships and planes made possible night detection and often surprise of the surfaced submarine.

The escort carriers provided air search and attack close to the convoy, forcing U-boats to remain submerged and making it harder for them to get into position for attack. Ultimately, when patrol planes gained endurance to accompany a convoy over much of its route, the escort carriers operated independently in areas of known submarine concentration, making all of the parts of the ocean near shipping routes unsafe for submarines.

Late in the war, when surfacing even at night to recharge batteries had become very hazardous, the Germans adopted the snorkel, a Dutch invention. This air-intake-and-exhaust funnel permitted running the engines while submerged, to recharge batteries without surfacing, and presented a very small radar target.

Both the United States and Japanese navies made extensive use of submarines in attack roles in the Pacific, and, as the war progressed, United States submarines played a key role in the air-naval blockade of the Japanese home islands. They sank many warships and were responsible for 55 percent of Japan's critical merchant ship losses. There were few important innovations; the most dramatic, perhaps, being the Japanese employment of small, two-man submarines, launched from a mother ship, designed to penetrate enemy harbours. These achieved little success, however.

Mines. Both Great Britain and Germany devised magnetic mines in World War I. Germany continued development, and early in the Battle of Britain small minecraft, submarines, and airplanes laid magnetic bottom mines, detonated by changes in the magnetic field caused by the passage of the iron hull of a ship. The mines caused serious loss and dislocation until one was recovered and suitable minesweeping gear devised. A supplementary countermeasure was degaussing, passing an electrical current through a cable strung horizontally around the ship, thus setting up a magnetic field to counter the mine or the magnetic torpedo-firing mechanism.

In the following years, navies brought out a wide variety of firing mechanisms for mines that included a combination of various influence types, such as the acoustic and, near the end, the almost unsweepable pressure type, actuated by a change in pressure caused by a ship's passage.

Surface vessels, aircraft, and submarines on both sides laid mines in every theatre. British air-laid mines caused many losses and severely hampered Axis operations from the Baltic Sea to the Mediterranean. The Allies lost numerous warships and 1.4 million tons of merchant shipping to mines.

In the Pacific, United States carrier planes, submarines, and surface vessels laid mines, but the largest effort was by the United States Air Force, laying naval mines. In the spring and summer of 1945, B-29s, operating from the

Mariana Islands, laid over 12,000 influence-type mines in Japan's home waters, sinking about half-million tons of Japan's merchant marine.

Cruisers and destroyers. Powerful new warships of these types appeared in all of the major navies in the 1930s. Two cruiser classifications came into common use: "heavy," armed with 8-inch guns, and "light," with 6-inch guns. Both mounted 5-inch double purpose batteries, and in the war added 40 millimetre and 20 millimetre. The United States also built anti-aircraft cruisers with 5-inch guns as the main battery. Several other nations also built anti-aircraft cruisers. Cased ammunition and automatic loading systems increased the rate of fire of all of the naval anti-aircraft. Radar, developed for gun directors, greatly improved accuracy, making possible automatic tracking of targets and precise firing in fog and darkness. Another anti-aircraft improvement was the influence or proximity fuze, a tiny electronic device that detonated the projectile at a predetermined distance from the target to produce maximum damage.

New destroyer types

Because the disarmament treaties did not limit them, most nations built a series of new destroyers of increasing capabilities. In 1939 the British Navy had over 100 of modern construction. These and older destroyers satisfied only a beginning of Great Britain's needs, despite the small number of German submarines. Beginning in 1941 the British produced convoy-escort ships called sloops and corvettes, smaller, slower, and less complex than destroyers. The United States commissioned over 400 fast destroyers between 1939 and 1945, and, starting in 1942, turned out a stream of nearly twice that many smaller and slower destroyer escorts that were effective both for convoy escort and in hunter–killer task groups.

The Japanese also improved their destroyers, notably in the areas of night optics and torpedoes. They inflicted severe losses on the United States and Allies in cruisers and to the United States in destroyers. The large United States building program soon changed the balance in destroyers as in other ships.

Service force and logistics. Logistic ships, indispensable for World War II fleet operations, included tenders with spare parts and repair shops to act as mother ships for destroyers, submarines, tankers, supply ships, ammunition ships, netlayer-tenders, and various other types. Minesweepers were indispensable, both for attack and defense.

In operational handling of service and logistics ships, the United States Navy pioneered two developments widely copied since: first, the establishment of floating advanced bases, capable of taking care of the whole fleet's needs and including floating dry docks, floating cranes, repair barges and ships, barges for degaussing (demagnetizing), and storage and issue of ammunition and supplies; and second, underway replenishment, which made it possible for task forces to remain at sea for months at a time without returning to port. Fuel for ships and planes far outweighs in tonnage any other logistic requirement of warships, followed, in combat operations, by munitions, food, and other supplies.

Amphibians. Although the failure of the Dardanelles campaign in World War I had somewhat discredited amphibious operations, both the United States and Japanese navies practiced such operations between the two wars. The Japanese opened their offensive in 1941–42 with successful amphibious assaults against Wake Island, the Philippines, Indonesia, and several other points. After Midway, the United States launched its first amphibious assault, against Guadalcanal, in August 1942, an operation that involved several new types of landing craft as well as all classes of ship, from battleship to converted merchantman. A long series of amphibious assaults followed in both Pacific and European waters, with increasing refinements of landing and support craft. The final amphibious operation of the war, against Okinawa in 1945, involved about 1,500 vessels. An advance force of battleships, destroyers, minesweepers, landing craft, and other auxiliaries entered the area a week before the main assault, sweeping mines, clearing obstructions, and establishing a repair–logistic anchorage in a nearby island group, simultaneously carrying out an intensive bombardment of the landing area. In the assault, large merchantmen types, converted or built for assault, participated. They carried numbers of landing craft with bow ramps, some for troops, some for vehicles and troops. Some landing craft were armed with guns, mortars, or rockets. Amphibious tractors and trucks also waded ashore. The highly complex operation, with its great variety of ships and craft effectively coordinated, significantly illustrated the growing ability of sea-based power to outweigh that ashore.

Amphibious assaults

Warships in the nuclear age and the future

The generation since World War II has seen the continuation of swift change in warships that has characterized the past century and a half. Among developments that may be termed epochal are nuclear propulsion, ballistic missiles with atomic warheads, guided missiles, and space satellites for naval operations. Many other advances have taken place; carrier jet planes fly at two to three times the speed of sound, and submarines extend their operations to thousands of feet below the surface.

SUBMARINES

Nuclear power in submarines. The first government support of atomic energy in the United States was the assignment of small research funds by the navy in 1939. Interested because of the promise for propulsion, the navy thereafter made important progress toward solving the problem of controlled nuclear fission until later when all of the effort was concentrated toward producing the atomic bomb.

After the war, the Navy was able to get funds for research on nuclear propulsion. Capt. Hyman George Rickover was assigned to head the project. In less than a decade a revolution, perhaps even greater than that from sail to steam, was launched with the USS "Nautilus" (January 21, 1954).

Steam had freed ships from the vagaries of wind and tide but at the same time had imposed the limitations of large fuel consumption at high speed and the requirement for frequent refueling. Overnight, atomic energy freed ships from both limitations. Nuclear power plants can drive ships at maximum speed virtually continuously.

Advantages of nuclear power

Another advantage of nuclear power has special meaning to submarine operations. Until its advent, submarines were essentially surface ships that could submerge for relatively short periods. Atomic energy, which does not require oxygen from the air for combustion, at last made possible the true submarine. Hence submarines could be designed with hulls shaped for high underwater speed, rather than on the surface-ship lines that had hitherto prevailed. Naval constructors developed and tested a streamlined hull that provided maximum speed, efficiency, and manoeuvrability submerged. The resulting experimental "Albacore" marked a notable step forward in submarine design. Highly manoeuvrable in any direction, almost like an airplane, and swift under water, even with battery propulsion, her performance gave promise of the submarine of the future that would result from joining this hull design to atomic power.

The nuclear power plant in "Nautilus" surpassed the hopes of the most optimistic. In her first two years, this revolutionary submarine steamed more than 62,000 miles, setting new speed and submerged-endurance records. Her reactor cores were replaced early, after two years. Cores in the early 1970s had a life of a decade or more and drove the boat submerged at speeds considerably greater than the fastest submarine surface speed in World War II. In 1958, "Nautilus" voyaged over the top of the world, under the polar ice cap. In 1960, one of her successors cruised submerged on a 36,000-mile trek around the world.

The reactor of United States submarines lies to the rear of the control room. Water shielding and a thick layer of lead and polyethylene protect the crew from radiation. The reactor is on the lower level of the reactor compartment and, when in operation, is sealed off from the upper level where the crew functions. Many other safety devices

are part of the system. Pressurized water both cools the reactor and carries away the fission-produced heat through the primary system (or loop) to a heat exchanger. The water under pressure does not become steam, but, as it passes through the steam-generating tubes of the heat exchanger, it transmits the high heat to a secondary loop or steam-producing system; the pressurized water then circulates back through the reactor in a constant cycle. In the secondary loop (which is sealed off from the radioactive primary coolant water) the water boils and expands into steam and thence to the turbogenerators to propel the submarine. This steam then goes to the condensers that convert it to water to repeat the cycle.

New submarine designs

In 1959 the United States commissioned a radical new type of fleet submarine that combined nuclear power with a streamlined underwater hull design that had no protuberances except a slender "sail" (containing bridge, periscope tubes, etc.) with diving planes mounted on it. It was the world's fastest and most manoeuvrable submarine, vastly increasing the submarine's effectiveness and at the same time the difficulties of antisubmarine warfare. The United States next brought out attack submarines, boats designed primarily for antisubmarine warfare. Able to dive to unprecedented depths, these are exceedingly swift and manoeuvrable. They excell in stealth, concealment, and surprise. The boats have advanced sonar gear, four torpedo tubes approximately amidships, and the unique Subroc (submarine rocket) attack system—*i.e.*, an antisubmarine missile fired from torpedo tubes; after leaving the tube, the missile's solid-propellant motor ignites; directed thrust puts it on course; it then emerges from the water and flies as a rocket; at a preselected point, the warhead separates and dives into the water and continues on course to its target. This "flying torpedo" has a range of probably more than 20 miles (32 kilometres).

The United States has concentrated first on atomic power plants for submarines, as did other nations. Despite espionage, the Soviet Union lagged at first, experiencing technical problems; once these had been overcome, it made rapid progress. In the 1960s the Soviet Union constructed large, modern, automated building yards to produce nuclear-powered submarines—one huge yard alone has a capacity to build nuclear boats that is greater than all of the yards in the United States combined. The highest national priority was given to producing ever new and better types, mounting increasingly sophisticated weapons systems. The shipyards can build at least 20 nuclear submarines a year.

In 1971 the United States had almost 100 nuclear submarines of all types. The Soviet Union had about the same number but was building at a rate several times that of the United States, which launched only three nuclear boats in 1970. The Soviets were certain to gain marked superiority in numbers by 1974, perhaps by 1973. Besides the rapidly growing nuclear fleet, the Soviet Navy continues to introduce new designs for diesel-powered boats, with particular emphasis on guided and ballistic missile types.

Ballistic and guided missile submarines. *The United States.* The United States Navy began to fit guided missiles to submarines in the 1940s. USS "Cusk" fired a historic first guided missile from her deck on February 12, 1947. Several other conversions followed her. In 1959 the United States launched the nuclear-powered "Halibut" as the world's first submarine designed from the keel up to fire guided missiles.

While working with guided missiles, the United States Navy began the development of an even more significant naval weapon, the ballistic missile, the production of which represented an outstanding technological achievement. The task force overcame a series of apparent impossibilities to create a new type of solid-propellant ballistic missile and mate it with the nuclear submarine. Within four years, on December 30, 1959, the complex and powerful fleet-ballistic-missile submarine USS "George Washington" was commissioned, constituting a weapons system generally said to be without parallel for power, accuracy, concealment, range, and effectiveness.

On July 20, 1960, the submerged "George Washington" launched her first Polaris missile; it hurtled 1,000 miles (1,850 kilometres) downrange, precisely to target.

Polaris and Poseidon guided missiles

Subsequent versions of the missile extended the range in steps to 2,500 nautical miles (one nautical mile equals 1.15 miles or 1.85 kilometres). In 1970 the more advanced Poseidon, with similar range but twice as powerful and even more accurate, was perfected. It can carry either a single, huge warhead or about a dozen independently targeted ones.

USS "James Madison," the first to be altered to take the 30-ton Poseidon, has a submerged displacement of 8,250 tons (before conversion). An inertial navigation system positions the submarine accurately beneath the surface at all times. The missile itself carries a compact, self-contained, inertial guidance that takes over as it bursts out of the sea and steers it to target.

All of these boats have two crews, to alternate on the continuous patrols. Maintaining speeds of over 25 knots whenever and as long as desired, with no need to surface for air, navigation, or communications, they return to the surface only on entering port.

The Soviet Union. The Soviet Union began to adopt the Polaris submarine concept with conversions and newly constructed diesel boats, mounting two to three launching tubes, firing relatively short-range missiles. The first nuclear, fleet-ballistic-missile type with three launching tubes appeared in the 1960s. Missile ranges, beginning with about 400 miles (650 kilometres), progressively increased. By the end of the decade the Soviet Navy began commissioning what has been termed, in the North Atlantic Treaty Organization (NATO), the Yankee-type submarine. It appears to be a copy of the Polaris submarine, though its missile range is apparently on the order of 1,500 miles. A longer range missile is scheduled for use in the early 1970s.

The Soviet Union has developed several classes of boats designed or converted to fire cruise missiles. These are low-flying, self-propelled guided missiles with homing heads, effective within visual or radar range or, with midflight guidance as by an airplane, able to hit targets perhaps 400 miles from the boat. The missiles are fast, have variable flight profiles, including low-altitude terminal flight, and can deliver either a conventional or nuclear homing warhead. They carry sophisticated electronics with excellent countermeasure resistance. In the early 1970s the Soviet Navy had 70 or more submarines equipped with these missiles; about half are nuclear-powered and are capable of firing while submerged.

The Soviet Union's large fleet of conventional diesel submarines can carry torpedoes or mines either with conventional or nuclear explosives.

Other countries. France and Great Britain have also developed nuclear ballistic submarines in small numbers, and Britain has three nuclear attack submarines in commission, with others under construction. Communist China is believed to have the third largest submarine fleet, all diesel powered, a few vessels mounting ballistic missiles.

NAVAL AVIATION

Attack carriers. After World War II, the rapid development of jet aircraft required longer and stronger carrier decks. The angled deck and the steam catapult were developed by the British and quickly adopted by the United States to handle increasingly larger and faster planes.

Of the new carriers, the most powerful was "Enterprise," which displaced 85,600 tons with an overall length of 1,101 feet (336 metres) and extreme width of flight deck of 252 feet (77 metres). She carried over 70 of the new, large planes and her powerful reactors thrust her through the water at speeds much above 30 knots. Her greater manoeuvrability and endurance at high speed, without delays for refueling (except for planes), gave her outstanding advantages over other carriers.

The "Enterprise"

The modern carrier task force roughly follows the pattern of World War II, with one to three carriers accompanied by cruiser and destroyer types as available. Ships

and equipment are far more sophisticated. Topsides bristle with electronic gear, radars, communication antennas, and missile guidance and countermeasure equipment. Anti-aircraft armament consists of guided missiles, supplemented by a few rapid-fire, medium-calibre guns. The numerous small-calibre mounts of World War II have disappeared; future air attack is anticipated as coming from long-range missiles.

Several navies today employ antisubmarine carriers. Most are World War II types built by Great Britain or the United States, though France and the United Kingdom completed a handful during and after the Korean War. In general, all of these carry a mixture of helicopters and fixed-wing planes. Both carriers and aircraft have extensive electronic gear. Weapons include depth charges and homing torpedoes.

An important supplement may be the helicopter mated to destroyer types. Great Britain, Canada, and the United States participated with other NATO allies in development and test of suitable helicopters and equipment to handle and house helicopters on the rapidly pitching and rolling decks of smaller ships. Canada, for example, has solved most of the problems met even in heavy seas.

Amphibious carriers. As successful helicopters evolved, the U.S. Marines modified amphibious assault techniques to include vertical envelopment, landing by air to the rear of hostile beach defenses. The United States Navy converted some World War II carriers into helicopter carriers for amphibious assault, and their success led to the construction of "Iwo Jima," commissioned in 1961 as the first ship designed and constructed for helicopters. She and six sister ships can each carry a marine battalion landing team, with guns, vehicles, and equipment, and a helicopter squadron to lift them to the beach. As vertical-and-short-takeoff-and-landing planes go into service, this type may also take on functions of the escort carriers. Displacing 18,000 tons, full load, this type transports about 2,000 troops and helicopters to take them to the beach.

Soviet helicopter carriers

Carriers of the Soviet Union. The first carrier built for the Soviet Navy was a helicopter carrier; in 1967 "Moskva" was commissioned, followed by a sister ship, "Leningrad." "Moskva" and "Leningrad" combine a carrier deck for helicopters (situated aft) with the guided missile armament of a cruiser forward. At 18,000 to 19,000 tons, full load, they are suitable for antisubmarine or amphibious operations. Their appearance coincided with intensive work in the Soviet Union on vertical-and-short-takeoff-and-landing planes. The Soviet Union now flies at least three types of short-takeoff fighters with maximum speeds ranging from 2 to 2.8 times the speed of sound. Experimental models of vertical-takeoff planes are also being tested, in subsonic versions that represent important progress toward supersonic successors. A carrier, probably to handle these, was under construction in the mid 1970s.

Naval aircraft. Navies continue to employ aircraft for search, reconnaissance, patrol (especially against submarines), early warning (especially against air attack), interceptors (fighters), attack against ship and shore, amphibious lift and tactical air control, electronic countermeasures, antisubmarine warfare, and other duties including training and transport. The newest reconnaissance planes combine several means of detection, including low-light-level TV, sonar, radar, infrared, and magnetic detection devices. Detection of submarines, solution of the fire-control problem, and release of the missile comprise an automatic computer process (see AIRCRAFT, MILITARY).

Since World War II the helicopter has progressed from a small, light aircraft with feeble lift into a powerful craft that has wide use in a broad spectrum of naval as well as other operations. The small helicopter, with more powerful lift, is of course still in greatest demand, especially for antisubmarine duties.

CRUISERS AND SMALLER GUN–MISSILE WARSHIPS

Cruisers. Construction of this class with guns as its main armament appears to have ended. Except for the nuclear-powered, missile-armed "Long Beach," the United States has only a handful of cruisers in commission, laid down in World War II and converted to carry guided missiles. In the 1950s the Soviet Union built 14 gun-armed light cruisers (19,000 tons displacement) but thereafter changed to smaller types, mounting antiship or anti-aircraft missiles for the main battery and also fitted with strong antisubmarine capability. The largest of these are the 6,000-ton Kynda class, carrying two, surface-to-surface, quadruple, Shaddock missile mounts and the newer 7,000-ton Krestas, with two twin Shaddock launchers and considerably increased missile capability. Navies in the 1970s build surface warships not so much to fight one another as to combat submarines, air-craft, and guided missiles.

First nuclear-powered surface warship

The United States Navy's "Long Beach" was the first surface warship in the world to steam under atomic energy and remains the only cruiser so propelled. She can race through the water indefinitely at speeds probably exceeding 35 knots. Her armament consists of guided missiles, two-5 inch guns, and antisubmarine weapons.

Superdestroyers. While gun cruisers pass from the scene, destroyers have grown larger until some are, in fact, small cruisers. The United States calls her largest types frigates, a term most other navies tend to reserve for smaller escort or antisubmarine types.

The United States Belknap class, laid down in the early 1960s and the latest United States Navy operational nonnuclear type, displaces nearly 8,000 tons full load. Armament includes five- and three-inch guns and a twin missile launcher for anti-aircraft and antisubmarine missiles. Development of the antisubmarine missile concept as in an improved United States version and in the Australian Ikara missile, provides for sending target information from the firing ship's sonar or helicopter sonar into the automatic fire-control data-computing system that controls the missile throughout its flight to keep it directed on the target regardless of manoeuvres.

The United States has also built the only destroyers with nuclear power. The first, "Bainbridge," of 8,500 tons displacement, was commissioned in 1962. "Truxtun" was commissioned in 1967 and in the early 1970s two more were under construction.

Destroyers. The large frigates that merge the destroyer type with the small cruiser merely continue a process underway from the first torpedo-boat destroyer. Tasks multiplied for this high-speed, versatile vessel, whose appearance in the fleet coincided with the birth and swift growth of submarines and aircraft, and combatting these hazards became principal duties. The phenomenal growth in effectiveness of these two foes through nuclear power for submarines and jet engines for aircraft has coincided with a similar increase in the destroyer's powers to combat them.

Instead of many guns, destroyers bristle with an array of sensors and are packed with electronic gear for swift detection, identification, and computation of firing data. Magazines hold supersonic, homing, guided missiles—as well as projectiles for the minimum number of guns that must remain in the armament. The complex warship carrying all of this must also have high speed, excellent sea-keeping ability, and long endurance. Lightweight materials such as fibre glass and aluminum and the use of solid-state devices and other miniaturization steps have compensated for only part of the additions. The result is that the size of destroyers had to increase.

The newest in most fleets now range in displacement up to 5,000 tons. Soviet destroyers built in the 1960s displace 4,000 to 4,600 tons, as do most of those of the United States. Destroyers of France and The Netherlands on the ways displace about 1,000 tons more. The United States has begun to build the Spruance class, displacing more than 7,000 tons, driven by gas-turbine engines and carrying two helicopters.

United States terminology, distinguishing destroyer leaders (frigates) from conventional destroyers, largely implies only more command functions. Otherwise, the two have essentially the same armament, speed, and employment in fleet-escort duties. The United Kingdom and many other nations call both large types destroyers and

Growth of destroyer escorts

assign frigate classification to the slower, usually smaller, and lighter gunned ocean escort, sometimes called the junior destroyer. Destroyer escorts have also grown and have acquired characteristics in many cases close to those of destroyers. In the 1950s a number of nations built escort types of under 2,000 tons displacement. Yet the rapid advance in submarine performance, especially under nuclear propulsion, has caused these types to experience marked growth. This has been necessary to accommodate helicopters, the more complex sensors (radar and sonar; hull-mounted and variable-depth), weapons, and associated equipment more complex than ever before. At the end of the 1960s and in the 1970s, many displaced 4,000 tons or more. Canada, notably successful in building destroyer escorts of just under 3,000 tons, particularly in helicopter operations, now builds in the 4,000-ton range to accommodate advanced weapon systems. Great Britain has under construction gas-turbine patrol frigates estimated to displace under 3,000 tons and to run at a top speed of 40 knots. If successful in handling the most effective antisubmarine weapon systems, this type could bring marked improvement to surface-ship antisubmarine operations.

Other types. Corvettes, fast patrol ships, and other small types serve in various fleets for coastal and limited-radius deep-sea operations. These vessels may range in size from France's new corvette types of about 1,300 tons, and the Soviet Union's 1,200-ton Mirkas, to Japan's 500-ton submarine chasers. Several nations have also built small, fast, torpedo, gun, or missile boats, most of which do not have antisubmarine capability. Great Britain has two 114-ton fast patrol boats with over 50 knots maximum speed. The Soviet Union has 125 or more 35 to 40 knot surface-to-surface-missile boats displacing 100 or 200 tons according to class. One of these on loan to Egypt sank the Israeli destroyer "Elath" with Styx missiles at a range of 13–14 miles in 1967.

The Asheville 240-ton class of gunboats was commissioned in the late 1960s, with diesel and gas-turbine propulsion that gives top speed of over 40 knots. The United States also has two small 60-ton hydrofoil gunboats and two larger experimental vessels (one of 310 tons) in the 40–50 knot speed range, which may be forerunners of fast escort ships of the future.

SEABORNE MISSILES

Significant missile developments in the last generation fall into six categories: submarine-to-ship or shore target; antisubmarine; air-to-air; air-to-ship or shore; ship anti-aircraft; and surface-to-surface (ship-against-ship or shore).

Submarine-to-ship or shore target. The Polaris–Poseidon ballistic missiles and similar types brought revolutionary new power to sea forces.

Submarines, of course, continue to fire the ancestor of the guided-missile family, the torpedo. Submarines in most navies now carry acoustic-homing missiles, with conventional or nuclear warheads and with influence detonation at the target. This type will be employed particularly by nuclear-propelled attack submarines in hunting down other boats. With special modification, submarines can fire cruise guided missiles against surface targets in visual or radar range of the firing boat or of a midflight guidance assistant.

Soviet cruise missile

The navy of the Soviet Union pressed ahead with employment of the cruise missile. In the early 1970s it had 70 to 75 nuclear and conventional submarines with this type of missile. Called Shaddock by NATO, the missile can deliver either a conventional or nuclear warhead and has variable flight profiles, including low-altitude terminal flight, which, along with good countermeasure equipment, makes it a difficult missile to combat.

Antisubmarine. The United States did develop a submarine air-flight guided missile against its primary naval rival, the large Soviet submarine fleet. Subroc, previously described, is unique among guided missiles in that it starts underwater, flies through the air as a rocket, then dives into the water to become again a submerged missile as its inertial-guidance and homing equipment direct it.

Numerous surface-ship and air-launched antisubmarine missiles exist. These range from improved versions of the depth-charge and contact-hedgehog type of World War II to air-dropped nuclear depth bombs and acoustic-homing torpedoes launched by plane, ship, or submarine. The United States, Australia, and France, respectively, have the Asroc (antisubmarine rocket), Ikara, and Malafon that, with solid-propellant rockets, hurl an acoustic-homing torpedo or depth charge several miles through the air at very high speed toward the target. Sonar and other data feed into the fire-control computer that positions the launcher correctly in train and elevation. In some systems now and eventually in all, the missile track is changed in flight by radio–radar tracking and guidance to defeat target manoeuvres. Hence it is certain to be near the hostile submarine when it enters the water (slowed by parachute) and begins to home acoustically. To prevent hazards to its own forces, homing life terminates after a set length of time.

Air-to-air missile. As in other missile areas, the principal developers of naval air-to-air missiles have been the United States, the United Kingdom, France, and the Soviet Union. The United States Navy Sidewinder is probably the simplest and least expensive of guided missiles. The early 1970s version was a winged five-inch rocket nearly ten feet long with infrared homing (or alternately semi-active radar in which the firing plane's radar illuminates the target and the missile's receiver homes on the echo). It ranged over 3,000 yards at more than two and a half times the speed of sound. The much more complex and expensive Sparrow is a 12-foot long, eight-inch diameter, semi-active, radar-homing rocket propelling a 60-pound warhead for about seven miles, at somewhat greater speed than Sidewinder's. The British HSD Red Top (with infrared homing) and French Mafra (infrared to semi-active radar homer) have similar performance. In the early 1970s the United States had in the final development stages the 35–50-mile, radar-guided, very fast Phoenix missile to arm a new fighter plane.

The U.S. Sidewinder

Air-to-surface missiles. Of the several nations producing missiles for this function, the United States has the widest range, and most of its effective ones are Navy developed. Typical are Walleye, an unpowered, 1,100-pound, glide bomb with TV homing on target; Shrike, ranging ten miles or more and homing on radar emissions of target; Bullpup (improved version) carrying nuclear or conventional warhead, 50 percent heavier than Walleye, of greater range than Shrike, and radio-controlled to target by the pilot of the launching plane, with visual flares to aid in guidance. The United States Navy also has a later radar-emission-homing missile, Standard Missile (adapted from the anti-aircraft version), perhaps double the range of Shrike, with a more powerful warhead and improved homing features. Soon going into service in carrier-attack aircraft is TV-guided Condor, with a stand-off range of over 35 miles. France's small, short-range, wire-guided missiles AS.11 and AS.12 have wide use in maritime planes of NATO and other nations. Martel, a medium-size missile of over 30-mile range (in antiradar and TV-guidance versions) has been developed jointly by France and Great Britain. West Germany's Kormoran, of similar size and range, has inertial guidance with terminal-radar or infrared homing.

The Soviet Union has emphasized the production of large, long-range missiles—which, of course, are the most effective for employment against important warships or any ship without accompanying air protection. The Kipper and Kitchen (NATO names) missiles are over 30 feet long, with turbojet power plants, and are probably radio-controlled. These Soviet-produced missiles undoubtedly have active or semi-active radar homers (or infrared, or both) and extremely powerful conventional or nuclear warheads.

Ship anti-aircraft and antimissile. The United States Navy produced an ancestor of guided missiles in a robot plane in World War I, later developed into the drone target plane for ship-anti-aircraft-firing practice. Radar gave instantaneous, precise measurements, thus making it possible to guide the drone to intercept a target. The

navy went ahead on this concept in World War II, producing television-guided drones. The next step toward a workable guided missile was a suitable rocket or projectile-like vehicle to fly the explosive to the target. By 1947 naval laboratories and research contracts had produced the basic elements of the nation's first true guided missile: first, the "flying stovepipe" or ramjet rocket power; second, radar-beam-riding guidance; third, homing equipment for the final, precision approach on the target; and fourth, influence detonation.

From these and other achievements evolved guided missiles for every aspect of naval warfare. In the early 1950s, the anti-aircraft missile, Terrier, with its complex launcher-handling system, easily developed from naval experience with gun turrets, became the lead guided missile to become operational. The current generation of Terrier, with dual boosters supplementing the solid-propellant sustainer, flies about 20 miles at two and a half times the speed of sound. It is effective against low- as well as high-flying aircraft. Cousins of the Terrier, Tartar and Talos, also still fly in improved versions. Because planes speed up and fire faster missiles at longer ranges, navies continue to develop missiles. The United States Standard Missile, a semi-active homing missile, has a 30-mile (48-kilometre) range. An interim, short-range, point-defense, antimissile system, the Sea Sparrow (an adaptation of air-to-air Sparrow), also operates in a number of United States warships. Another new missile, Aegis (Shield), began operations in the early 1970s with the particular concept of combatting cruise missiles (as well as the vehicle launching them), whether fired from plane, ship, or submarine. It detects targets under most difficult weather and countermeasure conditions with a scanning radar that can search through 360° almost instantly, along with very rapid computing and fire-control equipment.

Aegis designed to combat cruise missiles

France has a medium-range missile and a short-range one for point defense. Great Britain's point-defense short-range Seacat, contact and influence-fuzed and usually mounted in four-round launchers, has wide use in British-Commonwealth and other navies. An improved missile, Sea Wolf, that can counter small, fast missiles as well as the firing vessel or plane, is designed to replace it. The Seaslug, now in its second version, gives British destroyers excellent capability against aircraft at about the same range as Terrier. Test firings have shown high effectiveness at altitudes up to 50,000 feet. As in the United States, advances in technology and in potency of attacker have brought an improved medium-range missile, the Sea Dart. Developed for new destroyers to meet the missile threat of the coming decade, it has improved anti-aircraft performance at very high and very low levels and is also an antiship weapon.

The Soviet Union's surface-to-air missiles, which proved effective in hostilities in Vietnam and in Egypt, operate from warships under the name Goa, a two-stage, solid-propellant, guided missile. Two versions have been developed for use ashore, one to combat planes flying at normal to high altitudes and a later model that is very effective against low-flying planes. Both models undoubtedly have been installed aboard ship.

Surface-to-surface missiles. In this type of guided missile, the Soviet Navy leads all of the others. Small ships can accommodate missiles with massive warheads because rocket firing does not create recoil. A rocket is inherently inaccurate, compared with a projectile, but the advances in guidance and homing after World War II gave the guided missile a theoretically much higher chance of hitting than the projectile, unless shot down or diverted by electronic countermeasures. The missile must perform better than a projectile to be of value, for a ship can carry only a few large ones.

Following earlier models, cruise missiles now on Soviet ships consist of the short-range Styx (about 20 miles) and the long-range Shaddock (perhaps several hundred miles with midflight guidance). The Styx is 20 feet (6 metres) long, Shaddock at least twice as large, with two jettisonable booster rockets. The 100-ton Komar patrol boats carry two Styx missiles, the 200-ton Osas carry four. Destroyers and missile cruisers carry the larger Shaddock. Ships armed with these missiles are primarily effective against ships (or coastal areas) without air protection.

Several other nations have surface-to-surface missiles, mostly very short range, though not with the emphasis of the Soviet Union. France has two types of small missiles developed from its air-to-surface AS.11 and AS.12 types. The larger have a range of about three and a half miles (five and a half kilometres) and the destructive power of a six-inch projectile. Italy has two Sea Killer models, the longer range effective to 11–12 miles. The foregoing, of course, are primarily useful as armament for small vessels. The two countries were jointly developing a medium-to-long-range antiship missile, Otomat, that it was hoped might be operational in 1973.

Sweden has a land- or destroyer-launched missile of over 100-mile range, weighing about one ton on launch. The U.S. is developing the Harpoon, a long-range, homing, antishipping missile for launch by ship or aircraft.

Several nations have new lightweight rapid firing guns. Their high rate of fire of simple and relatively inexpensive projectiles may make them competitive with the guided missile as missile killer.

AMPHIBIANS, MINECRAFT, AND AUXILIARIES

Amphibians. The United States has set the pace in amphibious developments since World War II. The Soviet Union has made much progress in amphibious build-up, including its new helicopter carriers and improved versions of old British–American landing vessels such as her 15-knot Alligator LST (tank landing ship). The United States, however, has brought out a whole family of new or vastly improved types—generally faster, larger, and far more effective. Examples are:

The World War II LST, of which the United States built 1,041, displaced about 4,000 tons full load and transported about 150 troops with equipment at 10–11 knots. The current, fourth-generation Newport class displaces over 8,000 tons, transports amphibious craft, tanks, and other combat vehicles, along with up to 500 men, to a hostile shore at over 20 knots. Instead of simply beaching, like her predecessor, she has an extendable ramp supported by huge projecting derrick extensions on each side of the bow. As the ship grounds, the ramp shoots forward hydraulically 112 feet (34 metres). While vehicles and troops land over the ramp, amphibious tractors in the tank deck move out the stern gates.

Capabilities of newest amphibious vessels

Besides the helicopter assault carriers earlier described, becoming operational in the middle 1970s is another completely new, giant type of amphibious assault ship displacing 40,000 tons and combining the functions of several types of landing ships. By carrying a balanced load of troops, combat vehicles, and cargo for a full battalion landing team, this vessel maintains their tactical integrity together. With a large dock well, under a flight deck extending the full length of the ship, it can land the team by helicopter and landing craft. Vertical-and-short-takeoff-and-landing planes will in time give it much of the necessary capability of close air support that World War II escort carriers provided.

Two other important ships are notable. The LSD (dock landing ship) that proved so useful in World War II has been improved in speed and troop-carrying capacity.

The LPD (amphibious transport dock) was developed from the LSD but provides more versatility. "Nashville," representative of the latest, displaces 17,000 tons and cruises at better than 20 knots.

Riverine warfare has close affinity to conventional amphibious operations. Since VE Day the Soviet Union has built numerous small ships and craft to maintain strong river and coastal forces. The powerful Soviet Danube River flotilla alone has about 100 craft including 120-ton armoured gunboats, large landing craft, fast artillery boats, assault boats, and hydrofoils. Missile patrol boats and smaller vessels of the deep-sea fleet can also participate in river operations.

As a result of the Vietnam War, the United States developed several new types of river craft, including 50-foot Swifts, adapted from oil-drilling support craft; river patrol boats developed from fibre glass yacht-design

hulls, with Styrofoam flotation gear to keep them afloat even when shot-riddled; monitors converted from medium landing craft, heavily armoured and armed with a 105-millimetre (4.1-inch) howitzer, 81-millimetre (three-inch) mortar, or 40-millimetre (1.5-inch) machine gun in the turret, along with machine guns; and assault-support boats, multipurpose craft, well armoured, heavily gunned, and capable of 15-knot speed, about twice that of the other armoured craft.

Minecraft. Like other weapons, mines of each decade are progressively more sophisticated. Acoustic, magnetic, and pressure-firing devices become harder to sweep. Nuclear mines have introduced the ultimate in explosive power. The Soviet Navy has the largest minelaying force, including fast surface minelayers with four launch tracks and below-deck capacity for 400 mines. Mine racks can be installed in any ship, naval or merchant. Most submarines can serve as minelayers, as can aircraft.

Since the Korean War, the United States has maintained a strong mine-warfare capability by development of mines and minecraft, including wooden-hull, nonmagnetic vessels for sweeping some of the advanced firing mechanisms in modern mines.

Auxiliaries. Many different types of ships and craft must serve to meet the everyday requirements of a fleet in normal operations. When crisis comes, the need mounts and is met in the initial stage by ships in reserve and by conversion of commercial vessels. Of notable potential value in this connection are the Soviet Union's new merchantmen, ocean-fishing and hydrographic ships, most of which are, in concept and design, fleet auxiliaries.

Fishing and hydrographic ships

In addition, the Soviet navy has constructed a series of destroyer, submarine, and other tenders, oilers, ammunition and other special-purpose ships, emphasizing at-sea logistic replenishment and service.

Of the United States Navy's approximately 100 types of ships, a good number are auxiliaries—tenders, tankers, refrigerator ships, ammunition ships, net, survey, oceanographic research, salvage, degaussing, and other types of essential and usually unsung ships. In key combat-type auxiliaries the United States has made significant progress during the last two decades, especially in design.

FUTURE DEVELOPMENTS

Though the future of navies is unclear, it is possible to speculate on the basis of current trends.

Manned-satellite space stations may come into use to perform or monitor naval missions. Unmanned satellites for communications, navigation, mapping, reconnaissance, weather information, and perhaps even antisubmarine warfare will increase in value.

Advances in vertical- and short-takeoff-and-landing planes will cause a proliferation in numbers and kinds of warships carrying high-performance supersonic planes. As a consequence, super aircraft carriers may have reached the maximum in size. Medium-to-small carriers will take over a number of the many functions of this indispensable type of warship. The Soviet Union, China, and other nations will begin or continue light-carrier programs. Helicopter programs in many navies are part of the increasingly widespread employment of aircraft from ships. Although slow, helicopters serve admirably for antisubmarine warfare, reconnaissance, enemy-missile warning, and midrange guidance of friendly missiles.

The principal menaces to ships will continue to be undersea weapons and long-range missiles from ships and planes. Antimissile systems and weapons will grow in complexity, speed of reaction, and effectiveness. Among these the gun may make a surprising comeback. With very high rates of fire, automatic operation, rocket-assisted projectiles, and, possibly, in-flight guidance, the shell from guns may supersede many, more expensive, guided missiles.

Hydrofoils and air-cushion or surface-effect war vessels will make striking advances in size and usefulness. They have particular promise for operations through submarine waters.

Nuclear-propulsion plants will become smaller and cheaper, though remaining costly for initial installation. More surface ships will enjoy their advantages. In nonnuclear plants, the trend will be toward the use of the gas turbine.

Automation, solid-state electronics, miniaturization, module replacement, and other steps will permit reduction in size of crews. These steps will also make possible small, fast warships to fill the gap left by the growth in size of destroyer types. Many navies have already built small, swift gunboats; a more versatile type, displacing between 1,000 and 2,000 tons, is likely to be an important development.

Antiballistic-missile ships will appear, capable of intercepting hostile missiles over the ocean. Ballistic missiles will probably go into some surface ships.

Submarines will run faster, quieter, deeper, and be armed with larger, longer-range missiles. Measures to combat them will include super-quiet attack submarines, helicopters on small ships, other airborne efforts, distant-detection devices, and advanced weapons.

BIBLIOGRAPHY. Useful general works on the strategic and tactical use of modern naval forces include SAMUEL ELIOT MORISON, *History of United States Naval Operations in World War II*, 15 vol. (1947–62); STEPHEN W. ROSKILL, *The War at Sea, 1939–1945*, 3 vol. in 4 (1954–61), which have no peer in covering the strategy, tactics, logistics, and types of naval vessels prior to and during World War II; Roskill's *Strategy of Sea Power* (1962); and the *United States Naval Institute Proceedings* (monthly) and its annual *Naval Review*. These give a useful look at the naval thinking of the World War II period and since. SIR HERBERT W. RICHMOND, *Sea Power in The Modern World* (1934), is valuable background for study of the pre-World War II period. PHILIP COWBURN, *The Warship in History* (1965); RICHARD A. HOUGH, *Fighting Ships* (1969); and DONALD G. MACINTYRE and B.W. BATHE, *Man-of-War* (1969), discuss and illustrate the general evolution of the warship from early to modern times. HANSON W. BALDWIN, *Strategy for Tomorrow* (1970), on the U.S. Navy; and E.M. ELLER, *Soviet Sea Challenge* (1971), cover the development of the two current leading navies and strategy. The origin and growth of the gun-armed warship are traced in DOUGLAS G. BROWNE, *The Floating Bulwark: The Story of the Fighting Ship, 1514–1942* (1963); and FREDERICK L. ROBERTSON, *The Evolution of Naval Armament* (1921), which devotes as much attention to ships as to weapons. MICHAEL A. LEWIS, *The Navy of Britain* (1948), while focussing on the Royal Navy, provides a lucid discussion not only of the development of ships and weapons but also of tactics of war at sea from the Middle Ages to World War II. PETER PADFIELD, *Guns at Sea* (in prep.), gives a solid and readable account of the history of naval guns and gunnery techniques. E.H.H. ARCHIBALD, *The Wooden Fighting Ship in the Royal Navy, A.D. 897–1860* (1970); and HOWARD I. CHAPELLE, *History of the American Sailing Navy: The Ships and Their Development* (1949), concentrate on the age of the wooden sailing warship. WILLIAM HOVGAARD, *Modern History of Warships* (1920); and the SOCIETY OF NAVAL ARCHITECTS AND MARINE ENGINEERS, *Historical Transactions, 1893–1943* (1945), provide concise summaries of developments in ships, armament, and machinery since the introduction of steam propulsion and armour. The multivolume *Dictionary of American Naval Fighting Ships* (1959–), contains not only concise histories of ships, with profuse illustrations, but also numerous appendixes on various types. Evolutionary treatments of major modern warship types include: OSCAR PARKES, *British Battleships* (1950), invaluable also to the study of foreign battleship development; SIR ARTHUR HEZLET, *Aircraft and Sea Power* (1970) and *The Submarine and Sea Power* (1967); and NORMAN POLMAR, *Aircraft Carriers* (1969). Four general descriptive handbooks of the world's warships are *Les Flottes de combat* (Paris, 1908–); *Jane's Fighting Ships* (London, 1898–); *Taschenbuch der Kriegsflotten* (Munich, 1900–); and *Weyer's Warships of the World* (United States, 1968–). These internationally known annuals give general descriptive and illustrative coverage to the navies of this century. More recent volumes also include information on naval aircraft. *Jane's Weapon Systems* (1969–), a new annual, includes descriptions and illustrations of naval guns, missiles, fire control systems, and the like. Eight editions of JAMES C. FAHEY, *The Ships and Aircraft of the U.S. Fleet* (1939–65 and 9th ed. by SAMUEL ELIOT MORISON and JOHN S. ROWE, 1971), contain photographs and much tabulated information on the United States Navy's materiel.

Navigation

Navigation, once considered an art, has become a science and a technology. The word is a combination of the Latin *navis*, a ship, and *agere*, to drive. Navigation therefore originally meant "ship driving," which included steering and setting the sails. At the start of the air age, the word "avigation," in which *avis* (bird) replaced *navis*, was suggested, but the older word came to be applied to air and, later, to space navigation.

Explorers in a new region must first find the way. As others follow, a path is made and signposts go up. As traffic grows, a new problem arises, avoiding collision, and in all fields of navigation, emphasis has tended to shift from finding the way toward avoiding collision. In space man is still finding the way. On the roads, the dangers are from collision. At sea and in the air, collision avoidance is growing in importance. Ships, large and easily seen, but slow moving, require a long time to stop. When many are in one area, avoiding one may bring danger to or from others. The one-way street principle is, therefore, being introduced in certain waters where the traffic is heavy. Aircraft, on the other hand, travel so fast that a pilot may fail to see another aircraft in time, particularly if it is approaching head-on. The ground organization, Air Traffic Control, therefore has the task of directing aircraft along selected paths to maintain safe intervals. Civil air navigation is governed almost entirely by the need to follow the paths chosen by the air traffic controller.

Fuel consumption is another problem the navigator must deal with. Air and sea navigators keep track of fuel consumption, chiefly for economy's sake. In space flight, fuel is the major navigational consideration. The route to be followed and even the moment for lift-off must be chosen to make the smallest possible demands on fuel.

Timekeeping, a matter of vital importance in space navigation in connection with fuel consumption, is growing important in sea and air navigation for a different reason. Today it is recognized that a voyage or a flight is a link in a chain of transport that carries people and goods from one place on land to another place on land. Ships and aircraft, therefore, increasingly must fit schedules into road and rail timetables.

The four basics of navigation

Navigation, in short, has to do with the whole of a journey from start to finish and is concerned with four basics: (a) finding the way; (b) avoiding collision; (c) fuel consumption; and (d) timekeeping.

The classical definition of navigation is "the art of conducting a vessel on its ways." Today, a better definition might be: "navigation is the science of conducting a craft or creature on its ways."

Development of navigation

ANIMAL INSTINCT

Remembering the way. An animal finds its way home by remembering what it saw or smelled on the way out. This process is common to all creatures, including birds, insects, and fish. The eel, which travels great distances across the ocean, is believed to find the way back by remembering traces of smell in the ocean around. Birds, on the other hand, navigate almost entirely by sight and are extraordinarily adept at recognizing landmarks from the air.

Direction and distance. When a young bird migrates, it instinctively aligns itself in a certain direction, flies until it has no more energy, and then lands. To set out in the right direction, the bird instinctively uses the sun by day or, by night, reacts to the pattern of stars around the pole. To use the sun by day, the bird has to make allowance for the change in direction from rising through to setting. It, therefore, needs a timing instinct that can correct for the passage of the sun across the sky. Not only birds but insects and fish have such timing instincts. Existence of these instincts and migration patterns has been confirmed by extensive experimentation (see MIGRATION, ANIMAL).

When a bee, laden with honey, returns to the hive, it dances on an upright piece of honeycomb. The slowness of the dance shows how tired it is and, therefore, suggests how far it has travelled; the direction of the dance shows the direction from which it has come in relation to the sun. The other bees can then set out knowing instinctively the distance and direction of the honey-bearing area.

Navigating by the sun. A little wild Manx Shearwater, taken from its nest off the coast of Wales, carried across the sea, and released in Boston was back on its nest in twelve days. Though nobody knows exactly how such exploits are achieved, it can be shown that a bird's eye can watch the sun and the horizon at the same time and is so sensitive that it is able to detect the motion of the sun across the sky by comparison with the horizon.

By such methods, wild birds have travelled extraordinary distances. When released hundreds of miles from their homes in sunny weather, they can often set out for their nests within a few minutes. When 50 or so miles away, they are able to pick up landmarks that they have seen before and home in to their mates.

HUMAN ART

Maps and charts. In featureless country, primitive man cut notches in tree trunks and built distinctive piles of stone; in the early days of sailing, he lighted bonfires on headlands. As ships became larger, channels of deep water were marked with sticks and eventually with buoys, lighted so they could be seen at night.

At the same time, men were developing records as aids to navigation. The Polynesians tied sticks together in a pattern in which the intersections represented islands. Arab and European sailors of the Middle Ages developed charts, at first only to help find the way but later to record their voyages. By the 17th century these charts showed coastlines and lights and, at the end of the 18th, depths of water. In the early 1900s, the airman developed special charts to record his paths, but he also carried maps to help him identify objects on the ground.

The spherical surface of a globe cannot be portrayed on a sheet of flat paper without distortion. For navigation, this distortion has to be "orthomorphic"; that is, the stretching at any point must be equal in all directions, even though the amount of stretching and therefore the scale may vary from one point to another. Unless a map or a chart is orthomorphic, a protractor cannot be used to draw directions accurately anywhere on its surface (see also MAPS AND MAPPING).

Types of navigational charts

Three types of orthomorphic charts are used in navigation. A cylinder may in effect be placed around the equator and the surface north or south of the equator stretched orthomorphically until it fits the cylinder. This produces the Mercator projection. Alternatively, a band of latitudes may be stretched orthomorphically into a cone to produce the Lambert conformal projection, known sometimes as a conical orthomorphic. Finally, a flat plate may be placed at either pole of the globe and the globe stretched orthomorphically to produce a stereographic projection.

The Mercator chart has one great advantage. Since it is produced by flattening an orthomorphic cylinder, all of the lines of longitude are parallel. Thus, a vessel travelling in a constant direction will cross these lines at the same angle and the path will appear as a straight line. As the distance from the Equator increases, so does the orthomorphic stretching, so that, on a Mercator chart of the world, Greenland appears larger than the United States.

The shortest distance between two points on a Mercator chart is only seldom a straight line and more often is a curve known as a great circle. In order to follow this shortest route, navigators formerly calculated the points at which the great circle from a starting point to the port of arrival would cut the various lines of longitude and joined these points by a series of straight line "legs" on the Mercator chart (see HYDROGRAPHIC CHARTING). The introduction of radio, the waves of which in general reach a craft by the shortest route, has made the Mercator projection even less convenient. It is, nevertheless, still used in marine navigation though frequently replaced by the Lambert conformal in air navigation. In polar regions, however, the stereographic projection is adopted.

Compasses and logs. Primitive man used the sun and stars as guides. When the sky was overcast, he learned to determine directions by the weathering of rocks sheltered from the sun, the branches on the sunless side of trees, the anthills oriented toward the warmth of the morning, and other such signs. Early seamen observed migrant birds and sometimes carried birds on board, releasing them to find land.

The magnetic compass

At about the beginning of the Christian Era, the Chinese discovered that a piece of iron ore, when floated on water, always points north. Carried westward by the Arabs, this early magnetic compass was universally used by Columbus's time.

It was soon realized that the direction indicated by a compass needle often varies considerably from true north though the reason for this was not understood till quite recently. The north magnetic pole, or the place on the earth to which a compass needle points, is located some distance from the actual North Pole. Thus, a magnetic compass is usually in error. This error may be great or small depending upon one's location on the earth's surface. In addition, iron ore bodies in the ground may affect compasses. A practical solution to the problem was found in the 19th century. Magnetic compass points were measured at a number of places, with the sun or the stars used as references. Compass error, recorded as so many degrees to the east or to the west of true north, was compiled and transferred to charts. Now a navigator can look at a chart to find the amount of compass error at his location.

As iron and steel replaced wood in hulls, the ship itself acted as a magnet, distorting the compass reading in the direction in which the ship was pointed. This deviation was corrected by experimentally fitting pieces of iron and steel close to the compass in such a way that they offset the magnetism of the ship. Compass compensation was later applied to aircraft.

In days of sail, a ship's speed could be crudely measured by throwing overboard a small log tied to a line which was paid out as the log drifted astern. The line was knotted at intervals and the number of knots paid out while a sandglass was emptied gave the speed of the vessel in knots.

In a later, more sophisticated method, the log of wood was replaced by a trailing propeller, whose revolutions recorded the ship's speed. A method, developed originally for aircraft, measured the pressure set up in the open end of a forward-facing tube, known as a pilot tube. Like the propeller, this gives a speed measurement that can be translated into distance if the time of travel is known. Seamen, however, continued to refer to all such devices as logs and to record speed in knots, a knot being one nautical mile per hour. A nautical mile, originally 6,080 feet, is today 1,852 metres, or 6076.12 feet.

Dead reckoning. Starting from a known point, the mariner with his compass could draw a line on his chart to represent his course, along which he marked off the distance given by the log. The calculation was known as deduced reckoning, shortened later to dead reckoning. In addition to errors in the compass and in the log, dead reckoning suffered from errors due to the drift of the water. When ocean currents were first marked on charts of the open sea, and tidal streams appeared on coastal charts, navigators could make allowance for drift. Fortunately, the currents were seldom fast and, on long voyages, often tended to cancel each other out. The situation in the air, however, was quite different. Early airplanes flew at around 100 knots and the air that supported them was blown over the ground by the wind at speeds of up to 40 knots. It was therefore necessary to determine the velocity of the aircraft through the air and the velocity of the air over the ground in order to find the true velocity of the aircraft with respect to the ground. This was achieved by the triangle of velocities as shown in Figure 1. A line was drawn to show the direction in which the aircraft was heading, the length of the line representing the distance the aircraft would travel through still air in one hour, in other words, the true air speed. Such a line is called a vector; *i.e.*, it indicates both magnitude and direction. From the end of this line, a second line or vector

Calculating aircraft velocity

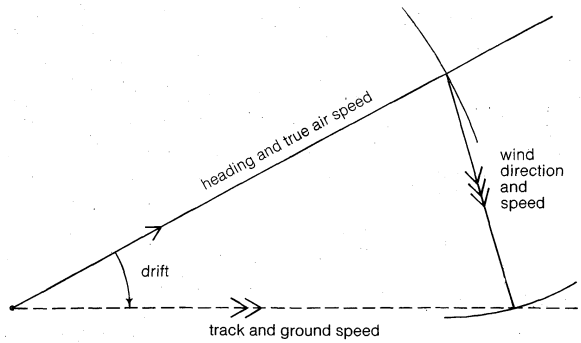

Figure 1: Triangle of velocities.

was drawn in the direction toward which the wind was blowing, the length of this second line being determined by the wind speed. Finally, a third line drawn from the starting point of the first line to the end of the second line showed the path that the aircraft was following over the ground, the distance representing the true ground speed. Stated mathematically, the true ground speed was the vector sum of the craft's air velocity and the wind velocity.

The angle between the heading of the aircraft and the track was known as the drift because it resulted from the drifting effect of the wind. Early aircraft were fitted with drift sights through which the airman visually aligned a grid with the moving ground below and so determined the drift. The plotting of triangles of velocity was simplified by using graphic instruments called computers before that term was appropriated for much more complex devices.

Paradoxically, higher aircraft speeds failed to eliminate the problem of wind drift because jet aircraft fly higher as well as faster and, above 20,000 feet (6,100 metres), very narrow belts of wind known as jet streams that travel at speeds of 100 or 200 knots occur under certain meteorological conditions.

Sea navigators did not follow the practice of air navigators and allow for ocean currents and tidal drifts in their initial calculations. Dead reckoning, long established as a navigational technique, continued to be used; an estimate for ocean current or tidal drift was added afterward. This practice continues today.

By dead reckoning, the navigator can quickly find a position that he can often check by a landmark. On the other hand, the errors that are inseparable from dead reckoning accumulate; when a position has been checked, the reckoning is therefore generally restarted from that position.

Dead reckoning enables the navigator to plot not only where he is but also where he will be provided he maintains his planned course and speed. It also makes it possible for him to plan his whole journey, including the time of arrival at his destination, before he sets out. Planning ahead is a part of all navigation; the preparation of a complete flight plan is mandatory before taking off in a civil aircraft. Space navigation is based even more completely on flight planning and the time of splashdown is calculated within minutes, many weeks before lift-off.

Direction finding. To avoid the shoals marked on his chart, a seaman needs to know his exact position. By means of a sight fitted to his compass, he can measure the direction of a headland or a light. This direction, or bearing, can be marked on a chart by a position line. A second line drawn from a second bearing will fix the position of the vessel as shown in Figure 2.

The invention of radio led to direction finding, an improvement in this navigational technique. A loop of wire perpendicular to the direction in which radio waves are travelling picks up a minimum signal. By tuning in a particular radio station and then rotating the loop for minimum signal pickup, the direction of the radio station can be plotted as a position line. Plotting a similar line for a second radio station enables a navigator to find his position.

Radio direction finding, known as DF, developed in two ways. First, radio transmitters, or "beacons," were

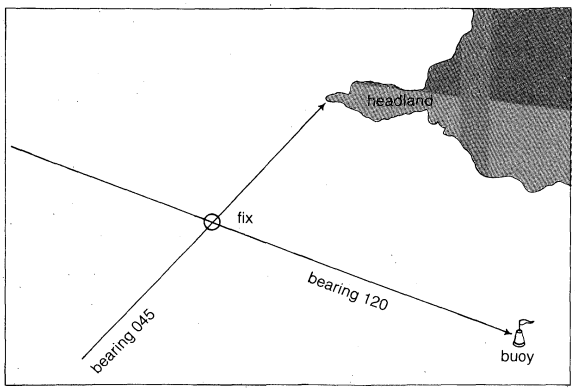

Figure 2: Determining position by intersection of compass bearings to known points.

Radio direction finding

sited, particularly along coasts, to enable ships or aircraft to fix their positions. Second, ground DF stations that could pick up radio signals sent out by a ship or an aircraft were built. If two or more stations could pick up the signals, they could fix the position of the craft. In spite of these developments, DF has remained an uncertain art, because reflections from layers of ionized air high in the sky (ionosphere) and refractions (bending of the radio waves by the atmosphere) distorted the direction of arrival of the waves.

Navigation by the sun and stars. The Polynesians used the stars effectively in navigating the South Pacific. They knew which stars passed directly over various islands and sailed their catamarans north or south until the proper star was overhead, then east or west, keeping their craft directly below the passage of the star, until they reached their destination.

The Polynesian had to wait until the star was at its zenith before he could tell whether it was passing overhead or not. Medieval Norse navigators, however, recognized that the Pole Star moved but little in the sky and that its altitude above the horizon was nearly constant for each destination. Still later it was realized that this altitude is approximately the same as the observer's latitude, as suggested in Figure 3. Thus, at the North Pole, latitude 90°, the Pole Star is roughly overhead, or at 90° altitude; at the equator, latitude 0°, the Pole Star is on the horizon at an altitude of 0°. Halfway between, the altitude and the latitude are both 45°.

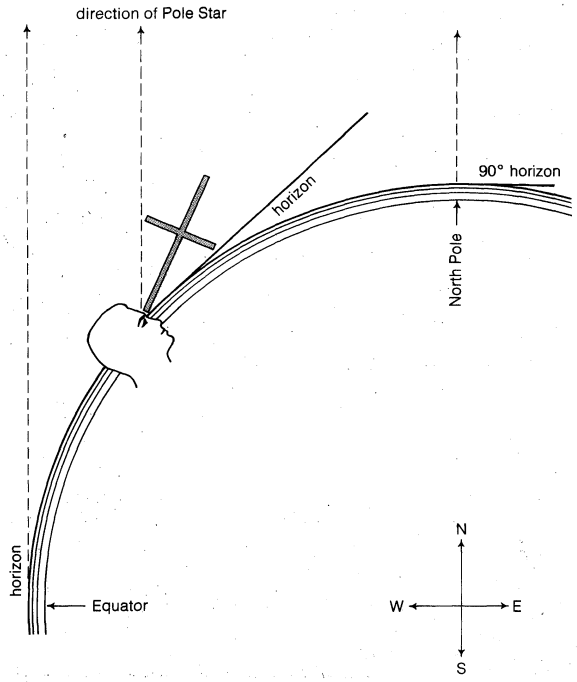

Figure 3: Altitude of Pole Star and latitude.

In Figure 3, the altitude of 45° is being measured by a simple instrument known as a cross staff, consisting of a cross piece that slides along a graduated haft or handle. One end of the haft was held against the eye and the cross piece moved until the horizon was at one end and the star at the other.

A method was subsequently developed for finding latitude by measuring the altitude of the sun at its highest point, at noon. Later on, the moon and the planets were used. Because these bodies move about the sky during the year, their heights compared to the vertical at the Equator were tabulated in almanacs, providing a reliable guide to latitude. But to determine longitude it was necessary to know the position above the earth that the stars had reached, which required an accurate means of measuring time. The water clocks of the ancients had been supplanted by pendulum clocks driven by weights, but pendulums were upset by the rolling of a ship and, besides, since gravity is not constant over the surface of the earth, the period of a pendulum varies. In the middle of the 17th century the offer of a large prize for an accurate means of measuring longitude hastened invention of the balance wheel and the hairspring (see CLOCKS, WATCHES, AND SUNDIALS) and led in turn to the development of the chronometer, a very accurate timepiece. Accurate timing was now possible. Chronometers became standard equipment on ships and, in the early 1900s, the development of radio made it possible to check a chronometer by time signals broadcast from a radio station.

Use of the sextant

Measurement of altitude was made much more precise by development of the sextant, an instrument consisting of a mirror that reflects the light from a star onto a silvered glass so arranged that an observer can simultaneously see both the star and the horizon. By shifting the angle between the mirror and the glass until the star appears to sit on the horizon, the observer produces an angle between the mirror and the glass that is just twice the altitude of the star. In a sextant, the angle can be as much as 60°. In a similar instrument called an octant, the angle is limited to 45°.

For air navigation, in which the horizon is seldom sharply defined, the sextant was equipped with an artificial horizon in the form of a liquid level, the star being aligned with the centre of the bubble. Because accelerations cause the bubble to swing, the sextant was provided with an automatic integrating or averaging device. Later developments included the periscopic sextant in which the star is viewed through a periscope protruding through the top of the fuselage.

Sea-navigation practice for many years was to take one altitude on a suitable body to find the latitude and a second altitude on another body to find the longitude and to calculate the position by basic trigonometry. In 1837 one Captain Sumner, finding himself close to a dangerous coast with only one star in sight, worked out a number of possible positions for his ship assuming various latitudes. These positions fell along a straight line. From this accidental discovery, systems were developed to translate an altitude taken on a star into a position line on a chart. A second observation on a second star produced a second position line. A third observation with a third position line was generally used as a check.

Other aids. The Viking sailor took soundings with a lead weight on a line, hauling in the line and measuring it by the span of his arms. The action reminded his companions of an embrace, and for centuries depth was measured in 6-foot (1.8-metre) intervals called fathoms from the Old Norse word *fathmr* meaning an embrace. The lead was often given a hollow bottom filled with tallow to pick up a sample of the seabed for comparison with the chart as a check on the position of the ship.

Distance from a cliff could be measured by timing the echo from a shout or the beat of a drum. In World War I, echo sounders were developed to time the interval between sending out a sound from the ship's keel and receiving an echo from the bottom, a system also used to detect submarines. Meanwhile, the airman, like the mountaineer, was using a form of barometer (atmospheric-pressure indicator) to get some idea of his height. The

height indicated by the barometer depended on the pressure at sea level and on temperature, and the errors were apt to be considerable. A height estimated by this method is accordingly known as an altitude, thus emphasizing that true height is not being recorded.

Up to the end of World War II, the shipping lanes were not unduly crowded. With a few exceptions, ships were not large and were reasonably manoeuvrable so that each master could avoid collision by using his own judgment. At night ships carried "navigation lights," which enabled other seamen to tell which way a ship was going. Similar lights were carried by aircraft but, to prevent these lights being mistaken for stars, they were made to wink. In general, the navigation light on the port side of a craft, the left-hand side looking forward, is red and the navigation light on the starboard side of a craft, the right-hand side looking forward, shows green.

NAVIGATION AS A SCIENCE

The three stages of navigation. Sailing or flying aimlessly is not navigating. To navigate, an objective is necessary. There are three stages of navigation. The first stage is the route along which the craft moves. The route has to do with position either on the surface of the sea or below or in the air, on land, or in space. To follow the route, the second stage is employed; the craft must move with a certain velocity, which has two elements: direction, which has already been defined as the course, and speed. Velocity must be built up at the start, slowed down at the finish, and adjusted at various stages during the voyage. These changes of velocity are accomplished by accelerations applied along the length of the craft by altering the motive power to adjust speed or across the length of the craft by steering. Accelerations are therefore concerned with the third stage of navigation, driving the craft.

The process of navigation. As a craft proceeds on its way, the navigator determines his position. This enables him to check his progress compared to the predetermined route and, if he finds an error, amend his route, select a new course, possibly change speed, and drive his craft accordingly. Progress along the amended route is then checked again by finding further positions, recorrecting course and speed, and driving the craft accordingly. The continuous flow of information and action involved is known as a "closed loop."

Closed loops

Navigation loops. Closed loops are seldom simple but consist of a series of loops one inside the other like the skins of an onion. Inside the outer position-finding loop there is an inner course and speed loop. In this loop, the course to be steered and the speed to be maintained are checked by compass and speedometer or log. Within the inner course and speed loop, there is also an innermost driving loop that relies on instruments to measure accelerations or, alternatively, uses the human being as an instrument. Finding the way thus involves three loops. Of these, the outer position-finding loop is used only at intervals, the course and speed loop is corrected more frequently, and the innermost driving loop is continually in action. A motor vehicle driver, by analogy, looks only occasionally at signposts but always keeps one hand on the steering wheel.

The aids that are employed in the outer position-finding loop cannot effectively be adapted to measure course and speed. For example, in the case of an aid that tells the distance to the destination, a minor irregularity, which momentarily diminishes this distance, would be translated as a complete reversal of speed, a particularly undesirable manoeuvre.

The reverse process is, however, quite possible. It has already been shown how, by dead reckoning, course, speed, and time can be used to find position. Similarly, devices used for driving may be adapted to give useful course and speed information and even position. To avoid collision, an outer position loop is used that relies on separation; for example, by one-way streets. There is also a device called an inner course and speed loop that enables vehicles to avoid more imminent collision with each other.

Modern navigation techniques

DRIVING

Steering a craft. That steering is a complex process can be seen in the problem of steering a ship down the centre of a canal. Presumably, if the ship veers to the left, turning the rudder to the right by an amount depending on how far the ship was off to the left would return the vessel to the centre line.

On arrival at the centre line, however, the ship will be headed to the right and the rudder will point dead ahead so the ship will veer off to the right. Though this can be corrected by turning the rudder left, the same thing will happen again, and the ship will weave back and forth across the centre line and never settle down on it.

If the rudder is turned by an amount gauged by how fast the ship is departing from the centre line, the ship will settle down in a straight line travelling along one side of the canal. If the system depending on distance and the system depending on speed or rate of change of distance are mixed, most of the problems are solved. In the initial stages both systems combine to correct the ship; as it turns toward the centre line, the rudder effect due to the rate of change of distance tends to steer the ship to the left as if anticipating arrival at the centre line.

Rudder effect

If the canal is straight, the ship settles down on the centre line with the rudder straight out astern. If the canal turns, however, the ship continues ahead at first, then drifts off to one side of the centre line. The rudder turns to offset the movement away from the centre line, the amount of turning increasing until eventually the craft settles down and follows the curve of the canal. The distance off the centre line is taken up with making the ship turn round the curve. Therefore, the ship travels round the outside of the bend. To correct for this "hang-off," the rudder is turned by an additional amount until the error is eliminated.

Thus it is evident that steering a craft is not simple. The human navigator uses his brain to apply the necessary corrections. Computers can do the same job; modern control systems in craft may be designed so that they can learn as they go along. Such equipment is described as "self-adaptive."

Stabilization. The faster a bicycle's wheels spin, the steadier the balance; the spinning wheels tend to keep spinning in the same direction. Since a ship or aircraft cannot be stabilized by fitting a huge wheel inside, a small model of a spinning wheel, a gyroscope, is used instead. This gyroscope is mounted on gimbals, devices that permit it to remain level even if its support (the craft) is tipped by rolling or pitching. Special electrical devices known as pick-offs are mounted on the gimbals so that, when the craft is not aligned with the gyroscope, electrical signals will indicate the amount of tilt or direction change (see also GYROSCOPE).

In a ship stabilizer, signals from the pick-offs on the gimbal control motors that drive fins fitted to either side of the hull. When the ship rolls to port, the gyrowheel stays upright but the pick-off sends a message to the port motor to drive the port fin so that the rear end is forced downward and the water flowing past the hull presses it upward. Simultaneously, a pick-off sends a message to the starboard motor to drive the starboard fin so that the rear end is forced upward and the water flowing past the hull presses it downward. Thus the pressure of the water on the fins tends to correct the roll.

Stabilizers are fitted to passenger liners. Similar devices, known as autostabilizers, are fitted to aircraft. Autostabilizers correct for roll by means of ailerons fitted in the wings that act exactly like the fins on a ship. Pick-offs on the other gimbals of the gyroscope detect also any changes in the fore-and-aft attitude, known as changes in pitch, which are corrected by signals sent to motors that drive the elevators up or down.

Gyroscope drift. Even the best gyroscopes tend to "drift"; *i.e.*, lose alignment. If not corrected, this drift causes a stabilizing gyroscope to tilt; and the ship in turn will lean at an angle instead of remaining upright. The gyroscope is therefore corrected by the force of gravity. The simplest method is to fit a small weight to the lower

part of the mounting of the wheel. The weight must be heavy enough to correct the tendency of the gyroscope to drift, and yet not so heavy that, when the ship rolls, it causes the gyroscope to swing to and fro like a pendulum.

In actual practice, the weight may not be mounted on the gyroscope but an accelerometer may be used instead, in the form of a spirit level that, when tilted by the rolling of the ship, will signal the gyroscope. These signals cause the gyroscope to react only very slowly so the effects of each individual roll are negligible. Over a long period, however, signals from the accelerometer ensure that the gyroscope remains upright in spite of its drift.

Autohelmsman and autopilot. Stabilizers and autostabilizers keep the craft level, greatly easing the task of the human helmsman or pilot. Autohelmsmen and autopilots are automatic devices that drive the craft, taking instructions for this purpose from steering and positional aids. Perhaps the simplest kind of autopilot is the steering vane fitted to single-handed ocean racers. The lone yachtsman sets the vane according to the wind and it then keeps the boat on a steady course as long as the wind comes from a constant direction. Perhaps the most complex form is the automatic landing autopilot, which consists of three separate autopilots arranged so that, if one should fail to function satisfactorily, the other two will override it and keep the aircraft on its correct path.

Autohelmsmen and autopilots use gyroscopes to measure any deviation of the craft from its desired path. In certain instances, accelerometers are also employed. In aircraft, autopilots are sometimes supported by autothrottles that keep the aircraft at a constant speed selected by the pilot. In addition, aircraft are fitted with directors. These instruments tell the pilot which way to move his controls and, in effect, are autopilots that use a human being as the source of control.

Instruments. Driving instruments measure and record engine conditions, fuel status, and the position or attitude of the craft in relation to the earth. Engine instruments usually measure the rotation of the engine or of the turbine that blows air into the engine. They also measure the pressure inside the engine either directly or by the temperature it generates. Fuel flow is also often displayed on an instrument, as a useful guide to engine performance. On a long-term basis, fuel in tanks is also recorded.

Artificial horizon

In aircraft, an artificial horizon is generally necessary. When flying visually, the pilot may use the natural horizon, but since this is often obscured by clouds, particularly when flying high, the pilot uses an instrument consisting of a model of an aircraft behind which is fitted a representation of the real horizon. This artificial horizon is kept parallel to the real horizon by means of a gyroscope; a linkage to the gyroscope causing the horizon to move down or up, exactly as a real horizon seems to, when the aircraft pitches nose up or down.

Aircraft also carry air-speed indicators that indicate the pressure set up by the forward motion of the aircraft. They therefore indicate the negative pressure set up on top of the wings due to the forward motion; that is, the lift of the wings. When this pressure falls below a minimum value, the pilot knows that the lift may collapse and the aircraft will stall; that is, fall out of control.

An aircraft and occasionally a ship, such as a powered barge that must continually negotiate bends in rivers, may carry a rate-of-turn indicator in which a gyroscope detects how fast the craft is turning. Most craft also carry devices to alert the driver to emergencies; these vary from the simple warning lights used in automobiles to complex electronic pictures and statements of malfunctions printed automatically on cathode-ray tubes.

Inertial navigators. By means of very precise accelerometers, it is possible to measure the direction of the force of gravity with extreme accuracy. Gyroscopes can also be set to spin in the direction of the force of gravity at the point where the journey started. The difference between these two directions shows the distance and direction in which the craft has travelled. Aircraft inertial navigation "platform" is the name given to such an accelerometer and gyroscope package. Inertial navigators also require computers to translate the indications of the platforms into headings, speeds, and positions and to correct the gyroscopes to allow for the rotation of the earth and other effects.

Inertial navigators used at sea are even more accurate than those used in aircraft. Submarines have been navigated automatically by these systems, travelling under the polar ice cap with errors of less than a mile a week. Inertial navigators are also used to guide long-range intercontinental ballistic missiles. These navigators steer the ballistic missile for the few minutes the motors are burning. At the end of that time, they ensure that the missile is on the desired trajectory. After that, the motors are shut off and no more guidance is necessary.

A space vehicle is effectively weightless when its propulsion motors are not operating. Therefore, inertial navigators cannot be used to find position except during launch. An inertial platform is used, however, to keep the space craft on a steady alignment during a brief period of acceleration, or "burn." Before acceleration it is aligned with the stars. This steady alignment is essential. Otherwise, the motor could accelerate the space craft in the wrong direction. The accelerometers on the platform can, of course, be used to measure the change of speed resulting from the brief acceleration.

STAYING ON COURSE

The modern compass. A magnetic compass is so seriously affected by the metal in a ship or an aircraft that it is mounted as far away as possible from ferrous material, necessitating that the signals from the compass be led into the ship's bridge or the pilot's cockpit. A distant reading compass of this kind does not use a magnetic needle mounted on a pivot but instead has fixed detectors that can sense the magnetic direction without rotating.

In a high-speed marine craft or in an aircraft, turning the craft causes the magnetic detector to swing in the direction of the turn, thus causing an error. Fixing the detector to the hull would also give erroneous readings when the ship or aircraft rolls. Similar errors occur when speed increases or decreases. Thus signals from the magnetic detector are passed to a gyroscope that acts like the gyroscope in a stabilizer when controlled by an accelerometer. The irregularities in magnetic direction are smoothed out and the gyroscope maintains correct alignment. The compass indicator is driven by the gyroscope. Such a device is known as a gyromagnetic compass.

Gyromagnetic compass

On turns, magnetic-compass errors may be very high, and even with a gyrocompass, they may be substantial. In general, however, a gyromagnetic compass will indicate the direction of the earth's magnetic field to within less than a degree. It is unfortunate that, over much of the world, this direction of the earth's magnetic field is only known to an accuracy of 2° or 3°.

Special compasses have been devised to measure direction by means of the sun and the stars. Originally little more than simple sighting devices, these "astro-compasses" required books of tables similar to those used for astronavigation. More recent, automatic devices, driven by clockwork, allow for passage of the sun across the sky. In spacecraft, alignment is not affected by the rotation of the earth and a relatively simple telescope can be used.

Gyrocompass. If a gyroscope is put on the rotating earth with its axis at right angles to the earth's axis as shown in Figure 4(a), it is tilted as the earth rotates and therefore turns until it is aligned with the earth's axis as shown in Figure 4(b). Thereafter it is not tilted by the earth's rotation unless it drifts off a little to one side. It is then automatically tilted back to the correct alignment. Such a device is called a gyrocompass.

The gyrocompass can be used in ships that travel along steady courses. It is affected, however, by turns which it cannot distinguish from rotation of the earth. Although on a steady course the error may be less than a degree, in a turn even at a moderate speed, the error can be two or three degrees. Hence the gyrocompass is not used in high-speed marine craft nor in aircraft. An inertial platform can act like a gyrocompass, however, and can be made to align itself in the correct direction before the start of a voyage or a flight.

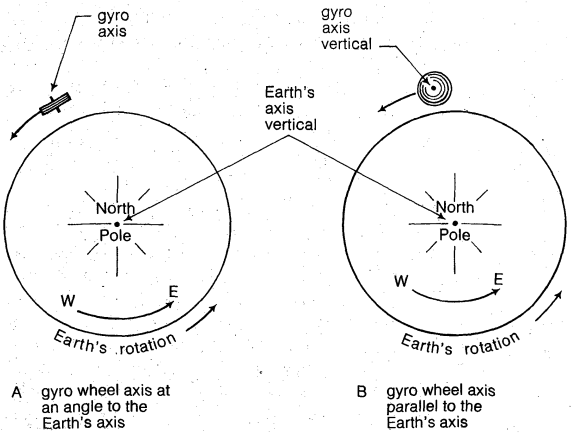

Figure 4: Principle of the gyrocompass.

Speed measurement. The classical methods of measuring speed through the water have already been described. In ships, the modern log may take the form of an electromagnetic detector that senses the speed of the water flowing past it. In many ships, as in racing cars, engine revolutions are used as an indication of speed. Inertial navigators also provide accurate measurements of speed.

The latest method used for measuring speed is known as Doppler. When a racing car goes by, the high pitched whine of the approaching engine falls to a low pitched growl as it disappears into the distance. By measuring the change of engine note, it is possible to measure the speed of the racing car. This principle is used in Doppler radio.

Doppler radio

Radio waves of a certain frequency are transmitted by a craft and, when they strike a moving object, are reflected either with a higher or a lower frequency according to whether the craft is approaching the object or receding from it. By this means an aircraft can measure the speed at which it is passing over objects on the ground and, by means of other transmissions at right angles, it can also measure the sideways speed over the ground. Similar Doppler systems have been used to measure the speed of hovercraft and land vehicles over the ground.

Collision avoidance. Figure 1 illustrates the calculation of an airplane's true velocity. A similar procedure can be used to calculate the course an airplane must avoid to prevent collision with another aircraft. In Figure 1 the wind is replaced by the course and speed of the craft drawn in the opposite direction. What was track and ground speed in Figure 1 becomes the line of sight to the craft to be intercepted and the speed at which the two planes are approaching each other. If both planes maintain the speeds and directions indicated in Figure 1, a collision will occur.

Recent interception theory is based on a development of the way in which an animal hunts its prey. It runs toward it and, as the prey tries to escape, it changes direction so that it is always running straight toward it. Thus the hunter changes course at the same rate as its line of sight to its prey changes direction. Missiles that have to intercept ships or aircraft do a little better than this; they alter course faster than the direction of the line of sight changes.

Modern collision-avoidance theory depends increasingly on the fact that, if course is altered in a direction opposite to that in which the line of sight to another craft is changing, the miss distance will be increased. Thus if a ship is apparently travelling across the bow to the left, the miss distance will be increased if the course is altered to the right. Similarly, if the other ship is on the same course but moving ahead, the miss distance will be increased by slowing down or, when it is well ahead, by turning toward it.

The real difficulty arises when the line of sight to the other craft is not changing direction. This means that either the other craft is diverging or converging directly toward the first. Traditional "rules of the road" at sea require two ships meeting head-on to both turn right. The turn has to be sharp to be effective and to make intentions clear.

Aircraft are too small and fast for visual avoidance. Air collisions have occurred in daytime in absolutely clear weather. Collision avoidance depends on systematic separation of flight paths. Radio systems are now being developed, however, to aid evasive action when, by some accident, the separation proves to be inadequate.

Dead reckoning by computer. In modern craft, dead reckoning is being left more and more to computers. Military land vehicles use computers fed by compasses and signals taken from the wheels. Ships depend on the gyrocompass and the log, and aircraft on the gyromagnetic compass and Doppler. Recently, computers have been devised that generate printed positional information. Generally, inertial navigation provides the dead-reckoning information only, though compass and Doppler data may be included with inertial outputs. Information from radio-fixing systems may be added to the dead reckoning; each item of information is automatically compared with the others.

Instead of using a chart, position may be continuously displayed on a moving map. If the route is known beforehand, the map may be in the form of a strip driven along by rollers with a pointer moving to and fro to indicate exact position. When greater flexibility of route is essential, a series of maps covering a very wide area may be printed on film and projected on a ground glass screen on the bridge or in the cockpit.

The most important use of dead reckoning is by Air Traffic Control. Not only does every aircraft have to file a complete flight plan showing courses and timings but, during the flight, air traffic controllers keep what is virtually a dead-reckoning check on each aircraft. The flight plans filed by each aircraft before take-off are split up into sections and "flight strips" are prepared showing height, speed, and timings of each aircraft in a section. The air traffic controller handling that section can thus see which aircraft will be arriving and in what sequence. These flight strips are continually updated by reports sent by radio from the aircraft and also by changes in height and course ordered by the air traffic controller to maintain adequate separation. In modern systems, automatic flight strips are displayed on cathode-ray tubes.

Flight strips

POSITION FINDING

Sound, radio, light waves. To find the position of a craft in relation to a ground feature, a link is needed between the craft and the earth. In inertial navigation, the link is the direction of gravity. In astronavigation the horizon is used. In all other systems, the link is waves. Sound waves travel through water at about 5,000 feet (1,520 metres) per second and through air at about 1,100 feet (335 metres) per second. Electromagnetic waves in the form of radio or light waves travel about 160,000 knots (nearly eight times round the world) in a second. The difference between radio and light waves is length; radio wavelength varies from many kilometres to less than a centimetre; light waves are so short that a thousand of them stretch only one millimetre. Because wavelength varies slightly according to whether the wave is passing through space, air, ground, or water, radio waves are normally described by frequency. Radio waves longer than one kilometre are termed low frequency and radio waves shorter than ten metres as high frequency.

At heights varying from tens to hundreds of kilometres above the earth, layers of ionized particles (ionosphere) are formed by the ultraviolet light from the sun, the lower levels dying away during the night. Long waves (low frequency) usually bounce off the ionosphere and also tend to follow the curvature of the earth, producing strong ground waves. As a result, they can be reliably transmitted over long distances. Short waves that strike the ionosphere at a small angle are also reflected, but those that strike at a large angle (nearly perpendicular, close to 90°) will pass through. At these frequencies, the ground wave dies out rapidly so that there may be a dead space before the first of the ionized layer reflections, known as "sky-waves," hits the ground. This dead space is known as the "skip distance" (see also RADIO).

As radio waves become shorter, they behave more like light. Centimetric waves travel mostly in straight lines

and penetrate the ionosphere easily. They bounce off objects including large rain drops and, as the length decreases, are more and more readily absorbed by mist and fog. Longer waves, on the other hand, though affected by lightning and static discharges, sweep undisturbed through water particles.

Radio-bearing systems. The loop antenna used for direction finding is almost as old as radio itself. It has been developed into an automatic direction finder (ADF) in which a motor turns the loop, the device originally being known as a "radio compass" because it could guide the navigator to a radio destination. ADF instruments are often linked to compass systems so they display not merely the direction of the radio station compared to the heading of the craft but the actual direction as plotted on a chart. In ground stations, two fixed-loop antennas at right angles have long been used; the direction of origin of a transmission may be displayed instantaneously on a cathode-ray tube. The device can also indicate the direction of thunderstorms.

Automatic direction finder

Direction-finding stations for aircraft appeared between the two world wars, consisting of loop antennas in pairs at right angles, arranged so one antenna radiated radio waves in a pattern of dots and the other radiated waves in a pattern of dashes. The dashes fitted into the intervals between the dots. Midway between the directions of maximum dots and maximum dashes, dots and dashes merge in the receiver into a steady note; this is called the "beam." Only a slight deviation of the pilot's headphones away from this beam produces a change in the steady note, and he determines the direction by which he is "off the beam" by whether the dots or dashes predominate. The pilot flies in one of four directions to and from the beacon, which is known as a "four course beacon" or a "radio range."

The limited range of the radio signals from this device limited the directions in which an aircraft could travel from one beacon to another, and it was therefore replaced by VOR (very-high-frequency omnidirectional radio range), the beacons of which operate on a completely different principle. One antenna sends out a steady wave in all directions. A second antenna rotates and sends out a narrow beam of waves such that, when on north, the beam coincides with the steady wave, when on east it diverges by 90°, when on south by 180° and so on. A receiver in the aircraft measures the divergence or phase difference and records the direction of the VOR beacon that is displayed together with the heading of the aircraft on a radio magnetic indicator (RMI). Today, beam antennas may be rotated electronically.

From the radio range, with its so-called beams, true beam systems have developed. In these the loops are replaced by antennas that concentrate the radio waves into narrow beams a few degrees wide, while the dots and dashes are replaced by more sophisticated patterns or modulations. In the instrument landing system (ILS), used to help aircraft approach and land on an airfield, the two beams use very short waves to keep antenna size small (see also ANTENNAS AND WAVE GUIDES). The beams point almost in the same direction and, once the aircraft has entered the beams, a receiver can measure the angular displacement from the centre line and display this displacement on an instrument or use it to guide the aircraft along a line toward the point of landing. In addition to the steering beams, which make up the localizer element of the ILS, there are two similar but ever narrower beams transmitted in the vertical plane that guide the aircraft down the correct glide slope to the point of touchdown.

Distance measurement. The echo sounder, already mentioned, transmits a short sharp "ping" from the keel of the ship and measures the time required for the echo to return from the bottom of the sea. A radar altimeter similarly measures the vertical distance from an aircraft to the ground below by transmitting a short sharp burst or pulse of radio waves. The radio altimeter is, however, more common. It transmits continuous waves and utilizes a device known as a phasemeter, which measures the extent to which the pattern received from ground reflections diverges from, or is out of phase with, the pattern transmitted by the antenna. Naturally, the height of which a radio altimeter can be used is limited to that at which the reflected patterns are in phase with the transmitted patterns. Within this limit, the radio altimeter is accurate and is used as an aid in landing aircraft automatically.

The radio altimeter

Distance measurement equipment (DME) uses pulses that are transmitted from the aircraft, received by a DME beacon on the ground, and transmitted back to the craft. The time taken for the pulse to make the round trip is measured by a very precise electronic clock; distance is displayed automatically on counters similar to the odometer in an automobile. DME beacons are located with VOR beacons to provide simultaneous bearing and distance information to an approaching aircraft, thus giving its position. DME is not used by ships because its range is not adequate.

Hyperbolic systems. If the two guns M and S in Figure 5 are fired simultaneously, each consecutive ring in the figure will represent a distance of 1,100 feet (340 metres) travelled by the sound in one second. Thus a craft anywhere on AB, the perpendicular bisector of MS, would

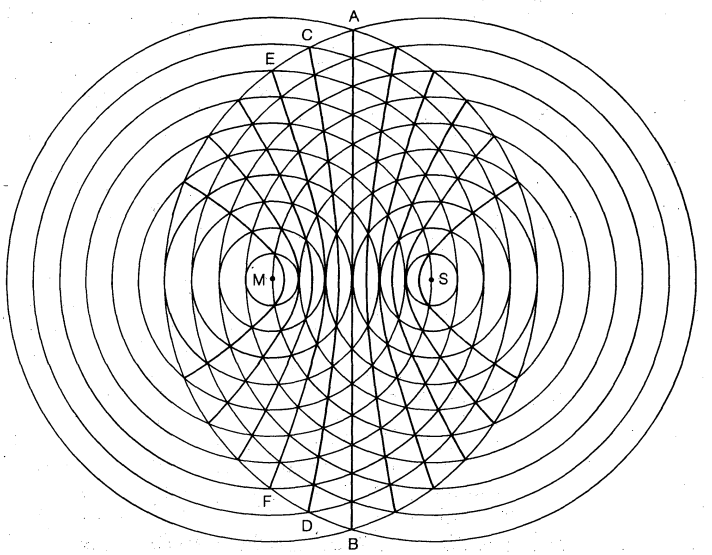

Figure 5: Hyperbolic position lines (see text).

hear both guns simultaneously. A craft 1,100 feet closer to the gun M will hear the gun S one second later and will lie on the hyperbola CD. A craft 2,200 feet closer to gun M will hear gun S two seconds later and will lie on the hyperbola EF. Hence, by timing the interval between hearing gun M and gun S, it is possible to find on which hyperbola the observer is located if the interval were an exact second. Other hyperbolas drawn proportionally represent intervals of fractions of a second.

In navigation the firing of guns is replaced by radio transmissions. The sheaf (family) of hyperbolas as shown in Figure 5 may be printed on a chart. A second sheaf of hyperbolas, from a second pair of stations, can be printed on the same chart; two position lines are plotted and a fix obtained. In radio systems, one of the two stations in a pair (the master) controls the other (the slave). In some systems, the stations are arranged in "chains" with two or three slaves distributed about the master and two or three sheafs of hyperbolas printed on the appropriate chart.

Loran, long range navigation, is a radio-navigation system that permits a ship to locate its position accurately by timing the arrival of pulses from synchronized shore transmitters. Either a master transmitter and two slaves keyed to it are necessary or two synchronized masters, each with a keyed slave. The difference in time of the arrival of pulses from a master and slave shows that the ship is somewhere on a curved line (hyperbola) running between the two and curving back around the nearer. The second pair of transmitters (or second slave) is necessary

The Loran system

to supply another, intersecting curve; the point of intersection is the ship's location.

In Loran systems, radio waves that are reflected from the ionosphere cannot be used. Such reflected waves, or sky waves, can cause confusion, arriving after the correct pulse and sometimes being much stronger.

Decca and other hyperbolic systems. Decca is a hyperbolic system similar to Loran but it operates at a longer wavelength and uses continuous transmission instead of pulses. The difference in time of arrival of the waves is determined by the difference in phase between the incoming signals; otherwise operation is similar to Loran. This arrangement provides a remarkably accurate and reliable system covering a range of 100–300 miles (160–480 kilometres) from the master station and widely used by ships and aircraft particularly for navigation close to the destination.

Omega is a new long wave hyperbolic system which probably has the longest range of all radio navigational aids. Like Decca, it is a hyperbolic system that uses continuous waves and, like Decca, it has a system of special transmissions for lane identification.

During World War II, Germany produced the Sonne beacon that has been developed into the Consol and Consolan systems, in which the masters and slaves are so close together that the hyperbolas become practically straight lines radiating out from the centre. By changing the phase of transmissions of the slaves, the hyperbolas can be made to swing to and fro. Morse signals are superimposed so that a craft can tell its location in a particular lane or sector.

The Decca system adapted for computer. Decca covers a wide area and is inherently a flexible navigation system. Before Decca's invention, however, aviation policy had been committed to signpost navigation using VOR beacons and subsequently VOR/DME. Consequently, the Decca system was adapted to work with a computer that would make the area system work as if there were beacons placed anywhere the navigator wished. Thus Decca could work as a signpost or "point" navigation system.

The "point" navigation philosophy has since run into difficulties. As air traffic builds up, more and more routes are needed; thus more and more signposts must be set up. VOR/DME computers, however, have been developed so an aircraft can follow any track irrespective of the position of the VOR/DME. Thus the computer has restored to the "point" navigation system the flexibility originally possessed only by the area navigation system, a flexibility increasingly needed to ensure adequate separation between aircraft.

The computer has already become part of the inertial navigator; it is used also in automatic dead reckoning. Originally, computers used in navigation systems were analogue, and calculations of a relatively simple nature involving inputs from various electrical sources were continuously performed. Today's trend is toward the use of digital computers for performing the necessary calculations.

Use of the digital computer

The digital computer works so fast that for navigational purposes it can be considered virtually instantaneous and can therefore provide continuous information for control purposes. It has a memory to store information for use when needed. It is built from electronic modules that are mass-produced at low cost. It has only one disadvantage. Conversion of analogue information into digital form is costly. Hence, although far superior to the analogue computer, it is less economical whenever a large number of electrical signals must be combined in relatively simple ways without any need for memory. Such situations still apply to control systems in many craft.

Navigation satellites. Satellites may be designed to function as navigational aids. It is possible to place a satellite in a stationary orbit, in which it circles the earth at an altitude of about 19,300 nautical miles. It then circles the earth once a day and, if positioned above the Equator to revolve in the same direction as the earth rotates, appears to be stationary in the sky. Stationary satellites can receive signals from various craft and retransmit these signals to the ground. They may thus act as relays to help measure the position of a craft by distance-measuring systems or by hyperbolic methods; they can then retransmit the position back to the craft.

Satellites that travel in orbits a few hundred miles above the surface of the earth circle it in a matter of an hour or two, with 80 minutes a typical period. Such satellites may be placed in orbits at an angle across the earth so that they cover a wide band of latitudes, moving a little further to the west at each orbit as viewed from the earth below. Such satellites may be used, as in the Transit system, to find the position of the craft by Doppler. The satellite transmits a steady radio frequency and a receiver in the craft detects the change of frequency. The speed at which the note changes establishes how far away the satellite is, just as one can detect how close a racing car is by the abruptness with which the engine note drops from a whine to a growl as it passes. The satellite also transmits continual details of its orbit so the craft can calculate its position at the moment the satellite passes by. Though the calculation may be made by arithmetic, a computer is often employed. Obviously a fix is obtainable only once every 80 minutes or so and, when the satellite passes almost directly overhead, it may not be possible to decide whether it has passed to the left or to the right of the craft. It may be necessary to wait another 80 minutes to obtain a useful fix.

RADAR

Operation. Radio waves with wavelengths in the centimetre range can be beamed by a reflector like light in an automobile head lamp to make up a radar system. The narrowness of the beam depends on the shortness of the waves and on the width of the reflector. For ships and aircraft, radio waves of a very few centimetres in length are commonly used to keep the reflector width down to a few feet. Ground radars can have much bigger reflectors and wavelengths of ten centimetres or more are common. A radar antenna mounted on a ship is wide and shallow to produce a beam that is narrow in the horizontal plane and wide in the vertical plane. Narrowness in the vertical plane could cause the radio waves to miss the target when the ship rolls. As the radar antenna rotates, the transmitter sends out a series of very short pulses every degree or so. When the pulse strikes an object, it is reflected back to the radar aerial and hence passed to the radar receiver. The pulse is displayed on a cathode-ray tube. Electronic lines are drawn from the centre outward, each starting out as the pulse starts out from the transmitter. When an echo returns, the image on the tube brightens up. Thus a spot of light appears on the cathode-ray tube at a distance from the centre proportional to the time the pulse takes to go out and back and in a direction the same as that in which the pulse was transmitted. Hence, on the cathode-ray tube a faint ray of light rotates around the screen like a searchlight, following the rotation of the antenna, and paints in the positions of any reflecting objects as if they were on a map. The face of the cathode-ray tube is coated with long-persistence phosphor that continues to glow for several seconds after it is excited, thus allowing the viewer time to study and analyze the image.

The strength of the return signals will vary depending on the reflectivity of the surface of the reflecting object and on its distance. There will be little reflection from water unless it is very rough. From cliffs, ships at sea, and buildings, there will be strong reflections due to the vertical surfaces. From the ground, there will be only scattered reflections, generally stronger in wooded country. Nevertheless, because the shortest radar waves are so much longer than light waves, the picture painted by radar is imperfect and requires careful interpretation.

Applications. Although radar can produce a map, its main use is in avoiding collision. Using radar, the navigator of a ship can see other vessels irrespective of light conditions. He can therefore proceed slowly even in thick fog, whereas without radar he would have to heave to or anchor. Since the radar picture is imperfect, collision avoidance requires great skill in interpretation. In particular, it is not easy to see the direction in which other vessels are travelling. Because of this, the seaman has to

Use of radar to avoid collision

make particularly bold alterations of course in order that other ships may know his intentions.

With radar, an air-traffic controller can watch the progress of aircraft in his area. Special height-finding radars, whose aerials are tall and narrow instead of broad and shallow, are also used. Radar is also used to watch aircraft approach and land, one radar following the aircraft in the vertical plane and the other following it in the horizontal plane. If necessary, the aircraft can be "talked down" (told exactly how to land) by the radar operator on the ground.

During World War II, craft carried radar responders that gave out coded signals when hit by radar beams, permitting identification of the craft as friend or foe. Similar systems are being developed for civil aviation in which the aircraft automatically identifies itself and gives its altitude when struck by an Air Traffic Control radar beam.

Special systems. For military purposes, infrared waves may be used. Midway in frequency between radio and light waves, these are, in fact, heat waves. An infrared detector can distinguish between objects of different temperatures and can identify a ship on the water or a man hidden in undergrowth. Infrared needs only a very small antenna and therefore has been used to guide small missiles launched from aircraft to strike at enemy planes. Infrared, however, is distracted by heat, from the sun and from friendly jet engines.

Lasers (*q.v.*) can also be adapted to produce radar-like devices of extreme precision. In addition, there is increased interest in simple television cameras; when equipped with light intensifiers, they can "see" in almost pitch darkness. Finally, for underwater detection of either submarines or shoals of fish, sonar radars are being developed.

Automation. The computer has already been mentioned in connection with point and area navigation systems, the use of satellites, and the mixing of various aids with inertial navigators. Automation is needed because craft speeds are increasing to meet demands for quick delivery of passengers and cargo and to lower operating costs. A jet aircraft with a crew of fewer than ten can carry more passengers across the Atlantic than an ocean liner with a crew of hundreds, because its greater speed enables it to make many more trips a year.

Automation can also reduce crew sizes by taking over tasks that machines can do more reliably and more consistently. On the other hand, because engineers must design machines years before they are used, they cannot foresee some situations that arise. The first landing of a man on the moon involved events not anticipated by the designers of the landing module. Had men not been in the spacecraft, it would have crashed. Therefore the human navigator will doubtless be required in many types of craft well into the foreseeable future. Although the machine can manipulate, it cannot manage except insofar as it is preprogrammed to do so.

The navigator of the future will become more and more a manager of systems. He may also be required to undertake certain manipulative tasks simply because under certain circumstances it is less costly and equally efficient to use a human.

Neanderthal Man

Human populations referred to as Neanderthal man inhabited much of Europe and the lands surrounding the Mediterranean during the extended time interval of the earlier upper Pleistocene. The name derives from the gorgelike Neander Valley above the small stream of Düssel, a tributary of the Rhine, seven miles east of Düsseldorf, Germany. There in the Feldhofer Cave in 1856 workers encountered portions of a human skeleton; 14 pieces were eventually salvaged by Johann Carl Fuhlrott, a professor at the Realschule in Elberfeld. Following the description of the remains (by German anthropologist Hermann Schaaffhausen), a lively controversy arose as to whether their unusual morphology was normal, and hence indicative of an archaic variety of man, or whether it was merely a case of pathology in modern man. The former view was duly proved correct after the discovery in 1886 of two similar skeletons in the Cave of Spy (Belgium) in association with implements of chipped stone and animal bones representative of a subarctic fauna including extinct species. In over a century of research on human evolution and the prehistory of man, much additional information has been gained concerning the Neanderthal peoples, their distribution in space and time, their origin and disappearance, and their ways of life.

Recognition of Neanderthal man

Figure 1: Distribution of pre-Neanderthal and Neanderthal finds in Europe, southwestern Asia, and northern Africa.

Ancestors of Neanderthal man. The forerunners of Neanderthal peoples are hardly known. Perhaps they are to be found among human populations in Europe dating back to the Riss Glacial Stage, 100,000 to 150,000 years ago. To date, however, only a half-dozen localities in France have yielded relevant fragmentary skull parts of that geologic age. These specimens diverge in dental and

skull morphology from an older human species, *Homo erectus*, and to the degree that they do so they approach more closely the structure characteristic of the modern human species, *Homo sapiens*. The skeletal parts available are too limited to permit an interpretation of their shape and structure as especially Neanderthal-like. Better preserved and more complete human crania of older (Great Interglacial) age are not particularly Neanderthalian, either. Some students of human evolution reasonably regard them as early representatives of *Homo sapiens*. The time and the place of Neanderthal origins, thus, still remains unknown.

Early Neanderthals

Neanderthals of the Third Interglacial Period. The first recognizably Neanderthal peoples occur during the Last Interglacial Age in Europe. Their jaws, teeth, and skull parts are known from some half-dozen sites in Czechoslovakia, Germany, France, and Italy. Among other features, they were characterized by moderately small cranial capacity; a short, narrow, and well-arched skull vault; large but somewhat separate and curved supraorbital ridges; moderately large cheekbones with some hollowing beneath them, and gracile and straight or only slightly curved limb bones, generally lacking enlarged ends. The general pattern of the anatomy of the face and even of the skull vault of these early Neanderthal peoples was not greatly unlike that of modern *Homo sapiens;* this was also true of the bones of the limbs, although these are still hardly known. There was nonetheless a complex of skeletal features that distinguished them from modern human populations.

Neanderthals of the Fourth Glacial Period. Far more numerous and complete skeletal remains have been recovered of Neanderthal peoples from the succeeding initial phases of the Last (Würm) Glacial Stage (between about 35,000 and 85,000 years ago). This is probably due in large part to the marked tendency toward utilization of cave fronts and rock shelters below cliffs for habitation sites, as well as the widespread practice of deliberate burial of the dead. Such peoples were distributed, evidently as small semi-isolated populations of hunting and gathering bands with a Mousterian stone industry, from western Asia throughout much of Europe, except the far north, as well as along the Mediterranean littoral of northern Africa.

The cultural adjustments of these extinct people can be inferred, and then only very imperfectly, from careful, well-controlled excavations of their habitation places. Hundreds of such occurrences are known, mostly cave fronts and rock shelters, but sometimes also open-air encampments. Many have been dug in some way, but relatively few have received really thorough scientific study. Some sites are quite small and were only visited by prehistoric men, probably briefly, on one or a few occasions. Other sites are of quite substantial size, and evince repeated episodes of human occupation, sometimes nearly continuously, sometimes interrupted by intervals of abandonment. The magnitude and intensity of occupation can be deduced from the extent, thickness, and overall quantity of occupational residues. In some instances sites were not merely occupied but were modified through stone emplacements, cobble pavings, and excavated depressions and holes; some of these were doubtless related to shelter-like structures. Persistent and extensive employment of fire is evidenced by reddened areas, hearth traces, charcoal and ashes, and even heat-fractured stone. Animal bone, often in abundance, testifies to efficiency and success in hunting and probably also in snaring and trapping. There is frequently some diversity in the representation of herbivorous and carnivorous species; but there may also be a predominance of one or several species—wild horse, reindeer, aurochs, bison, fallow deer or gazelle, red deer, goat or ibex, for example. These differences evidently reflect a combination of ancient environmental conditions, local availability of particular species, and dietary preferences. Remains of birds, even fish, are also known and in infrequent instances also invertebrates (*e.g.*, clams). The nature and extent of plant food utilization is scarcely known because of the very poor condition of their preservation; however, some traces may be preserved in charcoal, seeds, and pollen. Stones appropriate to the cracking and grinding of plant seeds have also been found at these sites.

The technological capabilities of Neanderthal peoples are best inferred from the products of their stoneworking; although bone was also fashioned into tools and weapons. Less durable materials, such as wood or cordage, are scarcely ever preserved; only a single wooden lance, apparently employed to kill a straight-tusked elephant, has been recovered (in Germany) from this time range. The stone technology reveals special procedures for the preparation of blanks (rough pieces of wood) for the eventual fashioning of chipped stone tools and other artifacts. The stone tool kit is quite diversified and there is a substantial number of "standardized" tool forms or types and subtypes. These are frequently found to occur in different sets or combinations, and some archaeologists consider that such recurring clusters of tool types and subtypes may reflect locally distinctive styles of life.

Stone-working technology

Deliberate burials are not uncommon in Neanderthal occupation sites. Both individual and group burials are known, which have yielded remains of adults and juveniles. Their emplacement, and accompanying artifactual materials, evidently reflect some concern for the deceased. In other instances human bones are incomplete and seem to have been so deliberately broken as to indicate cannibalistic practices. Some unusual ritual-like arrangements of animal remains, including bear and goat, are also known, and these are sometimes associated with human skeletons. In general, however, little can be confidently inferred about Neanderthal beliefs and rituals. Artistic or decorative proclivities are reflected in the frequent occurrence at some sites of natural colorants (manganese oxides, ochre) with evidences of their use, and more rarely of cut and incised bone.

The most numerous remains of these peoples, sometimes termed classic Neanderthals (Figure 2), have been recovered from the western and southwestern parts of Europe. Over this area, including Belgium, France, westernmost Germany, Spain, and Italy, lived short, stout, powerfully built Neanderthal peoples possessing a number of distinctive skeletal characteristics that have been thought to set them apart from their contemporaries elsewhere. This was true of the braincase (very large cranial capacity; long, low, and wide skull vault, flattened behind; heavy, bi-arched supraorbital ridges), of the face (projecting and large; round orbits; small cheekbones with no hollowing below them due to expanded sinuses; quite large teeth and palate), of the trunk (rounded, broad chest; short vertebrae with large muscular processes; long, slender collarbone), and of the limbs (heavy, curved thigh and forearm bones; large feet and hands but short fingers and toes; arm and leg bones with enlarged ends; long heel bone). The popular conception that these people were slouched in posture and walked with a shuffling, bent-knee gait seems to have been due in large part to faulty reconstruction of the skull base and to

Figure 2: Side view of Neanderthal skull of classic type, found at La Ferrassie, France.

Physical characteristics of Neanderthals

misinterpretation of certain features of the limb bones of one of the Neanderthal skeletons discovered early in the 20th century.

Such were the peoples to whom the specific name *Homo neanderthalensis* was applied in 1864 after the original discovery of the type skeleton in the Feldhofer Cave. (Actually two other such skulls had been found earlier in the 19th century but went unrecognized until after the Neanderthal discovery proper.) It is now apparent that these peoples represented merely the western periphery of a particular range of variation within a quite widespread human species. Since such peoples were in fact fundamentally like *Homo sapiens*, the use of *neanderthalensis* as a distinct species name can be most misleading. It is more reasonable to consider such people as no more than an extinct subspecies: *Homo sapiens neanderthalensis*.

Skeletal remains of other Neanderthal peoples are known from central Europe (Czechoslovakia, Hungary), southeastern Europe (Yugoslavia, Greece), Crimean Russia, southwestern Asia (Israel, Iraq), and from as far east as central Asia (Uzbekistan). Others are known from cave sites in Cyrenaica and Morocco. The skeletal anatomy of individuals from eastern Europe and western Asia is unquestionably Neanderthalian; but there are also divergences in morphology, particularly in those from western Asia (see Figure 3), from the characteristic European condition. This seeming progression in the variation of morphological features between geographic populations increasingly more distant one from another may merely reflect a gradient (cline), as often is observed within species.

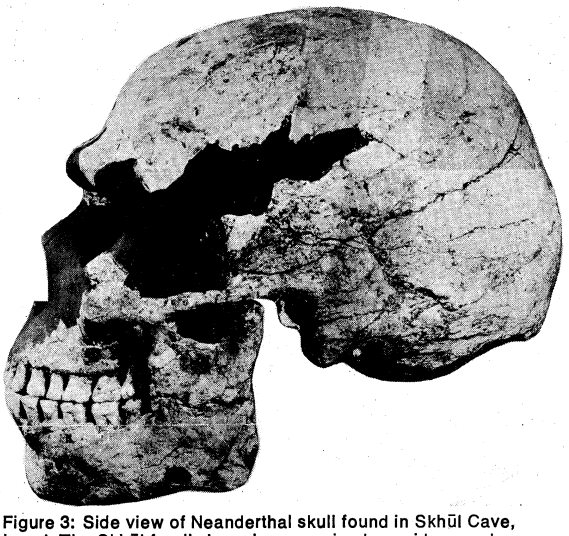

Figure 3: Side view of Neanderthal skull found in Skhūl Cave, Israel. The Skhūl fossils have less massive brow ridges and shorter, less massive crania than the classic Neanderthal type.

Causes of morphological distinctiveness. Populations referred to as classic Neanderthals have sometimes been thought to have been relatively isolated from other such peoples in the southwesterly parts of Europe as a consequence of the increasing severity of the climate during the initial phases of the Last Glacial Age. Such isolation could have restricted gene flow between populations; increased inbreeding; and perhaps tended to bring about shifts, even drift, in gene frequencies, because of accidents of sampling from the original population. Such changes would encourage a progressive increase of distinctiveness in the morphology of the isolated Neanderthal populations from others elsewhere, not so restricted in breeding possibilities.

Increased selection pressure under increasingly harsh environmental stresses could also have been effective in bringing about morphological change and also, perhaps, in reducing population size below a critical point beyond which eventual partial or total extinction could have occurred. This simple model is inadequate to account for the progressive variation now evident among Neanderthal populations. It fails to consider the several interstadial phases of climatic amelioration both prior and subsequent to the principal prolonged cold of that period. More extensive and thorough archaeological investigations in recent years have also revealed far more elaborate and sophisticated cultural adjustments of Neanderthal peoples than were known previously.

Neanderthal man and Cro-Magnon man. The factors responsible for the disappearance of the Neanderthal peoples are an important problem to which there is unfortunately still no clear solution. In fact quite different factors may have operated in different parts of their range of distribution. In Europe nearly all cave and rock-shelter sites where occupation was repeated reveal a sterile horizon between the last Mousterian or related cultures (presumably of Neanderthal peoples) and succeeding occupations of early upper Paleolithic type (either Chatelperronian or early Aurignacian). The latter occupations appear always to be associated with Cro-Magnon peoples, a modern variety of *Homo sapiens* that is characteristically European in skeletal anatomy (see CRO-MAGNON MAN). In western Europe these earliest upper Paleolithic occupations date to *c.* 32,000 BC. In central Europe (Poland, Hungary), however, related cultural manifestations appear to have been present locally by *c.* 38,000 BC (and this seems also to have been the case in southwestern Asia and in Cyrenaican Libya). The youngest radiometrically dated Mousterian occupation in southwestern France is *c.* 33,000 BC, but even later occurrences are inferred on geological grounds in southeastern France. A climatic amelioration (Hengelo Interstadial), resulting in warmer temperatures and substantial reforestation, occurred between *c.* 37,000 and 35,000 BC, when these changes in material culture and in population were taking place. There are still, however, many ambiguities in the results of such radiometric dating as well as in the enumeration and age assessment of episodes of climatic amelioration in Europe.

Disappearance of Neanderthal man

It is clear, at least in Europe, that several populations were involved and that the Cro-Magnons succeeded the Neanderthals; but it still cannot be demonstrated conclusively whether these different human populations overlapped in time in the same territory, the indigenous Neanderthals being perhaps ultimately eliminated or swamped by the immigrant anatomically modern peoples, or whether the Neanderthals were generally no longer present, except perhaps in small local groups.

Asian and African peoples with Mousterian culture. In some cave sites in southwestern Asia and in northwestern Africa there are human skeletal remains that verge on an anatomically modern morphology, yet the cultural association is Mousterian. The cave of as-Skhūl on Mount Carmel (Israel) and Jebel Irhoud (Morocco) are the principal examples. Most recently, the cave of Jabal Qafzah, in Galilee, has afforded a substantial series of burials of individuals still more modern in appearance, again in a Mousterian cultural context. Some workers believe that such populations, who were perhaps already coexisting with and were eventually to replace Neanderthals in southwestern Asia during these initial phases of the Last Glacial, indeed represented the forerunners of the Cro-Magnon populations who later replaced the Neanderthals of Europe.

Non-Mousterian contemporaneous populations. Specifically Neanderthal peoples are not known to have existed in either Africa south of the Sahara or in eastern or southeastern Asia. Broadly contemporaneous peoples in those areas, however, have been sometimes referred to as Neanderthaloid, since a number of features of their skull morphology simulate the Neanderthal condition. Human skeletal remains that approach the morphology of modern *Homo sapiens* in significant respects are now known from several localities in eastern Africa from a range of time that coincided with that of the Neanderthals of more temperate latitudes.

Near East, Ancient

In this article, the "Near East" (approximately equivalent to the "Middle East") is defined as the area of Egypt, Nubia, Palestine and Syria, Armenia, Asia Minor or Anatolia, and Mesopotamia, together with the outlying areas of North Africa, the Aegean, Iran or Persia, and the Indus Valley. Since many of these countries are referred to in biblical history, they are often called "Bible Lands." The term Fertile Crescent is often applied to Mesopotamia and Syria–Palestine. The article will deal with the period between the emergence of agriculture about 10,000 years ago and the conquest of virtually the whole ancient Near East by Alexander the Great in the 4th century BC. Iran and South Arabia, which continued to follow basically pre-Hellenistic cultural patterns until their conquest by the Islāmic Arabs, will be surveyed until the 7th century AD.

The ancient Near East.

Most scholars agree that the first sedentary (non-nomadic) human societies developed in the Near East and that the sedentary and urban way of life spread from the Near East to other parts of Asia and Africa and to Europe. Carbon-14 (radioactive carbon) and other methods of dating by the physical sciences have established with remarkable precision the general chronological framework of late prehistory and early history in the Near East and surrounding areas.

The emergence of sedentary cultures (*c.* 9000–*c.* 3000 BC). The high antiquity of civilization in the near East is largely due to the existence of convenient land bridges and easy sea lanes passable in summer or winter, in dry or wet seasons. Movement of large numbers of people north of the Caspian Sea was virtually impossible in winter, owing to the severity of the climate; central Eurasia was often too dry in summer. Land passage between Asia and Africa was in early times limited to narrow strips of land in the Isthmus of Suez. Large-scale desert travel was limited to special routes in Iran and in North Africa, both east and west of the Nile Valley.

Origins of agriculture

Another reason for the early significance of this area in world history is the fact that the water supply and the climate were ideal for the introduction of agriculture. Several species of grain grew wild, and there were marshes and tributary streams that could easily be drained or dammed in order to sow wild wheat and barley. The seed had only to be strewn over a sufficiently moist surface to ensure some kind of crop under normal conditions. It is therefore not surprising that there is evidence of simple agriculture as far back as the 8th or 9th millennium BC, especially in Palestine, where more excavating has been done in early sites than in any other country of the Near East. Many bone sickle handles and flint sickle edges dating from between *c.* 9000 and 7000 BC have been found in Palestinian sites.

Early irrigation cultures. In Mesopotamia and Iran remains of this period appear in caves on the lower slopes of the Zagros Mountains between western Iran and Iraq. The date of the systematic introduction of irrigation on a large scale in Mesopotamia is somewhat doubtful because most of the early sites of irrigation culture were covered long ago by accumulation of alluvial soil brought down by the spring floods of the Tigris and Euphrates rivers. Archaeologists once thought that all irrigation originated in the foothills of the Zagros and that the earliest true farmers lived in the plains of Iran. But recent excavations and surface explorations have proved that irrigation around the upper Tigris and Euphrates, as well as their tributaries, dates from the early 6th millennium BC (*e.g.*, at el-Kowm on the Upper Euphrates). Small-scale irrigation was practiced in Palestine (*e.g.*, at Jericho) in the 7th millennium BC.

In northern and eastern Mesopotamia, main streams were soon partly diverted during moderate river floods into canals running more or less parallel to the rivers, which could thus be used to irrigate an extensive area. Such deflector dam irrigation avoided the self-destructive weaknesses of large storage dams, in particular the danger of depositing great masses of refractory mud in the storage basin behind the dam. In the north and east considerable urban installations developed at sites such as Nineveh no later than the 5th millennium BC, when southern Mesopotamia was still mostly swampland like the early Egyptian delta. The Euphrates had a much smaller flow of water than the nearby Tigris. The latter was much swifter, however, so that it was potentially more important for irrigation, even though much harder to tame.

The Egyptian Nile had a much more predictable water flow than the Mesopotamian rivers because it flowed through hundreds of miles of swamp, where unusually high annual floods spread out, interfering with navigation but averting the danger of the occasional destructive inundations of Mesopotamia.

Mesopotamia and Egypt to c. 1600 BC. The oldest known urban and literate culture in the world was developed by the Sumerians in Mesopotamia beginning in the late 4th millennium BC. About 2300 BC a Semitic leader, Sargon I, conquered all of Babylonia and founded the first dynasty of Akkad (Akkadu), which held power for about a century and a half. Sargon and his successors

The Sumerians

were the first known rulers in southwest Asia to gain control of the Fertile Crescent as well as of adjacent territories. They sent trading expeditions to central Anatolia, Iran, and as far as India and Egypt. After the fall of the dynasty of Akkad there was a Sumerian revival under the 3rd dynasty of Ur (Ur III: [21st–20th centuries]), followed by another influx of Semites. These people founded the first dynasty of Babylon (19th–16th centuries), whose most important king was Hammurabi. In the 17th century new ethnic groups appeared in both Babylonia and Syria–Palestine: Kassites from the Zagros Mountains, Hurrians from what is now Armenia, and Indo-Europeans from Central Asia. This period marked the end of the formative phase of Mesopotamian civilization.

Shortly after 3000 BC the numerous small states that had arisen in the Nile Valley during the 4th millennium were united under the 1st dynasty of Egypt. At this time the Egyptians had already developed a system of writing. Between *c.* 2686 and *c.* 2160 BC, their country was united under a powerful monarchy (the Old Kingdom) served by a complex bureaucracy.

Toward the end of the 3rd millennium there was a period of disunity, followed by reunification under the 12th dynasty (1991–1786).

During these two centuries Egyptian control was established over Nubia, Libya, Palestine, and southern Syria. Soon after 1800 BC the Egyptian Empire fell apart, and *c.* 1700 Egypt was overwhelmed by the Asian "Hyksos," who ruled the country for a century and a half.

New states and peoples. Before the close of the 16th century BC the native 18th dynasty rose in Egypt; it expelled the Hyksos and founded the New Kingdom. The New Kingdom rulers moved back into Syria–Palestine and came into conflict first with the Hurrian state of Mitanni and later with the Anatolian Hittites, who were expanding into Syria from the north in the 14th century BC. The Amarna Letters (diplomatic correspondence written in Babylonian script and language, and discovered in Egypt by archaeologists) are an important source of information on this period. In Mesopotamia the dominant powers were Kassite Babylonia and Assyria (which emerged from subjection to Mitanni in the early 14th century BC). Relations between states were governed by elaborate treaties, which were constantly being broken. After the fall of Mitanni (*c.* 1350) the Hittites and Babylonians both directed their hostility against Assyria. Kassite Babylonia was subjugated by Assyria *c.* 1230. This, followed by the fall of the Hittite Empire (*c.* 1200), ended what has been called the first "International Age" in the civilized world.

The invasions of the 13th century BC

The latter part of the 13th century BC saw the irruption of new peoples into the Aegean, Anatolia, and the Fertile Crescent; their appearance coincided with the Trojan War, the collapse of the Hittite Empire, and the destruction of many coastal cities of Greece, Cyprus, and Syria–Palestine. Best known of the new settlers from the west are the Phrygians, who occupied most of the old Hittite heartland, and the Philistines, who moved into Palestine.

At the same time, in Transjordan and western Palestine, the Hebrews founded a tribal confederation that was changed into a monarchy by Saul and David (*c.* 1020–960 BC).

In the east, the Iranian tribes, led by the Medes, were pouring into Iran from Turkistan. From the south and west came the Semitic Aramaeans. The Aramaeans and Medes were to transform the old face of the ancient Near East.

The Assyrian state suffered an eclipse in the 11th century BC, when the Aramaeans and related tribes occupied most of its territory. It was not until the late 10th century that the Assyrians began to recover, but by 850 they had conquered much of western Media and southern Armenia as well as Babylonia and Syria. In the following centuries, until just before 630, the empire was greatly expanded. It was also highly organized administratively; its language became Aramaic.

The Canaanite Phoenicians on the Syrian coast re-established their trading communities after the Philistine and Aramaean invasions; in the 10th and 9th centuries they moved out into the Mediterranean, establishing colonies in North Africa and as far west as Spain. Their influence in the western Mediterranean declined after the 6th century. Their Carthaginian colony then took over Phoenician trade in the western and central Mediterranean.

Farther east, the Medes and Chaldeans destroyed the Assyrian Empire at the end of the 7th century. The Chaldean dynasty in Babylonia carried on Assyrian traditions of administration and encouraged commerce; under Nebuchadrezzar II (604–562 BC), their Neo-Babylonian Empire became the most powerful political entity of its time. Its rule extended from the Taurus Mountains in Anatolia to eastern Arabia and deep into southern Iran. This short-lived state made a tremendous impression on contemporaries, especially on the Jews, whose state was destroyed and who were carried into Babylonian Captivity, and on the Greeks, to whom the glory of Babylon became legendary.

The Achaemenian Empire and its successors. In the 6th century the Iranian Persians under Cyrus the Great conquered their Median cousins and established the Achaemenian state (549). This was followed by the conquest of Lydia (546) and the Babylonian Empire (539). Aramaic became the official language of the Persian Empire, and its official religion was Zoroastrianism. Cyrus' enlightened policy put an end to the Assyro-Babylonian practice of deporting conquered peoples and trying to destroy all local nationalisms.

At its height the Achaemenian Empire ruled the whole of the Near East; Greek resistance prevented it from expanding successfully into Europe.

The Macedonian conquest

The Parthian and Sāsānian empires. In 334 BC Alexander of Macedon invaded Anatolia and nine years later completed the conquest of the Persian realm. His vast empire was broken up into Macedonian "successor states" after his death. The Seleucid kings of Syria controlled most of Anatolia, Mesopotamia, and Iran. About 250 BC the still seminomadic Parthians emerged from a small area southeast of the Caspian Sea. Establishing control over Iran, they declared their independence of the Seleucid Empire and in the 2nd century BC expanded westward into Mesopotamia. In the 3rd century AD the semi-Hellenized Parthians were replaced by the Persian Sāsānians. The Sāsānians ruled Iran from AD 224 to 642; they extended its boundaries, reinvigorated its administration and cultural life, and challenged Roman power in the Near East. In 636 the Sāsānian Empire was conquered by the Muslim Arabs, bringing to an end the last phase of ancient Near Eastern civilization.

Pre-Islāmic Arabia. Arabia was drawn into the orbit of western Asiatic civilization toward the end of the 3rd millennium BC; caravan trade between south Arabia and the Fertile Crescent began about the middle of the 2nd millennium BC. The domestication of the camel around the 12th century BC made desert travel easier and gave rise to a flourishing society in South Arabia, centred around the state of Saba (Sheba). In eastern Arabia the island of Dilmun (Bahrain) had become a thriving entrepôt between Mesopotamia, South Arabia, and India as early as the 24th century BC.

The discovery by the Mediterranean peoples of the monsoon winds in the Indian Ocean made possible flourishing Roman and Byzantine seaborne trade between the northern Red Sea ports and South Arabia, extending to India and beyond.

In the 5th and 6th centuries AD, successive invasions of the Christian Ethiopians and the counterintervention of the Sāsānian kings disrupted the states of South Arabia. The resulting economic decline made the rapid Muslim conquest of the area an easy task in the 7th century.

The importance of Near Eastern higher cultures for world history. *Religion.* Near Eastern religious thought had a strong influence on the ancient Greeks. The cosmogonies of Egypt, Babylonia, Phoenicia, and Anatolia were transmitted in part to the West and formed the basis of much of the cosmogonies of Hesiod and the Orphics before 600 BC, as well as the background for the cosmogonies of Thales and Anaximander in the 6th century BC.

There is some influence from the Near East in Pythagorean and Platonic thinking, but it is often hard to define and still harder to prove in detail. From the early 3rd century BC on, the Near East began to influence Greek thought increasingly. Babylonian astrology influenced Stoic philosophy, and some Jewish influence on Stoic ethics is likely as well.

Late Egyptian religious speculations were transmitted to the Greeks, especially through the "Physiologists" and Hermetic writers who flourished in Hellenistic Egypt beginning in the 2nd century BC. Astrology and alchemy were transmitted to our time in substantially the forms they received in Hellenistic and Roman Egypt.

Jewish influence

With the partial Hellenization of Judaism and its Christian offshoot in the 1st century AD, Jewish influence on the West rapidly became dominant. Most of it came through the Pharisees, but such Jewish sects as the Essenes and Baptists were directly involved.

Even such a heterodox Jewish sect as the Samaritans exerted disproportionately great influence. In the first years of the nascent Christian Church a Samaritan diviner named Simon, later called "Magus," founded a new faith known as Gnosticism. The Gnostics spread rapidly over both the Roman and Iranian worlds, and by the end of the 3rd century AD they had subdivided into a multitude of different sects that covered a wide spectrum of possible combinations between Judaism, Christianity, Zoroastrianism, and Greco-Roman paganism.

In four centuries Christianity conquered the entire Roman Empire and many outlying regions, thanks to the intensity of its faith and the tenacity with which Christians held to their views, following Jewish models, through the bitterest persecutions.

In the East, Zoroastrianism maintained its hold over the Iranians and neighbouring peoples until the Islāmic conquest, when it was replaced by Islām, itself an offshoot of the monotheistic Judeo-Christian stem.

With the Hebrew Bible (which became the Christian Old Testament) almost the whole of traditional Israelite and early Jewish religion passed into Christianity, which was to a great extent an extension of Judaism. What was lost by the surrender of a large part of Jewish ritual law, with its stress on purity, was compensated by the triumph of monotheism over Greco-Roman polytheism and the transformation of ethical and spiritual ideas in the Greco-Roman world. Judaism itself survived to coexist with Christianity and Islām through all the intervening centuries to our own day.

Science and technology, law and logic. During the 3,000 years of urbanized life in Mesopotamia and Egypt tremendous strides were made in various branches of science and technology. The greatest advances were made in Mesopotamia—very possibly because of its constant shift of population and openness to foreign influence, in contrast to the relative isolation of Egypt and the consequent stability of its population. The Egyptians excelled in such applied sciences as medicine, engineering, and surveying; in Mesopotamia greater progress was made in astronomy and mathematics. The development of astronomy seems to have been greatly accelerated by that of astrology, which took the lead among the quasi-sciences involved in divination. The Egyptians remained far behind the Babylonians in developing astronomy, while Babylonian medicine, because of its chiefly magical character, was less advanced than that of Egypt. In engineering and architecture Egyptians took an early lead, owing largely to the stress they laid on the construction of such elaborate monuments as vast pyramids and temples of granite and sandstone. On the other hand, the Babylonians led in the development of such practical arts as irrigation.

Mesopotamian astronomy and mathematics

Both sciences and pseudosciences spread from Egypt and Mesopotamia to Phoenicia and Anatolia. The Phoenicians in particular transmitted much of this knowledge to the various lands of the Mediterranean, especially to the Greeks. The direction taken by these influences can be followed from Egypt to Syria, Phoenicia, and Cyprus, thanks to a combination of excavated art forms that prove the direction of movement, as well as to Greek tradition, which lays great stress on what the early Greek philosophers learned from Egypt. Mesopotamian influence can be traced especially through the partial borrowing of Babylonian science and divination by the Hittites and later by the transmission of information through Phoenicia. The Egyptians and Mesopotamians wrote no theoretical treatises; information had to be transmitted piecemeal through personal contacts.

The westward transmission of Babylonian mathematics was associated with that of law. All early Babylonian mathematics was transmitted in case form, introduced by a condition followed by its solution. This model appears first in late Sumerian law: from law it was extended to scientific problems, and the form remained the same until well into the 1st millennium BC. This was true also of such derived systems as Hittite law and the so-called covenant law of Israel, as well as the earliest Greek codes (Draco and Gortyn), all of which are formulated similarly: condition (protasis), secondary condition or conditions, and conclusion (apodosis). The Babylonian Code of Hammurabi provides an example: "If a man accuses another man and brings a charge of murder against him but does not prove it, the accuser shall be executed."

Logical thought

With the spread of case law in such conditional formulation, it was eventually discovered that formulation as generalized propositions or prohibitions was a simpler and more logical means of setting up a coherent code of laws than the case-law formulation (*e.g.*, in the Hebrew Decalogue). The next step was the formulation of generalized geometrical propositions. This was first done by the Ionian Greek Thales (about 600 BC), whose listing of mathematical propositions in this generalized form instead of as conditional sentences was quite naturally described later as the "discovery" of mathematical theorems. With Thales logical reasoning made a giant step forward from the age of empirical modes of thought.

The Judeo-Christian concept of ethics and morals in law often prevailed in the Roman law of Christian times. Roman forms of law were ultimately adopted in almost the entire Western world, and through their universal sway many biblical approaches to legal problems became dominant.

The place of the alphabet in world history. Of all the accomplishments of the ancient Near East, the invention of the alphabet is probably the greatest. While pre-alphabetic systems of writing in the Old World became steadily more phonetic, they were still exceedingly cumbersome, and the syllabic systems that gradually replaced them remained complex and difficult. In the early Hyksos period (17th century BC) the Northwestern Semites living in Egypt adapted hieroglyphic characters—in at least two slightly differing forms of letters—to their own purposes. Thus was developed the earliest known purely consonantal alphabet, imitated in northern Syria, with the addition of two letters to designate vowels used with the glottal catch.

This alphabet spread rapidly and was in quite common use among the Northwestern Semites (Canaanites, Hebrews, Aramaeans, and especially the Phoenicians) soon after its invention. By the 9th century BC the Phoenicians were using it in the western Mediterranean, and the Greeks and Phrygians adopted it in the 8th. The alphabet contributed vastly to the Greek cultural and literary revolution in the immediately following period. From the Greeks it was transmitted to other Western peoples. Since language must always remain the chief mode of communication for *Homo sapiens*, its union with hearing and vision in a uniquely simple phonetic structure has probably revolutionized civilization more than any other invention in history.

BIBLIOGRAPHY. Four general works are outstanding in quality; all but one are international in scope and authorship. First must be rated the *Cambridge Ancient History*, 4 vol. (1923–26), 2nd ed. of vol. 1–2 in over 60 fascicles (1961–), 3rd ed., vol. 1, pt. 1 (1970). Second comes *Historia Mundi*, esp. vol. 1–4 (1952–56), in which the individual contributions are much longer, which makes it more readable, although it is not so useful for the serious student. Third is the latest group of volumes, compact in size, of the *Fischer Weltgeschichte*,

vol. 2–4 by leading French scholars on *Die altorientalischen Reiche* (1965–67). Still very useful is EDUARD MEYER, *Geschichte des Altertums*, rev. ed. by H.E. STIER; 2 vol. (1931–39). All the following books dealing in English with single countries or cultures may be highly recommended: SIR ALAN GARDINER, *Egypt of the Pharaohs* (1961); S.N. KRAMER, *The Sumerians* (1963); A. LEO OPPENHEIM, *Ancient Mesopotamia* (1964); KURT BITTEL, *Hattusha: The Capital of the Hittites* (1970); J.A. BRINKMAN, *A Political History of Post-Kassite Babylonia, 1158–722* B.C. (1968); JOHN BRIGHT, *A History of Israel* (1959); and R.N. FRYE, *The Heritage of Persia* (1963).

Near Eastern Religions, Ancient

The religions of the ancient Near East (extending geographically from Iran to Egypt and from Anatolia and the Aegean Sea to the Arabian Peninsula, and temporally from *c.* 3000 to 330 BC, when Alexander the Great conquered much of the area) are the antecedents of the major Western religions; *i.e.*, Judaism, Christianity, and Islām. The religious beliefs, attitudes, and practices developed in the ancient Near East have had an enduring effect and influence on Western civilization. Among the many peoples whose religions contributed to this influence were the Egyptians, Hebrews, Moabites, Phoenicians, Ugaritians, Arabians, Aramaeans, Sumerians, Babylonians, Assyrians, Hittites, and Iranians.

NATURE AND SIGNIFICANCE

The ancient Near East cultural-historical area. The ancient Near East constituted an "ecumene." The term ecumene comes from the Greek word *oikoumenē*, which means the inhabited world and designates a distinct cultural-historical community. The material effects of the commercial and cultural interconnections that permeated the component regions of the ancient Near Eastern ecumene are richly supplied by archaeological excavations, which provide evidence of the spread of architectural, ceramic, metallurgical, and other products of ancient Near Eastern man's industry. Manufacturing and services tended to be monopolized by professional guilds, including religious personnel specializing in sacrifices, oracles, divination, and other kinds of priestcraft. The mobility of such guilds throughout the entire area helps to explain the spread of specific religious ideas and techniques over great distances. Just as guild potters spread ceramic forms and methods, so also guild priests spread their religious concepts and practices, from the Indian Ocean to the Aegean Sea, and from the Nile River to Central Asia. The Greek poet Homer, in the *Odyssey*, noted the mobility of guildsmen, mentioning religious personnel as well as architects, physicians, and minstrels. Guild priests called *kohanim* were found at ancient Ugarit on the Mediterranean coast of northern Syria as well as in Israel; and Mycenaean Greek (Late Bronze Age) methods of sacrifice are similar to the Hebraic methods, which are preserved in many countries to this day in the traditional techniques of Jewish ritual slaughter.

The spread of religious ideas and practices

Common elements in ancient Near Eastern religion. *Egypt and Mesopotamia.* In Mesopotamia, Egypt, and Canaan, each a sub-ecumene of the Near Eastern ecumene, the basic unit was the city-state with its own local religious cult. Each sub-ecumene had its universal gods; but in addition, each city-state within the sub-ecumene had its own local pantheon. In Egypt, from one end of the Nile Valley to the other, the sun god Re was revered as the universal god of life and Osiris as the universal god of the dead. But to those who dwelt in the Fayyum, or the Crocodile Nome (a political unit), Sebek, the crocodile god, had a special place. Similarly, in the Hare Nome, the hare god was worshipped. Each nome had its own cultic centre and its own priesthood that supervised the festivals, offerings, and other rites. An Egyptian who changed his residence from one nome to another put himself under the protection of a new local pantheon and its priesthood. His new religious calendar would prescribe a set of festivals differing from that of his former residence. He would have to acquaint himself with new customs and taboos. In the Hare Nome he would be forbidden to kill or eat rabbits; in the Crocodile Nome a parallel taboo would apply to crocodiles. Because of the widespread concept of such zoomorphic (animal-form) gods it therefore took little fundamental readjustment on the part of an individual who moved from one nome to another. Such was not the case, however, if an Egyptian moved to Mesopotamia. A ziggurat (tower temple) in Babylonia was functionally different from a pyramid (royal tomb) in Egypt; the former had to do with worshipping a living god, whereas the latter was the tomb of a dead king. Any nome in Egypt fostered the cult of Osiris and Isis (cult of the dead), which offered the prospect of a happy physical afterlife. Mesopotamia had nothing of the sort. Anywhere in Egypt the religious calendar was affected by the annual rising and subsiding of the same Nile. The situation was very different in Mesopotamia, where the twin rivers (Tigris and Euphrates) conveyed the concept that flooding was catastrophic—nothing like the beneficent inundation of the Nile.

Variety of local practices in Egypt

In Mesopotamia a man might move from Cuthah (in central Iraq), the cultic centre of the underworld deities Nergal and Ereshkigal, to Ur (in southern Iraq), the cultic centre of the lunar (moon) deities Nannar and Ningal. Each centre in Mesopotamia had its own cultic calendar, but the pantheon and the religious ideas were the same from one end of the sub-ecumene to the other.

Canaan. By the same token, the city-states of Canaan (on the eastern Mediterranean coast) adhered to a single world view that embraced a distinctive set of religious concepts and institutions. When the Moabite Ruth (in the Old Testament Book of Ruth) decided that she would leave her native land and attach herself permanently to Judah, the land of her mother-in-law, Naomi, she pronounced the formula for effecting the change: "where you go I will go, and where you lodge I will lodge; your people shall be my people, and your God my God; where you die I will die, and there will I be buried" (Ruth 1:16–17). This was not a conversion in the modern sense. Instead, it was a permanent change of residence within the same sub-ecumene, implying that one joins the people of his new land, in life and in death, under the aegis of the gods of that land and people. Ruth did not have to learn new concepts; she merely left the god Chemosh's Moabite sector of Canaan for the god Yahweh's Judaen sector of Canaan. No major change of language or psychology was required, any more than would have been the case for an Egyptian moving from Memphis to Heliopolis, or for a Babylonian moving from Mari to Sippar.

Political, social, and religious organization. All urban societies in the ancient Near East were stratified. At the top was the ruling class, controlling warfare, administration, and religion. This class was generally established by conquerors who reduced the vanquished natives to the status of helots (to use the Greek Spartan terminology) or "hewers of wood and drawers of water" (as the Bible expresses it in Deut. 29:11; Josh. 9:21,23,27). The conquerors received land grants in perpetuity in exchange for continued service to the state. In theory the land was owned by the god. The Sumerian inscriptions of Gudea (*c.* 21st century BC) depict the local god Ningirsu as the owner of the city-state of Lagash. The human ruler, or *ensi*, was the god's agent, governing in accordance with the god's decrees as revealed through dreams interpreted by qualified religious personnel. In the Bible, Lev. 25:23 expresses the theory plainly; God says "The land shall not be sold in perpetuity, for the land is mine; for you are strangers and sojourners with me."

On the steppe, nomadic tribesmen, who raised cattle by extensive grazing, were independent or semi-independent of the urban states. Yet some sort of accommodation had to be maintained between the desert and the agricultural and urban peoples, if for no other reason to keep the trade routes open.

Mobility of religious personnel

Guild mobility was such that priests or prophets might be invited by one ethnolinguistic group from another over considerable distances. In the biblical book of Numbers (22:2–24:25) there is an account of the Moabites (living in the hills east of the Dead Sea) summoning Balaam, a seer from Aram on the Euphrates, to come and execrate their Israelite foes because of Balaam's international fame

in the black art of cursing. The biblical account does not question that Yahweh inspired Balaam's pronouncements (23:16 ff.), which to the disappointment of his employers turned out to be blessings instead of curses. Denominationalism, in the modern sense, was alien to the ancient Near East. Priests were specialists in the techniques of finding out the will of the gods, of influencing the gods in favour of the priests' clients, and of pleasing the gods through food, drink, and song so that gods would be well disposed to their devotees and bring them good fortune. Theological indoctrination was at most secondary, and generally unimportant to the ancient priest and layman.

The monarchical rulers were naturally tempted to monopolize the powers of society by controlling the religious, military, economic, and other forces that made up the state. At Ugarit, for example, the king consolidated his control by placing family and favourites in the positions of high priests and generals and by giving them large land grants in exchange for loyal service. The Hebrews, on the other hand, aimed at a balance of power in their commonwealth. Though the legitimate king had to be of the line of Jesse, a member of the Judaen tribe, the priesthood was restricted to the tribe of Levi; and within that tribe, the high priesthood was initially limited to the line of Zadok (the high priest of King Solomon in the First Temple in the 10th century BC). The lay citizenry also played a role in important affairs of state. When the northern tribes wanted assurances that Rehoboam would not continue the harsh program of his father, Solomon, it was "all Israel" (I Kings 12:1, 12:3) or "all the assembly of Israel" that issued the ultimatum. When Rehoboam rejected their demands, it was "the people" who repudiated him and seceded.

Monotheistic trends. Biblical monotheism, as a historic force, is rooted in the international Amarna Age (15th–14th centuries BC). Egypt was the aristocratic centre of the Amarna Age, but included in it also were Mesopotamia, Canaan, Anatolia, and the area surrounding the Aegean Sea. Traders and diplomats from Egypt, Canaan, and Babylonia could not avoid the conclusion that Re (the Egyptian god of the universe), the Canaanite "God the Most High, maker of heaven and earth" (Gen. 14:19), and Marduk (the Babylonian creator of the universe) were all essentially the same supreme god, and that their names were merely translations of each other. When Alexander the Great (356–323 BC) claimed to be the son of Zeus for Greek acceptability, but the son of Amon for Egyptian acceptability, he was not talking out of both sides of his mouth. He was merely translating into action the phrase of the Greek historian Herodotus (2:42), "Amon is the Egyptian name for Zeus." By the same token Cyrus the Great was not hypocritical in calling the god of the heavens "Ahura Mazdā" for his Iranian subjects, "Marduk" for his Babylonian subjects, and "Yahweh" for his Jewish subjects.

Concept of an international supreme deity

Association of religion with the arts and sciences. Religion was associated with both the arts and sciences, though in the literature of the area it is hard to disentangle the secular from the sacred. Hymns, at one level, and omen or ritual texts, at another level, are clearly religious. But it would be difficult to categorize the Gilgamesh epic of Mesopotamia or the Homeric epics of Greece as definitely secular or religious. They deal with human events or worldly problems, but the gods are constantly on hand to affect the destiny of men. The same may be said for two Ugaritic epics, the epic of Kret and the epic of Daniel and Aqhat, of the Late Bronze Age. This also holds for the patriarchal narratives in the biblical Book of Genesis about Abraham, Isaac, and Jacob, in which God and his messengers play the same kind of role in human affairs as the gods in the Homeric or Ugaritic epics.

Religion had close ties with science as well as with literature and art. Astronomy, mathematics, and time reckoning are sciences in which the ancient Near East made great strides at an early date, long before 3000 BC. Heavenly bodies were at the same time both deities and personified numbers. The star Venus was the star that the Assyrians and Babylonians called Ishtar, which was at the same time both the goddess Ishtar and the deified number 15. The moon was not only earth's satellite but also the lunar deity Sin and the deified number 30. The most perfect number was one, for by advancing from zero to one men believed they proceeded from nonexistence to existence. Moreover, all other whole numbers were regarded as multiples of one, representative of the Creator, the Prime Mover, of the universe. The Egyptians called Re "the one One"; the Babylonians identified the divine "One" with Anu, the god of heaven. When the Hebrew prophet Zechariah (14:9) proclaimed "on that day the Lord will be one and his name one," he indicated that the Hebrews, like their neighbours, reckoned with sacred numbers and saw in the number one a symbol of the creator. Biblical monotheism, therefore, has more than one dimension, including not only the monotheistic principle that there is one God and none beside him, but also the mathematical principle of the primacy of "one" and its deification as the Prime Mover. Since even the earliest books of the Bible arose long after the development of the sciences in the ancient Near East, the Bible or its religious features cannot be regarded as primitive.

Significance of the number one

The importance and influence of Near Eastern culture and religion. Judaism, Christianity, and Islām are all products of ancient Near Eastern culture. The area is thus of primary importance in the history of Western religions. Unlike the paganisms of the ancient Near East, Judaism developed the concept of canonical (standardized and authoritative) Scripture that gave it continuity. No cuneiform (Mesopotamian wedge-shaped script) or hieroglyphic (Egyptian pictorial script) religious text ever gained such canonical exclusiveness as the Bible. The paganisms were also limited by idolatry. Various conquerors captured or destroyed the idols of the vanquished, whose morale was thereby crushed, because their gods were no longer present, or alive, to help them. The Hebraic insistence on an incorporeal God, with no tangible image, established bonds that were not material and therefore could not be broken. Moreover, the prophets of Israel developed a blueprint of history that prepared the Jewish people for the troubles that lay ahead, but with the eschatological promise that God had a happy ending in store for the saving remnant who deserved well, in a golden age under the messianic King.

The optimism of the Hebrews was quite different from the attitudes of other nations. The Mesopotamians, for example, were inclined to regard the gods as evil. In the 11th Tablet of the Gilgamesh epic all the gods except Ea were regarded as malevolent. The Egyptians cherished a cult of the dead whereby the individual could, under proper conditions, achieve a happy immortality of an earthly nature, but there was nothing built into the religion to perpetuate the Egyptian way of life, once Egypt was exposed to Christianity and Islām. Egyptian religion and culture eventually became bankrupt and vanished. The Mycenaean Greeks did not even look forward to a satisfactory afterlife at a personal level. When the Homeric hero Odysseus tries to comfort the spirit of Achilles (who had died in the Trojan War) in the underworld, Achilles replies: "Do not seek to speak to me soothingly of death, O glorious Odysseus. I would prefer so that I might live on earth, to work as the hireling of another, of some portionless man whose livelihood was not great, rather than be king over all the dead that have perished" (*Odyssey* 11:488–491). For the Greeks the poorest of men among the living was considered better off than the most fortunate in the afterlife.

Concepts of the afterlife

There is also a qualitative factor that helps explain why, of all the ancient Near Eastern religions, Judaism survived and laid the foundation for Christianity and Islām. Situated at the centre of the ancient Near East and open to influences from all sides, Judaism enjoyed the opportunity of absorbing a maximum of influences from its talented neighbours that it proceeded to build upon creatively. Sumero-Akkadian poetry at its best is impressive, but it falls short of the sublimity of the psalms of David or the oracles of Israel's prophets. Egypt gave the world its first secular prose literature: the novelette. But a comparison of the Joseph story in Genesis with a similar Egyptian story of an attempted seduction shows that the Hebrews

learned their lessons so well from the Egyptians that they eclipsed their masters. The same holds for religion. The ancient Near East had, long before the appearance of the Hebrews, a rich record of ethical, moral, and religious expression. But it remained for the Hebrews to make "social justice"—the standard whereby, in any conflict of interests, the poor or the weak is always right versus the rich or the strong—the supreme requirement laid down by God, to require international peace as a permanent condition for a world worth living in, and to proclaim that universal and total disarmament was the only way of achieving that goal (in Isa. 2:4; Mic. 4:3).

The standard of social justice

Materialism, no less than war, was a blight on the ancient Near East because of the great emphasis placed on trade. Several Ugaritic texts represent the god Baal not only as coveting, but revered all the more by his Canaanite devotees because he was mighty enough to get what he coveted. Reacting against this aspect of their milieu, the Hebrews came up with the Tenth Commandment (against covetousness).

SOURCES OF KNOWLEDGE

The "archaeological revolution." The decipherment of Mesopotamian and Egyptian literatures in the 19th century opened new vistas of ancient Near Eastern history. Hitherto, scholarly knowledge had been limited to the contents of classical Hebrew, Greek, and Latin literatures. Explorations and excavations in the Near East yielded not only texts but an abundance of ancient objects of art, artifacts of daily life, and architecture, and thus have revolutionized scholarly knowledge of the ancient Near East, including its religions. A ziggurat excavated at Babylon illustrates the form of the biblical Tower of Babel. The prototype of the biblical story of the Deluge has turned up in the Gilgamesh epic. A fragment (dating from about 1400 BC) of that Babylonian epic has been found at Megiddo in Israel, showing that the Mesopotamian version was current in Palestine before the Hebrews, under Joshua, conquered the land around 1200 BC. A previously little-known people, the Hittites, are, due to archaeological discoveries, now recognized as a major power of antiquity with a rich legacy of religious texts, especially rituals.

The earliest and certainly the most fundamental ancient Near Eastern civilization—the Sumerian—had vanished without a reference in the literatures of the world. Now, Sumerology is an important field of investigation. Biblical studies have been greatly revolutionized by the tablets (1400–1200 BC) found from 1929 onward at Ugarit. It has become extremely difficult for anyone to keep abreast of the continually growing body of material, and very few scholars today feel secure enough to venture beyond limited areas.

Kings and winged figures bearing offerings beside a sacred tree. Assyrian marble relief, reign of Ashurnasirpal II, *c.* 880 BC. In the British Museum.

Literary sources of knowledge of ancient Near Eastern religion. Classical literature remains an important source for ancient Near Eastern religion. The Roman historian Livy (59 or 64 BC–AD 17) wrote many descriptions of religious rites of the ancient Near East. The Roman poet Virgil's (70–19 BC) *Aeneid* and *Eclogues* reflect Egyptian, Semitic, and Anatolian, as well as Greek, antecedents. The Greek biographer Plutarch's (AD 40/50–120/125) *De Iside et Osiride* ("Concerning Isis and Osiris") is still the best description of the Egyptian myth of Isis and Osiris and of the cult of the dead. The Greek satirist Lucian's (*c.* AD 120/125–190) *De Dea Syria* ("Concerning the Syrian Goddess") is of enduring value for an understanding of Canaanite religion. The writings of Herodotus, the 5th-century-BC Greek historian, remain an indispensable source for the cultural history and religion of the ancient Near East. And due to the discovery of texts from Ugarit, the Homeric epic of the Greeks is now firmly linked to Near Eastern literature.

The Hebrew Bible is still the most important single source for knowledge of the ancient Near East, reflecting life from Egypt to Iran, and from the Bronze Age beginnings to the Hellenistic Age. There is very little in the Old Testament that does not follow the types of religious literatures in the older Near East: psalms, hymns, laws, rituals, prophecy, wisdom literature, and other types. Sometimes parts of the Bible are related in detail to specific outside sources. The Egyptian *Wisdom of Amenemope*, first published in modern times in 1923, parallels Prov. 22:17–24:22 so closely that it effectively opened up the comparative study of ancient Near Eastern wisdom literature.

The Old Testament as a source of knowledge

WORLD VIEWS AND BASIC RELIGIOUS THOUGHT

The sacrality of nature and natural forces. All of the ancient Near Eastern people saw the agency of the gods in every aspect of life and nature. Everything on earth was regarded as a reflex of its prototype in the divine or sacred sphere, such as in the biblical description of the creation of man "in the image of God"; God was viewed as the primary reality and man the reflection thereof. In Egypt Thoth was the scribe in the pantheon. Mortal scribes were viewed as the human reflections of Thoth, and "the beak of the Ibis [*i.e.*, Thoth] is the finger of the Scribe" (*Wisdom of Amenemope*, ch. XV, 17:7).

The ancient Near Eastern people believed that the universe resulted from the injecting of order (cosmos) into chaotic primordial beings or matter, followed by divine acts of creation. Gen. 1:1–3 says: "When God set about creating the heavens and the earth [*i.e.*, the universe], the earth was in a state of chaos and darkness was upon the face of the deep; and the Spirit of God was flying over the face of the waters. And God said, 'Let there be light!'; and there was light." Thus darkness (*i.e.*, evil) was pre-existent. Moreover, the deep (*tehom* in Hebrew) is the same as the primordial dragon called Tiamat (cognate to the Hebrew *tehom*) in the Babylonian epic of creation. The first act of creation is God's evoking light (*i.e.*, the forces of good) by fiat. Accordingly, God is not responsible for the forces of evil, which were there before he embarked on the creative process. Proceeding by fiat he separated the water-containing earth from the water-containing heaven, confined the earth's waters to the bodies of water (leaving the rest as dry land), created the various species of vegetation, the heavenly bodies, the animal kingdom, and finally man who is to rule over the earth. All this takes six days, after which God rests on the seventh, so that the sabbath crowns the epic of creation and imposes the obligation to observe the sabbath in keeping with the principle of *imitatio Dei* (the imitation of God).

Creation of the universe

The Babylonian creation epic (*Enuma elish*, "When on High") states that at first there existed only the male (Apsu) and female (Tiamat) gods of the deep. They raised a family of gods that were so unruly that Apsu resolved to destroy them. Rebellion and chaos ensued. Among the deities was Marduk, the god of Babylon. Since the main version of the epic of creation is the Babylonian, Marduk occupies the role of Creator. (In the Assyrian version, Ashur is important.) Tiamat, who had embarked on a course of destruction, was slain by Marduk, who cut her in two and used her carcass to create the universe. Out of half her body he fashioned the sky containing the heavenly bodies to mark the periods of time. The epic culminates in the glorification of Marduk and the establishment of his

order. The *Enuma elish* was read on the Akitu, or New Year festival, at Babylon, to re-establish order, in accordance with sympathetic transference principles, by reciting Marduk's creation. The function of the Akitu is thus to rejuvenate society for the new year.

Views of man and society. The lack of hard and fast barriers between gods and men left room for hybridizing. The aristocracy, in particular, claimed some divine form of ancestry. Gilgamesh, a mortal king who ruled Uruk in Mesopotamia, was, according to the Gilgamesh epic, born of the goddess Ninsun, even as among the Greeks Achilles was accepted as the son of the goddess Thetis. Sometimes kings claimed to have two divine parents. King Kret, whose epic was found at Ugarit, claimed to be the son of El, the head of the pantheon, and of Asherah, El's wife. Every Egyptian pharaoh was hailed as "the son of Re" (the sun god). This does not, however, imply the absence of a human father. The concept was one of paternity at two levels; qualitative superiority emanated from the notion of divine paternity, but one's position in society came from the human husband of one's mother. Odysseus "the Zeus-begotten son of Laertes" (*Iliad* 10:144) was a hero because Zeus presumably impregnated his mother; but he was also king of Ithaca because his mother's husband was King Laertes of Ithaca. In this regard the birth and station of Christ differ only in that Mary was a virgin when she was divinely impregnated. Though the divine component of Christ is due to his divine paternity, his position as king of the Jews comes not from his heavenly Father but from Mary's husband, Joseph, who was descended from King David (Matt. 1).

In the ancient Near Eastern world view, gods could become mortal, and men could become gods. Utnapishtim, the hero of the Babylonian Flood story, was deified together with his wife by the fiat of the great god Enlil: "Hitherto Utnapishtim has been but human; henceforth Utnapishtim and his wife shall be like us gods" (Gilgamesh epic 11:193–194). In the Hebrew Bible, God so loved Enoch (Gen. 5:24) and Elijah (II Kings 2:11) that he carried them aloft to heaven as immortals. But these were special cases, and in antiquity they set no precedent for common folk. Kings enjoyed deification regularly in Egypt, though in some other traditions only upon dying. The Hittite monarch Hattusilis III refers to his father's death as "when my father Mursilis became a god" (*Apology of Hattusilis*, line 22).

Purpose of man

From the ancient Near Eastern point of view, man was created to serve the gods, and he does so in the hope that the gods appreciate it and will reward him for it. The gods need food and drink and depend on men to supply them. After the Flood the biblical Noah won God's goodwill, for "the Lord smelled the pleasing odor" (Gen. 8:21) of the tasty flesh and fowl offered up to him. Noah was following a long tradition, for Utnapishtim (Gilgamesh epic 11:155–161) had, after the Flood, offered sacrifices and libations to the gods who "crowded like flies" as they "smelled the sweet savor." Though gods depend on man, man also depends on the gods, and therefore service to the deities must be maintained for the welfare of the state, even as the family and the individual must do what the gods expect of them for domestic and personal welfare.

Everything on earth reflects a divine prototype, and all human affairs are divinely ordered and scrutinized. Gods may even build the cities destined to be their cultic centres and in which they are to reside, at least part of the time. The Greek god Poseidon built the walls of Troy, according to the *Iliad* (21:446–447). At Ugarit, Baal's temple was designed and built by Kothar-wa-Hasis, the god of arts and crafts. The Israelite King David gave his son Solomon plans for the Temple drawn up by Yahweh's (the Lord's) own hand (I Chron. 28:19).

National policy went hand in hand with theology. Ashur was the god of Assyria; the kings of Assyria were in theory his chief executive officers. Thus Sennacherib, king of Assyria, in undertaking a military campaign, recorded that it was not on his own initiative but in conformity with Ashur's will: "In my second campaign, Ashur my Lord impelled me." When the Hebrews and Transjordanians had a border dispute, Jephthah told the latter: "Will you not possess what Chemosh your god gives you to possess? And all that the Lord our God has dispossessed before us, we will possess" (Judg. 11:24). There was no such thing as secular policy in the ancient Near East.

Since the king was the human agent of the god, he was exalted above other men. In Israel, the king was chosen by God to rule his people. God's representative was a priest or prophet who consecrated the king by anointing his head with oil. But the king of Israel was not divine, neither while on the throne nor after death.

The divinity of kings evoked certain fictions. By sucking the breasts of goddesses, crown princes imbibed a source of divinity. The baby pharaoh sucking the breasts of Isis (who was perhaps in real life represented by her high priestess) is a common motif in Egyptian art. In Mesopotamia, it was not the usual practice for kings to claim divinity, but now and then it cropped up. Naram-Sin (23rd century BC) prefixed the sign for divinity before his name and was officially a god. The same usage is attested among kings of the 3rd Dynasty of Ur (*c.* 2100 BC).

Views of basic values and ends of human life. The good life was one lived in accord with the regulations of one's god. In the realm of ethics and morals there was more international uniformity than there was in taboo and ritual. Honesty and kindness were universally recognized as good, theft and murder as bad. Wisdom literature tended to stress the same virtues and to condemn the same vices, regardless of the region and cult. It remained for the prophets of Israel to single out uncompromising virtue as the overriding consideration in the good life required by God. The most important factor in that system was "social justice," whereby the weak was always protected in conflicts of interest with the strong. This had an important place in what may be called "international religion"; *i.e.*, that governing relations between men from different areas belonging to different cults. That level of religion, called "fear of the gods," is tested when the strong man confronts the weak. The strong man who injures the weak lacks the fear of the gods; the strong man who helps the weak has the fear of the gods. This was religion transcending all the regional cults, and it came into play when strangers abroad were at the mercy of the local inhabitants. Odysseus in a foreign land wanted to know if the people there feared the gods or were lawless so that no stranger was safe (*Odyssey* 9:176). Abraham, too, was concerned in Philistia lest the inhabitants might kill him because there was no "Fear of God(s)" (Gen. 20:11). Men of all nations and all cults knew that only among god-fearing men was there decency or safety.

Ethical emphases

There was another common trend in international religion. No matter how polytheistic a cult may have been, it left a place for the god shared by all men. Theos, "God" (not merely "a god"), is in Homer; *pa netjer*, "the God," occurs in Egyptian exactly like Elohim, "(the) God," in Hebrew. Nebuchadrezzar, the 6th-century-BC Babylonian king, made Zedekiah, the Judaean king, swear by Elohim (II Chron. 36:13), the God of the universe for Babylonians and Hebrews alike. Similarly, when the Hebrews spoke of truth uttered by Pharaoh Necho, which fell on the deaf ears of the Judaean King Josiah, the text (II Chron. 35:21) states that Elohim, "God," had spoken through the mouth of the pharaoh.

In Egyptian religion (followed by Judaism, Christianity, and Islām), the concept of a happy afterlife depending on one's ethical and moral record in this world was developed. Vignettes in the various Egyptian books of the dead show the deceased's heart being weighed against the feather of truth in the balances before the scribe god Thoth, who records the text. When the Bible speaks of God as "who tests the heart and the kidneys" (Ps. 7:9; Jer. 11:20 and 20:12) it refers to the same concept.

Myths as the basic mode of religious thought. Myths were developed to account for the cosmos. How did the gods bring heavens, earth, plants, beasts, and men into existence? What is the divine origin of human institutions and of the ecumene? What divine process is responsible for prosperity or failure? To explain such basic questions etiological (origin or causal) myths were developed. For

Purpose of myths

example, the attraction between man and woman (and the consequent institution of marriage) is explained by the myth that primeval man was one creature, subsequently divided into two parts, male and female, which are attracted to one another to regain their pristine unity. Aristophanes expresses this theory of sexual attraction in Plato's *Symposium*. Genesis has the same theory in the familiar myth that a rib, taken out of Adam, was fashioned into Eve; and precisely because woman was taken out of man, man forsakes his father and mother to cleave unto his wife so that they become one flesh (Gen. 2:23–24).

Myths are often invoked in magic (which, unlike religion, aims at compelling, instead of imploring, the gods). To banish evil from the life of a client, the magician may invoke the cosmic myth whereby the forces of good triumph over the forces of evil. Evil is depicted as a seven-headed monster on a seal of the Akkad period (3rd millennium BC) in Mesopotamia, whose heads are being successively killed by good anthropomorphic (human-form) beings. At Ugarit, in mythological poems of the Late Bronze Age, the good gods Baal and Anath slay the wicked Leviathan of the Seven Heads, providing the precedent for the victory of good over evil. The Hebrews also nurtured this myth whereby God slays the many-headed Leviathan (Ps. 74:14) and will do so again at the end of days, to quell evil and establish good for all eternity (Isa. 27:1).

Magical concepts and attitudes. The loftier trends of ancient Near Eastern religion did not as a rule threaten to eliminate magic. White, or protective, magic was never seriously discouraged. Black, or destructive, magic was frowned on by organized society, regardless of whether the official religion was monotheistic or polytheistic, because black magic makes its victims unfit for functioning productively in society. Section II of the Babylonian King Hammurabi's (Hammurapi's) code punishes witchcraft (as well as false accusations of witchcraft) with the death penalty. Moreover, all organized religion tended to oppose magic that circumvented the official clergy. King Saul of Israel had characteristically banned sorcery, driving it underground. Yet when he wanted guidance from the dead prophet Samuel, Saul consulted the Witch of Endor who was practicing her art illegally (I Sam. 28:6–25). She was able to call up the spirit of the prophet from the underworld, which, incidentally, illustrates one of the reasons why society opposes spiritualism. The witch, by claiming to bring the greatest authorities of the past onto the current scene, threatens the authority of the establishment.

RELIGIOUS PRACTICES AND INSTITUTIONS

Nature: the framework of ideas and practices. Fertility of agriculture, of edible animals, and of the human population was a paramount factor in the life and religion of the ancient Near East. The forms that the fertility rites assumed varied from region to region, depending on climate and geography. Rain and dew were all-important in Canaan, but of little significance in Egypt. In both areas water was crucial, but the source of the life-giving water was entirely different. The agricultural year varied in the two regions. In Egypt the year was divided into three seasons: inundation, sowing, and harvest. In Canaan there were two seasons: the winter characterized by rainfall and the summer characterized by dew. The year was punctuated by different agricultural activities, as is indicated in the Gezer Calendar in which all 12 months are accounted for as times of profitable agricultural activity, with harvests in the rainless summer as well as in the green winter. Anxiety was caused by the uncertainty of rain in the rainy season and of dew in its season. All of the regions of the ancient Near East schematized the blessing of good years and the threat of bad years in terms of seven-year cycles. A Mesopotamian text illustrating this is the Gilgamesh epic (8:101–113), in which the slaying of the hero Gilgamesh would initiate seven lean years. At Ugarit the slaying of the hero Aqhat evokes a curse depriving the land of rain and dew for seven (or, climactically, eight) years. The seven lean and seven fat years in the biblical story of Joseph in Egypt reflect the same system. In Egypt, of course, rain and dew are out of the picture; instead, generous Nile risings mean prosperity; inadequate risings in the season of inundation spells misery. A text of the Ptolematic period (4th–1st centuries BC), purporting to record events of the Pyramid age, tells of seven lean years in the reign of Djoser (3rd dynasty; *i.e.*, *c.* 2686–*c* 2613 BC). The pharoah appealed to the gods, who responded by restoring an abundant flow of the Nile.

Seasonal patterns

The population desired the normal pattern of times and seasons, so that "seedtime and harvest, cold and heat, summer and winter, day and night, shall not cease" (Gen. 8:22). But since the seasonal pattern is not dependable, the need for order evoked a system of cycles: notably the sabbatical cycle. A Ugaritic liturgical text especially designed for this phenomenon aims at terminating a sabbatical cycle of privation and ushering in one of fertility by celebrating the birth and triumphal entrance of the Seven Good Gods, whose advent brings an abundance of food and wine.

(Lower portion) The Syrian goddess Anath (seated right) and worshippers. In the British Museum.

Fertility rites

It was only natural that fertility rites should include sexual myths acted out dramatically. The Ugaritic text just alluded to describes El, the head of the pantheon, copulating with two human women. This has echoes in Hosea and Ezekiel where God, as in the Canaanite literary tradition, is referred to as having figuratively a love affair with two women, symbolizing Judah and Israel. The Hebrews, however, eventually eliminated sex from their official theology and religious practices. Up to the time of King Josiah's reform (621 BC) there was a women's cult of Asherah (under *qedeshim*—or consecrated for fertility practices—auspices, according to II Kings 23:7) in the Jerusalem Temple, alongside the male cult of Yahweh. Asherah's devotees considered her the chief wife of Yahweh, even as she was the wife of El, head of the Canaanite pantheon, for in the Bible, El is identified with Yahweh. But Josiah eliminated the cult of Asherah, and official Judaism has since then left no place for other gods, which meant the elimination of every goddess. Popular religion, to be sure, persisted in the female fertility principle until the destruction of the Temple in 586 BC. In Judaean excavations Astarte figurines were found in private homes down to that time. Further purification of the

Hebrew religion, intensified by the catastrophe of 586, put an end to the practice of pagan fertility rites, including the use of goddess figurines. Without goddesses there could be no sexual activity in the pantheon, and thus Judaism has developed without any divine mother figure.

The ancient Near East made a place for homosexuality and bestiality in its myths and rites. In the Asherah cult the *qedeshim* priests had a reputation for homosexual practices, even as the *qedeshot* priestesses for prostitution. Israel eventually banned both the *qedeshim* and *qedeshot*, while in Ugarit the *qedeshim* and *kohanim* were priestly guilds in equally good standing. Baal is portrayed in Ugaritic mythology as impregnating a heifer to sire the young bull god. The biblical book of Leviticus (18:22–27) bans homosexuality and bestiality expressly because the Canaanite population had been practicing those rites, which the Hebrews rejected as abominations.

Ritual and myth

According to ancient views, the myth came first, and the rite imitated or re-enacted it. This, however, is not necessarily the order in which religion develops. Rites can be very tenacious; and when the origin of a rite had been forgotten, a myth was often invented to explain it.

Types of religious organization and authority. Religion occurs at different levels of society: personal, familial, local, national, and international. At the personal and international extremes there is need for but little organization. And yet in religion as the ancient Near Easteners saw it, there was a progression from one stage to the next. In the early myths of Genesis, God and Noah have direct personal relations. This leads to a covenant between God and all who went out of the ark: birds and beasts as well as mankind (Gen. 9:9–10). Through the sons of Noah and their descendants, who form the nations of the world (Gen. 10), there is a theoretical progress to international religion. This scheme of the relations between God and mankind, from the personal to the universal level, mirrors the historical record of religion. Judaism (followed by Christianity and Islām) traces "the Religion" back to Abraham, who had personal and direct relations with God, as was customary in the ancient Near Eastern milieu. Abraham's intimacy with God is similar to the intimacy between Odysseus and the Greek goddess Athena. The next step is a covenant between a particular deity and a particular man, binding the two together in a contractual relationship for all eternity from generation to generation. Such covenants were not rare; the Hittite King Hattusilis III made such a covenant with Ishtar. Abraham's covenant is unique simply because it was the only one destined to last in history.

The descendants of able men who established a dynasty or tradition would worship the God of their father, or fathers, and adhere to the original covenant. Gen. 31 portrays Jacob and Laban swearing by their respective ancestral gods: Jacob by the god(s) of Abraham and Laban by the god(s) of Nahor. Once a group expanded into a federation of clans or tribes, religious organization became necessary. A central shrine (such as the one at Shiloh in Israel) for amphictyonic (religious confederational) pilgrimage festivals required a professional priesthood and other religious personnel to take care of sacrifices, give oracular guidance, interpret dreams and omens, as well as to provide instruction. In an amphictyony of 12 tribes, each tribe could render federal service for religious and secular purposes, one month each year. A special tribe (such as the Levites in Israel, or the Magians in Iran) could be dedicated full time to cultic duties. A greater degree of centralization and organization of the cult would generally follow from the establishment of a powerful state. The cult of Marduk of Babylon spread in importance and influence because Babylon became the capital of a powerful kingdom in the time of Hammurabi (18th century BC) and of a mighty empire during the reign of Nebuchadrezzar (604–562 BC). The Egyptian cult of Amon-Re not only became powerful but took on the form of a universal religion as a result of the military and political triumphs of the rulers of Thebes, particularly during the reign of Thutmose III (1504–1450 BC). Under Solomon, Jerusalem became the centre of a great commercial empire. The Temple of Solomon and its God, the God of Israel, were catapulted into international prominence quite different from the national status that marked the extent of Hebraic religion previously. The new internationalism of Israel's involvements paved the way for the universality of the views of the prophets. The God of Israel was subsequently concerned with all mankind and not merely with one people in one small land. This ultimately meant the transformation of biblical religion from the cult of a people to a more subtle, spiritual movement that required different organization and different personnel. The priesthood became defunct with the destruction of Herod's Temple and the cessation of sacrifices in AD 70. The new religious leaders (rabbis) were rather teachers and spiritual guides united by dedication to the same scripture. The spread of the devotees over the face of the earth meant that they were now divided into regional groups, under different sovereigns, and the individual Jewish communities were organized independently, each with its own house of worship.

Professional priesthoods

There were various devices for holding an ethnic-religious group together even though it was fragmentized into scattered communities. Laws of purity, especially those pertaining to diet, kept different groups apart. Each respected the other's rules, but the fact that each group had different taboos kept them from breaking bread together and mingling socially. They could do business with each other in the marketplace, but they could not fraternize in each other's homes. Above all, laws of purity were deterrents to intermarriage, the major factor that breaks up religious communities and encourages homogenization.

Laws of purity

Folk religion. Alongside the official religion, folk or popular religion had a place. The devotees in ancient temples and houses of worship were mainly males. The women were more concerned with fertility. Love charms, magical rites to end barrenness, and amulets to help in childbirth and keep the children alive were important in the minds of the women; and their popular religion was very different from the official cults of their husbands.

Funerary cults. From the earliest times funerary rites were an important aspect of religion. All cults of the dead assume that there is some sort of continuity of the deceased's personality. Moreover, there was always the possibility of contact between the living and the dead. The community was conceived in terms of the deities, the living, and the dead—all in contact with each other. For this reason burial grounds were an important part of the community's installations. The dead might be buried under the floor of the home, in a family vault, in nearby caves, or in a necropolis—but in some way, the connection between the living and their dead must be perpetuated.

CONCLUSION

The soil of the Near East, which is the cradle of the most dynamic religions in the world today, continues to yield so many artifacts, texts, and monuments bearing on religion that the study of ancient Near Eastern religion is likely to remain a dynamic field for many years to come.

BIBLIOGRAPHY. An excellent unified cultural history of the ancient Near East is EDUARD MEYER, *Geschichte des Alterthums*, 2nd ed., 3 vol. (1907–37). More up-to-date, but very uneven, is the new edition of *Cambridge Ancient History*, now appearing in fascicles. A concise treatment is C.H. GORDON, *The Ancient Near East*, 3rd rev. ed. (1965). Biblical religion has an enormous bibliography. Among the many treatments is W.O.E. OESTERLEY and T.H. ROBINSON, *Hebrew Religion: Its Origin and Development* (1930). ROLAND DE VAUX, *Les Institutions de l'Ancien Testament*, 2 vol. (1958–60; Eng. trans., *Ancient Israel: Its Life and Institutions*, 1961), discusses Israelite religion and provides a copious bibliography. The best set of translations, with a bibliography for each text, is J.B. PRITCHARD (ed.), *Ancient Near Eastern Texts*, 2nd ed. (1955), updated by *The Ancient Near East: Supplementary Texts and Pictures Relating to the Old Testament* (1969). A handy, abridged version of Pritchard's works is available in a paperback edition, *The Ancient Near East: An Anthology of Texts and Pictures* (1958). Two excellent works providing a background for the whole subject are S. MOSCATI, *The Face of the Ancient Orient* (1962); and H. and H.A. FRANKFORT, *The Intellectual Adventure of Ancient Man* (1946).

(C.H.G.)

Nebraska

One of the west central states of the United States, Nebraska, during its early history in the first half of the 19th century, served primarily as a water and land route to the rich trapping country to the north and west. With the coming of railroads after the Civil War and the consequent immigrations, however, the excellent soils of Nebraska were broken by the plow, and its grasslands gave rise to a range cattle industry. As a result, the state has been, almost since its admission to the Union in 1867 as the 37th state, one of the major producers of food commodities for the nation.

An overview of the state

Rivers were important to Nebraska's geography and settlement. The Missouri River, a major highway to the trans-Mississippi West in the early 19th century, forms the eastern boundary with Iowa and Missouri, and about a fourth of the northern boundary with South Dakota. The name Nebraska is derived from an Indian word meaning "flat water," a reference to the Platte River, which served as a magnet for urban clusters as it crossed the state. It is formed by the confluence of the North and South Platte rivers, both of which rise in Colorado on the southwest, though the North Platte swings northward through Wyoming, on the west, before entering Nebraska. The southern boundary with Kansas was established when the two territories were created by the Kansas–Nebraska Act in 1854, legislation that heightened the sectional hostilities that exploded into the Civil War. In 1970 a majority of the nearly 1,500,000 Nebraskans counted in the census lived close to the Missouri and Platte, leaving much of the state's 77,227 square miles (200,017 square kilometres) relatively lightly populated.

Agriculture is basic to Nebraska's economy, but only one-fifth of its labour force is employed directly in farming or ranching. Economic conditions long have had a direct bearing on the state's political life, including a brief period of protest through the agrarian-oriented Populist Party in the 1890s. Although Nebraska traditionally has been considered a stronghold of Republicanism, the changing fortunes of its people make this generalization dubious. (For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; NORTH AMERICA; and GREAT PLAINS.)

THE HISTORY OF NEBRASKA

Various prehistoric peoples inhabited Nebraska as early as 8000 BC. In modern times semisedentary Indian tribes, most notably the Poncas, Omahas, Otoes, and Pawnees, inhabited eastern and central Nebraska. The west was the domain of the nomadic Brulé and Oglala Sioux, but Arapahoes, Comanches, and Cheyennes, likewise nomads, were often present.

Exploration and settlement. The region that was to become Nebraska was included in the Louisiana Purchase, the vast tract of midcontinent America acquired from France in 1803. The French had lost interest in the trans-Mississippi West after less than three years' rule, and the Spanish before them had done little to develop the vast, ill-defined area.

In 1804 the Lewis and Clark Expedition visited the Nebraska shore of the Missouri River and conducted the first systematic exploration of the area. Shortly thereafter, a vigorous fur trade developed along the Missouri, but Nebraska was primarily a highway to richer fur areas to the north and west. In the 1840s the Platte Valley became another highway, as thousands of Americans moved westward over the Oregon, Mormon, and California trails.

Roles of speculators and railroads

Much interest soon developed in Nebraska and in the Platte Valley as a potential railroad route to the Pacific. Moreover, frontier land speculators in western Missouri and Iowa anticipated great financial gains if the Nebraska country, part of the large Indian domaine between the Missouri River and the Rocky Mountains, were opened for settlement. With the adoption of the Kansas–Nebraska Act in 1854, the federal government extended political organization to the trans-Missouri region. As originally established, Nebraska Territory comprised 351,558 square miles, but by 1863 the organization of the Colorado, Dakota, and Idaho (including future Montana and Wyoming) territories had reduced Nebraska almost to its present dimensions.

Much of the economy of the early Nebraska settlements along the Missouri River focussed upon land speculation. Agriculture began to develop within a few years, however, and some river towns became important transfer points for freight and passengers going west. The completion of the Union Pacific Railroad in 1869 and the further railroad construction that followed made possible the development of the interior of Nebraska.

Statehood. After Nebraska's admission to the Union, in 1867, and despite a depression and grasshopper plague, its population grew from about 120,000 to more than 1,000,000 by 1890. The Indian resistance on the frontier was broken, and settlement extended westward into the panhandle of the state. In the 1880s Omaha became an important industrial and meat-packing centre, and Lincoln grew to prominence as the state capital and seat of the University of Nebraska.

Impact of economic cycles

In the 1890s, Nebraska's farmers, afflicted with poor crop prices, high transportation costs, and depression, expressed their protest through the Populist Party. Although the Populist movement was short-lived, it invigorated the political life of the state. Yet prosperity returned by 1900, and Nebraska enjoyed two decades of economic advancement. Through the 1920s, Nebraska's agriculture again was beset with mediocre marketing conditions, and with the advent of the Great Depression of the 1930s the state's entire economy suffered its greatest adversity, a condition that was alleviated by massive federal assistance. World War II brought an economic recovery, and since then Nebraska has enjoyed a steady, though unspectacular, economic growth.

THE NATURAL AND HUMAN LANDSCAPE

The natural environment. Nebraska takes in parts of two physiographic regions, the till plains of the Central Lowland (in the eastern third) and the Great Plains.

The surface features. The elevation rises from a minimum of 840 feet above sea level in the southeast to a maximum of 5,424 feet near the Colorado–Wyoming boundaries. Much of the land is gently rolling prairie, although the river valleys, much of south central Nebraska, and a large portion of the panhandle district are flatlands. The Sand Hills country of north central and northwestern Nebraska is a vast, treeless, grass-covered region that comprises almost one-fourth of the state.

Soils. All of Nebraska's six basic soils are excellent for agriculture. The prairie soils of the southeast are outstanding for the production of corn, while the rich humus soils of central and northeastern Nebraska are, given adequate moisture, highly suitable for general farming. South of the Platte and west of the prairie-soil area, the soil is best suited to small-grain production. Winter wheat adapts to the soil and marginal precipitation of western Nebraska. The unique, wind-deposited soil of the Sand Hills, because of limited precipitation and the danger of erosion, is suited solely to cattle grazing. The many small lakes and luxuriant grasses of the Sand Hills have made the area one of the best rangelands in North America. The alluvial soils of the Missouri and Platte river valleys and the valleys of smaller streams are outstanding for raising corn and other crops.

Waters. Nebraska is entirely within the Missouri River drainage system; the Platte, the major Nebraska tributary, joins the Missouri south of Omaha. Although the Platte is shallow and unnavigable, its water is vital to the state's irrigation. The Elkhorn River enters the Platte west of Omaha, while the Loup River, formed by three tributaries flowing out of the Sand Hills, also discharges into the Platte. The Republican and Big Blue rivers flow through southern Nebraska, emptying into the Missouri in Kansas via the Kansas (Kaw) River. The Niobrara, a swift-moving stream that rises in the high country just east of the Wyoming border, flows across extreme northern Nebraska. Nebraska also has a vast supply of underground water that has made possible the extensive development of well irrigation.

Drainage to the Missouri River

Climate. Hot winds from the southwest often push summer temperatures in Nebraska above 90° F (32° C) and sometimes above 100° F (38° C). Average July temperatures range from 74° F (23° C) in the panhandle to 78° F (26° C) in the southeast. In the winter, northwest winds often bring in Arctic high-pressure masses from Canada, and temperatures commonly fall well below 0° F (−18° C). Low-pressure systems, moving out of the southwestern states, sometimes bring great blizzards to the state and present a danger to travellers and stock raisers. Average January temperatures vary from 25° F (−4° C) in the panhandle to about 21° F (−6° C) in the northeast. The average growing season is 168 days in the southeast, 133 days in the panhandle. The average annual precipitation varies from 33 inches (840 millimetres) in the southeast to less than 16 inches (400 millimetres) in the extreme west. Since a minimum of 20 inches (500 millimetres) is usually considered necessary for normal crop production, approximately one-half of Nebraska may be considered semi-arid. Irrigation is carried on extensively in eastern and central Nebraska, whereas the practice is essential to certain types of agriculture in the west.

Vegetation and animal life. A wide variety of grasses originally covered Nebraska's prairies, and the slopes of the river valleys were well covered with deciduous trees. At present, cottonwood, elm, and some oak and walnut are found along the bluffs of eastern Nebraska, while conifers grow in the Wild Cat and Pine Ridge highlands and the Niobrara Valley. The Nebraska National Forest in west central Nebraska resulted from a human effort to bring trees to the barren plains. Until their near-extermination at the hands of white men, bison roamed widely over the Nebraska plains. Some of these animals remain in their natural habitat on the Fort Niobrara National Wildlife Refuge, near Valentine. Antelope and deer are also native to the state, as are prairie dogs, coyotes, jackrabbits, skunks, and squirrels. Migratory birds, especially the pheasant, are common.

Patterns of settlement. Following the specifications of the Ordinance of 1785, the land was surveyed into townships six miles square and containing 36 sections; the section, comprising 640 acres (260 hectares), was the basic unit of land. To the present day Nebraska has retained this orderly gridlike survey system, which has its American roots in New England. Most of the towns and villages serving the surrounding countryside were located close to rivers, streams, and timber. Several developed as railroad terminals, but changing patterns of transportation decreed growth for some communities and stagnation or oblivion for many others.

Economics, geography, and politics created certain sectional distinctions within Nebraska. The placing of the capital of Nebraska Territory at Omaha so enraged the people south of the Platte that they sought annexation to Kansas. The animus against Omaha did not die, and in 1867 the state capital was moved to Lincoln, south of the Platte. The polarity between Omaha and "out-state" has continued, with the life-style of Omaha reflecting the boisterousness of urban commercialism, a contrast to the more sedate and university-oriented atmosphere of Lincoln and the generally conservative face of the smaller communities to the west.

Diversity of life styles

THE PEOPLE OF NEBRASKA

Ethnic groups. In addition to the native white Americans who came to Nebraska, large numbers of persons of European birth settled in the state in the late 19th century. From 1866 to 1879, the Nebraska State Board of Immigration employed an agent in Europe to recruit settlers. The Burlington and Union Pacific railroads made much greater efforts than did the state government in this direction. The largest immigrant group was the Germans, who in 1890 numbered 72,000, and the Scandinavian countries (particularly Sweden), Bohemia, and the British Isles contributed significantly to the settlement of Nebraska.

As a result of this European immigration, Nebraska was not molded in the traditional Anglo-American form that had characterized much of the nation's earlier development. Large numbers of Roman Catholics from Bohemia, Germany, and Ireland and Lutherans from Germany and Scandinavia gave diversity to the religious life of Nebraska. For many years Nebraska had a number of German-language newspapers, although the linguistic identity of the Germans and other non-English-speaking groups gradually faded away.

Negroes came to Nebraska early in the history of the state. Most settled in Omaha, which by 1900 had a black population of over 3,400 persons, a figure that by 1970 had risen tenfold. They concentrated in Omaha's near North Side, an area that increasingly became characterized by the usual social and economic problems common to the ghettos of other large cities. During the 1960s this traditional core of the black community has declined markedly in population as many Negroes moved to immediately adjacent neighbourhoods. At the same time, the usual decrease in the white population occurred in these areas. A number of racial disturbances took place during the decade, though none of them brought about comprehensive steps toward either repression or amelioration of the urban conditions.

The black community

Demography. Between 1960 and 1970 Nebraska's birth rate dropped by nearly one-third to about 17 per 1,000 population, and the death rate rose slightly. In addition, the state continued to lose more people to other states than it gained by immigration. Since the 1880s, a decade of tremendous growth during which most of the best farmlands were claimed, Nebraska has grown in population at a pace generally well below the national average.

The most striking trend in Nebraska's demography—one that is neither new nor unique to the state—has been the steady decline of the population of the rural areas and the marked growth of the cities and their suburbs. During the 1960s, 67 of the 93 counties in the state lost population. An overall 5 percent increase occurred because the growth of the urban areas more than offset the rural declines. As a result of the growth of metropolitan Omaha and Lincoln, the population centre of the state has moved steadily eastward, in 1970 lying only about 40 miles west of the Missouri.

Patterns of migration

Urban growth has been stimulated further by the mechanization of agriculture, which brought about the working of more land by fewer persons, decreases in the number of farms, and increases in average farm sizes. Similarly, most small towns, long reliant upon the local farm trade, continued to lose population, a condition undoubtedly hastened by a modern highway system that enlarged the trade areas of the cities. As employment opportunities continued to diminish in rural Nebraska, the 1960s saw an increase of nearly 30 percent in the number of work opportunities in manufacturing. The exodus from the farms and small towns may continue for some time, and Nebraska's urban areas will probably absorb much of the moving tide of Nebraskans.

THE STATE'S ECONOMY

Nebraska stood 23rd among the states in per capita personal income in 1970. The state's average of $3,700 was slightly below the national figure but above the average of the West Central states. Property income, manufacturing, wholesale and retail trades, farm proprietor's income, and state, and local governments were, in that order, the major sources of income. The total annual income of Nebraskans rose more than 50 percent from 1960 to 1968, but inflation accounted for a relatively large proportion of this.

Agriculture. Despite the fact that farm income showed the slowest growth rate among the major components of the Nebraska economy, the state remains a leading agricultural producer. In 1970 the principal crops, in order of value, were corn (maize), hay, wheat, and sorghum grain. Nebraska ranked fifth in the nation in the production of corn for feed, fifth in wheat, third in sorghum, and sixth in sugar-beet yield. In 1971 Nebraska ranked third in the number of cattle on its farms and sixth in the number of hogs and pigs.

National rankings in farm production

Manufacturing and processing. The processing of agricultural commodities is the most important of the state's industrial activities in terms of value added by manufacture. Other leading industrial activities are machinery, chemicals and allied products, printing and publishing, primary- and fabricated-metal industries, and transportation equipment.

Mineral and energy resources. The value of Nebraska's mineral output declined sharply during the 1960s. Crude petroleum accounts for almost one-half of the value of the state's mineral extraction. Nebraska also produces some natural gas and gas products, as well as significant amounts of cement, lime, pumice, sand, gravel, stone, and clay, but additional quantities of natural gas must be imported to serve the commercial, industrial, and residential needs of the state. All electrical utilities are publicly owned, and consumer rates are among the lowest in the nation.

Insurance. Nebraska, Omaha in particular, is known as one of the centres of the American insurance industry. During the 1960s the industry showed great dynamism within the state. The number of companies doubled, to 40, while the companies' policies in force rose from about $5,000,000,000 to nearly $14,000,000,000.

Public financing and economic management. In addition to local property taxes, Nebraska has state and local sales taxes, a state income tax based upon the federal income tax, and a gasoline tax, which is an important source of revenue. The state generally has been conservative in labour matters, and in 1968 the state ranked 40th, nationally, in percentage of unionized nonagricultural workers. Nebraska has a right-to-work law that forbids compulsory union membership; in recent years the time lost through work stoppages has been below the national average.

As has been the case throughout its history, Nebraska's future development will be heavily dependent upon private investment from outside its borders. A state Department of Economic Development seeks to bring new industry to Nebraska. As the problems of urban life in the great economic and industrial centres of the nation become more acute, the incentive for decentralization may work to the benefit of Nebraska.

Transportation. Nebraska is located on some of the most important arteries linking the East and West. Within the state, traffic flows toward Omaha, Lincoln, and Sioux City, Iowa, in the east and toward the cities in the Platte Valley. Much of western Iowa is within the trade area of metropolitan Omaha. A significant amount of the traffic from western Nebraska moves to Denver, Colorado.

Nebraska has modern highways that cross the state in all directions. The most important route is Interstate Highway 80, which carries heavy traffic between Iowa and the western borders of Nebraska, Colorado, and Wyoming. The state is served by five railroads. Omaha is an important port for commercial barge traffic on the Missouri. Air carriers serving Nebraska include both nationwide lines and those providing local and regional "feeder" service.

ADMINISTRATION AND SOCIAL CONDITIONS

Structures of government. *State level.* Nebraska functions under a frequently amended constitution dating from 1875. Since 1937 it has had a one-house legislature whose members are elected without political-party affiliation—the only such legislative body in the nation. The 49 members of the legislature, or "Unicameral," as it is commonly called, are popularly elected for four-year terms following primary and runoff elections in their districts, which are equally proportioned by population. Unicameral meets for sessions of 90 legislative days in odd-numbered years and 60 in even-numbered years.

The unicameral, nonpartisan legislature

The nonpartisan feature of the legislature has many critics, who charge that the lack of political parties in the Unicameral results in a lack of leadership in that body. The results of an independent study of American state legislatures released in 1971, however, ranked Nebraska's Unicameral ninth among the 50 legislatures in terms of procedural qualities. In addition, although the majority of legislators generally are Republican in political inclination, the system allows the electoral campaigns to be fought on the basis of local issues rather than party loyalties. Omaha's black community long has had representation in Unicameral.

The governor, elected for a four-year term on a partisan ballot, is the chief executive officer; his tenure is limited to two consecutive terms. The governor is responsible for the operation of 15 administrative departments and is an ex officio member of various boards and commissions. As the state's chief fiscal officer, he must present a detailed budget to the legislature, which needs an affirmative three-fifths vote to appropriate more funds than recommended by the governor or for overriding a veto. Other elected officers also run on partisan ballots.

Nebraska's court system comprises a Supreme Court with seven justices and 21 district courts with a total of 38 judges. In addition, there are two conciliation courts, the Nebraska Industrial Relations Court, a Workmen's Compensation Court, 93 county courts, and over 1,500 local justice of the peace courts. Some of the larger communities have police courts, while Omaha and Lincoln each have a municipal court and a juvenile court. Nebraska has adopted the Missouri Plan, originated in that state in an attempt to create a nonpolitical judiciary. Judicial nominating commissions, chosen by the governor and the Nebraska Bar Association, compose lists of nominees to fill vacancies on the bench. The governor then appoints one of the nominees to fill a particular position. Nebraska also has a merit system under which the electorate determines whether judges will be retained in office.

The nonpartisan judicial system

Local government and political life. County government is vested in boards of supervisors or commissioners of from three to seven members, who like other county officials are elected on partisan ballots. The city manager and mayor–council forms of government are used in Nebraska's cities, and governmental authority in villages is vested in elective boards of trustees.

The Territory of Nebraska was the creation of a Democratic administration in Washington, D.C., and Democrats dominated Nebraska politics until the Civil War. The 30 years after 1860 was a period of Republican pre-eminence in Nebraska, but the political ferment during and after the 1890s brought an end to one-party rule. Although a slight majority of Nebraska's voters are registered Republicans, Democrats often are elected to office.

The social milieu. The social and economic problems of Nebraska, while manageable, are pressing. Better housing, improved educational and employment opportunities, and an upgrading of police–community relations are fundamental necessities in Omaha's black community. An active civil rights movement has pressed for these improvements in the conditions of life. In certain rural counties as well, the level of income is far below state and national averages. Overall wage levels in Nebraska are slightly below the national average, yet inflation and unemployment have been less pronounced than in many other parts of the country.

Health and welfare. Nebraska maintains programs of public assistance: medical aid and aid for dependent children, the aged, the blind, and other disabled persons. Federal funding in 1970 provided over 60 percent of Nebraska's public-assistance expenditures, compared to the national average of about 50 percent. Although federal, state, and county welfare funding has steadily increased, the average monthly public-assistance payments in Nebraska are below the national averages. Nebraska also has participated in various antipoverty operations of the federal Office of Economic Opportunity.

The state maintains a system of mental hospitals and other specialized health, correctional, and care facilities. Health conditions in Nebraska are generally sound. Although expanded medical facilities are needed in some rural areas, Omaha ranks as a medical centre of national significance.

Education. Nebraska's public elementary and secondary schools and ten vocational–technical schools had a per pupil expenditure of $682 in 1971, compared with the national average of $867. Since 1967 an increasing

amount of direct state aid has supplemented local appropriations. Beginning in 1949, the number of school districts was cut drastically to offer more efficient educational facilities and programs.

Higher education

Of the institutions of higher education in Nebraska, 10 are private, five are state operated, and six are public junior colleges. The University of Nebraska (established 1869) is the largest in the state and is composed of three semi-autonomous campuses, the main one in Lincoln and two, including the medical school, in Omaha. Graduate-degree programs are offered at the University of Nebraska and Creighton University (Omaha), both of which offer programs in medicine, law, and dentistry, and at state colleges in Chadron, Kearney, and Wayne.

CULTURAL LIFE AND INSTITUTIONS

The arts and historical preservation. In less than two generations, Nebraska was converted from a wilderness inhabited by a small number of native Indians to a settled commonwealth of over 1,000,000 persons. This conquest of space was one of the most important achievements of the 19th century, and it is natural that the cultural contributions of Nebraska, like those of the other western states, would focus upon this frontier experience.

Such Nebraska novelists as Willa Cather, Mari Sandoz, and Bess Streeter Aldrich were among those who wrote perceptively of life on the plains and won national audiences. The relationship of the pioneers to a capricious natural environment, the life styles and interaction of settlers of diverse social and ethnic backgrounds, and the plight of the Indians were important themes of these writers. The epic poetry of John G. Neihardt spoke feelingly of plains Indian life and re-created the adventures of the explorers of the 19th-century West. In the early 1970s his poetic narrative *Black Elk Speaks* achieved national recognition some 40 years after its original publication.

The Nebraska State Historical Society, organized in 1878, continues to make important contributions to an understanding of life in Nebraska and the West. In 1960 the University of Nebraska Press launched the paperback Bison Series, reprints of early and modern works on the American West, including histories, collections of lore from Indian and white settlers, and other important documents, many of which had been long out of print.

Increased urbanization and affluence have promoted continued artistic expression in Nebraska. The Joslyn Art Museum in Omaha and the Sheldon Memorial Art Gallery in Lincoln are the state's major collections in the visual arts. Omaha and Lincoln have theatrical groups and symphony orchestras that enrich the life of the state.

Folk and historical festivals

Various folk observances, such as the Czech Festival at Wilber, are periodic reminders of the diverse origins of the people of Nebraska. Ogallala, a roaring cow town in the 1870s and 1880s, relives its colourful past with its "Front Street" festivities held each summer. Each October, the Knights of Ak-Sar-Ben (Nebraska spelled in reverse), an Omaha civic organization founded in 1895, crown a king and queen of Quivira. This elaborate social event commemorates the search through the plains in 1541 of the Spanish explorer Francisco Vásquez de Coronado for the legendary Seven Cities of Cibola in the Kingdom of Quivira. Over the years the University of Nebraska football team has attained national prominence and no single subject holds the attention of Nebraskans as does the plight of the "Cornhuskers." The benefits derived from football enthusiasm are significant in several areas of the state's economy.

Communications. Journalism has always been important to the cultural and political development of Nebraska. The state has about 50 newspapers, with a circulation of over 3,000 copies each; of these, 18 are dailies. The two middle-of-the-road Lincoln dailies have a wide circulation in southeastern and south central Nebraska, while the generally conservative *Omaha World Herald* is read throughout Nebraska and southwestern Iowa. The state is served by 14 commercial television stations, while the Nebraska Educational Television Network, a noncommercial system operated by the University of Nebraska, serves the schools and general public across the state. There are more than 60 standard broadcasting stations in Nebraska.

Prospects. Agriculture remains vital, either directly or indirectly, to the livelihood of Nebraska. The agrarian stereotype of the state is increasingly invalid, yet Nebraska's large towns and cities maintain a certain closeness to the land, in spirit as well as in economic and geographic fact. Although Nebraska inevitably will become more urbanized, this physical and spiritual proximity to the land may enable the state to minimize the problems of city life. It is likely, also, that the urban experience will propel the people of Nebraska toward newer themes of cultural expression.

BIBLIOGRAPHY. JAMES C. OLSON, *History of Nebraska*, 2nd ed. (1966), is an excellent general historical work, including a useful bibliography. The NEBRASKA STATE HISTORICAL SOCIETY, *Proceedings and Collections*, 25 vol., and *Nebraska History*, a quarterly magazine, are essential to an understanding of the history of the state. The NEBRASKA LEGISLATIVE COUNCIL, *Nebraska Blue Book and Historical Register* (published biennially since 1915), is a useful compendium of information on government. The NEBRASKA DEPARTMENT OF ECONOMIC DEVELOPMENT, *Nebraska Statistical Handbook* (1970), has information on economic and other aspects of Nebraska life.

(H.A.D.)

Nebuchadrezzar II

Nebuchadrezzar, or Nebuchadnezzar, II was the oldest son and successor of Nabopolassar, founder of the Chaldean (or Neo-Babylonian) Empire, and the greatest king of his dynasty. He was celebrated for his military might; the splendour of his capital, Babylon; and for his important role in Jewish history. He is known from cuneiform inscriptions, the Bible and later Jewish sources, and from classical authors. His name, from the Akkadian Nabu-kudurri-usur, means "O Nabu, protect my boundary stone," "boundary stone" connoting line of succession.

While his father disclaimed royal descent, Nebuchadrezzar claimed the third-millennium ruler Naram-Sin as ancestor. The year of his birth is uncertain, but it is not likely to have been before 630 BC, for according to tradition Nebuchadrezzar began his military career as a young man, appearing as a military administrator by 610. He is first mentioned by his father as working as a labourer in the restoration of the temple of Marduk, the chief god of the city of Babylon and the national god of Babylonia.

Service as a military commander

In 607/606, as crown prince, he commanded an army with his father in the mountains north of Assyria, subsequently leading independent operations after Nabopolassar's return to Babylon. After a Babylonian reverse at the hands of Egypt in 606/605, he served as commander in chief in his father's place, and by brilliant generalship he shattered the Egyptian army at Carchemish and Hamath, thereby securing control of all Syria. After his father's death on August 16, 605, Nebuchadrezzar returned to Babylon and ascended the throne within three weeks. This rapid consolidation of his accession and the fact that he could return to Syria shortly afterward reflected his strong grip on the empire.

On expeditions in Syria and Palestine from June to December of 604, he received the submission of local states, including Judah, and captured the city of Ashkelon. With Greek mercenaries in his armies, further campaigns to extend Babylonian control in Palestine followed in the three succeeding years. On the last occasion (601/600), Nebuchadrezzar clashed with an Egyptian army, with heavy losses; this reverse was followed by the defection of certain vassal states, Judah among them. This brought an intermission in the series of annual campaigns in 600/599, while Nebuchadrezzar remained in Babylonia repairing his losses of chariots. Measures to regain control were resumed at the end of 599/598 (December to March). Nebuchadrezzar's strategic planning appeared in his attack on the Arab tribes of northwest Arabia, in preparation for the occupation of Judah. He attacked Judah a year later and captured Jerusalem on March 16, 597 BC, deporting King Jehoiachin to Babylon. After a further brief Syrian campaign in 596/595, Nebuchadrezzar had to act in east Babylonia to repel a threatened invasion, probably from Elam (modern southwest Iran).

Tensions in Babylonia were revealed by a rebellion late in 595/594 involving elements of the army, but Nebuchadrezzar was able to put this down decisively enough to undertake two further campaigns in Syria during 594.

His further military activities are known not from extant chronicles but from other sources, particularly the Bible, which records another attack on Jerusalem and a siege of Tyre (lasting 13 years, according to the Jewish historian Flavius Josephus) and hints at an invasion of Egypt. The siege of Jerusalem ended in its capture in August 586 and in the deportation of prominent citizens, with a further deportation in 582. In this respect Nebuchadrezzar followed the methods of his Assyrian predecessors.

Much influenced by the Assyrian imperial tradition, Nebuchadrezzar consciously pursued a policy of expansion, claiming the grant of universal kingship by Marduk and praying to have "no opponent from horizon to sky." From cuneiform fragments he is known to have attempted the invasion of Egypt, the culmination of his expansionist policy, in 568/567.

In addition to being a brilliant tactician and strategist, Nebuchadrezzar was also prominent in international diplomacy, as shown in his sending an ambassador (probably Nabonidus, a successor) to mediate between the Medes and Lydians in Asia Minor. He died in August or September 562 and was succeeded by his son Amel-Marduk (Evil-Merodach of II Kings).

The rebuilding of Babylon

Nebuchadrezzar's main activity, other than as military commander, was the rebuilding of Babylon. He completed and extended fortifications begun by his father, built a great moat and a new outer defense wall, paved the ceremonial Processional Way with limestone, rebuilt and embellished the principal temples, and cut canals. This he did not only for his own glorification but also in honour of the gods. He claimed to be "the one who set in the mouth of the people reverence for the great gods" and disparaged predecessors who had built palaces elsewhere than at Babylon and had only journeyed there for the New Year Feast.

Little is known of his family life beyond the tradition that he married a Median princess, whose yearning for her native terrain he sought to ease by creating gardens simulating hills. A structure representing these hanging gardens cannot be positively identified in either the cuneiform texts or the archaeological remains.

Assessment

Despite the fateful part he played in Judah's history, Nebuchadrezzar is seen in Jewish tradition in a predominantly favourable light. It was claimed that he gave orders for the protection of Jeremiah, who regarded him as God's appointed instrument whom it was impiety to disobey, and the prophet Ezekiel expressed a similar view at the attack on Tyre. A corresponding attitude to Nebuchadrezzar, as God's instrument against wrongdoers, occurs in I Esdras and, as protector to be prayed for, in Baruch. In Daniel and in Bel and the Dragon, Nebuchadrezzar appears as a man, initially deceived by bad advisers, who welcomes the situation in which truth is triumphant and God is vindicated.

There is no independent support for the tradition in Daniel of Nebuchadrezzar's seven years' madness, and the story probably arose from a fanciful later interpretation of texts concerned with events under Nabonidus, who showed apparent eccentricity in deserting Babylon for a decade to live in Arabia.

In modern times Nebuchadrezzar has been treated as the type of godless conqueror; Napoleon was compared to him. The story of Nebuchadrezzar is the basis of Giuseppe Verdi's opera *Nabucco*, while his supposed madness is the theme of William Blake's picture "Nebuchadnezzar."

BIBLIOGRAPHY. There is no standard biography. Most of Nebuchadrezzar's building inscriptions, containing some historical material, are edited in STEPHEN LANGDON, *Die neubabylonischen Königsinschriften*, pp. 70–209 (1912). Relevant chronicles are edited in D.J. WISEMAN, *Chronicles of Chaldaean Kings (626–556 B.C.) in the British Museum* (1956). The principal classical references to Nebuchadrezzar are contained in I.P. CORY, *Ancient Fragments*, 2nd ed. (1832).

(H.W.F.S.)

Nebula

"Nebula" (Latin: "mist") is a term formerly used in astronomy to denote any object situated beyond the solar system that is seen as a bright or dark area, in contrast to the pointlike images of stars. This definition, adopted at a time when very distant objects could not be resolved into great detail, unfortunately includes two unrelated classes of objects: the extragalactic nebulae, now called galaxies, which are huge collections of stars and gas; and the galactic nebulae, which are much smaller clouds of gas (with traces of solid particles) within a single galaxy. The term nebula is now restricted to the latter class of object. The galactic nebulae collectively amount to only a few percent of the mass of their galaxy, the rest being made up by the stars within the galaxy. Galactic nebulae are also called gaseous nebulae. The present article will be concerned only with the galactic nebulae.

CLASSES OF NEBULAE

The galactic nebulae are divided into two subclasses on the basis of their appearance: (1) dark nebulae appear as black patches in the sky that are usually very irregular in shape, blotting out the light of the stars beyond them; (2) bright nebulae appear as faintly luminous, glowing surfaces, either emitting their own light or reflecting the light of nearby stars.

The bright nebulae can be subdivided into four classes on the basis of their origin and the details of their appearance: (*a*) diffuse nebulae, which are usually faint and irregular in shape and produce the radiation they emit; (*b*) reflection nebulae, which reflect light from a nearby bright star; (*c*) planetary nebulae, which typically appear as rather symmetrical round disks or rings of fairly high surface brightness (the name arises from the fact that many of them appear rather like out-of-focus images of planets seen through a telescope of poor resolution); and (*d*) supernova remnants, which are clouds of gas expanding away from the site of a stellar explosion called a supernova, which disrupts the star and ejects most of its mass at speeds of thousands of miles per second.

Densities in nebulae

The diffuse nebulae, reflection nebulae, and dark nebulae are basically the same type of physical entity, seen under different conditions. All are irregular clouds of gas, typically several light-years across but with a density of ten to 1,000 atoms per cubic inch, which is 1,000 times less dense than an excellent laboratory vacuum. About 1 percent of their mass is in the form of "dust," or small, solid particles that are efficient in absorbing and scattering starlight. When the gas cloud happens to be near one of the massive, hot O-type stars or very close to a slightly cooler B star, it glows because these stars, with temperatures five to ten times that of the Sun, emit enough ultraviolet radiation to ionize the gas in the cloud; the ionized gas then emits the radiation seen in the visible part of the spectrum. (An ion is an atom that has lost one or more of its electrons.) If the nebula is close to a cooler star that does not emit enough ultraviolet radiation to ionize the gas, the starlight may still be partially reflected from the dust grains, and the cloud is then seen as a reflection nebula. Finally, if the cloud lies between the observer and more distant stars, the dust either scatters the starlight into other directions or absorbs it, in either case reducing the amount of starlight that comes to the observer directly. Therefore, the starlight is dimmed, and, when the cloud is extensive enough, it is seen as a gap in the star field; that is, as a dark nebula. Thus, the same cloud could appear to hypothetical observers at different points in space as a reflection nebula (if viewed with a star near to it but in front of or beside it) or a dark nebula (if viewed with the same star behind it, so that it blocks the starlight).

Sizes of nebulae

Nebulae differ greatly in size. The only one easily visible to the naked eye is the beautiful Orion Nebula (see Plate I), which is seen as the central star in Orion's sword. It is the brightest and best studied diffuse nebula. Some nebulae are extremely large; the largest, the Gum Nebula (named after its discoverer, the Australian astronomer Colin S. Gum), is 40° in angular diameter. The whole constellation of Orion is embedded in extremely faint diffuse nebulosity that cannot be detected by eye.

Such large nebulae are so faint that they require special techniques (see below *Advances brought by photography*) to detect them. Most supernova remnants are similar to these large, faint diffuse nebulae.

The planetary nebulae are all telescopic objects. The largest known, the Helix Nebula, in the constellation Aquarius, subtends an angle of about 20′ of arc—two-thirds of the angular size of the Full Moon; such large nebulae, however, have very low surface brightness and are not easily seen. Most bright planetary nebulae are less than 0.5′ of arc in size—that is, only 0.02 of the angular diameter of the Moon. The Crab Nebula, the best known supernova remnant, is slightly larger—approximately 3′ of arc.

PRE-20TH-CENTURY OBSERVATIONS OF NEBULAE

Naked-eye observations of "cloudy stars" were mentioned by the Greek astronomers Hipparchus (*c.* 190–125 BC) and Ptolemy (*c.* AD 138), but these objects are known to have been compact clusters of stars. In 1610, two years after the invention of the telescope, the Orion Nebula, which looks like a star to the naked eye, was discovered by the French scholar and naturalist Nicolas-Claude Fabri de Peiresc. In 1656 Christian Huyghens, the Dutch scholar and scientist, using his own greatly superior instruments, was the first to describe the bright inner region of the nebula and to determine that its inner star is not single but a compact quadruple system —the well-known "Trapezium." The inner regions of the nebula are still referred to by his name.

Early-18th-century observational astronomers gave high priority to comet seeking. A by-product of their search was the discovery of many bright nebulae. The first catalog of nebulae was compiled by Edmund Halley, second astronomer royal, whose name was given to the great comet whose appearances he correctly predicted. He included in his catalog six nebulae, which he correctly surmised were composed of a "lucid medium shining with its own proper lustre" and "filling space immensely great." Several catalogs of special objects were subsequently compiled by other comet researchers; by far the best known is that of the Frenchman Charles Messier, who, in 1781, compiled a catalog of 103 nebulous, or extended, objects to avoid their confusion with comets. Most are clusters of stars, 35 are galaxies, and 11 are nebulae. Even today many of these objects are commonly referred to by their Messier catalog number: M 20, for instance, is the great Trifid Nebula, in the constellation Sagittarius (see Plate I).

The work of the Herschels. By far the greatest observers of the early and middle 19th century were the English astronomers William Herschel and his son John. Between 1786 and 1802 William Herschel, aided by his sister Caroline, compiled three catalogs totalling about 2,500 clusters, nebulae, and galaxies. He also observed patchy areas in which there appeared extremely few stars even in the midst of the brilliant star clouds of the Milky Way. He tentatively but incorrectly interpreted these dark nebulae, which were obscuring the stars behind them, as holes in the distribution of stars through which it is possible to see the empty distances of space. John Herschel later added to the catalogs 1,700 other nebulous objects in the southern sky visible from the Cape Observatory in South Africa but not from London and 500 more objects in the northern sky visible from England.

The origin of NGC and IC numbers

The catalogs of the Herschels formed the basis for the great *New General Catalogue* (NGC) of J.L. Dreyer, published in 1888. It contains the location and a brief description of 7,840 nebulae, galaxies, and clusters. In 1895 and 1908 it was supplemented by two *Index Catalogues* (IC) of 5,386 additional objects. The list still included galaxies as well as true nebulae, for they were often at this time still indistinguishable. Most of the brighter galaxies are still identified by their NGC or IC numbers according to their listing in the *New General Catalogue* or *Index Catalogues*.

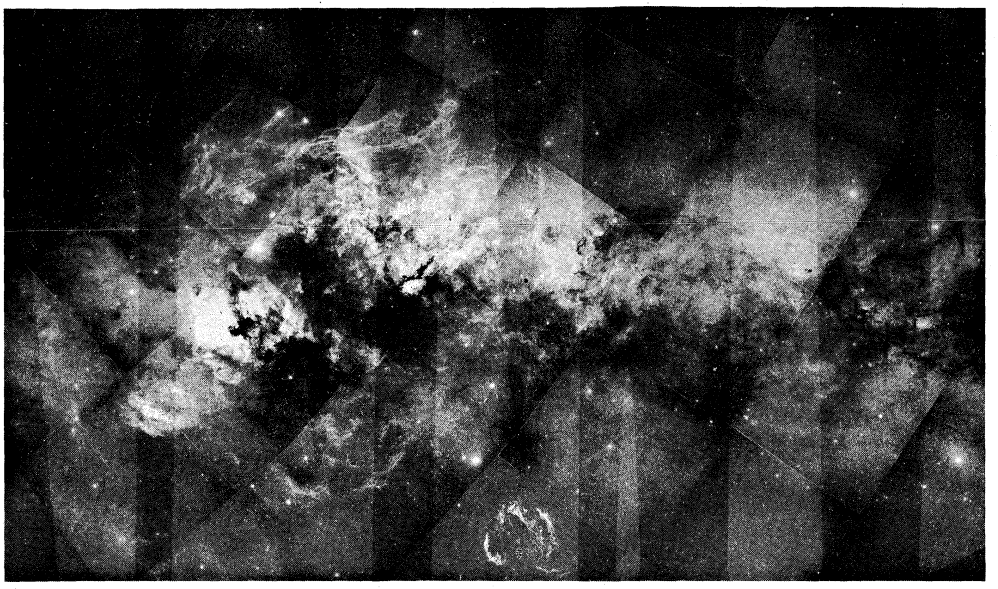
Advances brought by photography. The advent of photography, which allows the recording of faint details invisible to the naked eye and provides a permanent record of the observation for study of fine details at leisure, caused a revolution in the understanding of nebulae.

In 1880 the first photograph of the Orion Nebula was made, but really good ones were not obtained until 1883; these early photographs showed a wealth of detail extending out to distances unsuspected by visual observers. Around 1885 the use of modestly sized but short-focal-length ("fast") lenses, instead of the long-focus instruments used previously, greatly increased astronomers' ability to photograph nebulae. The long-focus instrument is useful if a large-scale photograph is wanted, because it spreads the light from a given area in the sky into a large area of photographic plate, widely separating stellar images. For nebular photography, however, the nebular light is also spread over a wide area and is consequently fainter if photographed with a long-focus lens rather than a short-focus lens of the same aperture. Furthermore, the short-focal-length lenses can be made to cover a much wider area of the sky in one photograph than the long-focus instrument can, especially if the lens consists of several elements to reduce aberrations. In 1885 the faint reflection nebulosity in the Pleiades star cluster was photographed for the first time, and in 1889 the full extent of the Pleiades nebulosity was photographed with a wide-angle camera at Lick Observatory. Later the sky was systematically photographed and many nebulae recorded, especially in the Milky Way (see illustration).

The study of nebular spectra. The physical nature of an astronomical object can be discovered in detail by studying its spectrum; that is, the resolution of its light into different wavelengths (or colours). Study of the spectrum of a cloudy-looking object provides a decisive test as to whether it is composed of unresolved stars (as are galaxies) or glowing gas, because the natures of the spectra of stars and of gas are quite different. According to the laws of radiation as stated by the chemist Robert Bunsen and the physicist Gustav Kirchoff, both German, in 1859, opaque, hot bodies (such as stars) should radiate continuously at all wavelengths, with perhaps dark absorption lines superimposed, while hot, transparent gas clouds should radiate only emission lines at certain wavelengths, or colours, characteristic of their constituent gases. In 1864 observation of the spectrum of the Orion Nebula showed bright emission lines of glowing gases, with conspicuous hydrogen lines and some green lines even brighter. The spectrum of galaxies was found to be stellar, so that a distinction between galaxies and nebulae—that nebulae are gaseous and galaxies are stellar—was appreciated at this time, although the true sizes and distances of galaxies were not demonstrated until the 20th century.

TWENTIETH-CENTURY DISCOVERIES

Observationally, there have been at least four major developments in the 20th century. (1) Very fast, wide-angle telescopes of excellent resolution, patterned after a type invented by the German optical worker Bernhard Schmidt in 1930, have made it possible to detect very faint nebulae; increased speed of available photographic plates has also been important in this regard. (2) Other powerful observational techniques using photoelectric devices (in which the light liberates electrons from specially sensitized materials) have been devised; the principles are discussed below. These techniques can be more than 100 times more sensitive than photography. They also allow quantitative measurements of the faint nebular spectrum. (3) Better methods for obtaining spectra have been devised. These include the use of interference filters that reject all colours but those in a very narrow spectral range, or of Fabry-Perot or Fourier spectrometers. (4) Spectral observation has been extended to wavelength ranges inaccessible to the eye or photographic plates. The most important new range is the radio region, where waves are relatively unaffected by the absorption of cosmic dust. The infrared region (wavelengths longer than the visible) has also become accessible; many of the important emission lines are in this region, and their study will become increasingly important. So far, the ultraviolet (short wavelength) region of the spectrum has not been of great value in the study of nebulae.



Red-light photomosaic shows many star clouds, glowing gas, and dark dust in the Milky Way, near the galactic plane. The brightest object (centre left) is the North American Nebula; the loop-shaped object (bottom) is the Cygnus Loop. The rich pattern of bright and dark nebulae, stars, and star clouds is due to the direction of the line of sight, in this region nearly parallel to the outer spiral arms of the Galaxy. (Photo taken by 48 inch Schmidt telescope; photograph, The Hale Observatories.)
By courtesy of © National Geographic Society—Palomar Observatory Sky Survey

During the 20th century scientists have been able to acquire a reasonably good theoretical understanding of the nebulae, although challenging and exciting problems still remain. During the 1920s astrophysics received added impetus from the detailed quantum-mechanical study of atoms (their emission and absorption processes and spectra), and this was applied to the study of nebulae. During the 1930s and 1940s the ionization and heating of nebulae were studied, on the assumption that motions are negligible. During the 1950s problems of gas dynamics were considered, and since about 1960 the use of high-speed electronic computers has made it possible to take rather accurate account of ionization processes, heating and cooling, and even (to a limited extent) the dynamics of the resultant nebular motion. The agreement of these models with observations is encouraging.

Modern observations. Two types of telescopes, which allow complementary types of observations, are used for nebular photography. To photograph the finest details possible, a conventional parabolic reflector is used, with a special additional lens to correct the worst image defect, coma. Even with the correcting lens, the usable field for the 200-inch telescope is very small, about 10′ of arc—which is about twice the angular diameter of a pinhead held at arm's length. The size of the smallest visible details is set by the degree of steadiness of the air above the telescope. Under the best conditions, one can observe details as small as 0.5″ of arc—the width of the pinhead as seen from 500 metres away but still larger than our solar system at the distance of even the nearest nebula.

Devices for the photography of very fine details

The structure of large nebulae. The structure of large nebulae, covering many angular minutes or degrees in size, can be best revealed in photographs made with a Schmidt-type telescope. This has extremely good definition over an area of several (usually about 5 × 5) square degrees, which is about the angular size of a playing card held at arm's length, or ten times the angular dimensions of the Moon.

Spectrographic studies

A great deal of information may sometimes be obtained about an object by photographing it in a limited wavelength region; for example, by cutting out the light beyond the desired region by filters. Some filters can be used to photograph nebulae in the light of only one emission line while rejecting all others. The appearance of the nebula in the light of each emission line indicates how the ions giving rise to that line are distributed throughout the nebula. Another device, the Fabry-Perot etalon, makes it possible to calculate the speeds of the gas inside the nebula in the line of sight of the observer by measuring the Doppler shift of the nebular emission lines. The wavelength shift of the centre of the emission lines determines the average speed of the gas in the nebula, while the width of the line indicates how much difference in velocity there is in material along the line of sight.

The spectra of nebulae are usually obtained with spectrographs of design similar to those used for stars. For large, very faint nebulae, however, it is more useful to be able to receive light from a large portion of the sky, whereas for stars the light comes from a point of the sky. The so-called nebular spectrographs are very fast cameras (*i.e.*, with focal length as little as 0.65 times the aperture, or f/0.65) that photograph the spectrum produced by a large diffraction grating.

Small planetary nebulae are most easily discovered from photographs made with an objective prism placed in front of the optics of a Schmidt telescope. This arrangement yields low-dispersion spectra of all objects appearing on the plate. Stars appear as streaks because their spectra are continuous, but nebulae show up as dots because much of their energy is concentrated in a few colours, especially the red emission lines of hydrogen and nitrogen near 6563 angstroms and of hydrogen and oxygen near 5000 angstroms.

Physical conditions in nebulae. There are several different types of nonreflecting bright nebulae (diffuse, planetary, supernovae remnants), but all of their basic physical processes are similar. These processes must be understood in order to understand the physical nature of the nebulae (for individual characteristics, as well as the origin and evolution of each nebular type, see below).

The composition of cosmic matter

Analysis of cosmic matter shows almost a uniform chemical composition, regardless of the object. This material is predominately hydrogen (about 65 percent by weight, or 90 percent by number of atoms). There is about 3 percent by weight of heavy elements—*i.e.*, of all elements heavier than hydrogen and helium. By number of atoms these heavy elements make up only 0.1 percent of the atoms. The rest—about 30 percent by weight, 10 percent by number of atoms—is helium, which on Earth is one of the rare, or noble, gases.

The diffuse nebulae, planetary nebulae, or supernovae remnants consist of such material in which every atom has been ionized; that is, had one or more electrons stripped from it. The other types of nebulae—dark and

reflection—are composed of almost completely neutral, or nonionized gases. The reason for this separation into two classes, one almost completely ionized and the other almost completely neutral, can be seen from consideration of a pure hydrogen cloud, because the basic idea applies equally well to a real nebula. The hydrogen in the cloud can be ionized by ultraviolet light at a wavelength of less than 912 angstroms or, equivalently, a photon energy of more than 13.6 electron volts. Such radiation, if produced by a star inside a cloud of gas, will ionize a region around the star. At a typical point within the ionized region, only one hydrogen atom in 10,000 is neutral. Since only neutral hydrogen can absorb the radiation, the absorption, once the gas has been ionized, is rather low, just enough to offset the "recombinations" (or captures of a free electron by an ion, resulting again in a neutral atom that must eventually be re-ionized). The intensity of ionizing radiation decreases with distance from the source, and the fraction of neutral material therefore increases. But the increasing fraction of neutral material absorbs the remaining radiation: when the fraction of neutral atoms has increased to 1 percent, the absorption is 100 times as large as it was when the matter was only 0.01 percent neutral. The remaining radiation is very quickly absorbed. Thus, the edge to the ionized region is very sharp, and one can divide the gas into almost completely ionized or almost completely neutral regions.

When several species of atoms are present, it is still found that the ionized region has a sharp boundary, because hydrogen and helium behave similarly and together make up 99.9 percent of the atoms of cosmic bodies. There is, in a sense, a competition for the ultraviolet radiation among the various species of ions and atoms, and a balance is quickly reached in which each stage of ionization is destroyed at the same rate as it is produced. A given stage of ionization is produced by (1) recombination (electron capture) from the next higher stage of ionization and (2) ionization (by absorption of radiation) of the next lower stage of ionization. It is destroyed by either the capture of an electron or the absorption of a photon so that the ionization goes a step further. The exact composition of the gas, for a given radiation field, is completely determined by the balance of these processes.

Physics of the nebular spectrum. The simplest atom, hydrogen, consists of a positively charged nucleus encircled by a negatively charged electron. The electron is attracted to the nucleus because of its opposite charge and therefore has a binding energy. One of the rather astonishing results of quantum mechanics, or the laws of atomic behaviour, is that only certain energies characteristic of the type of atom are available to the bound electron. The levels of hydrogen are designated by a quantum number, n. The higher levels are much more closely spaced than the lower ones. The lowest energy level is called the ground level; higher levels are said to be excited. An atom can change its level; if it radiates energy, it emits a quantum or photon of light and drops to a lower energy level, such that the photon energy exactly matches the difference in energy of the initial and final atomic levels. According to Planck's law of radiation, the energy of the photon is related to its wavelength, so that when an atom drops from one level to another a photon of a characteristic wavelength is emitted. Hα, the red hydrogen line at 6563 angstroms, corresponds to a transition from level 3 to level 2; the blue-green Hβ, 4 to 2. All of the hydrogen transitions ending on the level 2 are called the Balmer series and are the only hydrogen lines in the visible region of the spectrum. The Lyman lines ending on the ground level, n = 1, are stronger but are all at short wavelengths (1215 angstroms or less) in the ultraviolet absorbed by the Earth's atmosphere.

Energy levels of atoms

Not all changes in energy levels are downward to lower energies: an atom can absorb a photon, using the photon's energy to move the electron into a larger orbit. If the absorbed photon is energetic enough, the electron may even be removed completely, and the atom is ionized. The energy required to ionize the ground level is called the ionization potential of the atom.

Besides emitting and absorbing photons, the atom can change its energy because of its close approach to another atom, ion, or electron when an exchange of energy may take place. Most such "collisions" do not change the energy level of either particle and are "elastic"; that is, the particles have the same kinetic energy after the collision that they did before. Occasionally, however, the collision can either raise the energy of the atom to a higher energy level, at the expense of the kinetic energy (an inelastic collision), or cause the atom to drop to a lower energy level, increasing the kinetic energy (a superelastic collision).

Collisions between atoms and other particles

The spectrum of the nebulae can be understood in terms of such transitions between the energy levels of the atoms in the nebula.

Recombination. The hydrogen emission lines in nebulae are produced by the hydrogen nucleus (proton) passing near enough to an electron to recapture it into some bound energy level, emitting a photon in the process. Since the free electron can have any energy above the ionization energy, the photon produced can have any energy, from the ionization energy of the level upward. This gives rise to a continuum of radiation.

The atom is left neutral but, in general, is in an excited state after the recapture. It then drops down to lower energy levels, remaining for only a few hundred-millionths of a second in each level. Most of the nebulae are transparent to the emitted photons except those corresponding to transitions to the lowest, or ground, level; hence, the emitted photon usually escapes. The nebula is opaque to photons matching transitions of the Lyman series (n = 1) of hydrogen because almost all of the neutral atoms are in the ground level (they cascade down into it from excited states almost instantaneously), and the photon has exactly the right energy to be absorbed by that level. The result is that the photon can rarely escape, and the nebula is opaque to the Lyman-series lines. The probability of the hydrogen atom emitting the various lines can be calculated from atomic theory; the results agree very well with the observations of actual nebulae.

Since the higher levels are closely spaced, the transitions between two high levels have low energies and correspondingly long wavelengths that are usually in the radio region. Here, there is some action of the nebula to amplify the emission by "stimulated emission," which is the action of the laser or maser. One of the commonly observed radio lines is between the 110th and 109th levels. It has a wavelength of 2.4 inches (six centimetres).

After an atom has regained its electrons through recombination and cascaded down to the ground state, it remains in the ground state until it absorbs another ionizing photon and is re-ionized. In a typical diffuse nebula this takes about one year. It then remains ionized for about 10,000 years, on the average, before recombining again. During the time it is ionized, the ion undergoes elastic encounters with electrons every few hours as it wanders through the vast spaces of the nebula at a speed of seven miles (ten kilometres) per second.

All elements undergo recombination and ionization, but, of course, the strength of the lines emitted varies with the atomic abundance. Since hydrogen dominates the atomic abundances, it has by far the strongest recombination lines. The helium lines, however, are easily observed. There are weak recombination lines of carbon and oxygen detected.

Collisionally excited lines. The strongest lines in most nebulae are green lines; they are not emitted from hydrogen and are never observed in the laboratory. When first discovered, they were attributed to a hypothetical element, "nebulium," but it was known that there was no place for another element in the periodic table and that nebulium must be a known element in an unusual state of ionization or excitation. In 1927 the U.S. astronomer Ira Sprague Bowen identified nebulium as doubly ionized oxygen, which can be produced in the laboratory. The green nebular lines are not observed terrestrially because they are "forbidden"; that is, the transition from the upper level to the lower level that produces the emission requires a long time to take place. In the laboratory the

"Forbidden" lines

excited atom hits another particle or the container walls before it emits the photon. In the nebulae the atom remains undisturbed long enough to emit the photon.

The doubly ionized oxygen ion enters the upper level of the transition through collisions with electrons, typically undergone about once every year for each ion. This is a comparatively rapid rate. In comparison, ionized hydrogen takes about 10,000 years to recombine and emit a photon at a hydrogen-line wavelength. The "rapid" rate of collisional excitation of the oxygen more than makes up for the fact that its abundance is lower than hydrogen by a factor of about 1,000.

The hydrogen lines are not produced by collisions, because the energy-level spacing is different in hydrogen and doubly ionized oxygen. Practically no electrons have enough energy to excite the hydrogen atom. In contrast, doubly ionized oxygen and many other heavy ions have low-lying levels that can be excited by the electrons.

In nebulae the forbidden lines provide an important means of measuring the density and temperature. The rate at which collisions excite the various upper levels depends on the temperature, which can be determined by comparing the strengths of lines arising from different upper levels of the same atom. The derived values are 6,000°–9,000° K (0° K = −273° C or −460° F) for diffuse nebulae and 7,000°–17,000° K for planetary nebulae. Similarly, for rather high-density objects the densities can be found by comparing two forbidden lines that are collisionally de-excited at different rates. The strongest lines of singly ionized oxygen, at 3726 and 3729 angstroms, are usually used for this purpose. The densities derived for the centre of the Orion Nebula are about 10,000 atoms per cubic centimetre (160,000 atoms per cubic inch).

The nebular continuum. In addition to the emission lines, there is a rather faint continuous background spectrum of continuum. It has already been mentioned that recombination to a bound level can give rise to some of it. Another cause is the bremsstrahlung, radiation emitted by free electrons as they are accelerated by passing near ions. This is the strongest source of nebular continuous radiation in the radio-wavelength region. For short radio wavelengths the radiation escapes from the nebula, but for longer wavelengths the nebula absorbs the radiation, and only the radiation emitted close enough to the edge to escape can be observed.

In the diffuse nebulae there is also a continuum contribution from starlight reflected from dust grains within the nebula. Thus, a diffuse nebula may have a weak reflection component, but its own line emission greatly dominates the light produced.

The temperature of nebulae. Nebulae differ from one another by factors of hundreds in mass, size, and density; their sources of ionization vary from stars whose temperatures are 30,000° K (B-type stars, for some diffuse nebulae) to the central stars of small, peculiar planetary nebula that may be as high as perhaps 150,000° K. Yet practically all nebular temperatures fall in the range from about 6,000° to about 12,000° K. To see why the temperature is kept within so small a range, it may be recalled that the temperature is a measure of the kinetic energy of the free electrons; hence, it is fixed by the balance of the energy losses and gains of the electrons. An energy gain occurs when an atom absorbs an energetic ionizing photon. The electron is ejected with a kinetic energy equal to the excess of the photon energy over the ionization energy of the atom—often several electron volts. The electrons constantly interact with one another (and with ions) through their electric forces. The fast electrons from ionizations quickly share their energy with the many lower speed neighbouring electrons, which have a definite distribution of speeds set up by the collisions. This distribution is characterized by the temperature. On the other hand, there are also processes removing kinetic energy from the collection of electrons; the main one is inelastic collisions of electrons with the heavy ions (usually O^{2+}) that excite the ion while the colliding electron is left with less energy after the collision than it had before. Recall that this process results in the emission of a forbidden-line photon that escapes the nebula; the energy carried away by this photon was provided by the electrons.

The reason that nebulae have narrow ranges of temperatures is that the cooling process is very inefficient below about 5,000° K; not enough energetic electrons exist to produce forbidden lines. Hence, only a small amount of heating suffices to bring the temperature up to this level. Above this value the cooling increases very rapidly, and a great deal of heating is needed to bring the temperature much above 10,000° K. The heavy ions of the nebula act as a thermostat set on the rather formidable temperature of 8,000° K.

DIFFUSE, DARK, AND REFLECTION NEBULAE

Forms taken by diffuse nebulae. The diffuse nebulae are clouds of gas and dust, ionized by one or more young, massive stars (the "exciting" stars) within or near them. Their sizes and masses vary enormously; there is really no lower limit to their size, since a very faint nebula must exist around almost every star, while the largest nebulae are about 200 light-years across and contain about 100,000 solar masses of ionized gas. A typical diffuse nebula is about 30 light-years across and has a density of roughly ten atoms per cubic centimetre (160 atoms per cubic inch), which represents an ounce of matter for every 10^9 cubic miles. In spite of this low density, the total mass of gas in such a nebula would be several times that of the Sun. The density distribution is chaotic and irregular, and the obscuration caused by the dust within and in front of the nebula makes it difficult to get an accurate idea of the gas distribution by optical means. Radio waves penetrate the dust unhindered, and radio observations reveal that on a large scale diffuse nebulae are more regular than their photographs would suggest. For instance, the Trapezium, a group of bright stars exciting the Orion Nebula, appears in visible light near the edge of the nebula (see Plate I). The radio contours reveal that the nebula is really rather symmetrical about the Trapezium; there is a dark cloud that acts as a curtain in front of about half of it. One problem with the radio observations is that the resolving power (ability to distinguish detail) of a single radio telescope is much poorer than that of an optical telescope: details covering about 10′ of arc rather than 1″ can be separated, so that the rather smooth radio contours may to some extent be illusory. It is possible but expensive in observing time to overcome this limitation by an interference technique called aperture synthesis, in which the outputs of two widely separated radio telescopes are used. The resolving power increases as the distance between the radio receivers is increased, and the radio-resolving power achieved in this way is comparable to or better than optical resolution.

Luminous filaments

High-resolution studies of diffuse nebulae reveal one of the surprises that make the study of astrophysics delightful. Instead of the smooth structure that might be expected of a gas, a delicate tracery of luminous filaments can be detected, down to the smallest scale that can be resolved. In the Orion Nebula this is about 400 astronomical units, or ten times the diameter of the orbit of Pluto, the outermost known planet, about the Sun. Even finer detail may exist, and there is evidence from spectra that much of the matter may be gathered into dense condensations, or knots, the rest of the space being comparatively empty. The time it would take unrestrained gas to fill a vacuum between the visible filaments is only about 200 years, much less time than the age of the nebula. How the gas is held together in the small knots is one of the intriguing questions still to be answered.

The largest diffuse nebulae in the Galaxy are revealed only by the radio telescope—they are so heavily obscured by dust that they are inconspicuous optically. These giant nebulae are hundreds of times as bright at radio wavelengths as the Orion Nebula. Similar objects, about 200 light-years in diameter, can be detected in other galaxies; if they were located at the Orion Nebula, they would cover the entire constellation of Orion with brightly glowing gas. The sizes of these giants seem to be about the same in all of the several nearby galaxies in

which they are observed and whose distances are known. If it is assumed that such nebulae at greater distances are also of about the same dimensions, a very useful yardstick becomes available for distance measurement. The angular size of such nebulae in other galaxies can be determined at great distances—up to 30,000,000 light-years. If both the true and angular size are known, the distance of the nebula and thus of the galaxy can be determined.

Forms taken by dark nebulae. Intimately associated with the diffuse nebulae are cold, neutral clouds of material that show up as dark nebulae because of the obscuring dust they contain. (The word cloud is used for convenience; actually there is probably some material everywhere, and cloud is used to mean a region with a local increase in density.) Sometimes the dark nebulae project as long, serpentine shapes seen against a background of stars beyond them; more typically, their borders are not sharp or obvious. A few dark nebulae are very opaque, allowing only $\frac{1}{1,000}$ of the incident light or less to pass through them, but more usually they absorb half of it or less. Most (perhaps 90 percent) of the mass of gas in the Galaxy is in this neutral material and can be seen as dark nebulae only when concentrated in dense clouds. On the average, the galactic material absorbs half of the light in a distance of about 3,000 light-years.

The dark nebulae are neutral and cold because not enough ultraviolet radiation is available in the regions they occupy to cause any appreciable ionization of hydrogen or helium (although the X-rays and cosmic rays in the Galaxy will always provide at least some ionization, about 1 percent or less). Such a lack of radiation energy is very important to the physical state of the gas; theoretical studies suggest that at typical pressures the gas separates into two different phases according to its state of ionization, one at about 50° K and the other nearer 1,000° K but with the same pressure (see also INTERSTELLAR MEDIUM).

Absorption is a major difficulty for optical-observational astronomers studying stars, since it dims the starlight being studied, but it does provide the means for studying the nature of the tiny particles that cause the absorption. Their exact nature is still not known, but it appears that they are in general a few millionths of an inch in size, spaced about 100 yards apart. An ounce would be distributed over a volume larger than the Earth. It is very likely that a significant fraction of these particles are graphite, similar to soot; there may well be particles of rocklike materials (silicates), silicon carbide (Carborundum), or other materials as well. An individual particle may possibly consist of a matrix of several different constituents. It has recently been shown that ordinary water ice does not exist in large quantities on the particles.

The origin of the particles is an interesting theoretical problem. While the grains are probably composed of common substances, solid grains cannot form from a completely gaseous, dilute medium, such as interstellar clouds. Nuclei of a few hundred atoms must somehow first stick together into a tiny "seed" particle; until the grain is large enough to radiate away the energy gained by a collision with an approaching atom, the atom will simply rebound instead of sticking. Such grains may form in the outer atmospheres of cool supergiant stars where the gas density is comparatively high (perhaps 10^9 times what it is in the nebula). If so, the gas in the star can carry away the heat liberated by the grains in capturing atoms. The grains are then blown out of the atmosphere into space by the radiation pressure (the mechanical force of the light they absorb and scatter). Calculations indicate that refracting materials, such as the constituents of the grains proposed above, should condense in this way.

The formation of stars

In the inner regions of dark nebulae important events take place: the formation of stars. The discussion that follows will be slightly oversimplified by the assumption that the nebula has very little net rotation. Since the density in a star is immensely greater than that in a nebula, star formation must occur through condensation. The force of gravity in the nebula constantly pulls it together, working against the disruptive collisions of any one nebula or cloud with its neighbours. But, even if gravity can hold the cloud together against other forces, the cloud cannot collapse unless it can cool; gravitational energy is released in a contraction and would heat the gas cloud, thus increasing the outward pressure and preventing further collapse. The dust grains are efficient emitters of infrared radiation, which escapes, removing the energy from the nebula. A cloud, therefore, contracts under its own gravity, radiating away half of the gravitational energy of the contraction, the other half going into heating the gas. As it contracts, the density and gravitational binding increase, and finally the cloud's gravity so dominates the internal pressure that the material rushes inward in almost a free fall.

While the entire cloud has been collapsing, it does not have a smooth density distribution but rather consists of a chaotic jumble of smaller clouds. These cloudlets pull themselves together by their own gravity into "protostars," each of which is destined to be an individual stellar system. Most of these protostars are smaller than one solar mass, but a very few may be several (up to about 100) times as massive as the Sun. These few massive stars have a profound influence in the evolution of the nebula.

Each protostar collapses very quickly; its gas falls inward in free fall. A protostar can collapse from a size equal to the outer diameter of the solar system to about 30 times the Sun's size (the size of Mercury's orbit) in about six months. After it reaches that size, the material becomes so hot it has become a star; that is, an opaque body radiating energy only from its surface. Around it is a whirling ring of cold, dusty material, which will also break up into even smaller fragments, the "protoplanets." It is now believed that planetary systems are made out of this dusty chaos.

Many such newly formed stars continue to contract, becoming hotter but less luminous in the process, until they start to produce heat by converting hydrogen into helium rather than by contracting. Such a star would then pour forth this energy from thermonuclear reactions into the dark clouds around it and begin to ionize the nebular material, producing a bright nebula around it.

These ideas are given encouraging confirmation by observations of dark nebulae in very long wavelength infrared radiation. Some of the brightest infrared sources are associated with such dark dust clouds; a good example is the class of T Tauri variables, named for their prototype star in the constellation Taurus. The T Tauri stars are known for a variety of reasons to be extremely young. The variables are always found in or near dark nebulae; they are often also powerful sources of infrared radiation, corresponding to warm clouds of dust heated by the T Tauri star to a few hundred degrees K. There are some strong infrared sources (especially in the constellation of Orion) that have no visible stars with them; these are presumably "cocoon stars" completely hidden by their veils of dust.

Formation of reflection nebulae. In 1912 it was discovered that the bright nebula in the Pleiades star cluster has a spectrum like that of the nearby stars rather than a typical nebular spectrum of bright emission lines. The interpretation is clear; the nebula is shining by starlight reflected from the dust particles rather than by any emission of the gas itself. The star illuminating such a reflection nebula is almost always a bright star of type B2 (temperature about 20,000° K) or cooler; hotter stars would ionize the gas and cause nebular emission lines. Studies of the angular sizes of the reflection nebulae led to the conclusion that about 60 percent of the light incident upon the dust is reflected (scattered) rather than absorbed, showing that the material is almost as reflective as snow. Calculations show that even graphite, which, of course, is black in bulk, can produce this effect when dispersed into tiny particles.

According to present theories the fate of the gas remaining in a cloud after star formation depends critically on the kind of star formed; most stars can be created in the interior of the cloud without much influence on the gas (other than to use it up in their formation). The situation

changes abruptly when one or more of the rare, massive hot stars, called O stars, form. These stars produce ultraviolet radiation that ionizes the gas, heating it from perhaps 50° to 8,000° K in the process. Each atom is separated into two parts, the nucleus and the electron, by the ionization, and the pressure in the gas is consequently increased by about 300 times. The ionized gas expands into the surrounding neutral, cold gas like a giant piston, compressing it tremendously. Just as in an explosion, a shock front is formed between the compressed gas and the quiet, undisturbed material ahead of it. Rapid star formation may occur in the compressed region, producing an expanding group of young stars. Such expanding groups, the so-called O Associations (with O stars) or T Associations (with T Tauri stars), have been observed, but it is not known from observations that these associations are formed in the manner just described. The great concentration of gas very close to the Trapezium stars ionizing the Orion Nebula shows clearly that the stars are very young indeed; otherwise, the gas would have expanded and smoothed itself out. It has been suggested that their age is only 20,000 or 30,000 years—hardly more than four-millionths of the age of the Sun, or comparable to two hours in the average life expectancy of man. Early men would not then have been able to see the fascinating "star" in the middle of Orion's sword.

Stellar associations

The gas expansion ends when the ionized gas has reached pressure equilibrium with the neutral material around it; it can hardly act as a piston after this but more resembles a hot bubble. In the time available the gas may not reach this state, which needs perhaps 10,000,000 years to achieve, a time that is comparable to the lifetime of the star that provides the outgoing energy. When the star has "died" after consumption of its nuclear fuel, the diffuse nebula is without its hot central star, and its material presumably recombines—unless the star's life ends with a spectacular supernova explosion, described below.

This picture of the evolution of diffuse and dark nebulae is one of constant turmoil, a few transient O stars serving to keep the material stirred, in constant motion, constantly producing new stars and churning clouds of gas and dust. In this way the thermonuclear energy of stars is converted into kinetic energy of interstellar gas.

Location of diffuse and dark nebulae in the Galaxy. One of the remarkable features of the diffuse and dark nebulae is their extreme concentration in the spiral arms in the plane of the Galaxy. While there is no rigid boundary to the arms, which have irregularities and bifurcations (or "spurs"), the nebulae in other spiral galaxies are strung out along these narrow lanes and form a beautifully symmetric system when viewed from another galaxy. The nebulae are remarkably close to the galactic plane; most are within 300 light-years, only 1 percent of the distance of the Sun from the centre.

The details of the explanation of why the gas is largely confined to the spiral arms is beyond the scope of this article (see GALAXY, THE). Briefly, the higher density of the stars in the arms produces sufficient gravity to hold the gas to them.

The question may be asked: why doesn't the gas simply condense into stars and disappear? The present rate of star formation is about one solar mass per year in the entire Galaxy, which contains something like two times 10^9 solar masses of gas. Clearly, if the gas received no return of material from stars, it would be depleted in roughly two times 10^9 years, about one-fifth the present age of the Galaxy. Several processes by which gas is returned to the interstellar medium from stars have been observed. Possibly the most important is the ejection of planetary nebula shells, discussed below; other processes are ejection of material from massive O- and B-type normal stars or from cool M giants and supergiants. This rate of gas ejection is roughly equal to the rate of star formation, so that the mass of free gas is declining very slowly.

This cycling of the gas through stars presumably has had one major effect: the chemical composition of the gas has been changed by the nuclear reactions inside the stars (see CHEMICAL ELEMENTS, ORIGIN OF). There is excellent evidence that the Galaxy originally consisted of almost pure hydrogen with (probably) some helium and that all of the heavier elements have been produced inside stars by being subjected to the exceedingly high temperatures in the central regions. Thus, most of the atoms and molecules on the Earth, as well as in human bodies, owe their very existence to processes that take place within stars.

Original composition of the Galaxy

Chemical composition of diffuse nebulae. The composition of the diffuse nebulae can be estimated by relating the strengths of the emission lines found in their spectra to the numbers of atoms producing them, and great strides have now been made in calculating the necessary atomic properties. The principal difficulties in gauging the accuracy of the determination are, however: (1) the use of average temperatures and densities when the material is actually clumped into regions with very different physical conditions and (2) making the right adjustment to the line strengths to allow for the absorption by the dust both within the nebula and between the nebula and the observer on the Earth. Nevertheless, nebulae appear to be remarkably consistent in their composition. In particular, the ratio of numbers of helium atoms to hydrogen atoms has been shown to be about 1 to 10 in many different objects, observational and theoretical uncertainties being about 15 percent; even nebulae in several other galaxies show the same value. Oxygen is the most abundant heavy element (the number of oxygen atoms is one-thousandth of the number of hydrogen atoms) and nitrogen is about one-sixth as abundant as oxygen. A few apparent exceptions occur in nebulae in which the helium abundance is measured by using radio (rather than the optical) recombination lines, always in the sense that the helium abundance seems low. One possible explanation is that hydrogen is ionized in a larger region than helium, which would make the helium lines appear weak or absent in the measurements.

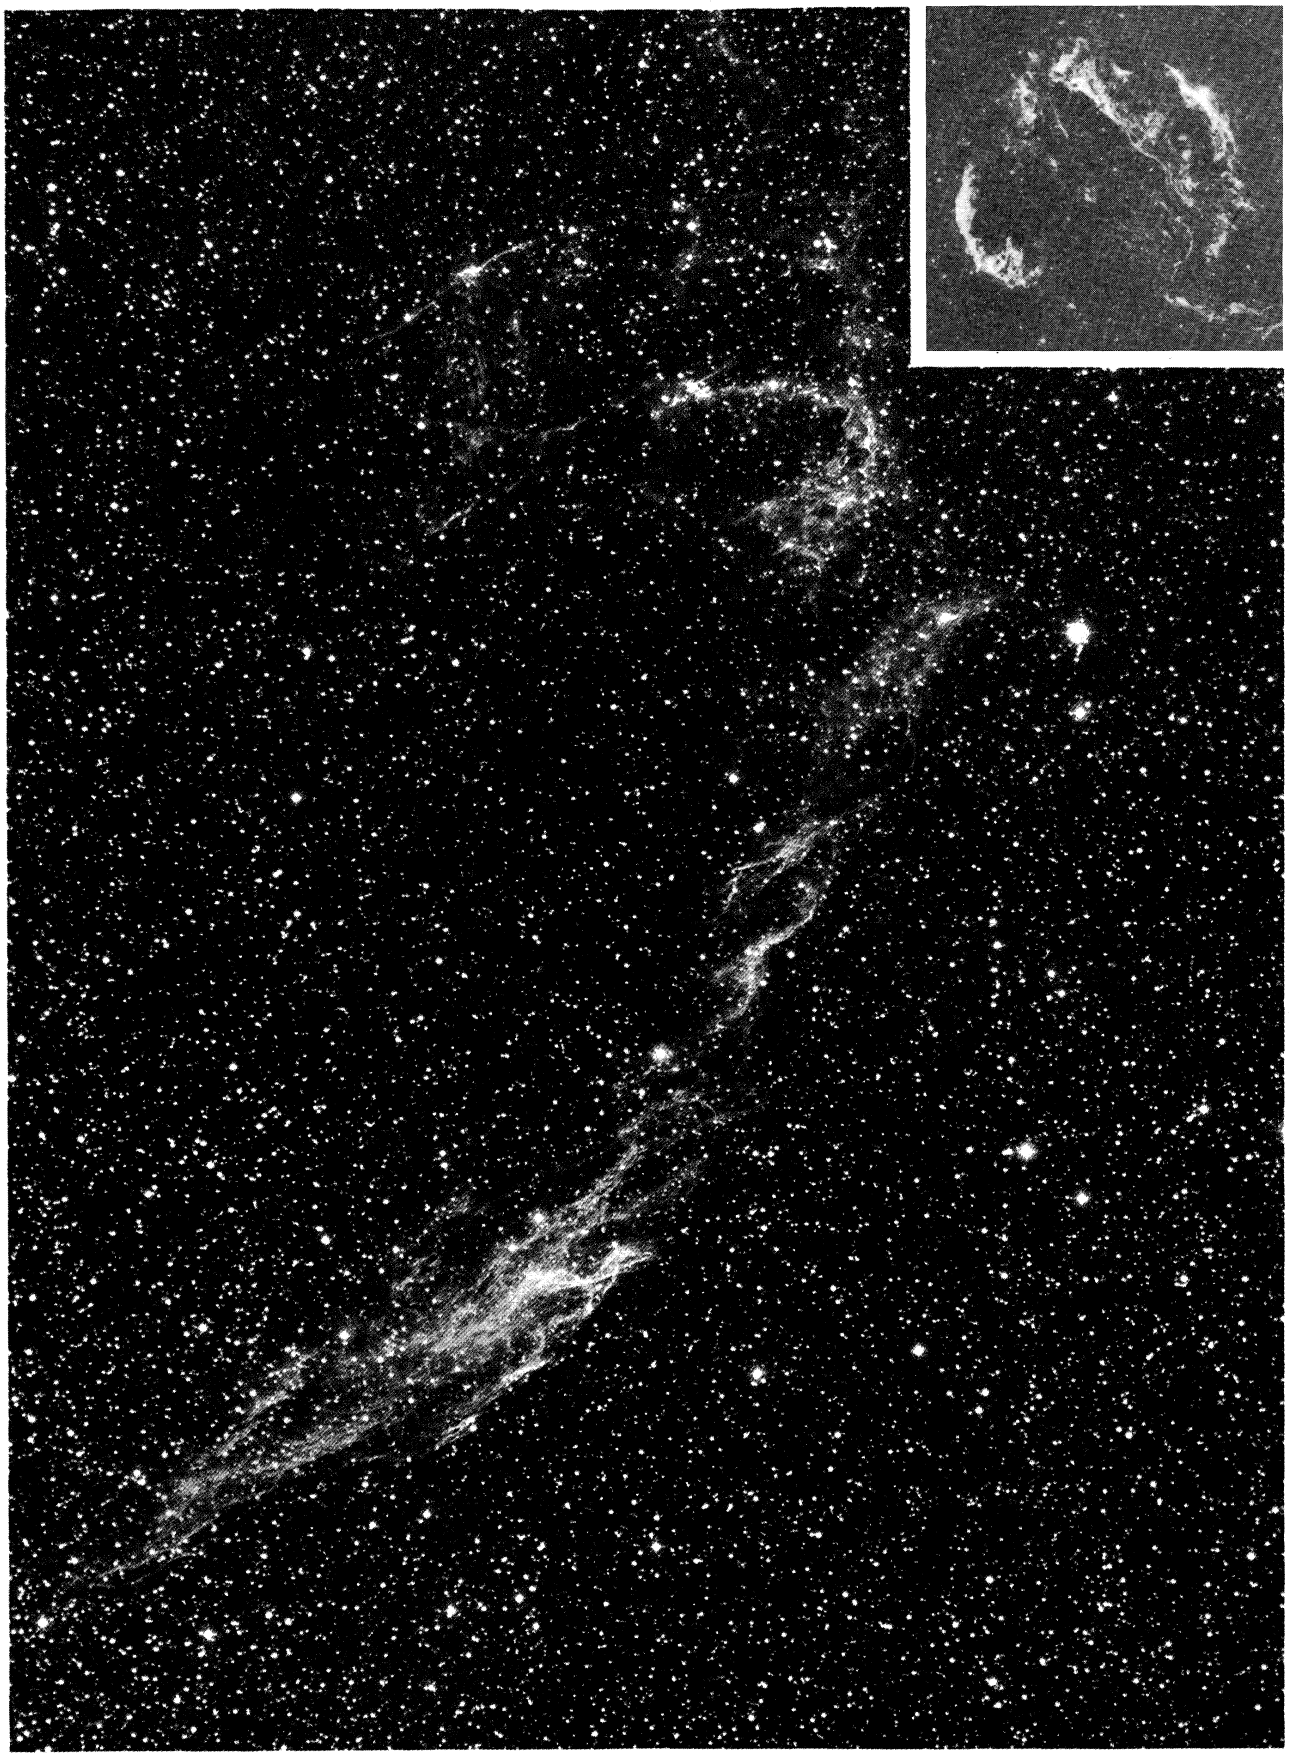
THE PLANETARY NEBULAE

Forms and structure. Compared to the diffuse nebulae, planetary nebulae are small objects, having a radius, typically, of one light-year and containing a mass of gas equivalent to about 0.3 solar mass. They are considerably denser than most diffuse nebulae, typically containing 1,000–10,000 atoms per cubic centimetre (16,000–160,000 atoms per cubic inch) within their dense regions. Many are so far away that they appear stellar when photographed directly, but the conspicuous examples measure up to 20′ of arc across, 10″–30″ being usual. Those that show a bright disk have much more regular forms than the chaotic diffuse nebulae, but there are still usually some brightness fluctuations over the disk. The planetaries generally have regular, sharp outer boundaries; often they have a relatively regular inner boundary as well, giving them an appearance like a ring. Many have two lobes of bright material, resembling arcs of a circle, connected by a bridge—somewhat resembling the letter Z.

Most planetaries show a central star, called the nucleus, which provides the ultraviolet radiation required for ionizing the gas in the ring or shell surrounding it. Those stars are among the hottest known and are in a state of comparatively rapid evolution.

The central star

As with diffuse nebulae, the overall structural regularity conceals large-scale fluctuations in density. High-resolution photographs of a planetary nebula usually reveal tiny knots and filaments down to the resolution limit of the photograph. The spectrum of the planetary nebula is basically the same as that of the diffuse nebula; it contains bright lines from hydrogen and helium recombinations and the forbidden lines (defined above) of other ions. In general, the spectra of planetaries differ from those of diffuse nebulae in that they show much higher degrees of ionization. In some planetaries most of the helium is doubly ionized, and appreciable amounts of five-times-ionized oxygen and argon and four-times-ionized neon exist. In diffuse nebulae helium is mainly once ionized and neon and argon only once or twice. This difference in the states of the atoms results from the temperature of the planetary nucleus (up to about 150,000° K), which is



Veil Nebula (NGC 6992 and 6995) in the northern constellation Cygnus, which is part of a much larger spherical supernova remnant (inset). The nebula glows as it collides with dust and gas in interstellar space. Blue light is emitted from the hot leading edge of the nebula, where the most energetic collisions occur; the red glow is from hydrogen in the cooler gas.

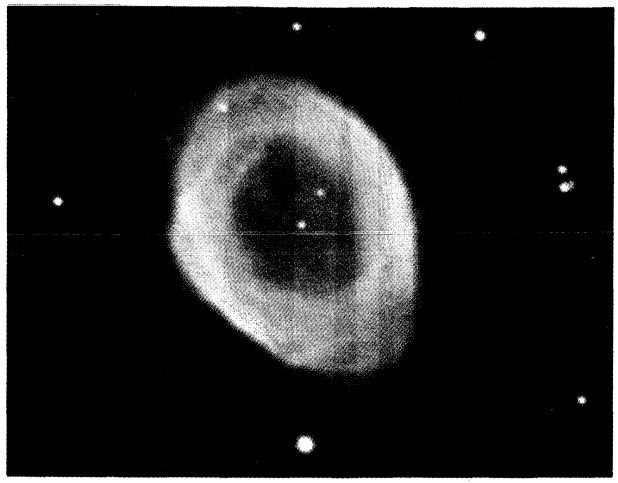
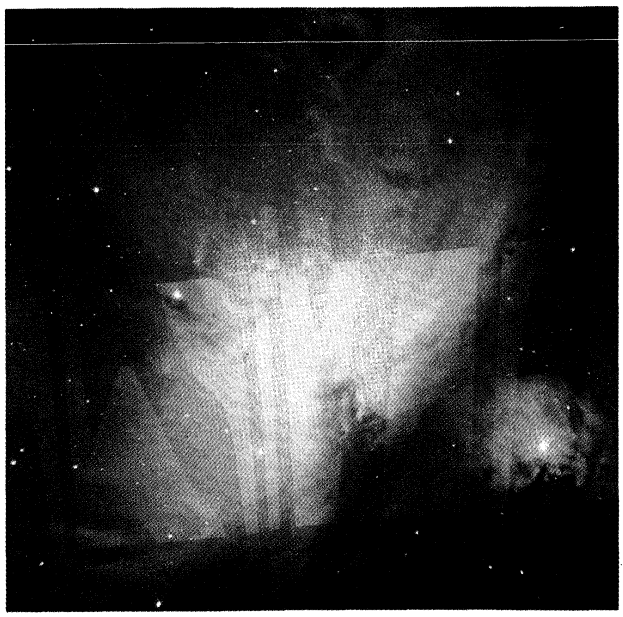
Crab Nebula (M1, NGC 1958) in the constellation Taurus, a gaseous remnant of the galactic supernova of AD 1054, 6,000 light-years away, expanding at 700 miles/second.

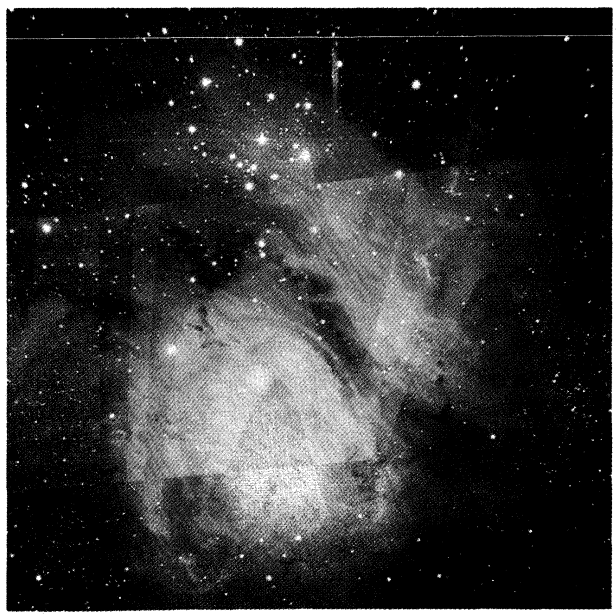


Ring Nebula (M57, NGC 6720) in the constellation Lyra, a planetary nebula consisting mainly of gases thrown off by the star in the centre.

(Above) Trifid Nebula (M20, NGC 6514) in the constellation Sagittarius, a bright diffuse nebula with lanes of dark material in front of it.
(Left) Bright nebulosity in the Pleiades (M45), distance 420 light-years. Cluster stars provide the light and surrounding clouds of dust reflect and scatter the rays from the stars.



Great Nebula in the constellation Orion (M42, NGC 1976), surrounded by glowing gas cloud, one of the largest gas-dust complexes in the Galaxy. Radiation from stars excites atoms of gas, causing them to emit the fluorescent light visible here.



Lagoon Nebula (M8, NGC 6526), in the constellation Sagittarius. This bright diffuse nebula is so large that light from the involved stars does not penetrate its boundaries and the bright nebula appears to be seen against a larger darker one.

Plate 2: By courtesy of Hale Observatories; photographs, © California Institute of Technology and Carnegie Institution of Washington

much higher than that of the exciting star of the diffuse nebula (less than 60,000° K for an O star, the hottest). One of the conspicuous features of planetaries is that the high stages of ionization are found close to the central star. The rare heavy ions, rather than hydrogen, absorb the photons of several hundred volts' energy. Beyond a certain distance from the central star, all the photons of energy sufficient to ionize a given species of ion have been absorbed, and that species therefore cannot exist farther out. Detailed theoretical calculations have rather successfully predicted the spectra of the best observed nebulae.

The planetary nebulae contain no optically detectable dust; their spectra do not contain an observable reflection component. There is, however, evidence gathered from the anomalously strong infrared emission from several well-observed planetaries that some dust exists—too little to detect optically but enough to absorb the strong ultraviolet emission line of hydrogen called Lyman alpha. Presumably, absorption of the Lyman-alpha radiation heats the dust to about 200° K, and the dust radiates in the infrared.

Expansion of planetaries

The spectra of the planetary nebulae reveals another interesting general fact: they are expanding from the central star at speeds of 15 to 35 miles per second. The gravitational pull of the star is quite small at the distance of the shell from the star, so the shell will continue its expansion until it finally merges with the interstellar gas around it. The expansion is proportional to the distance from the central star, consistent with the entire mass of gas having been ejected at one brief period from the star in some sort of instability.

The distances of planetary nebulae. Not a single planetary nebula is close enough to the Sun to allow a direct determination of its distance; the nearest one (NGC 7293) is about 300 light-years away. It is necessary, therefore, to use indirect methods to find the distances. One method is to estimate the true rate of emission of one of the hydrogen lines from the nebula (from the gas density and temperature) and compare this with the observed brightness. From the intrinsic and apparent brightness the distance can be found. One planetary, NGC 246, has a normal G star as a companion and its distance can be estimated if it is assumed that the companion is similar in intrinsic brightness to nearby G stars of similar type. Once the distance is known, other quantities (such as size and mass) can easily be found. Unfortunately, different methods of estimating distances give results differing by factors of more than two. A more reliable way of estimating distance is to consider the planetaries found in the Magellanic Clouds, the nearest external galaxies, whose distance (about 150,000 light-years) is known from reliable distance estimates of their other stars. At this distance, however, planetaries are very faint and correspondingly difficult to observe.

From the best available average distance determination, the true size of any nebula can be found, within the limits of error, from its angular size; typically, planetary nebulae are found to be a few tenths of a light-year in radius. If this distance is divided by the expansion speed, the age of the nebula since ejection is obtained, with values up to roughly 30,000 years.

Chemical composition. The chemical composition of planetaries can be found from their spectra in the way discussed above for diffuse nebulae. Almost all planetaries are found to have compositions remarkably similar to that of the diffuse nebulae. In particular, the helium abundance is about the same or only slightly higher, indicating that the ejection mechanism does not greatly disrupt the helium-rich interior of the parent star. The heavy-element content is similar, with two very interesting known exceptions: the planetary in the globular cluster M15 and a planetary in the "halo" (tenuous outer regions) of the Galaxy. Both have very low heavy-element content (down from normal by factors of about 50) but normal helium. Both objects are very old, and this result suggests that, while the primeval gas in the Galaxy had a low heavy-element content, it did have helium. The origin of helium in the Galaxy may very possibly have been the initial explosion of the universe itself.

Positions in the Galaxy. One of the best indicators of the average age of astronomical objects is their position and motion in the Galaxy. The youngest are in the spiral arms, near the gas out of which they have formed; the oldest are not concentrated to the plane of the Galaxy, nor are they found within the spiral arms. By these criteria, the planetaries reveal themselves to be rather middle-aged; they are moderately but not strongly concentrated to the plane; rather, they are concentrated toward the galactic centre, as the older objects are. Their motions in the Galaxy follow elliptical paths, whereas circular orbits are characteristic of younger stars. They belong to the type of distribution often called a "disk population," to distinguish it from Population II (very old) and Population I (young) objects of U.S. astronomer Walter Baade. It is possible that there is a wide variation in the ages of planetaries and that some are very young objects.

Stellar populations

Only about 1,000 planetaries are known, but their discovery is much hampered by obscuring dust. Their local (nearby) density suggests that there may be 50,000 in the Galaxy; if so, about 98 percent of them are hidden.

Evolution of planetary nebulae. A description of the evolution of a planetary nebula after it has been ejected from the central star begins with the cloud of gas perhaps a few light months from the star, at which distance gravity of the star is negligible. The expansion speed of the gas is typically 30 miles (50 kilometres) per second. Nebulae in this stage are bright but have starlike images as seen from the Earth, because they are too small to show a disk. The gas is at a comparatively high density—about 1,000,000 atoms per cubic centimetre—but becomes more dilute as the gas expands.

Now the chance that an ion will collide with an electron and recombine in a given length of time increases with the density. When the density is high, the matter nearest to the star can absorb the entire amount of ionizing radiation, and most of the gas is then in a neutral region outside the ionized (bright) part. That there is neutral hydrogen present can be deduced from the presence of forbidden lines (see above) of neutral oxygen in the spectrum; oxygen and hydrogen happen to have the same ionization potential, so, if neutral oxygen is present, neutral hydrogen must be also. During this stage the nebula appears to expand faster than the individual atoms of gas in it are moving; the ionized shell is "eating into" the neutral material as the density falls.

The middle stage of evolution occurs when the density has dropped to the point where the entire mass of gas is ionized. After this stage is reached, some of the ultraviolet radiation escapes into space, and the expansion of the nebula is caused entirely by the motion of the gas. Most planetaries are now in this middle stage. Finally the central star becomes less luminous and can no longer provide enough ultraviolet radiation to keep even the dilute nebula ionized. Once again the outer regions of the nebula become neutral and therefore invisible. Eventually the gas is mingled with the general interstellar gas.

A curious feature of several planetaries is that faint rings surrounding the bright, inner nebula can be observed. Possibly the outer rings are the remnants of a previous shell ejected earlier by the star. Alternately, they might be at the outer edge of the expanding neutral (and invisible) gas, which is ramming into quiescent interstellar gas originally present when the planetary ejection occurred. There would be a strong shock wave at this interface, and the shocked matter would be heated to several thousand degrees, causing the emission. The matter would quickly radiate its heat and become cold and invisible again. The key to the choice of those alternatives would be the spectrum of the faint ring, if it could be determined.

The central stars. The central stars are known from their spectra to be very hot. A common type of spectrum has very broad emission lines of carbon or nitrogen, as well as of ionized helium, superimposed upon a bluish continuum. These spectra are indistinguishable from those from the very bright rare stars known as Wolf-Rayet stars, but the planetary nuclei are about 100 times fainter than true Wolf-Rayet objects. The line widths are

interpreted as Doppler shifts caused by velocities in the line of sight of over 1,000 miles (1,600 kilometres) per second, enough for the mass to escape from the star. Thus, the stars appear to be losing some mass at the present time although evidently not enough to contribute appreciably to the shell.

The evolution of the central star. The presence of the nebula allows a comparatively precise determination of the evolution of the central star. The temperature of the star can be estimated from the nebula from the amounts of emission of ionized helium and hydrogen by a method devised by the Dutch astronomer H. Zanstra. The amount of ionized-helium radiation is determined by the number of photons of more than 54 volts' energy, while hydrogen is ionized by photons of more than 13.6 volts. The relative numbers of photons in the two groups depend strongly on the temperature, since the spectrum shifts dramatically to higher energies as the temperature of the star increases. Hence, the temperature can be found from the observed strengths of the hydrogen and helium lines. The rate of evolution of the stars can be found from the sizes of their nebulae, as the time since ejection of the shell is simply the radius of the nebula divided by the expansion rate. The energy output, or luminosity, of the central star can be estimated from the brightness of the nebula, because the nebula is converting the star's invisible ultraviolet radiation (which contains the greater part of the star's luminous energy) into visible radiation. The results pertain to only one nebula at one particular epoch, but consideration of the statistics of many nebulae provides a consistent picture of the evolution, just as one could learn about the human aging process by considering the vital statistics of an entire human population at any instant.

The resulting theoretical description of the star's evolution is quite interesting. While there seem to be real differences in stars at a given stage, the trends are quite clear. The central stars in the youngest planetary nebulae are about as hot as the massive O and B stars—35,000°–40,000° K—but roughly ten times fainter. They have half the diameter of the Sun but are 1,000 times as luminous. As the nebula expands, the star increases its brightness and temperature, but its radius decreases steadily. It reaches a maximum energy output, when it is roughly 10,000 times as luminous as the Sun, about 5,000 years after the initial expansion. This is an amazingly small fraction of the star's age of several times 10^9 years; it represents a period equivalent to about half an hour in a human life. From this point on the star becomes fainter, but for some time the temperature continues to increase while the shrinkage continues. At its hottest the star is perhaps 200,000° K, almost five times hotter than the hottest of most of the stars. It then cools and after about 10,000 years becomes a very dense white dwarf star, hardly larger than the Earth but with a density of several tons per cubic inch. From this point it cools very slowly, becoming redder and fainter indefinitely.

Final stages of central star's evolution

While there is not yet a very detailed theoretical picture of this contraction, a few results have emerged rather clearly: (1) white dwarf stars must obtain almost all of their energy from the contraction noted above, not from nuclear sources; therefore, (2) they must contain practically no hydrogen or helium, except perhaps in a very thin shell on their surfaces. These conditions would have to be met for the evolution to take place so quickly.

The absence of hydrogen in the star's interior is quite surprising; the planetary nebulae are all found to have a normal hydrogen abundance of about 1,000 times as many hydrogen atoms as heavy elements, such as oxygen. Thus, the mechanism of expulsion of the envelope must be very efficient at ejecting the hydrogen-rich outer layers of a star while leaving heavy-element-rich material behind.

The nature of the progenitor stars. A complete agreement on the kind of star that produced the nebula or the means by which it produced the nebula had not been reached in the early 1970s, but rather specific limits could be set on the probable nature of the progenitors.

First, the progenitor must have mass not much in excess of a solar mass because of the distribution of the planetaries in the Galaxy. Very massive stars are young and more closely confined than are nebulae to the galactic plane. Also, the mass of the nebula is roughly 0.3 solar mass, and the mass of a typical white dwarf (the final state of the central star) is roughly 0.7 solar mass. Next, the expansion velocity of the nebula is probably comparable with the velocity of escape from its progenitor, which implies that the progenitor was a red giant star, large and cool, completely unlike the small, hot, blue, nuclear star remaining after the ejection. Likely candidates are members of the class of Long-Period Variable stars, which have about the right size and mass and are known to be unstable. Symbiotic stars—*i.e.*, stars with characteristics of both cool giants and very hot stars—are also candidates. The novae (stars that brighten temporarily while ejecting a shell explosively) are definitely not candidates; the nova shell is expanding at hundreds of miles per second.

The cause of the ejection is not yet known; at least three different plausible explanations have been advanced. Perhaps the true situation is produced by a combination of several effects.

FILAMENTARY BRIGHT NEBULAE: SUPERNOVA REMNANTS

Some of the most fascinating objects in the sky are the remnants of supernovae. The supernova phenomenon is a spectacular explosion in which a star is almost completely disrupted and most of its mass ejected in a violently expanding cloud of debris that soon becomes an observable and remarkable nebula. At the brightest phase of the explosion, the expanding cloud radiates as much energy in a day as the Sun has done in the last 3,000,000 years. Such explosions are infrequent—one may occur roughly every 50 years within an entire galaxy. They have been observed less frequently in the Galaxy because most of them have been hidden by the obscuring clouds of dust. The known galactic supernovae were observed in 1006 in Lupus, in 1054 in Taurus, in 1572 in Cassiopeia (Tycho's nova, named after Tycho Brahe, its observer), and finally in 1604 in Serpens, called Kepler's nova. The stars became bright enough to be visible in the daytime.

Known galactic supernovae

In spite of the rarity of supernovae in the Galaxy, they have been found in large numbers in other galaxies. For a few days the brightness of the supernova is comparable to that of the entire galaxy, and it is easy to detect a supernova within a not-too-distant galaxy. Hundreds have been photographed and studied spectroscopically. At the site of Kepler's and Tycho's novae, there are heavy obscuring clouds, and the optical objects remaining are now inconspicuous knots of glowing gas. Near Tycho's nova, in Cassiopeia, there are similar optically insignificant wisps that appear to be remnants of yet another supernova explosion. To a radio telescope, however, the situation is spectacularly different: the Cassiopeia remnant is the strongest radio source in the entire sky (easily outshining the Sun, although the Sun is almost 10^9 times closer). Study of this remnant, called Cassiopeia A, reveals that a supernova explosion occurred there in approximately 1700, missed by observers because of the obscuring dust.

The Crab Nebula. At the site of the 1054 supernova is one of the most remarkable objects in the sky, the Crab Nebula. Photographed in colour, it is revealed as a beautiful red, lacy network of long and sinuous, glowing hydrogen filaments surrounding a bluish, structureless region whose light is strongly polarized. The filaments emit the spectrum characteristic of a diffuse nebula—*i.e.*, the emission lines of hydrogen, oxygen, and other elements. The gas is expanding at 700 miles (1,100 kilometres) per second—but still slower than the 4,000 miles (6,400 kilometres) per second in the shells of new supernovae in other galaxies.

The bluish, amorphous inner region of the Crab Nebula is even more remarkable. The glow is produced by the so-called synchrotron radiation—*i.e.*, from electrons spiralling about a magnetic field at almost the speed of light. This radiation is dramatically different from what it would be if it were emitted from electrons moving at low speeds: it becomes (1) strongly concentrated in the

Synchrotron radiation

forward direction, like the beam of a searchlight, (2) spread out over a broad range of frequencies but with the average frequency increasing with the electron's energy, and (3) highly polarized. Electrons of many different energies produce radiation in a large range of wavelengths: radio, infrared, optical, and ultraviolet. Even X-rays are emitted copiously by the Crab, which is the second-brightest X-ray source in the sky, indicating (for reasonable values of the magnetic field) that the electrons must have energies in the cosmic-ray range. After almost 1,000 years, the nebula is still losing 100,000 times as much energy per second as the Sun.

On the basis of this huge outpouring of energy, it is easy to calculate how long the nebula can shine without a new supply of energy. The electrons emitting the X-rays should decay, or drop to lower energies, in about 30 years —far less than the age of the nebula. The source of energy within the Crab Nebula supplying energy to the electrons that emit the X-rays was discovered in 1969 to be the pulsar NP 0532, the remains of the star that exploded to form the nebula (see PULSARS).

In the case of the Crab Nebula, the pulsar has been found to flash optically as well as at radio wavelengths, blinking on and off with the same period, believed to be a result of rotation: 0.033099324 second (on June 28, 1969). This period is slowly increasing (at the rate of 0.0012 second per century), which implies the pulsar is slowing down and thereby losing its energy to the nebula. The corresponding rate of energy loss is about equal to the nebula's rate of energy loss, convincing evidence that a tiny, extremely dense pulsar can supply the energy to the nebula, which is about four light-years across.

The Crab Nebula is unique in being a young supernova remnant and relatively free from obscuration, while Tycho's and Kepler's supernovae are conspicuous radio sources, apparently radiating by synchrotron emission; in neither case has a detectable pulsar been found. The Crab's pulsar, NP 0532, has the shortest known period, which suggests that it is the youngest known pulsar. The failure to detect pulsars at the sites of Kepler's and Tycho's novae, or Cassiopeia A, does not mean that they are not there; the radiation from the pulsar is probably strongly beamed, and the Earth may not be located in the direction to which the pulsars are sending their energy.

The Crab Nebula is still in a stage of violent expansion, and it is interesting to consider how it will appear a few thousand years hence. The gas will continue to expand and the pulsar lose energy until the nebula enters a second stage: one in which the pulsar can no longer put much energy into the nebula, and the nebula expands like a hot bubble of gas into the cold, surrounding interstellar gas. As the hot gas rams into the cold much faster than its speed of sound, a strong shock wave results. The cold gas is heated to about 100,000° K as it is hit by the shock wave and then cools by radiating forbidden and recombination lines. Almost all of the mass inside the shocked "bubble" will consist of this interstellar material swept up by the expanding shock wave.

The Cygnus Loop. As a general mechanism this picture seems well confirmed. The best observed old supernova remnant is the Cygnus Loop (or the Veil Nebula; see Plate II), a beautiful, filamentary object roughly in the form of a circular arc in Cygnus. Its patchiness is striking: the loop consists of a series of wisps rather than a continuous cloud of gas (see illustration). The most likely interpretation of this patchiness is that the interstellar medium into which the shock wave is propagating contains small clouds of denser material; many lines of reasoning from other evidence lead to the same result (see INTERSTELLAR MEDIUM). The present speed of the filaments is about 60 miles (100 kilometres) per second; the approximate age of the Cygnus Loop is about 50,000 years.

Other supernova remnants. Many other such old supernova remnants in the Galaxy are recognized, because they are also sources of radio emission from synchrotron radiation. Optically, in general they show a wispy appearance similar to that of the Cygnus Loop.

The eventual fate of these supernova remnants is to cool down, stop expanding, and finally merge with the interstellar medium. In the process they have modified the interstellar medium in two important ways: (1) They leave behind the elements that have been made in the presupernova star by a long process of heating and thermonuclear processing. Some very heavy elements are made in the very high temperatures right after the explosion. These elements are ejected into the supernova nebula and are finally merged with the interstellar medium. In this way the heavy-element content of the interstellar medium is increased. There is observational confirmation of this; both the Crab Nebula and the remnant of Tycho's supernova seem heavy-element rich. (2) They have provided kinetic energy to the surrounding gas by violent expansion, heating and accelerating the interstellar gas clouds. In addition, the original explosion emitted large quantities of very high energy particles that probably are the cosmic rays. These cosmic rays, as well as the X-rays emitted by the remnant, serve to heat the interstellar gas. It seems that supernovae play a very important role in the history of a galaxy, just as remarkable individuals shape the course of human history.

BIBLIOGRAPHY. B.M. MIDDLEHURST and L.H. ALLER (eds.), *Nebulae and Interstellar Matter* (1968), an excellent collection of chapters on various aspects of nebulae, each written by an expert in the field, especially good on the observational characteristics of nebulae; L.H. SPITZER, *Diffuse Matter in Space* (1968), a brief but excellent work on the physics of nebulae and interstellar matter; L.H. ALLER, *Gaseous Nebulae* (1956), a general monograph, slightly out of date, especially good on observational results; D.E. OSTERBROCK and C.R. O'DELL (eds.), *Planetary Nebulae* (1968), the proceedings of an International Astronomical Union conference on planetary nebulae in which the status of almost every aspect of this subject is summarized; H.J. HABING (ed.), *Interstellar Gas Dynamics* (1970), the proceedings of another IAU conference containing valuable discussions of supernova remnants and dynamics of diffuse and planetary nebulae; JEAN DUFAY, *Galactic Nebulae and Interstellar Matter* (1957), a somewhat more general summary than the above.

(J.S.M.)

Necker, Jacques

A Swiss banker and minister of finance under the French king Louis XVI, Jacques Necker was overpraised in his lifetime for his somewhat dubious skill with public finances and unduly depreciated by historians for his alleged vacillation and lack of statesmanship in the opening phases of the French Revolution.

Necker was born in Geneva on September 30, 1732, the younger son of Charles-Frédéric Necker, a lawyer from Küstrin in the Electorate of Brandenburg who had become a citizen of the Genevan republic in January 1726. At the age of 16, Jacques Necker became a clerk in the bank of a friend of his father; and in 1750 he was transferred to the bank's headquarters in Paris. In 1762 Necker was promoted to the position of junior partner. As a result of adroit speculation in the public funds and in the grain trade during the Seven Years' War, Necker became a prominent and wealthy banker. In 1764 he married Suzanne Curchod, the cultivated and talented daughter of a former Vaudois pastor (among her earlier suitors had been the historian Edward Gibbon). She encouraged him to embark on a public career. Geneva appointed him its resident minister in Paris in 1768; and he also became a director of the French East India Company. In 1772, at his wife's suggestion, Necker transferred his banking responsibilities to his brother Louis. He then acquired a reputation as a writer on financial topics with a eulogy written in memory of Jean-Baptiste Colbert, Louis XIV's great finance minister, and with an attack (1775) on the current free-trade policy in corn. Though he was a foreigner and a Protestant, Necker was placed in virtual control of French finances, as director of the royal treasury, on October 22, 1776, and by his appointment as director general of the finances on June 29, 1777.

First ministry

In his first ministry, Necker made several cautious experiments in social and administrative reform. He abolished mortmain (possession of lands by a corporation) on the royal domains in August 1779; reduced the numbers of the general tax farmers from 60 to 40; and

Necker, portrait by Augustin de Saint-Aubin (1736–1807), after a painting by Joseph-Sifford Duplessis.
H. Roger-Viollet

established "provincial assemblies" for Berry and for Haute-Guyenne with administrative powers in which the Third Estate (the commons) had as many representatives as the clergy and the nobility combined and voting was by head (1778–79). The first and the last of these experiments met with opposition from the privileged orders and were not extended, as had been hoped, to the country as a whole. Necker's principal mistake, however, was his misguided attempt to finance French participation in the American War of Independence without recourse to additional taxation. In trying to raise the necessary loans, Necker published in 1781 his celebrated *Compte rendu au Roi,* claiming a surplus of 10,000,000 livres in the hope of concealing an actual deficit of 46,000,000. The opposition of the leading minister, Jean-Frédéric Phelypeaux, comte de Maurepas, and the hostility of the queen, Marie-Antoinette, forced Necker to resign on May 19, 1781. He retired to Saint-Ouen, where he wrote his *De l'administration des finances de la France* to justify his policy (1784).

Outbreak of revolution

After both Charles-Alexandre de Calonne and Étienne-Charles de Loménie de Brienne had failed to solve the financial problems for which Necker was at least partially responsible, Necker himself was recalled as finance minister on August 26, 1788. France was now on the verge of bankruptcy, in spite of the aristocracy's agreement to surrender its immunity from taxation. In the face of the financial crisis it was decided to summon a meeting of the States General (the representatives of the clergy, nobility, and commons), which was to set in motion the French Revolution (see FRANCE, HISTORY OF). As the decision to summon the States General for 1789 had already been taken, Necker's main preoccupation lay in the field of politics rather than in finance, though he was too complacent in assuming that the surrender of the fiscal immunities of the nobility would remove his financial anxieties. In preparing for the meeting of the States General, Necker had to steer a difficult course between the claims of the Third Estate for double representation, which were conceded by the royal council on his recommendation in December 1788, and the insistence of the privileged classes on the traditional method of debate, order by order. He has often been blamed for not having clearly laid down the government's proposals for political as well as financial reform in his opening speech to the States General on May 5, 1789. He did, however, propose a reasoned program of social and constitutional reforms that was overlooked in the struggle over procedure. This struggle might have been avoided if Necker's suggestion for conciliation had been adopted. His program of liberal concessions to the National Assembly (formed between June 10 and June 17) was drastically modified by the court reactionaries just before the "royal session" of June 23, 1789. His objective was a limited constitutional monarchy with a bicameral legislature on the English model. His dismissal, on July 11, 1789, an overt sign of court reaction, did much to provoke the disturbances in Paris that culminated in the storming of the Bastille. Having retired to Switzerland, he received the summons to return to office on July 20, 1789.

In his third ministry Necker struggled ineffectively with the rapidly mounting deficit and was overshadowed by Talleyrand and the Comte de Mirabeau, who dictated revolutionary finance at that stage. Necker's chief weakness as a politician was his vanity and his anxiety to preserve his popularity at all costs. After his final resignation (September 18, 1790), he lived in retirement until his death at Coppet on April 9, 1804.

BIBLIOGRAPHY. No definitive biography in English has, as yet, been written. The most scholarly account (in French) of Necker and his Franco-Swiss background is EDOUARD CHAPUISAT, *Necker: 1732–1804* (1938). Other more popular biographies are EUGENE LAVAQUERY, *Necker, fourrier de la Révolution, 1732–1804* (1933); and PIERRE JOLLY, *Necker* (1947). For technical studies of Necker's financial policies, see MARCEL MARION, *Histoire financière de la France depuis 1715 . . .* , vol. 2 (1919, reprinted 1965); and two articles, the first by HENRI CARRE, "Le Premier Ministère de Necker, 1776–1781" in the review *La Révolution française*, 44:97–136 (1903); and the second by JULES FLAMMERMONT, "Le Second Ministère de Necker," *Revue historique*, 46:1–67 (1891).

Negro Churches (in the United States)

Negro churches are the churches of those Americans who have been known variously as Negroes, Africans, Afro-Americans, and blacks. These churches have also increasingly been termed black churches.

NATURE AND SIGNIFICANCE

Influence of the slave system

The historical and cultural importance of the black church in American Christianity is tied up with the *origin* of the black people in America. Unlike European immigrants, who went to America seeking religious and political freedom or better living conditions, Africans did not go by choice but as bondmen, chained on ships. The slave system shaped black life, especially its religious expressions. An investigation of the nature and significance of the black church in the United States, therefore, involves an assessment of what in pre-Civil War times was called the "peculiar institution" of slavery, and of its brutalizing effect on black life in America—its reduction of black people to a brute, subhuman existence.

The black churches as a distinguishable group during the 18th and 19th centuries represented the enslaved black people who were trying to come to terms with their existence as slaves in the acclaimed land of "freedom" and "equality." Black slavery in America meant not only unrewarded manual labour; it meant also a disruption of African family life and culture. Black people were forced to live in environmental conditions without accustomed cultural and religious values necessary for the regulation of their lives, and it was thus incumbent upon them to create order amid an imposed societal disorder. The creation of the black churches provided the much needed spiritual and social order that enabled oppressed black people to withstand the pain and suffering of slavery without losing their emotional and mental balance.

Though black people were enslaved physically and culturally, they usually refused to accept those white interpretations of Christianity that attempted to reconcile slavery with the gospel of Jesus Christ. The significance of this refusal is not found in formalized church creeds; the black churches did not differ significantly from their white counterparts. Almost without exception black people merely adopted the already existing creeds of the white Protestant churches. Their quarrel with white Christians originated not from abstract theological doctrines about God, Jesus Christ, or the Holy Spirit but from the overt and covert hypocrisy of the doctrinal formulations of white churches and their ethical ambiguity when applied to slavery and racial discrimination.

The liturgical style of the black churches has provided a religious framework for black affirmations and black negations in a society in which black people have lacked

social, political, and economic justice. The distinctive black "soul" is found in the spirit of black people who realize that their humanity does not depend upon the legal and moral codes of their oppressors. This spirit has shaped the distinctive liturgical style of the black churches in America.

Significance of black worship forms and styles

During the pre-Civil War period of enslavement "invisible" black churches (comprising blacks who worshipped with whites or held secret services) in the South expressed their reaction to involuntary servitude by projecting their view of life's meaning into an eschatological future (the consummation of history), a supernatural world in which God would make right what men had made wrong. In the "free" North, black people became involved in political, economic, and social affairs, attempting to make earthly justice a reality and not just a theoretical concept. Radical black preachers such as Henry Garnet (1815–82), Nathaniel Paul, and Daniel Payne (1811–93) were representatives of this tradition. Black spirituals (songs, or hymns) were sometimes the expressions of black people looking for justice in a heavenly world.

In worship, black people tend to transcend the formalized moral and legal codes of the white culture; their worship is related to their spiritual and physical survival. God is seen from a viewpoint arising out of the black condition, and worship is a spiritual response to the political and social limitations that were placed on black people. Thus, black worship emphasizes the *immediacy* of God's presence with black people, especially during adverse times. Black people tend to believe that "God will make a way out of no-way"—which means that they need not despair about seemingly impossible circumstances—and that as God delivered the Hebrews from Egyptian bondage, so also will he deliver black people from their oppressors. Black worship is an expression of this certainty, which explains the freedom of spirit in black worship that is characterized by spontaneous shouting, praying, singing, and preaching. Black people believe that God is at work in the world, and that despite the overwhelming power of various oppressors, his righteousness will become a reality in his ordained future.

Black theology

In the second half of the 20th century, some black American theologians have attempted to create a "black theology," based on the expression of certainty and peculiar style of black worship. These theologians believe that the essence of the Christian gospel is found in human liberation. God is the God of the oppressed, and his revelation is understood to be found in his historical identification with oppressed men, liberating them from human bondage. In America, this means that God is identified with the goal of strivings for liberation from white injustice.

The black theological emphasis on liberation and the freedom expressed in styles of worship are the chief contributions of the black churches to ecumenical discussions. Moreover, from the viewpoint of black theology, the very presence of the black church is ecumenically significant: it reminds Christians of European descent of past and present injustices committed against black people in the name of God and country and challenges them to recognize that the gospel of Jesus Christ cannot be reconciled with slavery and racism.

Academic study of black churches. Written sources about black churches are limited. Since black people were, by and large, excluded from the mainstream of American life, most scholars in religion simply ignored the black churches. Except for a few brief references, the black churches have seldom been mentioned in textbooks on American Christianity.

The black churches have been a subject of academic interest since the beginning of the 20th century, when black scholars began to reflect on the meaning of black life in America. Among the black scholars who have contributed studies of the black churches have been W.E.B. Du Bois (1868–1963), Charles Wesley (1891–), Carter G. Woodson (1875–1950), Benjamin Mays (1895–) and E. Franklin Frazier (1894–1962). These men, however, were not trained *church* historians, and a thorough study of the black churches from a historical-theological perspective still remains to be done.

HISTORY

The period of slavery (from the 17th century to the Civil War). In 1619, one year before the arrival of the ship "Mayflower" in Massachusetts, 20 Africans were sold as indentured servants at Jamestown, Virginia. At that time, no one could predict the profound implications of their presence, for not until 1661 did the colony of Virginia reveal the future significance of the presence of blacks in America, when it legally decreed that black people and their children would be slaves—chattels—for the duration of their earthly existence. Maryland legalized black slavery two years later. Shortly thereafter, other English colonies followed suit.

Early slave religion

For black people, slavery not only meant involuntary servitude; it also meant that slaveholders used various methods to destroy their African religious practices and beliefs. Initially, slaveholders not only forbade Africans to communicate in their native languages or to practice the worship of their gods but they also opposed teaching Christianity to slaves because of the unwritten law that a Christian could not be held as a slave. The established Anglican Church, however, assured slaveholders that the Christian gospel did not affect the civil status of men, and that the biblical emphasis on equality had nothing to do with the political equality of Africans with Englishmen. The Anglican Church contended that Christianity made Africans "better" slaves. With that assurance, slaveholders reluctantly permitted slaves to be baptized. But the Anglican Church had little success in gaining black converts. This is usually attributed to its alleged indifference to the civil freedom of black people, along with its rigid liturgical style and the apparent philosophical abstractness of Anglican Church doctrine.

Not until the 18th century, with the appearance of the Baptists and Methodists in the English colonies, did black people respond enthusiastically to Christianity. The appeal of the Baptists and Methodists may be found in their emphasis on civil freedom and equality, and in their simple styles of church worship. They provided an opportunity for black people to experience the emotional aspects of their religion and at the same time to affirm the right of civil freedom.

As a rule, slaveholders did not permit black slaves to organize independent churches because of the fear of insurrections and repressed early attempts to establish black churches. Slaves were at first required to worship with their masters. Most scholars believe that the first black Baptist church was founded sometime between 1773 and 1775 by a Mr. Palmer (about whom little is known) at Silver Bluff, South Carolina. This church was driven into exile when Savannah was evacuated by the Americans during the Revolution in 1778. Some of the members of the Silver Bluff church formed the nucleus for the first black Baptist church in Savannah, Georgia. George Liele (*c.* 1750–?) was a key figure in the organization of the church in Savannah; and before leaving for Jamaica, where he became an influential preacher among the blacks, he baptized Andrew Bryan (1737–1812), who later became an important leader in the Savannah church. Although Bryan did not speak out against the cruelty of the slave system, the slaveholders were fearful that his great influence among the slaves would result in insurrection. Many slaves were beaten and arrested for attending his church. Eventually Bryan and his brother Sampson were imprisoned and beaten severely.

Effects of the Nat Turner Rebellion

The Nat Turner Rebellion in 1831 confirmed the slaveholders' fear that black preachers were a serious threat to the stability of the slave system. Turner (1800–31) was a Baptist preacher who believed that God had ordained him to be the Moses of his people and led black people in armed revolt against their white masters. Fifty-five white people died as a result of his vision, and black preachers were consequently outlawed in most Southern states. The Mississippi law of 1831 is representative of such legislation: "It is unlawful for any slave, free Negro, or mulatto to preach the gospel under the pains of receiving thirty-nine lashes upon the naked back of the preacher."

Black churches in the North. Because slavery was not an important economic necessity in the North, most

Northern white churches did not seriously object to the organization of independent black churches, and indeed, they often encouraged it, particularly when the numbers of blacks increased, necessitating "Negro Pews" or galleries in white churches. The oldest independent black church was organized through the efforts of Richard Allen (1760–1831), who became the first bishop of the African Methodist Episcopal Church. In 1787 Allen and his black brothers were forced out of the church service during prayer at St. George Methodist Episcopal Church of Philadelphia. The blacks left and formed the Free African Society. The incident at St. George's Church convinced Allen that black people needed a church of their own where they would be free to worship God without having to encounter the racist attitudes and actions of white Christians. He was instrumental in organizing the Bethel African Methodist Church. In 1816 the Methodist Societies of Free Africans met at Philadelphia and founded the African Methodist Episcopal Church, of which Allen was elected the first bishop.

Events similar to the one that occurred at St. George's Church happened throughout the Northern states, resulting in the formation of the African Methodist Episcopal Zion Church in 1821, and of many independent African Baptist churches. White churches did not welcome black people, and it is noteworthy that segregation in public places had its origin in the churches. The post-Reconstruction South merely practiced in a wider sense what white churches had already initiated in the North.

The independent black churches and their preachers became involved in the movement to abolish slavery. Most white historians, however, have overlooked the significant role of black abolitionists, concentrating on white abolitionists, such as William Garrison (1805–79) and Arthur (1786–1865) and Lewis (1788–1873) Tappan. Mid-20th-century studies in black history by black scholars have changed this one-sided view. Many black Northern churches served as Underground Railroad "stations," and their ministers spoke out vehemently against slavery. Henry Garnett (1815–82), a Presbyterian preacher and an opponent of the Garrisonian abolitionists, even urged rebellion and cited the names of Nat Turner and Denmark Vesey (*c.* 1767–1822) as prominent examples of those who had led slave insurrections. Because of the involvement of the independent black churches in protest movements against slavery, slaveholders attempted to exclude the churches from operating in the slave states.

The period of entrenchment (from the Emancipation Proclamation of 1863 to World War I). During the post-Civil War period the involvement of the black churches in the struggle for the civil freedom of black people was discontinued. By and large, they replaced concern about earthly justice with concern for heavenly justice and became primarily concerned with the next life rather than with the problems of this life. The black churches withdrew from the politics of society at large and became a small isolated society, serving as a haven for oppressed black people. They became centres for the circumscribed political, economic, and social aspirations of black people who had been denied participation in the overall social and political affairs affecting their lives. Ministers of these churches, to a great extent, were more interested in who would be elected bishop or president of a convention than they were in the social and political liberation of the black people.

The retreat from civil concerns

In part, this change of emphasis is understandable as a response to new forms of oppression that emerged in post-Civil War America, "invisible" forms of slavery that were difficult and dangerous to cope with. Black ministers no doubt recognized this reality and attempted, consciously or not, to create a style of Christian life and worship that would not subject black people to mass murder. It could be argued that the black church (perhaps unknowingly) preserved the lives of black people for a later time when black unity against oppression could be more fully developed.

Not all black ministers, however, retreated from political life. During the post-Civil War Reconstruction period, black people entered politics, and a significant number of black politicians were preachers. Hiram Revels (1822–1901), an African Methodist minister from Mississippi, became the first black United States senator. Henry M. Turner (1834–1915) was a representative (1868) in the Georgia State Legislature until he and other blacks were expelled because of their race. He also served as postmaster in Georgia until he was forced to resign (1869) because of racial biases. Later, Turner was elected a bishop (1880) in the African Methodist Episcopal Church and became a strong advocate of the "Back to Africa" nationalist tradition.

Henry Turner, however, was an exception to the general fortunes of black people after the Civil War. Though the Thirteenth Amendment had ended legalized slavery, the masses of black people were subject to the vicissitudes of racial policies being developed by whites. The black church not only provided a structure for the regulation of the "morality" of black people; it also protected them from the fears of white people, assuring the societal leaders that black religion did not conflict with the values of American society.

Segregation in the churches

The "invisible" black churches in the South merged with existing independent black churches. Baptist and Methodist churches were the most successful. In most cases, however, white Southern churches excluded blacks. The Colored Methodist Episcopal Church (since 1954 called the Christian Methodist Episcopal Church) was founded in 1870. This church was an outgrowth of the Methodist Episcopal Church, South. Segregation thus became a way of life for all churches, North and South. Even churches that retained blacks on their membership lists (Methodists and Presbyterians among them) practiced segregation and refused to allow blacks to participate in policy-making decisions.

Nor was the Roman Catholic Church's relation to black people significantly different from that of the Protestant's. A vulnerable minority itself, it failed to extend itself on behalf of black freedom, and not until the Second Plenary Council of Baltimore, in 1866, did black people become a matter of interest in the Roman Catholic Church. At the Council the Roman Catholic Church, following the racial ethos of America, decided to organize separate schools and churches for black people. The first black Catholic church, however, had been founded in Baltimore in 1863. The most significant black priest of the period was Father James A. Healy (1830–1900), who was appointed a bishop of the diocese of Maine and later became an assistant to the papal throne.

By the beginning of the 20th century, the political disfranchisement of black people was virtually complete, and the black churches had withdrawn from the larger society. Most blacks apparently believed that earthly justice was hopeless, and they, therefore, placed their hopes in an eschatological future located in a transcendent, heavenly reality.

The period of urbanization (from World War I to World War II). During and after World War I (1914–18) large numbers of black people migrated from southern rural areas to northern industrial cities. Before this period, only one-tenth of the blacks in the United States lived in northern areas. World War I created an unprecedented demand for unskilled labour in northern industrial centres. Because the war cut off the immigration of European workers, there was a great demand for black labour. Other factors contributing to the influx of blacks to northern cities included the long-standing oppression of blacks in the South, the utopian image of the North held by blacks, and the effect of the boll weevil in the cotton-producing areas in creating a high percentage of unemployment among blacks throughout the South.

New styles of black churchmanship

In this period the black ghetto emerged in northern cities and with it new styles of black ministry and black churches. Unlike the rural South, where the church was the centre of the social and moral stability of the black community, the urban northern environment produced a breakdown of traditional black moral and religious values. Though many urban blacks continued to hold their traditional religious affiliations in existent Protestant churches, the religious behaviour of blacks was no longer

the same. This change has often been described as the "secularization" of the black churches—which means that the otherworldly outlook became this-worldly, focussing upon the existing social conditions of black people. Strict rules regarding card playing, dancing, and theatregoing (regulations derived from Baptist, Methodist, and other Protestant churches) were no longer enforced, and this may be cited as an example of the new secular emphasis. More important, however, was the black churches' growing interest in community affairs that involved relationships with the National Urban League (a voluntary interracial community service agency founded in 1910) and the National Association for the Advancement of Colored People (a voluntary interracial organization founded in 1909 to combat racial discrimination and segregation). Black ministers began to preach sermons related to the political affairs of black people. A most notable example of this practice was Adam Clayton Powell, Jr. (1908–72), pastor of Abyssinian Baptist Church in New York City, who led boycotts and marches against stores and other businesses that discriminated on the basis of colour. He was elected to the United States Congress (1945–70) and rose to the post of chairman of the prestigious House Committee on Labor and Education.

This was also the period of the rise of the "storefront" churches (congregations worshipping in empty stores) and black sects. The emergence of the storefront churches was primarily caused by the inability of traditional Protestant churches to satisfy the particular religious spirit of the southern blacks, who were accustomed to intimate and warm associations in the church. Most of the storefront churches were related to Baptist, Holiness, and some Methodist churches. The members of the storefront churches were, to a great extent, concerned about the freedom of worship; *i.e.*, the freedom to "shout" and praise the name of God without being sensitive about a lack of intellectual sophistication. They were concerned about the presence of the Holy Spirit and his effect on the lives of men. Thus they emphasized that people can know the *real* Christians by what they say and do. They believed that the sins of the flesh (drinking, smoking, adultery, etc.) are never found among Christians, and that God will never allow unclean persons to enter heaven.

Also present during this period were the black cults (religious groups), which should not be confused with the storefront churches. Both the cults and the churches often practiced in abandoned buildings and stores but differed markedly on religious beliefs. While the storefront churches tended to maintain traditional Protestant beliefs, the cults were characterized by new notions about God and, what is very important, about black people and being black. Some of the cults focussed on sanctification and holiness, attempting to restore the purest form of religion. Others focussed on black people as a race, attempting to relate religion to the economic, political, and social conditions of blacks. The former usually affirmed beliefs similar to those of traditional Protestant churches, and the latter tended to reject Christianity as a white man's religion, often affirming that Islām was the black people's religion.

The period of reformation (from the end of World War II to the present). Even before the civil rights movement in the 1950s and 1960s, Adam Clayton Powell, among others, had begun to relate the church to the political, social, and economic conditions of black people. He used his church as a power base for the black people's struggle against racial discrimination in New York City.

The Martin Luther King era

It was not until the appearance in 1955 of Martin Luther King, Jr. (1929–68), black clergyman and later Nobel Peace Prize recipient, that the black churches became focal points of protests against racial injustices and discrimination. Because of various movements and groups led by King—the Montgomery, Alabama, bus boycott (1955), initiated after Mrs. Rosa Parks refused to give up her seat to a white person, the organization of the Southern Christian Leadership Conference, a civil rights group, and the March on Washington (1963) by 200,000 blacks and white sympathizers calling for an end of segregation practices—it was no longer possible for the black churches to remain on the sidelines, without being condemned for their silence. The black churches and their leaders responded with enthusiasm to the call for civil justice, and the churches became meeting places for planning strategies and for rallies. Black ministers were often chosen as the leaders of civil rights marches and sit-ins (nonviolent noncooperation in public buildings).

During the period of Martin Luther King's leadership, the main emphasis was on the Indian leader Gandhi's (1869–1948) concept of nonviolence and on Christian love. Appealing to the biblical tradition of both the Old and New Testaments and relevant philosophical and theological ideas, King invited black people to follow him in nonviolently confronting the racism of white Americans with the aim of transforming it. Many blacks followed him, and the black churches once again became involved in the political life of the United States.

The movement led by King was neither regional nor racial; it involved the South and North, blacks and whites. White students and churchmen became involved in the civil rights movement and some died in the attempt to change the social, political, and economic conditions of blacks. The largest number of those who died as a result of their involvement in the civil rights movement, however, were members of the black community.

Before the assassination of King in 1968, a new emphasis in black concepts and practices emerged with profound implications for the civil rights movement and the black churches. In 1966 Stokely Carmichael, leader of the Student Nonviolent Coordinating Committee, verbalized the deep feelings and aspirations of many black Americans when he called for "Black Power." Advocates of Black Power held the view that blacks should not expect to achieve self-determination as a particular community as long as they depended on white people for aid and assistance; that as the oppressed, they should never expect their oppressors to relinquish power by merely appealing to Christian love but must be willing to fight for what is rightfully theirs—using violence if necessary.

This was the message of Black Power, and it was difficult for the black churches to decide how to respond to it. Christianity is generally known for its emphases on human equality and racial justice, as well as for its emphases on love and turning the other cheek. Thus, black churches found it difficult to respond to the new mood of many blacks who believed that the emphasis on nonviolence was politically irrelevant for the black people.

Faced with this dilemma, many black ministers and members followed the conservative tradition of emphasizing love and obedience to law as the only answer. This emphasis is found particularly in many black Baptist churches that are affiliated with the National Baptist Convention, USA, Inc., whose main spokesman is Joseph H. Jackson (1900–), president of the convention since 1953.

On the other hand, other black ministers and theologians argued that Black Power is a significant political reality not unrelated to the religious aspirations of black people. In 1966, the National Committee of Negro Churchmen (later, the National Committee of Black Churchmen) responded to criticisms of whites about Black Power by insisting that white racism was the basic reason for black unrest in America.

In 1968, black ministers and laymen in the United Methodist Church met in Cincinnati, Ohio, and proclaimed that their church was racist. They also endorsed Black Power as a relevant concept in the religious and political lives of black people. Soon after these two important events, caucuses of black ministers and laymen arose in various Protestant and Catholic churches.

The rise of Black Theology

Also, during this period, the term Black Theology emerged as a significant theological concept. The term was first used by an ad hoc group of black theologians within the National Committee of Black Churchmen, and it received academic respectability with the publication of *Black Theology and Black Power* and *A Black Theology of Liberation* by James H. Cone. In 1969, the National Committee of Black Churchmen issued a formalized statement on Black Theology, and in April 1970, the first

Consultation on Black Theology was held at Atlanta, Georgia.

The affirmation of a black theology is an attempt of the black churches to relate themselves to the self-determination of the black community as defined by Black Power. The advocates of Black Theology hold that the Christian gospel and black liberation are identical realities, and they refuse to accept a view of Christianity that denies the significance of blackness in the American society. They assert that oppressed people are God's chosen people, and that in America that means black people. They insist that the oppressed are chosen, not for suffering, but for liberation, and that they are free to achieve it by whatever means they regard as suitable.

Not all black theologians, however, have accepted the view as proposed by the adherents of Black Theology. The opponents contend that the emphasis on "black" is too exclusive and thus reductionist; they emphasize that the gospel is for all men—blacks and whites.

BLACK CHURCHES AND SECTS

Major Protestant churches. *Baptist churches.* The first black Baptist church, as noted earlier, was organized between 1773 and 1775 at Silver Bluff, South Carolina, across the river from Augusta, Georgia. During the slavery era black people were attracted to the Baptists because of their lack of rigid ritualistic requirements, and this denomination has continued to be the most influential church among the masses of black people. It was not until 1886 that the black National Baptist Convention was organized, and that was the result of an attempt by white Baptists to control the associations and conventions of black Baptists. When, in order to please their Southern white constituency, the American Baptist Publication Society (white) refused to accept the contributions of black ministers, Richard Henry Boyd (1843–1922) established the National Baptist Publishing House for black Baptist churches. Schisms among the black Baptists occurred in 1917 and 1961. The schism of 1917 resulted in the foundation of the National Baptist Convention, USA, Inc. (about 6,000,000 members in 1970) and the National Baptist Convention of America (nearly 3,000,000 members). The 1961 schism occurred in the larger group (of the USA, Inc.), producing The Progressive National Baptist Convention, Inc. (521,692 members).

Methodist churches. The oldest black Methodist denomination in America is the African Methodist Episcopal Church, organized in 1816 at Philadelphia, Pennsylvania. Richard Allen is usually referred to as the founder, and he was elected the first bishop. Like the doctrine and polity of all black Methodist churches, those of the African Methodist Episcopal Church do not differ significantly from those of white Methodist bodies, for its origin was due to racial discrimination rather than theological disagreement. This church is the largest of all among black Methodists, with over 1,000,000 members and over 6,000 churches. It also has churches in Africa and the West Indies.

The African Methodist Episcopal Zion Church, the second oldest and largest of the black Methodist Churches, held its first annual conference in 1821. James Varick (1750–1828) was elected the first bishop. Its doctrine and polity are similar to that of the African Methodist Episcopal Church, and it has nearly 1,000,000 members and over 4,000 churches in the United States, Africa, the West Indies, and South America.

The African Union First Colored Methodist Protestant Church, Inc., is the result of a union that occurred in 1866 between the African Union Church and the First Colored Methodist Protestant Church. Its doctrine is similar to other Methodist bodies but the polity is significantly different. This church has no bishops, and laymen have equal power with ministers in annual and general conferences. There are approximately 10,000 members.

Another Methodist denomination is the Christian Methodist Episcopal Church (originally called Colored Methodist Episcopal Church, its name changed in 1954). This church is an outgrowth of the Methodist Episcopal Church, South, in 1870. It has nearly 500,000 members.

Other churches. Another significant denomination is the African Orthodox Church, which is an outgrowth of the Protestant Episcopal Church. Like other black churches, it was founded because blacks believed that they should have a church of their own. The African Orthodox Church was founded by a Protestant Episcopal rector, George Alexander McGuire, in 1919, but it was not until 1921 that the first general synod was held and the present name adopted. McGuire was elected the first bishop. Of particular importance was McGuire's association with the black nationalist leader Marcus Garvey (1887–1940); he became a chaplain of Garvey's Universal Negro Improvement Association. This church strongly emphasizes apostolic succession, sacraments, and rituals. In 1957 there were 24 churches and 6,000 members in the United States.

Blacks in white Protestant churches

No exact figures are available for the number of blacks found in the major denominations with predominantly white memberships. The largest number of blacks own and operate their own churches, and only a small percentage is found in predominantly white denominations. The United Methodist Church has the largest number of black members (approximately 400,000) among such denominations. Blacks are found, however, in all major denominations, and recently almost all have organized black caucuses within these church bodies in order to confront the white majorities with their stated need for black self-determination as defined by various expressions of the Black Power movement.

Protestant sects. Most of the black religious sects owe their origins to Protestant Christianity and the urban migration of the second decade of the 20th century. Black sects often use biblical images and are usually found in large northern cities, such as New York City, Chicago, Detroit, and Philadelphia, and also, more recently, in large southern cities such as Atlanta. These sects seek to speak to particular needs of black people by attempting to offer "salvation" from political, social, and economic conditions. Release from humiliation and oppression stands at the centre of their messages. Often a state of "holiness," the freedom from sins of the flesh, is offered as the only cure to man's wretched condition. To be saved is to accept the Holy Spirit into one's heart, and this is believed to enable men to live the "good" and "holy" life and thus to prepare them to be received into heaven.

Of the many black sects, only a representative number that best illustrate the influence of the Protestant tradition can be mentioned here. See also NEGRO CULTS (IN THE UNITED STATES).

Pentecostal and Holiness sects

The Fire-Baptized Holiness Church separated from the white Fire-Baptized Holiness Association of America in 1908 and adopted its present name in 1922. Like most Pentecostal sects, its doctrines include repentance, regeneration, divine healing, premillennial (before the 1,000-year reign of Christ) Second Coming, justification, sanctification, pentecostal baptism, and speaking in tongues. It is ruled by one bishop, and it has over 1,000 members and 53 churches, with headquarters in Atlanta, Georgia.

The Church of Christ (Holiness) USA was founded in 1894 by C.P. Jones, a Baptist preacher, who "was dissatisfied with his religious experience and longed for a new faith which would make him one of wisdom's true sons and, like Abraham, 'a Friend of God.' " This church is similar to other holiness sects, emphasizing original sin, the gift of the Holy Spirit, and Christ's Second Coming. It is reported to have nearly 10,000 members and 146 churches, and it performs missionary work in Liberia and Nigeria.

The Mt. Sinai Holy Church of America, Inc., was founded in 1924 by Ida Robinson at Philadelphia. Bishop Robinson, as she is called, is the supreme head of the church because her authority is believed to come directly from God. The beliefs of this church include the gift of the Holy Spirit, divine healing, sanctification, and baptism.

The United House of Prayer for all People had its origin in the South. The founder was Bishop Charles Emmanuel Grace (1882–1960), who began preaching in 1925. "Daddy Grace," as he was often called, was the undisputed head of the church. Though the basic beliefs of this church

are similar to other holiness churches, "Daddy Grace," before his death, was reputed by his followers to have attained an authority equal with God. He often admonished his worshippers: "Never mind about God. Salvation is by Grace only. . . . Grace has given God a vacation, and since God is on vacation, don't worry him. . . ."

The Roman Catholic Church. The Roman Catholic Church's behaviour in regard to segregation and integration has not significantly differed from the Protestant churches'. Its schools and churches were segregated before the United States Supreme Court decision in 1954, and the progress of integration in them since that decision has been relatively slow. There is perhaps one significant difference, however, between the Roman Catholic Church and Protestant churches. The Roman Catholic Church has been able to enforce its decisions on integration in a more authoritative fashion, undoubtedly because of the locus of power in its hierarchy. Some black people joined the Roman Catholic Church during the 1950s and '60s precisely because of its power to enforce integration.

BLACK CHURCH PRACTICES

Worship. The distinguishing characteristic of black church worship is its freedom of expression. The desire for free expression probably accounts for the large number of blacks in Methodist, Baptist, Pentecostal, and Holiness churches. Some scholars have attributed this desire for an unstructured expression in worship to the black people's African heritage, and others have claimed that it is due to their peculiar economic, political, and social condition and to the unique ways in which black people have appropriated Christian beliefs and practices to meet their emotional and spiritual needs. Whatever the reason or reasons, black people have not responded enthusiastically to denominations with rigid ritual and liturgical requirement. Both their African heritage and their remaking of white Christianity under the most adverse conditions have probably shared in the shaping of black worship styles. A complete removal of African memories was not possible, and it may be assumed that such memories are reflected in black church worship. Nevertheless, the fact remains that black worship styles in the United States originated in the context of slavery and have been nurtured in oppression and racial injustice.

African and American influences on worship

Black worship styles were created and have endured because they are attempts by blacks to deal with their own peculiar position in America. Hence black ministers preached about an otherworldly reality, and black spirituals (religious songs) were poetic expressions of that reality. To preach and sing about heaven was to assert that, regardless of the cruelty inflicted on the blacks, the whites are not God and cannot have ultimate authority over the blacks. The freedom of expression in worship is regarded as an expression of this conviction.

Further, and more doctrinally, ritual may be viewed by most blacks as impeding the work of the Holy Spirit, the free-flowing power of God that can change the character of men, making them new persons. Spontaneous prayer, singing, preaching, and shouting are key ingredients in black worship.

Prayer is usually extemporaneous, and it is accepted as a sign of the work of the Spirit. Carefully prepared, written prayers are rare in black worship. Prayer is generally understood as man's communication with God through his Spirit; and this means that there is no reason to write it down as if one is addressing someone he does not know. In prayer, most blacks insist, one should come just as he is, not worrying about his speech or education, for Jesus is to be regarded as friend, and God his Father. The black man believes that God knows his condition, his sorrow, and wretched pain. He does not come to God to inform him of something that God does not know; he comes because he wants to renew his faith so that he can continue the troublesome journey. It is this emphasis that creates the freedom of expression in black worship.

Singing and shouting are also important aspects in black worship. Black spirituals are a tribute to the creativity of black people in poetry and song; they are a way of saying that, though enslaved, oppressed, and segregated, black people have refused to let their humanity be determined by white governmental officials and have affirmed their dignity through song and poetry. The spirituals were the creations of the "black soul" reaching for life and beauty in the midst of death and ugliness. Black people profess that they are a beautiful people because God has created them, and they lift their praise to him in song. There can be no authentic black worship without the singing of God's praises, for singing is viewed as a sign of the presence of the Holy Spirit; to sing is to express thanksgiving to God for the revelation of the certainty that oppression in this world is not the extent of life's existence. Shouting and the clapping of hands thus often accompany songs.

Preaching stands at the centre of black church worship. Those who are able to expound the Word of God are believed by black worshippers to have been "called" or "set aside" by the power of the Holy Spirit. Whatever may be said of the importance of prayer or song, they are merely prologues to the heart of black worship—the preaching of the Word. According to black worshippers, to be able to preach means that the individual has been grasped by the Holy Spirit, and it is not uncommon for the preacher to tell the hour and place that the Spirit first moved him. The content of the sermon is not confined to personal reflections on the preacher's conversion experience or call to the ministry; he also uses biblical images and stories as well as contemporary experiences of the community in order to demonstrate his understanding of the gospel message. The worship service usually ends after the sermon with a collection, song, and benediction.

Preaching: the centre of black worship

The role of the minister. The black minister is not only the chief spiritual adviser in the black community, he is often the leader of all its major community activities. During the 19th century, the minister was the major spokesman for the black community. Not until World War I and the black migration from the South to urban centres did black ministers begin to experience significant competition from other black professionals for leadership in the black community. Even today, however, despite the prestige of other professional groups, the black minister is still regarded as the most influential person in the black community.

He visits the sick, buries the dead, administers the sacraments, and plans the overall spiritual life of the community. But he also seeks and is often elected to political office. He is viewed as the key to the spirit and ethos of the black community. This is not too difficult to understand in view of the authority of the minister among blacks even in the more traditional Baptist and Methodist churches, and particularly in the Pentecostal churches. The churches are accepted by blacks as the most important institutions that provide structure to the life-style of the black communities, and the minister, the central figure in the church, occupies a significant role in that community. The minister is often accepted as the one who represents the goals and aspirations of the community as a whole, conveying to the larger society what the black community believes and feels.

Other practices. Since the black church has been the most important institution in the black community, it is the centre for many social, cultural, and political activities. Of particular importance are the revivals, the occasions when a special evangelist is invited to preach for a week or two weeks in order to add more members to the church. The entire community is always invited, and it is a time for renewal of faith and the offering of the opportunity to believe to those who do not believe.

The black churches' concern for its youth is reflected in the establishment of many educational institutions—high schools and two- and four-year colleges. For many black people, the black church schools offered the only possibility for higher education. Before blacks were more freely accepted in white colleges and universities, the church colleges laid the basic foundation for black college education in America.

CONCLUSION

Born in the context of slavery and oppression, the black churches have created a style of existence related to the

political, economic, and social condition of their members. Theologically, the churches may constitute a religious community of victims. Its activities naturally differ significantly from the churches of its asserted victimizers.

Negro Cults (in the United States)

The Negro cult—an extremely varied urban phenomenon—is a syncretistic religious group in revolt against the mainstream of American white and Negro religion and society, which it regards as unresponsive to its needs. The main roots of Negro cults—Judaism, Islām, and Christianity—each have passed through a cult phase (an early stage of a religious movement), as did countless other groups in Western society that have failed to grow into a sect, denomination, universal church, or religion. Negro cults are, with few important exceptions, short-lived, unstable, local, small in size, structureless, dominated by a charismatic leader, schism-prone, and mystically oriented.

"Race consciousness"—which may be described as the will to realize the natural dignity and integrity of all Negro people by reconstructing their moral, spiritual, economic, and political life—is instinctive with the Negro masses and is constantly renewed by the lives and teachings of the earliest esteemed "race men," or leaders. This earlier indigenous leadership was replaced by World War I with the "talented tenth," or black bourgeoisie. In the breach, the Negro masses—cut off from the regenerating source of a "race ethos" that was capable of inspiring cooperation for liberation and overmatched by objective limitations—were pressed by various forms of frustration, confusion, disillusionment, and apathy. They clutched their only possessions: a primordial race consciousness, religion, superstition, magic, rhythm, music, antiphonal singing, and improvisation. These floundering people, deprived both socially and economically, were forced to confront a leadership vacuum, which was filled by purveyors of voodoo (a religion of African origin), prophets, fortune-tellers, miracle workers, and other such personages who dealt with the aspirations of the Negro people. In this historical and cultural crucible the Negro cults evolved, originating among a plethora of refugees from a hundred different countries, replete with dozens of foreign dialects, and worshipping many strange gods. Before the advent of these later religious beliefs and languages, Islām and Judaism were unfamiliar to Afro-Americans.

Leadership of "race men"

HISTORY

The formative period. The ancestors of the Afro-American Negroes arrived in chains from a variety of complex African cultures, dominated by pervasive religions. In North America their religious needs were largely ignored from the beginning. Religion reached the slaves as tidal waves of enthusiasm, initially emanating from the revivalistic upheavals of the 18th-century Great Awakening and the later revivals of the 19th-century Second Awakening. These demonstrative ecstatic ventures of white American religion were primed by fervent preaching and pumped by wild frenzies, shouting, sobbing, weeping, fainting, swooning, and incoherent ejaculations. Isolated and segregated, Negroes first embraced and then re-created white religion in their own experience; they fashioned the "invisible institution," or black religion, a combination of other worldly aspirations and this-worldly protest, which developed in "field hollers" and "praise houses," shouts and plantation churches.

The expansionist period. While Southern Negro peasants were demoralized by lingering slave mores and "Jim Crow" (segregation) conditions after the Civil War, the new city-dwelling whites were unnerved by urban "worldliness." Their reaction to urban licentiousness created the "Holiness Movement," which built on the demand for freedom from sin, conversion, or justification (first blessing) that was generated in the revivals, and added the quest for perfect sanctification by grace or holiness (second blessing). This movement became national in scope and appeal around 1867 and encouraged the formation of the "Pentecostal Movement" that was distinguished by faith or spiritual healing and by baptism of the Holy Spirit (third blessing), which was manifested by "speaking in tongues." These movements welcomed the new urban Negroes who had moved to the cities and caught their imagination in storefront fellowships (churches occupying unused stores) where they were integrated into older Negro religious views and practices and restyled.

Types of cults that developed in urban centres. In the main, Negro cults follow two different, but not inherently conflicting, patterns. One, the Pentecostal or Holiness type, emphasizes separation from the world with separate religious and moral standards and has the tendency to substitute status gained through trances, visions, and gifts of tongues for social status. Strict spiritually oriented living, severe puritan morality, and concentration on personal problems serve as surrogates for the power to change conditions through unified Negro efforts. Explicitly, Pentecostal and Holiness cults equally abhor race consciousness and racism. Consequently, cults that are solely Pentecostal or Holiness oriented, without ties to the black protest heritage, do not ultimately satisfy and, indeed, increase the opportunity for more exotic cults to develop, along with some attendant charlatans who exploit the Negroes' urban miseries for personal gain and power, and offer simple solutions to complex problems of poverty, illness, despair, and discrimination.

Holiness, Pentecostal, black protest/black consciousness cults

Cults of the second pattern may have Pentecostal, Holiness elements, but they emphasize the connection with black religion in the form of black protest and black consciousness, or incipient black nationalism. In these cults, spiritual concerns serve various moral and social issues. Their major concern is the union of black people for self-direction and self-acceleration through a cherishing of the African heritage and Afro-American experience. These cults are militant and aggressive, and they exert an influence far beyond that of their numerical strength or that of their pessimistic, world-rejecting religious rivals.

SPIRITUALIST CULTS

Spiritualist cults, with their alleged beginnings in the voodoo- and Roman Catholic-influenced environs of New Orleans, combine typical Holiness and Pentecostal jubilant worship and spiritual healing, emotional Methodist and Baptist gospel hymns to the beat of secular rhythm and blues music, and the accoutrements from the Roman Catholic traditions such as altars, candles, and statues. The spiritualistic cultic leaders of the lower class segments that seek pleasure with religious blessings create a cult to fit the desires of Negroes for success in love, marriage, gambling, employment, and healing instead of remolding them to fit a religious ideal. Leaders of spiritualist cults often claim to be mediums in contact with the spirit of wisdom, rather than of the dead. Negroes who work hard but also yearn for "extras," or just sheer good times in social drinking, dancing, card playing, or gambling, find spiritual advisers and readers to be comforting

and inexpensive counsellors. Spiritualist advisers meet a need born of individual inclinations toward superstition, magic, religion, and spiritual power. They do not advertise themselves as advocates of the displacement of ability or initiative but simply as persons who can augment the natural through contact with the supernatural wisdom. The healing of illness and advice for any problem are available from spiritualist leaders who sell good-luck charms, holy flowers, sacred statues, or candles as means by which the objects of desires may be gained.

CULTS CENTRED AROUND INDIVIDUALS

Father Divine

Peace Mission movement. Father Divine (1877–1965) is regarded by his followers as God, Dean of the Universe, and Harnesser of Atomic Energy, according to the unique beliefs of the Peace Mission movement, which he founded. Worship of this five-foot-two rotund Negro by whites and blacks comprised its salient practice. According to some accounts, he was given the name George Baker at birth and reared in Savannah, Georgia, during the post-Reconstruction period when, out of unimaginable misery, black messiahs flourished, offering answers to the Negro's problems. He gained indelible impressions through immersion in primitive mysticism and the holiness and pentecostal movements. The transition from George Baker to Major J. Devine to Father Divine was completed when he set up his first heaven in Sayville, Long Island, in 1919. Legal entanglements forced him to relocate in Manhattan and Philadelphia and also fostered phenomenal growth through extensions in cities of the North and West. Heaven, according to Father Divine, is symbolized by separation of sexes and union of all races in a communion composed of a multicourse feast. He also taught a belief that there should be total racial integration, that the Bible is the *New Day* newspaper, that all things and persons are to be forsaken for the Father, and that heaven is on earth. He owned nothing, but a cult of 500,000 provided him free access to a $1,500,000 fortune. Father Divine supported blacks in businesses that became successful and fulfilled basic needs. Following the death of his wife, Penninah, called Mother Divine, he married in 1946, at the age of 70, a 21-year-old white follower, Edna Rose Richings. The new Mother Divine remained a virgin. The key to Father Divine's "success" was the devotion of competent disciples. At present, the movement lives off its past; it is contracting rather than expanding.

The United House of Prayer for All People. The United House of Prayer for All People differs from traditional Holiness cults in its belief that its founder, Bishop Charles Emmanuel Grace (1882–1960), is God; he is worshipped as "Daddy Grace." His followers genuflect and pray before his picture. A cook on a Southern railway, he was "called" to preach in 1926, assumed the name "Grace," and proclaimed himself "Bishop." The key to the success of this cult was that the many offerings went directly to "Daddy Grace" to advance the sale of his healing-power products: soap, stationery, tea, coffee, cookies, toothpaste, facial creams, talcum powder, hair dressing, and the *Grace Magazine*. Today this cult continues in skeleton form, a mere shadow of its earlier substance.

NATIONALISTIC CULTS

Marcus Garvey

Universal Negro Improvement Association. Marcus Garvey, born in 1887, established in his native Jamaica the Universal Negro Improvement Association (1914). It failed for lack of support. He re-established it in New York (1916) with extraordinarily successful results. In ten years he built the only Negro mass-based organization in American history. His effectiveness was due to putting into words and deeds what blacks were thinking, by means of great oratory and production of the *Negro World*, regarded by many as the best edited black weekly in New York. Thousands, and some reports indicate millions, followed him. He frequently spoke of the greatness of coloured civilizations and taught that God is black and Jesus was black, that subservience would end when blacks stopped worshipping a white God, and that black is beautiful. By his teachings he encouraged the Negro masses to organize, cooperate, and awaken to black consciousness. The principal plank of his movement was "back to Africa," to set up there an independent nation so that blacks everywhere could gain self-respect from pride, strength, and protection. The strength of this appeal, however, was his undoing. A master propagandist, his program was fiercely protestant, strongly emotional, and bitterly chauvinistic, thereby creating enemies who allegedly entangled him in a mail fraud charge resulting in his deportation from the United States (1927). Garvey remains important as the principal architect of black nationalism, which advocates possession of a distinct territory, a common heritage and culture, and self-help for self-determination.

Black Jewish cults. The Church of God (Black Jews of Philadelphia) is headed by Prophet F.S. Cherry. It is open to any black person. Members identify as black Jews those who believe that black people originated with Jacob and that white Jews should worship Jesus. The worship service begins and ends with the Prophet beating a drum. Castanets and tambourines, without piano, play a large part in the service. There is no Hebrew service or "Temple worship"; Baptism is observed, but Passover replaces the Lord's Supper.

The Black Jews of Philadelphia, Harlem, and Washington

The Commandment Keepers of the Living God (Black Jews of Harlem) is a tightly knit West Indian community of about 3,000 members, led by rabbinically trained (in Jewish traditions) Wentworth D. Matthew. The group holds Judaism to be their own and the one true religion, that Negroes are really Ethiopian Hebrews or Falashas, and that Jesus was black. These are the only black Jews with extensive contact among white Jews; they strictly observe the dietary laws and celebrate all Jewish holidays. Christianity is rejected by this group, and non-believing Negroes are held in low esteem.

The Church of God and Saints of Christ (Black Jews of Washington, D.C.) began under the leadership of Prophet William S. Crowdy. He passed his mantle of leadership to Bishop William Plummer who announced himself as "Grand Father Abraham." This group believes that all Jews were originally black and that Negroes are descendants of the "lost tribes of Israel." Their beliefs centre around the "Seven Keys," the "Stone of Truth," and the Ten Commandments. They cultivate 1,000 acres of land in Virginia, operate several industries, a school, and a home for orphans and the aged.

Moorish Science Temple of America. The Moorish Science Temple of America was founded by Timothy Drew in Newark, New Jersey, in 1913. He is believed to have been ordained Prophet Noble Drew Ali by Allāh. A Holy Koran, the sacred text, was created out of his study of Oriental philosophy. The prophet's central teaching is that salvation will come when Negroes discover and identify with their national origin as Asiatics, Moors, or Moorish Americans. Men are to wear fezzes at all times. The term Negro, or black, signifies death and the loss of power, authority, and their God. All laws are to be obeyed; prayers are offered three times daily; alcohol, sports, eggs, smoking, and meat are forbidden. This group was a forerunner of the Black Muslims (see also BLACK MUSLIMS). Drew died mysteriously during a period of internal strife, and the cult split and withered.

NATIVISTIC MOVEMENTS

Voodooism is the belief that the spirit-power resides in the python (snake) and is communicated through a priest. It entered the United States in 1809 by way of Ewe-speaking African slaves brought from Haiti by planters escaping the Cuban revolution at that time. It became virtually extinct as a cult in the United States with the death of its last queen, Marie Laveau (died 1881). Voodoo imposters, however, with Voodoo-like conjurations gain occasional hearings today among black Americans.

CONCLUSION

Negro cults do not differ in religious intention, intensity, form, or substance from other cults. Even the stated worship of a man (Father Divine) is not historically unique, as can be noted in the case of Jesus. Moreover, in such

Negro cults the spirit believed to be in the man, and not the man himself, is what is revered. Father Divine, for example, did not claim to be God. The significant distinction to be noted about Negro cults is their collective aspect as impacted depositories of residual Afro-American cultural elements during their phenomenal rise and subsequent decline into harbingers of change for Negroes in the United States.

BIBLIOGRAPHY. A.H. FAUSET, *Black Gods of the Metropolis: Negro Religious Cults of the Urban North* (1944); and R.J. JONES, *A Comparative Study of Religious Cult Behavior Among Negroes; with Special Reference to Emotional Group Conditioning Factors* (1940), are two classic cultural studies. E.T. CLARK, *The Small Sects in America*, rev. ed. (1949), sets Negro cults in the context of white Holiness and Pentecostal primitive religion. ST. CLAIR DRAKE and H.R. CAYTON, *Black Metropolis*, 2 vol., rev. ed. (1962), is most important as a source of religious creations in urban ghettoes. R.A. PARKER, *The Incredible Messiah* (1937), traces the influences bearing upon Father Divine. Two key critical essays are C.E. LINCOLN, *The Black Muslims in America* (1961); and E.U. ESSIEN-UDOM, *Black Nationalism* (1962). H. BROTZ, *The Black Jews of Harlem: Negro Nationalism and the Dilemmas of Negro Leadership* (1964), is an important but brief exploration of the phenomenon of Black Jews. E. FRANKLIN FRAZIER, *The Negro Church in America* (1964); and J.R. WASHINGTON, JR., *Black Religion: The Negro and Christianity in the United States* (1964), are more general works that supply a framework within which the cults' deviations find perspective.

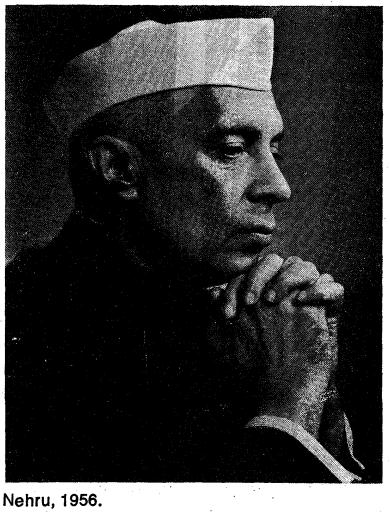
(J.R.W.)

Nehru, Jawaharlal

Jawaharlal Nehru, the first prime minister of independent India, was in many ways the antithesis of his leader, Mahatma Gandhi, the architect of India's freedom. Reared in a patrician household, educated at an exclusive English school and at Cambridge University, Nehru's outlook was more modern and forward-looking than that of the Mahatma. Nehru did not conceal his differences with Gandhi on many basic economic, social, and political issues. He did not share Gandhi's aversion to industrialization, and he saw to it that the early five-year plans after independence were geared to heavy industrialization. If Nehru accepted Gandhi's nonviolence, he did so not as a matter of principle but because he regarded nonviolence as a useful political weapon and the right policy for India under prevailing conditions. He deprecated the inordinate value the older man attached to austerity and asceticism and questioned his idealization of poverty. While Gandhi was more interested in individuals than in institutions and preferred to build upward from the people rather than to impose his ideas from above through a parliament, Nehru's economic thinking was basically ideological, tied to Socialist doctrine.

Early years. Nehru came of a family of Kashmiri Brahmins, noted for their administrative aptitude and scholarship, that had migrated to India early in the 18th century. He was born at Allāhābād in what was then known as the United Provinces, India, on November 14, 1889, the son of Motilal Nehru, a renowned lawyer and one of Gandhi's prominent lieutenants. Jawaharlal was the eldest of four children, two of whom were daughters. A sister, Mrs. Vijaya Lakshmi Pandit, was to earn celebrity in her own right as the first woman president of the U.N. General Assembly.

© Karsh



Nehru, 1956.

Education

Until the age of 16, Nehru was educated at home by a series of English governesses and tutors. Only one of these, a part-Irish, part-Belgian theosophist, Ferdinand Brooks, appears to have made any impression on him. Jawaharlal also had a venerable Indian tutor who taught him Hindi and Sanskrit. In 1905 he went to Harrow, a leading English school, where he stayed for two years. His housemaster describes him as "a very nice boy, quiet and very refined. He was not demonstrative but one felt there was great strength of character. I should doubt if he told many boys what his opinions were, or the masters with whom he had a good name, as he worked well and seldom (almost never) gave trouble."

Nehru's academic career at school and college was in no way outstanding. From Harrow he went to Trinity College, Cambridge, where he spent three years earning an honours degree in natural science. On leaving Cambridge he qualified as a barrister after two years at the Inner Temple, London, where in his own words he passed his examinations "with neither glory nor ignominy."

The seven years Nehru spent in England left him in a hazy half-world, at home neither in England nor in India. "I have become," he wrote some years later, "a queer mixture of the East and West, out of place everywhere, at home nowhere." He came back to India to discover India. The contending pulls and pressures that his experience in England was to exert on his personality were never completely resolved.

Four years after his return to India, in March 1916, Nehru married Kamala Kaul, who came from a Kashmiri family settled in Delhi. Their only child, Indira Priyadarshini, now Mrs. Indira Gandhi, prime minister of India, was born in 1917. Kamala Nehru, who suffered from poor health for the greater part of her brief life, died in 1936.

Political apprenticeship. On his return to India in 1912, Nehru at first tried to settle down as a lawyer. But, unlike his father, he had only a desultory interest in his profession and did not relish either the practice of law or the company of lawyers. At this time he might be described, like many of his generation, as an instinctive nationalist who yearned for his country's freedom, but, like most of his contemporaries, he had not formulated any precise ideas on how it could be achieved.

Nehru's autobiography discloses his lively interest in Indian politics not only as an undergraduate at Cambridge but as a boy at Harrow. His letters to his father over the same period reveal their common interest in India's freedom. But not until father and son met Gandhi and were persuaded to follow in his political footsteps did either of them develop any definite ideas on how freedom was to be attained. The quality in Gandhi that impressed the two Nehrus was his insistence on action. A wrong, the Mahatma argued, should not only be condemned, it should be resisted. Earlier, Nehru and his father had been contemptuous of the run of contemporary Indian politicians, whose nationalism, with a few notable exceptions, consisted of interminable speeches and long-winded resolutions. Jawaharlal was also attracted by Gandhi's insistence on fighting Britain without fear or hate.

First meeting with Gandhi

Nehru met Gandhi for the first time in 1916 at the annual meeting of the Indian National Congress Party in Lucknow. Gandhi was 20 years his senior. Neither seems to have made any initial impact on the other. Gandhi's autobiography, *The Story of My Experiments with Truth*, which he dictated while in prison between 1922 and 1924, contains not a single reference to Jawaharlal. The omission is understandable, since Nehru's role in Indian politics was secondary until his election as Congress president in 1929, when he presided over the historic Lahore session that proclaimed complete independence

as India's political goal. Until then the objective had been dominion status.

Nehru's close association with the Congress Party dates from 1919 in the immediate aftermath of World War I. This period saw a wave of nationalist activity and governmental repression culminating in the massacre of Amritsar in April 1919; 379 persons were killed and at least 1,200 wounded when the local British military commander ordered his troops to fire on a crowd of unarmed Indians assembled for a meeting.

When, late in 1921, the prominent leaders and workers of the Congress Party were outlawed in some provinces, Nehru went to prison for the first time. Over the next 24 years he was to serve another eight periods of detention, the last and longest ending in June 1945, after an imprisonment of almost three years. In all, Nehru spent over nine years in jail. Characteristically, he described his terms of incarceration as normal interludes in a life of abnormal political activity.

General secretary of Congress Party

His political apprenticeship with the Congress lasted from 1919 to 1929. In 1923 he became general secretary of the party for two years and again, in 1927, for another two years. His interests and duties took him on journeys over wide areas of India, particularly in his native United Provinces, where his first exposure to the overwhelming poverty and degradation of the peasantry (which he describes so movingly in his autobiography) had a profound influence on his basic ideas for solving these vital problems.

Though vaguely inclined toward Socialism and interested in the Soviet experiment, until then Nehru's radicalism had set in no definite mold. The watershed in his political and economic thinking was his tour of Europe and Soviet Russia during most of 1926–27. Nehru's real interest in Marxism and his Socialist pattern of thought stem from that tour, even though it did not appreciably increase his knowledge of Communist theory and practice. His subsequent sojourns in prison enabled him to study Marxism in more depth. Interested in its ideas, but repelled by some of its methods, such as the regimentation and heresy hunts of the Communists, he could never bring himself to accept Karl Marx's writings as revealed scripture. Yet from then on, the yardstick of his economic thinking remained Marxist, adjusted, where necessary, to Indian conditions.

Struggle for Indian independence. After the Lahore session of 1929, Nehru emerged as the leader of the country's intellectuals and youth. Hoping that Nehru would draw India's youth, at that time gravitating toward extreme leftist causes, into the mainstream of the Congress movement, Gandhi had shrewdly elevated him to the presidency of the Congress Party over the heads of some of his seniors. The Mahatma also correctly calculated that, with added responsibility, Nehru himself would be inclined to keep to the middle way.

After his father's death in 1931, Jawaharlal moved into the inner councils of the Congress Party and became closer to the Mahatma. Although Gandhi did not officially designate him his political heir until 1942, the country as early as the mid-1930s saw in Nehru the natural successor to Gandhi. The Gandhi–Irwin pact of March 1931, signed between the Mahatma and the British viceroy, Lord Irwin (later Lord Halifax), signalized a truce between the two principal protagonists in India. It climaxed one of Gandhi's more effective civil-disobedience movements, launched the year before, in the course of which Nehru had been arrested.

Hopes that the Gandhi–Irwin pact would be the prelude to a more relaxed period of Indo-British relations were not borne out; Lord Willingdon (who replaced Irwin as viceroy in 1931), jailed Gandhi in January 1932, shortly after the Mahatma's return from the Second Round Table Conference in London. He was charged with attempting to mount another civil-disobedience movement; Nehru was also arrested and sentenced to two years' imprisonment.

The Round Table Conferences in London, held to advance India's progress to self-government, eventually resulted in the Government of India Act of 1935, giving the Indian provinces a system of popular autonomous government. Ultimately, it provided for a federal system comprising the autonomous provinces and princely states. Although for various reasons federation never came into being, provincial autonomy was implemented.

During the middle '30s Nehru was much concerned with developments in Europe, which seemed to be drifting toward another world war. He was in Europe early in 1936, visiting his ailing wife, shortly before she died in a sanitarium in Switzerland. Even at this time he emphasized that in the event of war India's place was alongside the democracies, though he insisted that India could only fight in support of Britain and France as a free country.

When the elections following the introduction of provincial autonomy brought the Congress Party to power in a majority of the provinces, Nehru was faced with a dilemma. The Muslim League under Mohammed Ali Jinnah (who was to become the creator of Pakistan) had fared badly at the polls. Congress, therefore, unwisely rejected Jinnah's plea for the formation of coalition Congress–Muslim League governments in some of the provinces, a decision on which Nehru had not a little influence. The subsequent clash between the Congress and the Muslim League hardened into a conflict between Hindus and Muslims that was ultimately to lead to the partition of India and the creation of Pakistan.

Imprisonment during World War II. When, at the outbreak of World War II in September 1939, the viceroy, Lord Linlithgow, committed India to war without consulting the autonomous provincial ministries, the Congress Party's high command withdrew its provincial ministries as a protest against this action. Congress's action left the political field virtually open to Jinnah and the Muslim League.

Nehru's views on India's war role

Nehru's views on the war differed from those of Gandhi. Initially, the Mahatma believed that whatever support was given to the British should be given unconditionally and that it should be of a nonviolent character. Nehru, on the other hand, held that nonviolence had no place in defense against armed aggression and that India should support Britain in a war against Nazism, but only as a free nation. If it could not help, it should not hinder. He held broadly to this view, regardless of Gandhi's shifting postures.

In October 1940, Gandhi, abandoning his original stand, decided to launch a limited civil-disobedience campaign in which leading advocates of Indian independence were selected to participate one by one. Nehru, the second of these leaders, was promptly arrested and sentenced to four years' imprisonment—his eighth term of detention. After spending a little over a year in jail, he was released along with other Congress prisoners, three days before Pearl Harbor.

When, after Pearl Harbor, the Japanese carried their attack through Burma to the borders of India in the spring of 1942, the British government, faced by this new military threat, decided to make some overtures to India. Prime Minister Winston Churchill dispatched Sir Stafford Cripps, a member of the war Cabinet who was politically close to Nehru and also knew Jinnah, with proposals for a settlement of the constitutional problem. Cripps's mission failed, however, for Gandhi would accept nothing less than independence, even though Nehru would have accepted an arrangement enabling India to participate honorably in the war effort.

The initiative in the Congress Party now passed to Gandhi, who called on the British to leave India; Nehru, though reluctant to embarrass the war effort, had no alternative but to join Gandhi. Following the Quit India resolution passed by the Congress Party in Bombay on August 8, 1942, the entire Congress working committee, including Gandhi and Nehru, were arrested and imprisoned. Nehru emerged from this—his last detention—only on June 15, 1945.

Within two years India was to be partitioned and free. A final attempt by the viceroy, Lord Wavell, to bring the Congress Party and the Muslim League together failed. The Labour government that had meanwhile displaced Churchill's wartime administration dispatched, as one of

its first acts, a Cabinet mission to India and later also replaced Lord Wavell with Lord Mountbatten. The question was no longer whether India was to be independent but whether it was to consist of one or more independent states. Hindu–Muslim antagonism, culminating late in 1946 in clashes costing 7,000 lives, made the partition of India inevitable. While Gandhi refused to accept it, Nehru reluctantly but realistically acquiesced. On August 15, 1947, India and Pakistan emerged as two separate independent nations. Jawaharlal Nehru became independent India's first prime minister.

Achievements as prime minister. In the 35 years from 1929, when Gandhi chose Nehru over his seniors as president of the Congress session at Lahore, until his death as prime minister in 1964, Nehru remained—despite the Chinese debacle of 1962—the idol of his people. Superficially, his secular approach to politics contrasted with Gandhi's religious and traditionalist attitude, which during the Mahatma's lifetime had given Indian politics a religious cast—misleadingly so, for, although Gandhi might have appeared to be a religious conservative, he was actually a social nonconformist trying to secularize Hinduism.

Nehru as modernizer

The real difference between Nehru and Gandhi was not in their attitude to religion but in their attitude to modern civilization. While Nehru talked in an increasingly modern idiom, Gandhi was harking back to the glories of ancient Indian civilization. Yet within the Hindu framework, Gandhi was socially as much a protestant as Nehru outside it. Both men were, in the eyes of orthodox Hindus, secular in respecting their own religion while simultaneously respecting the religions of other Indians and other peoples.

The importance of Nehru in the perspective of Indian history is that he imported and imparted values and ways of thinking, which he adapted to Indian conditions. Apart from his stress on secularism and on the basic unity of India, despite its racial and religious diversities, Nehru was deeply concerned in carrying India forward into the modern age of scientific discovery and technological development. In addition, he aroused in his people an awareness of the necessity of social concern with the poor and the outcast and of respect for democratic values. One of the achievements of which he was particularly proud was the reform of the ancient Hindu civil code that finally enabled Hindu widows to enjoy equality with men in matters of inheritance and property.

Internationally, Nehru's star was in the ascendant until October 1956, when India's attitude on the Hungarian revolt against the Soviets brought his policy of nonalignment with either the Communist or non-Communist powers under sharp scrutiny by the non-Communist countries. In the United Nations, India was the only nonaligned country to vote with the Soviet Union on the invasion of Hungary, and thereafter it was difficult for Nehru to command credence in his calls for nonalignment. In the early years after independence, anticolonialism had been the cornerstone of his foreign policy, but after Chou En-lai, the Chinese prime minister, stole his thunder at the Bandung Conference of Afro-Asian states in 1955, Nehru's interest in this issue waned. By the time of the Belgrade conference of nonaligned countries in 1961, Nehru had substituted nonalignment for anticolonialism as the most pressing concern of the developing countries.

The Sino-Indian conflict of 1962 exposed the limitations of Nehru's wishful thinking on nonalignment. When the Chinese threatened to overrun the Brahmaputra Valley in November 1962, they exposed the hollowness of Nehru's euphoric commitment to the policy of "Hindu-Chini bhai bhai" ("Indians and Chinese are brothers"); his call for all-out Western aid made virtual nonsense of nonalignment.

The claims on Kashmir and Goa

Kashmir—claimed by both India and Pakistan—remained a perennial problem throughout Nehru's term as prime minister. His tentative efforts to settle the dispute by adjustments along the cease-fire lines having failed, Pakistan, in 1948, made an unsuccessful attempt to seize Kashmir by force. In solving the problem of the Portuguese colony of Goa—the last remaining colony in India—Nehru was more fortunate. Although its military occupation by Indian troops in December 1961 raised a furor in many Western countries, in the hindsight of history, Nehru's action is justifiable. With the withdrawal of the British and the French, the Portuguese colonial presence in India became an anachronism. Both the British and the French had withdrawn peacefully. If the Portuguese were not prepared to follow suit, Nehru had to find ways to dislodge them. After first trying persuasion, in August 1955 he had permitted a group of unarmed Indians to march into Portuguese territory in a nonviolent demonstration. Even though the Portuguese opened fire on the demonstrators, killing nearly 30, Nehru stayed his hand for six years, appealing meanwhile to Portugal's Western friends to persuade its government to cede the colony. When India finally struck, Nehru could claim that neither he nor the government of India had ever been committed to nonviolence as a policy.

Nehru's health showed signs of deteriorating not long after the clash with China. He had a slight stroke in 1963, followed by a more debilitating attack in January 1964. He died in New Delhi on May 27, 1964, from a third and fatal stroke.

Assessment. While consciously assertive in his Indianness, Nehru never exuded the Hindu aura and atmosphere clinging to Gandhi's personality. Because of his modern political and economic outlook, he was able to attract the younger intelligentsia of India to Gandhi's movement of nonviolent resistance against the British and later to rally them around him after independence had been gained. Nehru's Western upbringing and his visits to Europe before independence had acclimatized him to Western ways of thinking. Of all the leaders of the Congress Party, including Gandhi, he alone had given serious thought to India's place in the world community. This enabled him not only to educate his people on foreign affairs before independence but to project his own views on India's foreign policy when freedom came. If Gandhi made Indians aware of India, Nehru made them also aware of others. When India achieved independence the image it presented to the world was really Nehru's image: in the early years of India's independence, the world identified India with Nehru.

Throughout his 17 years in office, Nehru held up democratic Socialism as the guiding star for his country. Emphasizing the necessity of both democracy and Socialism for India, he set out to achieve Socialism through democracy. With the help of the overwhelming majority that the Congress Party maintained in Parliament during his term of office, he was able to advance toward that goal. The four pillars of his domestic policies were democracy, Socialism, unity, and secularism. He succeeded to a large extent in maintaining the edifice supported by these four pillars during his lifetime.

BIBLIOGRAPHY. For a biography of Nehru, see MICHAEL BRECHER, *Nehru* (1959); and *The New States of Asia: A Political Analysis* (1963), which contains, as an appendix, the author's talks with Nehru on many subjects. See also WALTER R. CROCKER, *Nehru: A Contemporary's Estimate* (1966); and GEOFFREY W. TYSON, *Nehru: The Years of Power* (1966). In A.B. SHAH (ed.), *Jawaharlal Nehru: A Critical Tribute* (1965), ARNOLD TOYNBEE's article published in *Encounter* is reprinted. BIMLA PRASAD, *The Origins of Indian Foreign Policy*, 2nd ed. (1962), contains a wealth of material on Nehru's views on foreign affairs before 1947. The appendixes include his letter to Roosevelt dated April 12, 1942, and his inaugural address to the Asian Relations Conference, March 23, 1947. TAYA ZINKIN, *Reporting India* (1962), contains material unpublished until then. It is excellent on the relationship between father and son, covering the years 1861 to 1931. SUDHIR GHOSH, *Gandhi's Emissary* (1967), discusses in part 2, "The Nehru Era," and throws much light on Nehru after the Chinese invasion and on his relations with Kennedy. Other recommended works include: V.B. KULKARNI, *The Indian Triumvirate; A Political Biography of Mahatma Gandhi, Sardar Patel, and Pandit Nehru* (1969); the memoirs of ABUL KALAM AZAD, *India Wins Freedom* (1959); and H.V. HODSON, *The Great Divide: Britain, India, Pakistan* (1969), on Nehru's relations with Mountbatten.

(F.R.M.)

Nelson, Lord

Horatio Nelson, the most successful and popular British naval commander in the wars with Revolutionary and Napoleonic France, set abiding standards of originality and initiative in strategical and tactical thinking and in leadership for every major navy and is still generally accepted as the most appealing of British national heroes.

Nelson's flair and forcefulness as a commander in battle were decisive factors in his two major victories—the battles of the Nile and Trafalgar. In the former, he destroyed the French fleet upon which Napoleon Bonaparte had based his hopes of Eastern conquest, and in the latter he destroyed the combined French and Spanish fleets, thus ensuring the safety of the British Isles from invasion and the supremacy of British sea power for more than a century. Spectacular success in battle, combined with humanity as a commander and a scandalous private life, raised Nelson to godlike status in his lifetime; and after his death at Trafalgar in 1805, he was enshrined in popular myth and iconography.

Nelson, oil painting by J.F. Rigaud (1742–1810). In the National Maritime Museum, Greenwich, England.

Horatio Nelson was born on September 29, 1758, in Burnham Thorpe, Norfolk, the sixth of 11 children of its rector, Edmund Nelson, and his wife Catherine. The Nelsons were genteel, scholarly, but poor. The family's most important connection from which Nelson could expect preferment was that with a distant relation, Lord Walpole, the descendant of Sir Robert Walpole, who had been prime minister earlier in the century.

Decisive for Nelson's life, however, was his mother's brother, Captain Maurice Suckling, who was to become comptroller of the British navy. When Horatio's mother died, Captain Suckling agreed to relieve the widower's burden by taking the boy to sea. So, although apparently a delicate, sensitive child, the nine-year-old Horatio, after attending local school, joined his uncle's ship, the "Raisonnable," at Chatham in 1771.

First years in the navy. Nelson's first years in the navy were a mixture of routine experience and high adventure. The former was gained particularly in the Thames estuary; the latter comprised a voyage to the West Indies in a merchant ship and a dangerous and unsuccessful scientific expedition to the Arctic in 1773.

Nelson had his first taste of action in the Indian Ocean. Soon after, struck down by fever—probably malaria—he was invalided home, and while recovering from the consequent depression, Nelson experienced a dramatic surge of optimism. A vision of "a radiant orb" inspired

> a sudden glow of patriotism . . . and presented my king and country as my patron. . . . 'Well then,' I exclaimed, 'I will be a hero, and confiding in Providence, I will brave every danger.'

From that moment, Nelson's ambition, fired by patriotism tempered by the Christian compassion instilled by his father, urged him to prove himself at least the equal of his eminent kinsmen.

Service in the war against the American colonies

In 1777 Nelson passed the examination for lieutenant and sailed for the West Indies, the most active theatre in the war against the American colonies. Promoted captain in 1779, at the early age of 20, he was given command of a frigate and took part in operations against Spanish settlements in Nicaragua, which became targets once Spain joined France in alliance with the American Revolutionaries. The attack on San Juan, in which he played a leading part, was militarily successful but ultimately disastrous when the British force was almost wiped out by yellow fever; Nelson himself was lucky to survive.

He was invalided home once more, before being given command of another frigate destined for operations off North America. At New York City he met Prince William Henry, later to become duke of Clarence and King William IV, who was then a midshipman in Admiral Lord Hood's flagship. The Prince, struck by "the merest boy of a captain" found "something irresistibly pleasing in his address and conversation; and an enthusiasm, when speaking on professional subjects, that showed he was no common being." The ensuing friendship led to Nelson's reception by King George III in London.

In 1783, after the end of the American Revolution, Nelson returned to England by way of France. He longed for feminine company and fell in love with an English girl in Saint-Omer who did not reciprocate his affections. On his return to London he was cheered by the appointment, in 1784, to command a frigate bound for the West Indies.

But this was not to be a happy commission. By rigidly enforcing the Navigation Act against American ships, which were still trading with the British privileges they had officially lost, he made enemies not only among merchants and shipowners but among the resident British authorities who, in their own interest, had failed to enforce the law. Under the strain of his difficulties and of the loneliness of command, Nelson was at his most vulnerable when he visited the island of Nevis in March 1785. There he met Frances Nisbet, the widow of a doctor, and her five-year-old son Josiah. Pleasant-looking, intelligent, and poised, Fanny Nisbet, a few months older than Nelson, seemed the ideal wife for a dedicated naval officer. Nelson conducted his courtship with formality and charm, and in March 1787 the couple was married at Nevis.

Marriage

Returning with his bride to Burnham Thorpe, Nelson found himself without another appointment and on half pay. He remained unemployed for four years, observing the routines of family visits, market days, harvests, and shooting parties. He read a great deal and followed the newspapers, writing to friends and possible patrons at the Admiralty in the hope of further employment. Aware of "a prejudice at the Admiralty evidently against me, which I can neither guess at, nor in the least account for"—but which may well have been connected with his zealous enforcement of the Navigation Act—Nelson was delighted to receive a new appointment. Within a few days of the execution of King Louis XVI in January 1793, he was given command of the 64-gun "Agamemnon."

Service in the Mediterranean. From this moment, Nelson the enthusiastic professional was gradually replaced by Nelson the commander of genius and Nelson the celebrity. The coming months were probably his most tranquil emotionally. At home waited a loving wife, whose son he had taken to sea with him. His ship, fast and manoeuvrable, his crew superbly trained, pleased him. His task was to fight the Revolutionary French and support British allies in the Mediterranean. Assigned to the forlorn defense of the port of Toulon against the revolutionaries—among them a 24-year-old officer of artillery, Napoleon Bonaparte—Nelson was dispatched to Naples to collect reinforcements. King Ferdinand IV (later Ferdinand I, of the Two Sicilies), who ruled Naples and Sicily with his domineering Queen Maria Carolina, sister

of the French queen Marie-Antoinette, readily agreed to send 4,000 men; and Nelson gratefully recognized that he owed the success of his mission largely to the British minister—the adroit and scholarly Sir William Hamilton, who had lived at Naples for 30 years and whose vivacious young wife Emma was in the Queen's confidence. In Emma Hamilton he at once recognized a remarkable woman but probably not one who was to alter his life. As a young courtesan with well-connected lovers, she had acquired an attractive smattering of smart etiquette, and her beauty had been recorded by prominent artists such as George Romney and Thomas Lawrence. Her zest, generosity, and quick intelligence won response from the Neapolitans, and Nelson wrote to his wife that Lady Hamilton "does honour to the station to which she is raised." The seeds of their infatuation had been planted. Emma Hamilton's warmth was both sexual and maternal; and her sense of humour and Sir William's erudition together may have been a luxurious echo of Parson Nelson's whimsical and scholarly company in Norfolk. But the passion was to lie dormant for several years.

First meeting with Emma Hamilton

When Toulon fell, Lord Hood, Nelson's commander, moved his base to Corsica, which was in revolt against the French, whose garrisons there were under siege. Nelson and his ship's company went ashore to assist first in the capture of Bastia, then of Calvi, where a French shot flung debris into Nelson's face, injuring his right eye and leaving it almost sightless. At the end of 1794, Hood was replaced by the uninspiring Adm. William Hotham, who failed to decisively defeat French men-of-war when they attempted to recapture Corsica. In this action, Nelson himself fought and, after two hours, captured the huge "Ça Ira," which had 120 guns. Exultant, yet frustrated, he wrote, "Sure I am, had I commanded our Fleet . . . that either the whole French fleet would have graced my triumph, or I should have been in a confounded scrape."

Hotham was replaced by an officer more to Nelson's liking. At 60, Adm. Sir John Jervis was an immensely experienced seaman who quickly recognized Nelson's qualities and who regarded Nelson "more as an associate than a subordinate Officer." The arrival of Jervis coincided with an upsurge of French success by land so that the British were forced to abandon their Mediterranean bases and retreat upon Gibraltar and the Tagus.

Battle of Cape St. Vincent. Making for a rendezvous with Jervis in the Atlantic off Cape St. Vincent, Nelson found himself sailing in mist through a Spanish fleet of 27 ships on its way to join with other Spanish, French, and Dutch squadrons for an attempted invasion of the British Isles. The Spaniards were sailing in two divisions and Jervis planned to cut between the two and destroy one before the other could come to its assistance. But he had miscalculated and, having passed between the two enemy columns, it became clear that the British ships would not be able to turn quickly enough to get into action before the Spanish squadrons closed up.

Without orders from Jervis, and violating the rigid tactical doctrine of the time, Nelson hauled out of the line and threw himself at the head of the second Spanish division. While the rest of Jervis's fleet slowly turned and came up in support, Nelson held the two Spanish squadrons apart with his one ship, at one time fighting seven enemy ships. The efficiency of British gunnery was decisive; and he not only boarded and captured one enemy man-of-war but, from her deck, boarded and took a second.

The Battle of Cape St. Vincent won for Jervis the earldom of St. Vincent and for Nelson a knighthood, which coincided with his promotion by seniority to rear admiral. His first action in command of a major independent force, however, was disastrous. During an assault on Tenerife a grapeshot shattered his right elbow, and back in his flagship, the arm was amputated.

Nelson's injury and recovery

Making a slow recovery in London, nursed by his wife, Nelson was agreeably surprised to find that his failure at Tenerife had in no way dimmed the fame of his daring at St. Vincent, and as he wrote, "my reception by John Bull has been just what I wished." In the spring of 1798, he was fit enough to rejoin the Earl of St. Vincent who assigned him to watching a French fleet and some 300 transports waiting to embark an expeditionary force of 35,000 men at Toulon for an unknown destination.

Cruising off the port in his flagship, the "Vanguard," Nelson was struck by a violent northwesterly gale that blew his squadron off station and carried the French well on their way to their destination, Egypt. The British set out in pursuit, first calling at Naples. Hamilton sent a message to say he considered the French to be bound for Malta, but Nelson believed they were going either to Sicily or Egypt and that if they passed by the former, "they are going on their scheme of possessing Alexandria and getting troops to India." Hearing that they had passed Sicily, the British made their best speed for Alexandria. On arrival, they found the harbour empty so, imagining the French objective had been Sicily after all, returned there. But no French were off Sicily, and Nelson was told that they had been seen a month earlier sailing east.

Battle of the Nile, August 1, 1798. Arriving off Alexandria a second time, the British saw the harbour crowded with empty transports and, to the east, their escorting squadron of 13 ships anchored in a defensive line across Abū Qīr Bay near the mouths of the Nile. Once the signal to engage had been hoisted in the "Vanguard," the 14 British captains—Nelson's "Band of Brothers"—flung themselves at the French. With the French ships immobilized, two British could anchor and concentrate their fire on each enemy before moving on to demolish their next target.

Its outcome never in doubt from its beginning at sunset, the battle raged all night. By dawn the French squadron had been all but annihilated. The strategic consequences were immense, and Nelson, who had been wounded slightly on the forehead, took immediate steps to broadcast the news throughout the Mediterranean as well as hastening it to London.

At Naples, the most convenient port for repairs, he was given an ecstatic hero's welcome, stage-managed by Lady Hamilton, who, although she had not seen him for five years, fell half-swooning into his arm exclaiming, "Oh God, is it possible!" A prolonged British naval presence here was useful in supporting the shaky military strength of King Ferdinand, the one major ruler in Italy to be resisting the southward march of the French, who had already taken Rome and deposed the Pope.

Beginning of the liaison with Emma Hamilton

His 40th birthday party in Naples, arranged by Emma Hamilton for the hero and 1,800 guests, established Nelson as a resident celebrity, a role that obviously delighted him. It was in startling contrast to his weary years at sea and to the homely letters from his wife in Norfolk. At home, it would be Rear Adm. Sir Horatio and Lady Nelson, but in Naples it was Mars and Venus.

The love affair between Nelson and Emma Hamilton developed at a time of crisis. With Nelson's encouragement, King Ferdinand had indulged his own fantasies of glory, and openly joining the alliance of Britain, Russia, and Austria against the French, led his own insignificant army to recapture Rome. This was not only a disastrous failure, but the French counteroffensive drove him back to Naples, which itself then fell. Nelson had to evacuate the Neapolitan royal family to Sicily, and at Palermo it became obvious to all that his infatuation with Emma Hamilton was complete. She had not only proved herself indispensable company to him but had supervised the continuing treatment of his wound and convalescence, had introduced him into Neapolitan society, kept him the centre of attention and soothed his irritation at being rewarded for his victory with a barony rather than a viscountcy.

Blockade of Naples. In the summer of 1799, Nelson's squadron supported Ferdinand's successful attempt to recapture Naples with an army led by a popular prelate, Cardinal Ruffo. The French withdrew and the Parthenopean Republic, declared by Neapolitan liberals, collapsed; its supporters surrendered to Ruffo on his promise of free passage to France. On arrival off Naples, Nelson held the prisoners under his guns until the arrival of

Ferdinand, who at once rescinded Ruffo's promise. Savage reprisals began, Nelson himself handing over the Republican admiral for trial and execution. He was to be harshly criticized for these actions, but as he saw it he was loyally supporting allies and no more. His ruthlessness may have been partly induced by the emotional stress resulting from his divided loyalties between Britain and Naples and the cumulative weariness of hard living at sea and a soft life ashore.

Word of his dalliance had reached the Admiralty, and his superiors began to lose patience. Bonaparte had escaped from Egypt to France, and the French still held Malta when Lord Keith, who had replaced St. Vincent as commander in chief, decided that the enemy's next objective would be Minorca. Nelson was ordered to the island with all available ships but refused on the grounds that he expected the threat to be towards Naples. Events justified him, but to disobey orders so blatantly was unforgivable. The Admiralty, also angered by his acceptance of the dukedom of Bronte in Sicily from King Ferdinand, sent him an icy order to return home because "you will be more likely to recover your health and strength in England than in an inactive situation at a Foreign Court."

In 1800 he returned but across the continent in company with the Hamiltons. He cut a poor figure in European cities: "The Lord of the Nile seems as clumsy and dim on land as he is adroit and notable at sea," was one view. But when the curious little party landed in England, it was at once clear that he was the nation's hero and his progress to London was triumphal until the bleak reunion with his wife. Husband and wife were together for about a month when, as the caricaturists made it plain, he returned to the cuckolding of Sir William Hamilton. While the British masses worshipped him, he became a figure of fun or scandal in London society and the King publicly snubbed him.

The nation's hero

Emma was pregnant by Nelson and, in a turmoil of guilt and delight, he was appointed second in command to the elderly and timid Adm. Sir Hyde Parker, who was to command an expedition to the Baltic. This was to take preventive action against the Armed Neutrality of the North, an alliance of Russia, Prussia, Sweden, and Denmark in support of France. Shortly before the expedition sailed, Nelson heard that Emma had borne him a daughter, and he made elaborate arrangements for concealing her parentage. His intense joy at the birth was matched by his jealous frenzy over Emma who, he thought, had caught the eye of the Prince of Wales. At this time he received a touching letter from his wife, pleading for a reconciliation but this was returned, marked, "Opened by mistake by Lord Nelson, but not read."

Battle of Copenhagen. Parker's fleet sailed for the first objective, Copenhagen, early in 1801. At first Nelson's advice was not sought; then, as Danish resistance became increasingly likely, he could record, "Now we are sure of fighting, I am sent for." By the stratagem of taking the fleet's ships of shallower draught through a difficult channel, Nelson bypassed the shore batteries covering the city's northern approaches. The next morning, April 2, he led his squadron into action. There was to be no room for tactical brilliance; only superior gunnery would tell.

The Danes resisted bravely, and Parker, fearing that Nelson was suffering unacceptable losses, hoisted the signal to disengage. Nelson disregarded it, delivering his famous quip, "I have only one eye—I have a right to be blind sometimes." An hour later, victory was his, and the Danish ships lay shattered and silent, their losses amounting to some 6,000 dead and wounded, six times heavier than those of the British.

Before this success could be followed by similar attacks on the other potential enemies, Tsar Paul of Russia died, and the threat faded. Parker was recalled and succeeded by Nelson, who at last became a commander in chief. The Admiralty, well aware of his popular appeal, now made maximum use of it by giving him a home command. At once he planned an ambitious attack on the naval base of Boulogne in order to foil a possible French invasion. He did not take part himself and the operation was a gory failure. A second attempt was abandoned because of peace negotiations with France, and in March 1802 the Treaty of Amiens was signed.

Nelson as commander in chief

At last there was time to enjoy the fruits of his victories. Emma had, on Nelson's instructions, bought an elegant country house, Merton Place, near London, and transformed it into an expensive mirror for their vanities. At last her husband rebelled against his cuckolding, writing to her, "I feel that the whole attention of my wife is given to Lord N. and his interest at Merton." But it was too late for change, and he appeared reconciled to his lot when, early in 1803, he died with his wife and her lover at his side.

Victory and death at Trafalgar. Bonaparte was known to be preparing for renewed war, and two days before it broke out, Nelson, in May 1803, was given command in the Mediterranean, hoisting his flag in the "Victory." Once again he was to blockade Toulon, now with the object of preventing a rendezvous between the French ships there with those at Brest in the Atlantic and, after Spain declared war on Britain, with Spanish ships from Cartagena and Cadiz. A combined force of that size could well enable Bonaparte to invade England; and in 1805, Napoleon, who the previous year had crowned himself emperor, ordered the fleets to converge for this purpose. The French and Spanish squadrons were to burst through the British blockade; run for the West Indies; and after ravaging British possessions and trade, return across the Atlantic in a single invincible fleet to destroy the British near Ushant, an island off Brittany, and take control of the English Channel while it was crossed by an invading army of 350,000.

In March of that year, Adm. Pierre Villeneuve, who was to be in overall command, broke out of Toulon under cover of bad weather and disappeared. Nelson was convinced that Villeneuve was making for the West Indies and set off in pursuit. Villeneuve, alarmed at the speed of the pursuit, cut short his marauding to make for Ushant as planned. A British squadron had been alerted, and Villeneuve's fleet was intercepted and damaged. Failing to win control of the Channel, he ran south to Cadiz.

Preparations for battle

Nelson put into Gibraltar, made dispositions for the blockade of Cadiz, and returned to England. During his 25 days at home, he planned the strategy for the confrontation with the Franco-Spanish fleets that now seemed inevitable. Thirty-four enemy ships were blockaded in Cadiz by smaller numbers under Adm. Cuthbert Collingwood. Although Napoleon, abandoning the plan of a cross-Channel invasion, began to re-deploy the Grand Army, in Britain the danger of invasion seemed as pressing as ever, and Nelson appeared the country's hope of deliverance.

While awaiting orders to sail, Nelson by chance met the Duke of Wellington, the future victor of Waterloo, in Whitehall. At first Wellington was shocked by the admiral's conversation "all about himself, and in, really, a style so vain and silly as to surprise and almost disgust me." Then Nelson, discovering his companion's identity, changed and "talked of the state of the country and of the aspect and probabilities of affairs on the Continent with a good sense, and a knowledge . . . that surprised me. . . . I don't know that I ever had a conversation that interested me more."

When his orders came, Nelson made his emotional farewells to Emma and Horatia, his daughter by her, and, on September 15, sailed from Spithead in the "Victory." He was now at the height of his professional powers. Worshipped by his officers and sailors alike, he was confident that his captains understood his tactical thinking so well that the minimum of consultation would be required. On his 47th birthday he dined 15 captains in his flagship and outlined his plans to bring on "a pell-mell battle" in which British gunnery and offensive spirit would be decisive. He planned to advance on the Franco-Spanish fleets in two divisions to break their line and destroy them piecemeal. This was the final abandonment of the traditionally rigid tactics of fighting in line of battle. "It was new—it was singular—it was simple!" wrote Nelson. He described his original idea as "The Nelson Touch."

After receiving Napoleon's orders that he must break the blockade, Villeneuve, on October 20, sailed out of Cadiz with 18 French and 15 Spanish men-of-war. At dawn next day, the Franco-Spanish fleets were silhouetted against the sunrise off Cape Trafalgar, and the British began to form the two divisions in which they were to fight, one led by Nelson, the other by Admiral Collingwood.

Before battle, Nelson signed a document bequeathing Emma Hamilton and Horatia to the nation and wrote in his diary a prayer; perhaps the finest of much good prose that he had written. As the opposing fleets closed, he made a signal, "England expects that every man will do his duty." The battle raged at its fiercest round the "Victory." Although broadsides and small-arms fire were being exchanged at point-blank range, Nelson and his flag captain, Thomas Hardy, paced the quarterdeck, the former wearing his four stars of chivalry on his coat, so making himself an obvious target. A French sniper, firing from the mast of the "Redoutable," shot Nelson through the shoulder and chest. He was carried below to the surgeon, and it was soon clear that he was dying. The future of Emma and Horatia was much on his mind, but he listened attentively to news of the battle. When told that 15 enemy ships had been taken, he replied, "That is well, but I had bargained for 20." Hardy kissed his forehead in farewell and Nelson spoke his last words, "Now I am satisfied. Thank God, I have done my duty." At 4:30 PM he died.

"England expects . . ."

Although the victory of Trafalgar finally made Britain safe from invasion, it was, at the time, overshadowed by the news of Nelson's death. A nation racked with grief gave him a majestic funeral in St. Paul's Cathedral, and his popularity was recorded in countless monuments, streets, and inns named after him, paintings and prints, busts and plaques and, eventually, in the preservation at Portsmouth of the "Victory." Emma Hamilton and his daughter, however, were ignored. Emma died, raddled and almost destitute, in Calais nine years later. Horatia, showing her father's resilience, married a clergyman in Norfolk and mothered a large and sturdy family.

Nelson had finally broken the unimaginative strategical and tactical doctrines of the previous century and taught individual officers to think for themselves. He had introduced as normal practice a new personal quality of leadership in which subordinates were treated as individual human beings.

BIBLIOGRAPHY. A.T. MAHAN, *The Life of Nelson*, 2 vol. (1897), a biographical study by the great American naval historian, should be read in conjunction with his other works, such as *The Influence of Sea Power upon the French Revolution and Empire* and *The Influence of Sea Power upon History*. GEORGE P.B. NAISH (ed.), *Nelson's Letters to His Wife, and Other Documents, 1785–1831* (1958), is far more comprehensive than its title suggests since it includes many other letters and long explanatory passages by the editor, himself a noted British Naval historian working on the staff of the National Maritime Museum, Greenwich. SIR NICHOLAS HARRIS, *The Dispatches and Letters of Vice Admiral Lord Viscount Nelson*, 7 vol. (1844–46), remains the principal source for Nelson's biographers. CAROLA OMAN, *Nelson* (1947), a perceptive and intelligent biography, is accurate and well written but perhaps a little emotional for some tastes. TOM POCOCK, *Nelson and His World* (1968), is a short illustrated biography, laying particular stress on Nelson's early influences and their likely effects in later life. ROBERT SOUTHEY, *The Life of Nelson*, 2 vol. (1813), one of the first and the most reliable of the many biographies, treats with delicacy the more intimate aspects of Nelson's private life. OLIVER WARNER, *A Portrait of Lord Nelson* (1958), is perhaps the best all-round biography of Nelson, written with great personal and professional understanding by one of the most distinguished living British naval historians; GEOFFREY BENNETT, *Nelson the Commander* (1972), relates the Admiral's career to the naval practice of his own and later times.

(T.Po.)

Nemertea

The ribbonworms comprise the phylum Nemertea, which sometimes is called Nemertinea or Rhynchocoela. Nemerteans are the simplest animals to have a digestive system that begins with a mouth and ends with an anus and a true vascular system for blood circulation. All of the approximately 600 species are quite similar in appearance. Typically, nemerteans are long and thin, with little distinction between head and tail. Although they range in length from less than 1 centimetre to more than 30 metres, most nemerteans are less than 20 centimetres in length. Ribbonworms, usually white, yellow, or brown in colour, may be brightly patterned.

Natural history. The majority of ribbonworms are marine and inhabit the coastal waters of temperate regions, particularly the Mediterranean and Europe. Nemerteans occupy a variety of habitats, including the undersides of stones and seaweeds and burrows in sand or mud. A few nemerteans thrive at depths greater than those of coastal waters, and some live in the open sea. Ribbonworms are uncommon in tropical and subtropical regions; a variety of species lives in the Arctic and Antarctic, however.

One genus, *Prostoma,* occurs in fresh water throughout the world; another, *Geonemertes,* is terrestrial in subtropical areas, particularly Australia and New Zealand. Ribbonworms, carnivores that feed on living or dead animals (particularly annelid worms), actively pursue prey, entan-

Diversity of structure of nemerteans.

gle it with their proboscis, and sometimes inject a poisonous substance into it.

Reproduction

Male and female nemerteans occur in most species, with annual reproduction typical. Eggs and sperm are released separately, and fertilization takes place externally. The fertilized egg develops by a process similar to that of flatworms (phylum Platyhelminthes), annelids (phylum Annelida), and mollusks (phylum Mollusca). Ribbonworms can develop in one of two ways: the most common is the direct method—without a larval stage; the other is indirect and includes a larva, which may be one of two types. One kind, a free-swimming larva of complicated pattern known as the pilidium, is more common; the other type, similar to an adult, is called Desor's larva. Larvae change into young ribbonworms. Within the genera *Prostoma* and *Geonemertes*, the species may be either dioecious (*i.e.*, separate male and female animals) or hermaphroditic (*i.e.*, male and female reproductive organs in one animal). All ribbonworms have the ability to regenerate lost or damaged parts of their bodies; some species actually break up and form a number of fragments, which then grow into complete individuals. This mechanism provides asexual reproduction.

Form and function. The long, flat ribbonworm is characterized by a proboscis that lies in a sheath, which extends down the body dorsal to the gut. The wall of the sheath is continuous with the layers of the body wall. The proboscis, which is eversible (*i.e.*, can be turned outward), is attached to the posterior end of the proboscis sheath by a retractor muscle and may have one or more piercing stylets at its tip. The muscular body wall consists of two or three layers of circular or longitudinal muscles; the arrangement of the layers varies in different groups. The head often bears a number of eyes and a mouth that leads to a straight gut, which ends in an anus at the posterior end of the animal. The nervous system consists of an anterior brain; typically, a single dorsal and two lateral nerves extend the length of the body. The closed blood vascular system usually consists of a mid-dorsal vessel and two lateral ones.

Evolution and classification. The affinities of the nemerteans lie with the flatworms (phylum Platyhelminthes); both have similar types of embryonic development and the same basic body plan. Unlike the flatworms, however, the nemerteans have a complete gut and a circulatory system. The ribbonworms generally are regarded as a distinct phylum at the highest point of acoelomate (without a body cavity) development. The important features used to classify the nemerteans include the position of the brain relative to the mouth, the presence or absence of a stylet (or stylets) on the proboscis, and the position of the lateral nerves relative to the muscle layers. The classification that is outlined below has been in use for some time.

PHYLUM NEMERTEA (ribbonworms)
Elongated, muscular, nonsegmented worms.

Class Anopla
Brain anterior to the mouth, proboscis without stylets.
Order Palaeonemertini
Body wall with 2 or 3 muscle layers, the outer one circular.
Order Heteronemertini
Body wall with 3 muscle layers, the outer one longitudinal.

Class Enopla
Brain posterior to, or at same level as, mouth.
Order Hoplonemertini
Proboscis with 1 or more stylets.
Order Bdellonemertini
Proboscis with no stylets; single genus with less than 10 species, commensal in mollusks.

Nepal

The Kingdom of Nepal, lying along the southern slopes of the Himalayan mountain ranges, is a landlocked country located between Sikkim and India to the east, India to the south and west, and the Tibetan Autonomous Region of China to the north. Its territory, which has an area of 54,362 square miles (140,798 square kilometres), extends roughly 500 miles from east to west and 90 to 150 miles from north to south. Nepal, for long under the rule of hereditary prime ministers favouring a policy of isolation, remained closed to the outside world until a palace revolt in 1950 restored the king to his position of authority in 1951; the country gained admission to the United Nations in 1955. In 1960, King Mahendra assumed direct rule, and on his death in 1972, King Birendra succeeded his father to the throne. Wedged in between two giants, India and China, Nepal seeks to keep a balance between the two countries in its foreign policy—and thus to remain independent. A factor that contributes immensely to the geopolitical importance of Nepal is the fact that a strong Nepal can deny China access to the rich Gangetic Plain; Nepal thus marks the southern boundary of the Chinese sphere north of the Himalayas in Asia.

As a result of its years of geographic and self-imposed isolation, Nepal is one of the least developed nations of the world. In recent years India, China, the Soviet Union, the United States, the United Kingdom, Israel, New Zealand, and Switzerland have provided economic assistance to Nepal. The extent of foreign aid to Nepal has been influenced to a considerable degree by the strategic position of the country between India and China. (For associated physical features, see EVEREST, MOUNT and HIMALAYAN MOUNTAIN RANGES; for historical aspects, see NEPAL, HISTORY OF.)

THE NATURAL ENVIRONMENT

Relief and drainage patterns. Nepal contains some of the most rugged and difficult mountainous terrain in the world. Roughly 75 percent of the country is covered by mountains; along the southern border a belt of lowland comprises the only extensive area of flat, level land. From the south to the north, Nepal can be divided into four main physical belts, each of which extends east to west across the country, These are, firstly, the Tarai, a low, flat, fertile land adjacent to the border of India; secondly, the forested Churia foothills and the Inner Tarai zone, rising from the Tarai plain to the rugged Mahābhārat Lekh range; thirdly, the mid-mountain region between the Mahābhārat Lekh range and the Great Himalayas; and fourthly, the Great Himalaya Range, rising to more than 29,000 feet.

The Tarai forms the northern extension of the Gangetic Plain and varies in width from less than 16 to more than 20 miles, narrowing considerably in the Rāpti and Nārāyani administrative zones. A ten-mile-wide belt of rich agricultural land stretches along the southern part of the Tarai; the northern section, adjoining the foothills, is a marshy region that is inhabited by wild animals and in which malaria is endemic.

The Churia Hills, which are sparsely populated, rise in almost perpendicular escarpments to an altitude of more than 4,000 feet. Between the Churia Hills to the south and the Mahābhārat Lekh range to the north, there are some broad basins from 2,000 to 3,000 feet high, about ten miles wide, and 20 to 40 miles long; these basins are often referred to as the Inner Tarai. In many places they are being cleared of the forests and savanna grass to provide timber and areas for cultivation.

A complex system of mountain ranges some 50 miles in width and varying in elevation from 8,000 feet to 14,000 feet, lie between the Mahābhārat Lekh range and the Great Himalayas. The ridges of the Mahābhārat Lekh range present a steep escarpment toward the south and a relatively gentle slope to the north. To the north of the Mahābhārat Lekh range, which encloses the valley of Kāthmāndu, are the more lofty ranges of the Inner Himalaya (Lesser Himalaya), rising to perpetually snow-covered peaks. The Kāthmāndu and the Pokhara valleys

lying within this mid-mountain region are flat basins, formerly covered with lakes, formed by the deposition of fluvial and fluvio-glacial material brought down by rivers and glaciers from the enclosing ranges during the four glacial and intervening warm phases of the Pleistocene Epoch (from about 2,500,000 to 10,000 years ago).

The Kāthmāndu Valley

The Kāthmāndu Valley, the political and cultural hub of the nation, is drained by the Bāghmati River, flowing southward, which washes the steps of the sacred temple of Paśupatināth (Pashupatinath) and rushes out of the valley through the deeply cut Chhobar gorge. The Kāthmāndu International Airport (unofficially known as Gauchar Airport) is situated on the flat top of lacustrine deposits. Some sandy layers of the lacustrine beds act as aquifers (water-bearing strata of permeable rock, sand, or gravel), and springs occur in the Kāthmāndu Valley where the sands outcrop. The springwater often gushes out of dragon-shaped mouths of stone made by the Nepalese; it is then collected in tanks for drinking and washing and also for raising paddy nurseries in May, before the advent of the monsoon. Drained by the Seti River, the Pokhara Valley, 96 miles west of Kāthmāndu, is also a flat lacustrine basin. There are a few remnant lakes in the Pokhara basin, the largest being the Phewa Tāl, which is about two miles long and nearly a mile wide. North of the basin lies the Annapūrna massif of the Great Himalaya Range.

The Great Himalaya Range, ranging in elevation from 14,000 feet to more than 29,000 feet, contains 5 of the world's 13 highest peaks—Everest, Kānchenjunga, Makālu, Dhaulāgiri, and Annapūrna—that are above 26,400 feet. Except for scattered settlements in high mountain valleys, this entire area is uninhabited, and all areas over 16,000 feet in elevation are permanently covered with snow.

The major rivers of Nepal—the Kosi, Gandak, and Karnāli, running southward across the strike of the Himalayan ranges—form transverse valleys with deep gorges, which are generally several thousand feet in depth from the crest of the bordering ranges. The watershed of these rivers lies not along the line of highest peaks in the Himalayas but to the north of it, usually in Tibet.

In the upper courses of all Nepalese rivers, which run through mountain regions, there are little or no flood problems. In low-lying areas of the Tarai plain, however, floods are a serious problem.

The rivers and small streams of Tarai, especially those in which the dry season discharge is small, are polluted by large quantities of domestic waste thrown into them. Although no records exist to determine the rate of increase in pollution, it is certain that pollution of Nepal's rivers is increasing. Towns and villages are expanding without proper provision for sewage disposal facilities, and more industries are being established at selected centres in the Tarai. The polluted surface water in the Kāthmāndu and Pokhara valleys, as well as in the Tarai, are unacceptable for drinking purposes.

Climate, vegetation, and animal life. Nepal's climate, influenced by elevation as well as by its location in a subtropical latitude, ranges from subtropical monsoon conditions in the Tarai, through a warm temperate climate between 4,000 to 7,000 feet in the mid-mountain

region, to cool temperate conditions in the higher parts of mountains between 7,000 and 11,000 feet, to an Alpine climate at altitudes between 14,000 feet and 16,000 feet along the lower slopes of the Himalaya mountains. At altitudes above 16,000 feet the temperature is always below freezing and the surface covered by snow and ice. Rainfall is adequate in the eastern portion of the Tarai (which receives from 70 to 75 inches a year at Morang) and mountains, but the western portion of Nepal (where from 30 to 35 inches a year fall at Kanchanpur) is drier.

Temperatures

In Kāthmāndu Valley, average temperatures range from 50° F (10° C) in January to 78° F (26° C) in July, and the lowest and highest temperatures recorded have been 27° and 99° F (−3° and 37° C). The average annual rainfall is about 58 inches, most of which falls in the period from June to September. At Pokhara temperature ranges from 40° F (4° C) in January to approximately 100° F (38° C) in June, just before the monsoon. In winter, temperature during the day will rise to 70° F (21° C), creating pleasant climatic conditions with cool nights and warm days. Rainfall is quite heavy (about 100 inches) in Pokhara valley because warm rain-bearing monsoon winds discharge most of their moisture as they encounter the Annapūrna range.

Natural vegetation of Nepal follows the pattern of climate and altitude. A tropical, moist zone of deciduous vegetation occurs in southern Nepal, in the Tarai and the Churia Hills. These forests consist mainly of khair (*Acacia catechu*), a spring tree with yellow flowers and flat pods; sissoo (*Dalbergia sissoo*), an East Indian tree yielding dark-brown durable timber; and sal (*Shorea robusta*), an East Indian timber tree with foliage furnishing food for lac insects (which deposit lac, a resinous substance used for the manufacture of shellac and varnishes, on the tree's twigs). On the Mahābhārat Lekh Range, at elevations between 5,000 to 10,000 feet, vegetation consists of a mixture of many species, chiefly pines, oaks, rhododendrons, poplars, walnuts and larch. Between 10,000 and 12,000 feet, fir mixed with birch, as well as rhododendron, abound. In the mid-mountain region of Nepal a fairly dense population has cleared all but the most inaccessible and remote parts of the forest, which are restricted to areas of steep slopes and rocky terrain. Similarly all readily accessible parts of valuable sal forest in the Terai have been devasted by overcutting and deplete practices. The vast forested area below the timber line in the Great Himalaya Range bears some of the most valuable forests in Nepal, containing spruce, fir, cypress, juniper, and birch. Alpine vegetation occupies higher parts of the Great Himalaya Range. Just below the snow line, grassy vegetation affords favourable grazing ground in summer between 14,000 and 15,000 feet. (P.P.K.)

Animal life

The forested areas of the Tarai are the home of tigers and leopards, gaurs (wild ox), occasional elephants and buffalo, and many deer; the deer include chital, or axis, deer (which have white-spotted bodies), sambar (a large Asiatic deer with coarse hair on the throat and strong antlers), and swamp deer. The Lesser Rāpti Valley, in the Chitawan district, is one of the last homes of the great Indian rhinoceros (*Rhinoceros unicornis*), of which only about 700 are believed to exist, 300 of these being in Nepal. Much poaching has gone on, as the horn of the rhinoceros is reputed to be valuable as an aphrodisiac, but in the 1960s the Nepal government was organizing protective measures.

There are few wild animals in the central zone, because of the clearing of forests. Occasional leopards, bears, and the smaller carnivores inhabit the forests and ravines, and muntjacs (a kind of small deer, also called the barking deer) are found in the woods. In the Alpine zone are musk deer, much persecuted for the musk pods they carry, the tahr (a Himalayan beardless wild goat), the goral (any of several goat antelopes, closely related to the Rocky Mountain goat), and wild sheep, which are preyed upon by wolves and snow leopards. Pheasant are common. The Yeti (bear-man, or Abominable Snowman) is said by the Sherpas to inhabit the high snow mountains but has eluded discovery by several expeditions that have set out to solve the mystery of this fable. Strange tracks are often found in the snow, but opinion inclines to the belief that they were probably made by bears. River wildlife includes the mahseer, a large Indian freshwater food and sport fish. (R.R.Pr./M.Zu.)

THE PEOPLE

Groups historically associated with the contemporary country. The large-scale migrations of Mongoloid groups from Tibet and Indo-Aryan people from northern India, which accompanied the early settlement of Nepal, have produced a diverse linguistic, ethnic, and religious pattern. Nepalese of Indo-Aryan ancestry comprise the people of the Tarai, the Pahari, the Newars, and the Tharus, numbering nearly 7,800,000 persons, or nearly 80 percent of the total population. Indo-Aryan ancestry has been a source of prestige in Nepal for centuries, and the ruling families have been of Indo-Aryan and Hindu background. Most of the Tibeto-Nepalese groups—the Tamang, Rai, Limbu, Bhote, and Sunwar—live in the north and east, while the Magar and Gurung inhabit west central Nepal. The bulk of the famous Gurkha contin-

gents in the British army have come from the Magar, Gurung, and Rai groups.

The main and official language of Nepal is Nepali (Gorkhali), spoken in the Tarai and the mid-mountain region. Nepali, a derivative of Sanskrit, belongs to the Indo-Aryan branch of the Indo-European family. There are a number of regional dialects found in the Tarai and mountain areas. The languages of the north and east belong predominantly to the Tibeto-Burman family. These include Magar, Gurung, Rai, Limbu, Sunwar, Tamang, Newari, and a number of Bhote dialects, including Sherpa and Thakali. Although Newari is commonly placed in the Tibeto-Burman family, it was influenced by both Tibeto-Burman and Indo-European languages.

*Because area and population data were not available according to administrative subdivisions, this table is organized according to the geographic census regions of the 1961 census. The actual administrative unit is the zone (anchal). There are 14 zones, namely Bāgmati, Bheri, Dhaulagiri, Gandaki, Janakpur, Karnali, Kosi, Lumbini, Mahakali, Mechi, Nārāyani, Rāpti, Sagarmatha, and Seti. †De jure. ‡Preliminary figures. §Converted area figures do not add to total given because of rounding. ‖Figures do not add to total given because of rounding.
Source: Official government figures.

Demography. Although population enumerations have been made approximately every ten years since 1911, the early census data of Nepal are not reliable. It was not until the early 1950s that the first systematic enumeration was made, and even then the data were limited in reliability and scope. The 1961 census recorded a population of 9,413,000. At the 1971 census the population was nearly 11,300,000; the rate of growth is estimated at 2 percent, which is expected to result in a total population figure of more than 12,000,000 by 1975.

Population density

The average population density of Nepal is 208 persons per square mile. If the area under snow and Alpine meadow (about 22 percent), timber (about 31 percent), and other unproductive land (about 12 percent) is subtracted from the total land area, the density on the area under cultivation or capable of being cultivated rises to 509 per square mile. Some 56 percent of the population lives in the mid-mountain region including the high Himalayan country (where 27 percent of the cultivated land is located mostly in valleys and terraced hill slopes); 5 percent lives in the Kāthmāndu Valley (with 2 percent of the cultivated land); and 42 percent lives in the Tarai (with 71 percent of the cultivated land).

The 1971 census recorded 26,478 more males than females in the total population, making the ratio of males to females about equal. Accurate data on mortality and birth rates are not available, but the death rate is estimated at 23 per 1000 and the birth rate about 45 per 1000. The high mortality rate will probably decrease as pure drinking water facilities become increasingly available, in addition to the mass-inoculation programs. In the early 1970s it appeared that Nepal's rate of population growth would remain high and that pressure of population on land would become more intense as the population increased in areas that were already overcrowded.

Almost all Nepalese live in villages or in small market centres. According to a 1970 projection, there were about 518,000 urban dwellers, representing less than 5 percent of the total population. Outside of Kāthmāndu itself (population 153,000), there are no major cities, though there are several smaller urban centres (Birātnagar, 45,000; Nepālganj, 36,000; Bīrganj, 20,000), located in the Tarai along the Indian border, in addition to a few townships—such as Hitaura, Butwal, and Dharān Bāzār —which are beginning to emerge in the foothills and hill areas, where economic activity is developing.

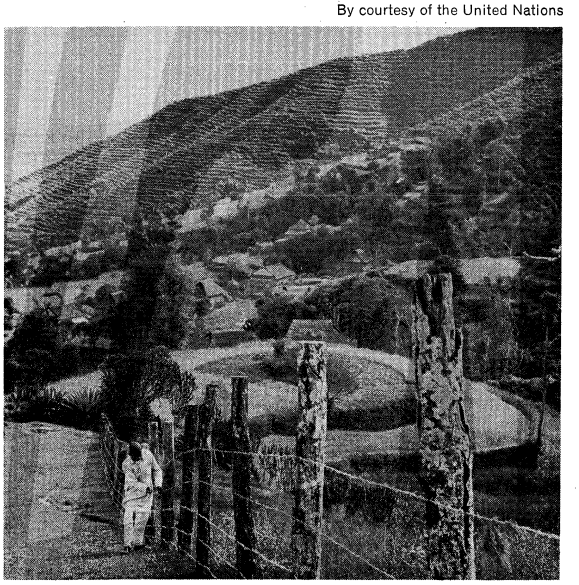
THE NATIONAL ECONOMY

Landlocked, lacking substantial resources for economic development, heavily dependent for basic materials and the market for its export, and with an inadequate transportation network, Nepal is one of the least developed nations in the world. Slow changes have occurred in the structure of the economy in the 1950s and 1960s, following the 1951 overthrow of the Rana regime. The lack of change in the political and administrative structure is largely responsible for the slow rate of economic growth. A tentative official estimate placed the 1961 to 1962 gross domestic product (based on market prices) at Nepalese rupees (NRs.) 3,680,000,000, giving a per capita income of about NRs. 390, or $51 U.S. In 1969, the gross domestic product was estimated at NRs. 9,449,000,000 (10.12 NRs = $1U.S.; 26.43NRs. = £1 sterling, on December 1, 1970), giving a per capita income of $80. The rapid increase in gross domestic product between 1961–62 and 1969 was the result of an increase in prices in the period. The increase in real output over the period is estimated at between 6 and 7 percent.

Resources and resource exploitation. *Agriculture.* Agriculture engages about 90 percent of Nepal's population and accounts for nearly 70 percent of the gross domestic product and over three-fifths of the country's export earnings. Yet agricultural productivity is very low. The average yield of paddy (rice), the main crop in Nepal, is about 1,713 pounds per acre; of maize (corn), the chief food item of the people in the mid-mountain region, 1,427 pounds per acre; and of wheat 892 pounds per acre.

Crop yields

By courtesy of the United Nations



Boundary of a reforestation project near Kāthmāndu sponsored by the government of Nepal. Over 240 acres of eucalyptus and acacia trees were planted here to help maintain one of the country's primary resources.

The low yield results from poor quality of seed, low fertilizer utilization, and use of inefficient techniques. Also, since only 4 percent of Nepal's cultivated land area of about 5,000,000 acres is under irrigation, output depends upon the vagaries of weather.

On the whole Nepal has a small surplus in food grains. There are, however, major dislocations in supply and demand. Periods of shortage between harvests of various crops occur in the mountain areas. At the same time, substantial amounts of food grain are moved to India from the Tarai. Because of the lack of adequate transportation, surplus food grain from the Tarai does not move north into the food deficit areas of the mid-mountain region. Some food grains move northward from the Tarai and the mountain areas into Tibet, despite a shortage in the mountain regions.

The greatest potential for future increases in agricultural production is in the Tarai. In the mid-mountain region the potential for increasing agricultural production is limited. Because of the high population concentration in this region, almost all land capable of cultivation is tilled. Increasing the cultivated land area by cutting into standing forests would aggravate erosion, resulting in reduced yields and land losses by landslides. Thus, in the early 1970s, the shortage of food in this region was expected to become even more severe in the near future.

Forests. About one-third of Nepal's total area is under forest; most of this area is state owned. In spite of overcutting and poor management, timber represents one of the country's most valuable resources and is a major source of potential revenue. Exports of forest products constitute an important source of Indian rupees. Almost all timber is exported to India. The saw mills of the Timber Corporation of Nepal, a government-owned lumber-processing concern, supply Kāthmāndu Valley with construction and furniture wood.

Minerals. Nepal's mineral resources are small, scattered, and barely developed. There are known deposits of coal, iron ore, pyrite (used for making sulfuric acid), limestone, and mica, but they are too small to warrant major investment for exploitation. Nepal's great river systems provide immense potential for hydroelectric development. If developed and utilized within the country and exported to India (the principal market for power generated in Nepal), it could become a mainstay of the country's economy.

Industry and trade. Industrial production represents a small but growing segment of economic activity. Most industries are small localized operations based on the processing of agricultural products. The jute industry, centred in Birātnagar, is Nepal's principal earner of foreign exchange. Sugar factories are located in Birātnagar, Bīrganj, Bhairawa, and Nepālganj. There is a cigarette factory at Janakpur. There are several saw mills in Hitaura, and a number of rice and oil mills are located in the Tarai. In general, there are more industrial enterprises in the private than in the public sector. In the early 1970s a pattern of selective industrial development was expected to continue, based on the limited capital and managerial resources available. The main areas of manufacturing concentration were Birātnagar, the Bīrganj-Hitaura corridor, and the Kāthmāndu Valley.

Tourism

Tourism represents a small but rapidly expanding industry. At present, foreign tourism is primarily confined to the Kāthmāndu Valley, which is the only area equipped with the necessary hotels, food supplies, roads, and international transport services. There are, however, many areas outside the Kāthmāndu Valley ripe for the development of tourism; these include Pokhara, the Mt. Everest area, and the Nārāyani area (where big game exists).

For geographical and historical reasons, nearly all of Nepal's trade is with India. Attempts have been made to diversify trade by new trade agreements with Pakistan, the United States, Poland, China, and the Soviet Union. The state trading agency, National Trading Limited, is expanding its activities by fostering the development of commercial entrepreneurial activity, which has been limited. Large-scale commercial activity has hitherto been in the hands of foreigners, primarily Indians.

Transportation. Transport facilities in Nepal are very limited; there are few independent nations in the world with such a low density of road mileage (11 miles of permanent road per 100,000 inhabitants) or such a high proportion of persons per vehicle (2,000 persons per vehicle). Nepal has only about 5,000 registered motor vehicles and a paved road mileage of only 424 miles to serve nearly 11,300,000 people. The main means of transportation has been the network of footpaths, which interlace the mountain terrain as well as the valleys. Trails have evolved into main trade routes, which tend to follow the river systems. Lack of adequate bridges across these rivers, however, has reduced the usefulness of many of the trails. In 1956, the Indian-made road from the border town of Raxaul to Kāthmāndu was completed; the Chinese have also built a 65-mile highway from Kāthmāndu to Kodari on the Tibetan frontier. In 1968, the Indian-built 130-mile highway from Sunauli, on the Indian border, to Pokhara was opened to traffic. In the early 1970s, the Chinese were assisting in the construction of a highway from Kāthmāndu to Pokhara. Furthermore, the East–West highway, a long cherished dream to unite the various sectors of the Tarai and thus help unify the nation, was under construction with foreign aid.

The meagre road-transport facilities in Nepal are supplemented by few railway- and air-transport links. Increased use of road transport has reduced the significance of the two narrow-gauge railroads that run from Amlekhganj to Raxaul (India) and from Janakpur to Jaynagar (India). The Royal Nepal Airline Corporation, an autonomous government agency, is the only commercial airline. Together with Indian Airlines, it operates flights from Kāthmāndu to Patna, Calcutta, Vārānasi, and Delhi in India. Domestic air service within the country is being expanded. The United States-built Kāthmāndu–Hitaura ropeway, although operational, is not used extensively for transporting food and supplies into the capital.

ADMINISTRATION, SOCIAL CONDITIONS, AND CULTURAL LIFE

Government and administration. Nepal is ruled by the King through a council of ministers and a four-tier system of panchayats (local bodies). The Basic units of government are the panchayats at the village level (more than 3,500 in all), where representatives are elected by a show of hands. These are followed by 75 district and 14 zonal panchayats, with a National Panchayat that resembles a parliament at the apex. The panchayats are supported by nonpolitical interest groups of workers and farmers. Political parties have been banned in Nepal since 1960 when King Mahendra suspended parliamentary democracy and imprisoned political leaders, including the prime minister.

The panchayat system of government

The decision to dismiss parliamentary democracy and assume complete powers, abolishing political parties, has been unpopular in Nepal. In 1963, the restoration of all fundamental rights (except the right to form political parties) brought a return to some political stability. The palace secretariat, comprising the immediate aides and assistants to the king, is of central importance in the prevailing system of government, in which royal initiative is the activating force. King Mahendra made several changes in the judicial system. In 1961, a Supreme Court act designed to bring the judicial appointment process under firm royal control was promulgated. Regional and district courts have been reorganized and there is now a district court in each of 75 development districts and zonal courts in each of the 14 zones.

Armed forces and police. Nepal's armed forces consist of the Royal Nepalese Army, predominantly an infantry force of about 14,000 men. Except for a few simple weapons, all military supplies are imported. Nepal is famous for the fighting qualities of its Gurkha soldiers; nearly 10,000 of these serve in British Gurkha units, and 50,000 in Indian Gurkha units. The British maintain a recruiting centre at Dharān Bāzār. Gurkha veterans represent a valuable human resource of Nepal.

For police purposes the country is divided into three zones: eastern, central, and western, with headquarters at Birātnagar, Kāthmāndu, and Nepālganj, respectively.

Each zonal headquarters, under a deputy inspector general of police, is responsible for several subsections composed of four to five police districts operating under a superintendent of police. A district superintendent is in charge of police stations in his area. Each station normally is supervised by a head constable who performs basic police functions.

Health and education. The administration of public-health services is the function of the Department of Health. It is responsible for the support and administration of more than 50 hospitals and 93 health clinic centres. The government has taken steps to improve existing health centres and to establish new ones. The welfare program is aimed at stimulating local initiative for a program of village development and is administered through the panchayat system. A small-scale relief operation for Tibetan refugees, who fled to Nepal after the Chinese invasion of Tibet in 1950, is supported by international agencies, including the Red Cross.

Between 1951 and the early 1970s tremendous gains took place in educational administration, supervision, and planning. The literacy rate rose from about 4 percent in the early 1950s to almost 12 percent in the early 1970s. The Director of Public Instruction is responsible for administration and supervision of all elementary and secondary education. Higher education has developed relatively recently. The first college was established in 1918, and Tribhuvan University in Kāthmāndu, with faculties of arts, sciences, commerce, and education, was charactered in 1959. The University Senate has sole legal responsibility for higher education and authority to grant academic recognition to colleges but is largely dependent upon the Education Ministry for funds.

Higher education

The cultural milieu. The relaxation of strict censorship, following the overthrow of Rana rule in 1951, encouraged a revival of artistic and intellectual expression during the 1950s and 1960s. In literature and poetry, Nepali works emphasize the cultural renaissance and national patriotism. In 1963, the government took steps to foster literary and intellectual development by subsidizing a number of young writers and by supporting and coordinating literary activities. King Mahendra, a poet whose Nepali lyrics have been published in English translation under the name of M.B.B. Shah (for Mahendra Bir Bikram Shah), did much to promote the revival of arts and literature.

The state of the arts. The cultural heritage of Nepal, particularly contributions made by Newars of Kāthmāndu Valley to sculpture, painting, and architecture, is a source of great pride. Hindu and Buddhist religious values have provided the basic source of inspiration to Newari artisans in their artistic expression. The themes of most artistic work have been primarily religious: the lives of the gods, saints, and heroes; the relationship of man to society and to the universe are expounded in sculpture, architecture, and drama. In the Kāthmāndu Valley, some 2,500 temples and shrines display the skill and highly developed aesthetic sense of Newar artisans.

Music and dance are favourite pastimes among the Nepalese. Religious ceremonies require the use of drums and wind instruments that have been preserved from ancient times. Devotional songs are an important feature on most religious and family occasions; these songs have elements of both classical and folk music and have been used by some contemporary musical revivalists in their attempt to bridge the gap between the two. The increasing urban demand for folk music is a manifestation of the new cultural nationalism; in response, Radio Nepal schedules programs featuring folk-music concerts.

The press. Newspapers and periodicals are published in Nepali and in English. The quality of the press is inferior and investigative reporting is not common. Newspapers are frequently sensational in tone and are poorly staffed and financed. *Gorkhapatra,* published by the government, occupies a commanding position in the Nepalese press. After 1960, King Mahendra required newspapers to obtain official clearance for all reports of political activity. Nepalese newspaper readers rely on the foreign press, particularly the Indian newspapers, which are daily flown into Kāthmāndu, for more sophisticated coverage of world and national news.

PROSPECTS FOR THE FUTURE

Upon assuming all power, King Mahendra promised a Nepalese form of democracy that would make the country bloom. By the early 1970s, King Mahendra's panchayat democracy had lasted over ten years, but it had still produced no substantial sign of democracy and little economic blooming. Decision making was centralized in the palace, where the palace secretariat acts as a counter to the entrenched bureaucrats of the central secretariat. The King maintained direct control over the army. The death of King Mahendra in 1972 strengthened pressures for social and political change, and some change appeared inevitable under the rule of King Birendra.

Situated between India's Gangetic Basin and the Tibetan Plateau, Nepal forms a stepping stone to the Indian subcontinent. As India becomes increasingly concerned with the security of South Asia, it has a big stake in assuring that Nepal remains politically stable and at least nonaligned. At present, India and China seem reasonably satisfied with the regime in Nepal or at least not so dissatisfied that they would be prepared to interfere. Should either nation feel that events in Nepal imperilled its interests, however, it would probably take action, for neither can afford to have the other in full control of this Himalayan state.

Historic, religious, cultural, social, and economic ties all bind Nepal more closely to India than to China. The only Hindu kingdom in the world, it naturally feels affinity with India. Yet precisely the strength of these ties stirs resentment, and since 1960 Nepal has attempted to balance India's influences by seeking a close relationship with China. Balance has been sought through nonalignment in the disputes between India and China that characterized the 1960s and early 1970s and through a process of political and economic diversification that was intended to modify Nepal's close economic and historic relationship to India. Neither policy has been a total success. Nepal's capacity to act independently remains limited, although the range of freedom allowed to Nepal has expanded.

Ties with India and China

Change is, nevertheless, slowly taking place, as the efforts made during the 1950s and 1960s begin to generate a process of modernization. Nepal's strategic location, as already mentioned, has prompted aid from many countries. India has a substantial aid program that supplies about US $13,000,000 annually; China's aid program, on the other hand, has been modest. The United States, for its part, has provided heavy financial support to encourage both economic development and the gradual growth of democratic institutions. Much of the foreign assistance, however, has not left an imprint on the national level; there is little evidence that the total of more than US $200,000,000 of aid from the United States, extended between the 1950s and 1970, has produced any significant improvement in the standard of living of any but a small minority of Nepalese people. **(P.P.K.)**

Nepal, History of

Nepal's name is derived from the Valley of Nepal, or Kāthmāndu. The country's rich prehistory consists mainly of legendary traditions of the Newar community, which inhabits the valley area.

Prehistory and early history. There are usually both Buddhist and Brahmanic Hindu versions of these various legends. Both are accepted indiscriminately in the festivals associated with these events—a tribute to the remarkable synthesis that has been achieved in Nepal between two related but divergent value systems.

References to Nepal Valley and Nepal's lower hill areas are found in the ancient Hindu classics, suggesting that the central Himalayan hills were closely related culturally and politically to the Gangetic Plains at least 2,500 years ago. Lumbinī, Gautama Buddha's birthplace in Nepal, and Nepal Valley also figure prominently in Buddhist accounts. There is substantial archaeological evidence of an early Buddhist influence in Nepal, including a famous column inscribed by Aśoka (emperor of India, 3rd century BC) at Lumbinī and several shrines in the valley.

A coherent dynastic history for Nepal Valley becomes possible, although with large gaps, with the rise of the Licchavi dynasty in the 4th or 5th centuries AD. Although the Kirati dynasty, which had ruled the valley for the preceding 800 years, had claimed Kṣatriya (ruler and warrior) caste status, the Licchavis were probably the first ruling family in that area of Indian (*i.e.*, plains) origin. This set a precedent for what became the normal pattern thereafter—Hindu kings claiming high-caste Indian origin, ruling over a population that was neither Indo-Aryan nor Hindu in ethnic origin.

The Licchavi dynastic chronicles, supplemented by numerous stone inscriptions, are particularly full from AD 500 to 700; a powerful, unified kingdom emerged in Tibet during this period, and the Himalayan passes to the north of the valley were opened. Extensive cultural, trade, and political relations developed across the Himalayas, transforming the valley from a relatively remote backwater into the major intellectual and commercial centre between South and Central Asia. Nepal's contacts with China began in the mid-7th century with the exchange of several missions. But intermittent warfare between Tibet and China terminated this relationship; and while there were briefly renewed contacts in subsequent centuries, these were re-established on a continuing basis only in the late 18th century.

Medieval period. The medieval period in Nepali history is usually considered coterminous with the rule of the Malla dynasty (10th–18th centuries). Although most of the Licchavi kings had been devout Hindus, they had not imposed Brahmanic social codes or values on their non-Hindu subjects; the Mallas perceived their responsibilities differently, however, and the great Malla ruler Jaya Sthiti, who reigned early in the 15th century, introduced the first legal and social code strongly influenced by contemporary Hindu principles.

The Malla dynasty

Jaya Sthiti's successor, Yakṣa Malla (reigned *c.* 1429–*c.* 1482), divided his kingdom among his three sons, thus creating the independent principalities of Kāthmāndu, Patan, and Bhatgaon in the valley. Each of these states controlled territory in the surrounding hill areas, with particular importance attached to the trade routes northward to Tibet and southward to India—these were vital to the valley's economy. There were also numerous small principalities in the western and eastern hill areas, whose independence was sustained through a delicate balance of power based upon traditional interrelationships and, in some cases, common ancestral origins (or claims thereto) among the ruling families. By the 16th century, virtually all of these principalities were ruled by dynasties claiming high-caste Indian origin whose members had fled to the hills in the wake of Muslim invasions of northern India.

In the early 18th century, one of these principalities—Gorkha, ruled by the Shah family—began to assert a predominant role in the hills and even to pose a challenge to Nepal Valley. The Mallas, weakened by familial dissension and widespread social and economic discontent, were no match for the great Gorkha ruler Prithvi Narayan Shah. The Gorkha ruler conquered the valley in 1769 and moved his capital to Kāthmāndu shortly thereafter, providing the foundation for the modern state of Nepal.

Modern period. The Shah rulers faced tremendous and persistent problems in trying to centralize an area long characterized by extreme diversity and ethnic and regional parochialism. They established a centralized political system by absorbing dominant regional and local elites into the central administration at Kāthmāndu. This action neutralized potentially disintegrative political forces and involved them in national politics; but it also severely limited the centre's authority in outlying areas because local administration was based upon a compromise division of responsibilities between these local elites and the central administration.

The Shah dynasty

Throughout most of the modern period, Nepali politics has been characterized by a confrontation between the royal family and several noble families. The position of the Shah dynasty was weakened by the fact that from 1775 to 1832 three minor kings sat on the throne in succession. The regents and the nobility competed for political power, using the young rulers as puppets; both factions wanted a monopoly of political offices and power for their families, with their rivals exterminated, exiled to India, or placed in a subordinate status. This was achieved by the Thapa family (1806–37) and, on an even more extensive basis, by the Rana family (1846–1951). In these periods the Shah ruler was relegated to an honorary but powerless position, while effective authority was concentrated in the hands of the leading members of the dominant family. Although intrafamilial arrangements on such questions as the succession and the distribution of responsibilities and spoils were achieved, no viable national political institutions were created. The excluded noble families thus had only two alternatives—to accept inferior posts in the administration and army or to conspire for the overthrow of the dominant family. Until 1950, and to some extent thereafter, Nepali politics was basically conspiratorial in character, with familial loyalty taking precedence over loyalty to the crown or nation.

External relations. Prithvi Narayan Shah (reigned 1742–75) and his successors established a unified state in the central Himalayas and launched an ambitious and remarkably vigorous program of expansion, seeking to bring the entire hill area, from Bhutan to Kashmir, under their authority. They made considerable progress, but successive setbacks in wars with China and Tibet (1788–92), with the Sikh kingdom in the Punjāb (1809), with British India (1814–16), and again with Tibet (1854–56), frustrated Nepal and set the present boundaries of the kingdom.

The British conquest of India in the 19th century posed a serious threat to Nepal—which expected to be another victim—and left Kāthmāndu with no real alternative but to seek an accommodation with the British to preserve Nepal's independence. This was accomplished by the Rana family regime after 1860 on terms that were mutually acceptable, if occasionally irritating, to both. Under this de facto alliance, Kāthmāndu permitted the recruitment of Nepalis for the highly valued "Gurkha" units in the British Indian Army and also accepted British "guidance" on foreign policy; in exchange, the British guaranteed the Rana regime against both foreign and domestic enemies and allowed it virtual autonomy in domestic affairs.

The Rana family

Contemporary politics. The British withdrawal from India in 1947 deprived the Ranas of a vital external source of support and exposed the regime to new dangers. The Ranas quickly evolved a new foreign policy, under which Nepal's traditional isolation policy—vigorously enforced until then—was abandoned and relations were established for the first time with several other governments as a counterbalance to the new democratic Indian regime. Meanwhile anti-Rana forces, composed mainly of Nepali residents in India who had served their political apprenticeship in the Indian nationalist movement,

formed an alliance with the Nepali royal family, led by King Tribhuvan, and launched a revolution in November 1950. With strong diplomatic support from New Delhi, the rebels accepted a settlement with the Ranas, under which the sovereignty of the crown was restored and the revolutionary forces, led by the Nepali Congress, gained an ascendant position in the administration.

The introduction of a democratic political system in Nepal, a country accustomed to autocracy and with no deep democratic tradition or experience, proved a formidable task. A constitution was finally approved in 1959, under which general elections for a parliament were held. The Nepali Congress won an overwhelming victory and was entrusted with the formation of Nepal's first popular government. But persistent controversy between the Cabinet and King Mahendra (whose reign began in 1955) led to the dismissal of the Nepali Congress government in December 1960. The 1959 constitution was abolished in 1962, and a new constitution was promulgated, making the crown the real source of authority. King Mahendra obtained both Indian and Chinese acceptance of his regime, and the internal opposition was weak, disorganized, and discouraged. Mahendra died in January 1972 and was succeeded by his son, Birenda.

The reign of King Mahendra

In the early 1970s there was substantial dissatisfaction with some aspects of the country's political and economic system, and Katmandu was the scene of anti-government rioting in August 1972.

(L.E.R.)

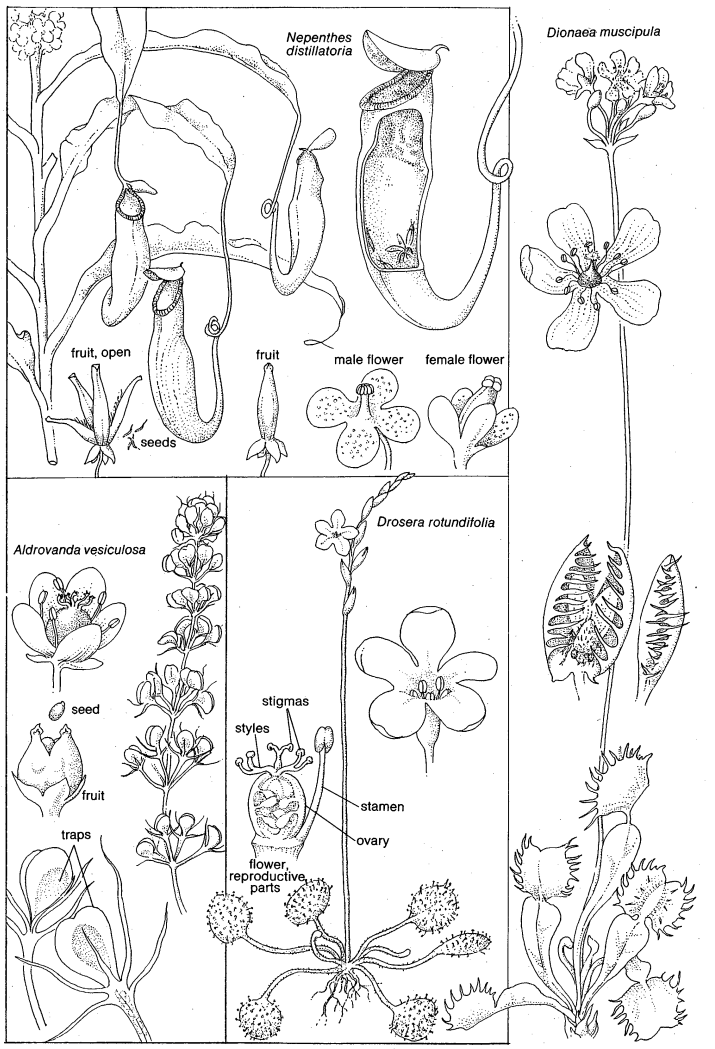
Nepenthales

The flowering plant order Nepenthales consists of two families, the Old World pitcher plants or monkey cups (family Nepenthaceae) and the sundews and Venus's-flytrap (family Droseraceae). All of the approximately 180 species have leaves that are ingeniously adapted as pitfalls and traps to capture insects and other tiny animals, digest them, and absorb the nutrients.

The family Nepenthaceae contains the single but large pitcher-plant genus *Nepenthes*. Its approximately 80 species are found in wet tropical forests from Ceylon and Madagascar to New Guinea and northern Australia. All of the species capture insects by means of pitcher-shaped leaves that function as pitfalls. The prey is attracted to the large showy leaves by nectar, and it slips from a treacherous lip into the pitcher-like hollow leaf, which in reality is a cistern of digestive liquid from which there is no escape.

The family Droseraceae contains species with leaves modified as real traps, active mechanisms that clamp shut or coil about victims lured by nectar secretions and delicate odours. The principal genus is *Drosera* (the sundew), with about 100 species, which together have a distribution in virtually all parts of the world. Three other genera each contain a single species. *Dionaea muscipula*, the Venus's-flytrap, is a narrowly distributed Atlantic North American endemic (a native species restricted to one region). *Drosophyllum lusitanicum* is an unusual sundew narrowly endemic to the Atlantic European area. *Aldrovanda vesiculosa* is a wide-ranging aquatic plant in the Old World.

Drawing by M. Pahl



Representative plants of the order Nepenthales. (Upper left) Family Nepenthaceae. (All others) Family Droseraceae (see text).

GENERAL FEATURES

Size range and diversity of structure. The species of *Nepenthes* are quite uniform in general appearance and, by comparison with other known plants, stand clearly by themselves. The sizes and shapes of the pitchers are characteristic for each species, although there may be as many as three distinct pitcher forms in a single species. The pitchers are colourful and are often mistaken for flowers. The plant typically is a coarse vine that grows over vegetation, sometimes climbing to the crowns of 50- to 60-foot (15- to 20-metre) trees.

The Venus's-flytrap has jawlike leaf blades, which dominate the vegetative aspect of the plant and are capable of clamping shut with amazing speed when properly stimulated.

The most common sundews are low, herbaceous (nonwoody) plants consisting of a slender rhizome, or rootlike stem, crowned by a rosette of sticky leaves that snare insects. The small, often tiny leaves are densely covered

The sundew plants

with slender, sensitive tentacles capped by globular red glands that secrete a highly viscid, clear mucilage. The droplets of mucilage glisten in sunlight, giving the plant a dewy appearance. This explains the generic name *Drosera*, derived from the Greek word for "dewy," and the common name, sundew. Because the clear mucilage magnifies the red gland, the whole plant may appear bright red. Species of *Drosera* vary in height from a few inches (*D. rotundifolia*) to three or more feet (*D. gigantea*).

Drosophyllum lusitanicum is a shrubby plant up to five feet (1.5 metres) tall with linear leaves that remain attached to the plant after they die, forming skirtlike layers around the base of the stem. The leaves are covered with numerous stalked glands bearing large droplets of clear mucilage that give the plant a dewy appearance responsible for the common name dewy pine. These glands are not capable of movement as in *Drosera*, but vast numbers of gnats and flies adhere to them, and, because of this, the plant is sometimes called flycatcher.

Although widespread and unusual, the inconspicuous *Aldrovanda vesiculosa* is not well-known except among the few botanists who specialize in carnivorous plants. *Aldrovanda* is a small freshwater plant that floats just below the surface of quiet waters, and its tiny steel-trap leaves function as in the Venus's-flytrap (*Dionaea*) except that the lobes are not hinged. In the "set" position, these leaf traps suggest a widely opened clam or mussel. The whole plant, however, is only four to six inches (ten to 15 centimetres) long and barely an inch across, including the spreading leaves.

Distribution and abundance. The geographic range of the pitcher plants radiates from Borneo, particularly around Mt. Kinabalu in Sabah (East Malaysia), where the most striking species occur. Some 20 species have been reported from the island. About 12 species occur on the adjacent island of Sumatra; eight to ten species are found in the Philippines and in northern Australia. The extremely light seeds seem to be well adapted for wind dispersal, which may explain the distribution in radial manner from Borneo as the focal point. Many of the species, such as those in Madagascar and Ceylon, are relatively local endemics. *Nepenthes phyllamphora*, on the other hand, ranges from southeastern China to New Guinea and has close relatives in northern Australia. Several other species (*N. ampullaria*, *N. gracilis*, *N. rafflesiana*) are less widespread but relatively wide-ranging.

The 100 or more species of *Drosera* are distributed primarily in the Southern Hemisphere. Half of them are found in Australia and New Zealand, the centre of greatest diversity of the genus. Southern Africa is second as a centre of speciation. Only a few species occur in the north Temperate Zone, among them two circumboreal ones (*D. anglica* and *D. rotundifolia*) and one nearly circumboreal species (*D. intermedia*). Only these three species are found in Europe and Soviet Asia, although in temperate North America there are four additional well-marked species (*D. brevifolia*, *D. capillaris*, and *D. filiformis* of the southeastern states and *D. linearis* of the northern states and Canada).

Distribution of the Venus's-flytrap

Dionaea, the Venus's-flytrap, is endemic to the Atlantic Coastal Plain from Beaufort County, North Carolina, to the south bank of the South Santee River, Charleston County, South Carolina. Within this highly restricted range, the flytrap tends to occur in widely scattered colonies but may be abundant locally. *Drosophyllum* is native only to northern Morocco and southern Spain and Portugal. By contrast, *Aldrovanda* ranges from Atlantic Europe to India and Japan and south to Mozambique (East Africa) and Australia.

Economic importance. The pitcher plants, sundews, and especially the Venus's-flytrap have always been valued as objects of curiosity, but they have never accounted for more than an insignificant element of the horticultural trade. Otherwise, the order Nepenthales is of little or no economic importance except on a local basis.

NATURAL HISTORY

Life cycle. Except for some annual species of *Drosera*, the plants of this order are perennial (*i.e.*, they grow for several years). In *Nepenthes* most species are caulescent (stemmed) and shrubby; in the Droseraceae the acaulescent (stemless) herbaceous habit predominates. Apart from a new crop of fine fibrous roots produced each year from the rhizome, few if any true roots are present. In some species of *Drosera*, the seedling has a short-lived taproot that functions while the earliest leaves are forming but never elongates. *Aldrovanda* is rootless and floating, and some species of *Nepenthes* are epiphytes, plants that grow upon the branches of other plants.

The stem is rudimentary or relatively short in most species of the Droseraceae, but in *Nepenthes* it may elongate considerably into a vine. The young *Nepenthes* stem is densely clothed with leaves, but the internodes (stem sections between leaf attachment points) lengthen with increasing age. When lying on the ground the stems of some species (*e.g.*, *N. ampullaria*) may root abundantly at the nodes (points of leaf attachment) and produce dense clusters of leaves with reduced blades and richly coloured pitchers. Two or three types of pitchers may be formed on the same plant at different heights on the stem and seem to function like flowers in attracting insects. Some species of *Drosera* have climbing stems as in *Nepenthes*, and some form tubers (enlarged underground stem structures) by which they overwinter to produce new shoots the following season. The tuber-bearing species have no roots. In the common sundew (*D. rotundifolia*) the stem dies off behind as the plant grows, and in winter the rosette is reduced to a tight bud that may have no measurable stem or root; successively, a series of dead rosettes forms. *Aldrovanda* produces new shoots each season from a persistent terminal bud. The temperate perennial species of the Droseraceae all go through a period of winter dormancy.

The flowering period of *Nepenthes* in the wild, though extended and inconstant for many species, is mainly from March to September. Under cultivation in the Northern Hemisphere *Nepenthes* blooms from August to October. The inflorescences (flower clusters) attract clouds of insects to sip on the nectar secreted abundantly by the flowers, which are cross-pollinated by insects. The male flowers give off a fetid odour that probably attracts insects. After pollination the fruits, containing 100 to 500 seeds per capsule, mature in six to eight weeks.

The common sundew, which is representative of north temperate species of *Drosera*, sends up a slender, arching flower stalk in early summer or later. The flowers open one at a time in sunlight, for one morning each. They are bisexual and pollinate themselves after closing if cross-pollination has not taken place while they are open. The single flower stalk of the Venus's-flytrap is produced in late May, June, or early July. Each flower remains open about three days, and the ripe pollen is shed before the stigmas (pollen receptive surfaces of the female flower parts) are receptive. The seeds are shed as early as mid-July.

Modes of reproduction

The seeds of *Nepenthes* germinate readily within five to six weeks after ripening in loose, moist habitats, such as humus or sphagnum moss. *Drosera* reproduces easily by seed, exhibits remarkable powers of vegetative regeneration, and in some species also reproduces prolifically by asexual means. Several species, including *D. pygmaea*, reproduce by brood bodies, or gemmae (small clusters of vegetative cells that break off and grow into new plants); in Australia, reproduction by tubers is common. The underground tubers are important as stored food and water reserves for the plant to use during the dormant season when the rosette leaves are not present. Some species (*e.g.*, *D. rotundifolia*) have strong axillary buds (buds located in the angles between leafstalks and stems) that form secondary rosettes below the main one; as the stem decays, these are separated and propagate the plant. The formation of plantlets by adventitious budding, especially from the leaves but also from the roots and inflorescence, rivals seed reproduction in this genus.

In *Dionaea* seeds germinate immediately in the summer, and they are viable in nature only for a relatively short period of time. High humidity and loose organic matter on a sandy surface are required for germination. As in

Drosera, regeneration from vegetative parts or the immature inflorescence is possible.

In *Nepenthes* hybridization, or cross-fertilization between different species, is common in cultivation and also takes place in the wild. All of the cultivated species have been hybridized, and the hybrids are highly fertile. As a result, many interesting artificial hybrids now exist in cultivation.

Carnivorous adaptations. *Trapping mechanisms.* The pitchers of *Nepenthes* are conspicuously supplied with glands that attract prey. Insects, particularly ants, are lured to the mouth of the pitcher by numerous nectar glands scattered over the stems and leaves, including the tendrils and the inner surface of the lid. An insect that successfully negotiates the peristome (corrugated lip of the pitcher) loses footing on the crumbly, waxy surface lining the upper half of the interior of the pitcher and drops into the pitcher. The surface of the digestive region in the lower part of the pitcher is crowded with more than 6,000 digestive glands per square centimetre.

All species of *Drosera* capture their prey by means of flexible tentacles on the upper surface of the leaf. As many as 400 tentacles have been counted on a leaf of the common sundew, which is about one centimetre in diameter. These tentacles really are stalked glands with globular heads that secrete a clear, sticky mucilage. When a midge, gnat, or mosquito lands on the leaf, the alluring mucilage becomes the first snare, smearing and smothering the insect. The struggling insect stimulates further secretion. Within minutes the inner tentacles bend over and gradually pin down the insect. Soon the outer tentacles, which become successively longer toward the edge of the leaf, also begin to curl inward. In a matter of minutes or hours, depending on the species and amount of stimulation, the insect is hopelessly engulfed by a web of sticky stalks.

Tentacle movement in the sundew

Bending and unbending of the tentacles are caused by differential rates of rapid growth. When the outer cells of the tentacles grow faster than the inner ones, incurving results. The tentacles straighten again when the inner cells grow faster than the outer ones. As a growth response, the action of the tentacles has limits; the bending and unbending can be repeated only about three times by any one tentacle. The action of the tentacles is slow compared to the trapping mechanism of the Venus's-flytrap, and the sundew can catch only small or very weak prey; flies and even ants are able to escape. After a few days to a week, digestion is completed, the leaf reopens, resetting the trap, and the remains of the previous victim fall off or are washed or blown away.

The trapping mechanism of *Drosophyllum* involves glandular tentacles like those of *Drosera*, but the tentacles do not move. The insect becomes caught among the copious sticky glands in much the same way as it might be stuck by flypaper.

In the Venus's-flytrap, *Dionaea*, the blade of the leaf consists of two lobes hinged to each other like the jaws of a steel trap and provided with spinelike teeth along the margins. On the face of the lobes are numerous nectar and digestive glands. The digestive glands, which secrete very actively when prey is captured, contain a red sap giving the entire surface a bright red and flowerlike appearance. In the middle of each lobe are three pressure-sensitive hairs that trigger trap closure when properly stimulated. Two or more stimuli are required to spring the trap, the number depending on the time intervals between the stimuli. Two stimuli are sufficient if the second comes not less than 1.5 seconds nor more than 20 seconds after the first. The same trigger hair may be struck twice or two hairs may be struck once each. If the stimuli are spaced over a period of five to six hours, as many as 18 to 20 separate stimuli may be required. When stimulated, the trap springs shut with amazing speed, usually in about a half second at normal daytime temperatures. The minimum closing time recorded is 80 milliseconds, less than one-tenth of a second. If prey is captured, the clamping movement continues slowly until the surfaces of the lobes press tightly against the body and the marginal teeth enmesh. The more times the hairs are stimulated, the tighter the leaf closes; thus, a struggling insect inside the trap causes the trap to close more tightly. A fly caught one afternoon may still be struggling the next morning; but, in the meantime, the trap will have contracted so tightly that the fly's form shows through the trap lobes. If no insect is caught, or if the insect is tiny and is able to escape between the teeth, the leaf reopens in five to ten hours. Otherwise the trap remains closed for seven to ten days or even longer. After having captured three or four victims, the trap has matured completely and dies.

In the aquatic *Aldrovanda* the trapping mechanism is similar to that of the Venus's-flytrap, although the trap is tiny by comparison. The number of stimuli required to trigger the trap depends on the age of the leaf. Small insects, larvae, copepods, and other tiny animals that spring the trap are locked into an ovate hollow formed when the two lobes snap together, a movement requiring only 1/50 of a second.

Digestive mechanisms. The pitchers of *Nepenthes* secrete a quantity of enzymatic fluid before opening, and, after opening, secretion is stimulated greatly by the presence of animal victims. The fluid contains a weak acid in addition to proteinase, the main enzyme, which breaks down protein. Bacteria live in the mature pitchers and help to break down the animal compounds. Under high temperatures digestion is accomplished in two to eight hours. The nitrogenous end products are then absorbed through the walls of the pitcher.

Bacteria and enzymes in digestive fluid

When an insect becomes stuck on the leaf of a sundew and struggles to get free, the tentacles are stimulated to secrete a digestive enzyme that breaks down the proteins in the insect body. In *Drosophyllum*, enzyme secretion is continuous, and the digestive cycle does not have a well-marked beginning and end.

Most of the upper surface of the leaf in *Dionaea* (*i.e.*, the inside of the trap) is covered with up to 50 sessile (stalkless) glands per square millimetre; the glands secrete a digestive fluid containing proteinase and formic acid after the trap has closed on an insect or other digestible victim. Digestion begins within 36 hours after trap closure and continues for about ten days.

Aldrovanda has glands lining the lobes of the trap that release digestive juices after the trap springs shut. The end products are absorbed by the plant, and the trap may reopen several times after feeding if the catches have been meagre.

Animals that exploit leaf traps. The pitchered leaf of *Nepenthes* constitutes a special habitat with both wet and dry ecological niches, and certain insects and other small animals have adapted to these niches. They may exploit the pitcher for food, shelter, or as a place to pass part of their life cycle. In some instances, the animal takes advantage of the trap by robbing the plant of its own victims; in other instances, the plant tissue itself is parasitized.

Adaptation to the pitcher-plant environment has become so specific in some cases that the animals have lost their ability to complete a life cycle elsewhere. Several species of spiders occur only in the pitchers of *Nepenthes*, in which they live in the mouth above the water level and prey on insects attracted to the pitchers. More than two dozen species of the insect order Diptera (flies) are known to occur exclusively in the aquatic environment of the pitchers; two-thirds of these species are mosquitos.

Many animals have been recorded as accidental or occasional inhabitants of *Nepenthes* pitchers, especially in the creeping species (notably *N. ampullaria*), in which the pitchers stand half buried in the forest floor. These include protozoans, slime molds, desmids (a group of green algae), diatoms, rotatoria, oligochaetes (worms), crustaceans, larvae of various flies, and even an occasional tadpole. In Sabah the small rodent *Tarsius spectrum* visits the pitchers of various species, perches on the margin, bends its head and neck into the opening, and scoops out and devours the insects caught there.

A few animals are able to inhabit the sundews (*Drosera*). A moth larva of the family Noctuidae feeds on the glandless portions of the plant, and certain Australian bugs of the order Heteroptera (family Capsidae) move

about the sticky leaves without apparent harm or difficulty, sucking the juices of ensnared victims. In Florida, the larva of the moth *Trichoptilus parvulus* (plume moth) has been discovered on the leaves of *Drosera capillaris*. It eats the stalked glands with their sticky secretion, the leaf blades, and even trapped dead insects.

Ecology. *Nepenthes* is a vinelike jungle plant (liana) that creeps over the ground or climbs on the trees of tropical swamp or rain forests. The genus ranges in altitude from sea level to 10,000 feet (3,000 metres), and only rarely does it grow in other than moist or very moist habitats. Around Mt. Kinabalu in Sabah, where the distribution of the group is centred, the species show a distinct zonation in their altitudinal distribution. Some species (*e.g.*, *N. gracilis*) grow at low elevations on the hot humid plains; others (*e.g.*, *N. ampullaria*) grow commonly at 2,000 to 2,300 feet (600 to 700 metres); still others (*e.g.*, *N. rajah*) reach the 5,000- to 10,000-foot (1,500- to 3,000-metre) zone where clouds or rain are always present, and they are exposed almost continuously to a cool, dripping wet environment. No species of pitcher plants occur between the 10,000-foot level and the 13,700-foot (4,200-metre) summit of Mt. Kinabalu. At least one species inhabits wet savannas (grassland areas with scattered trees), where it climbs on shrubs; the genus is even known to occur on dry, sandy hillsides.

Altitudinal distributions of pitcher plants

The species of the family Droseraceae typically inhabit damp heaths, bogs, swamps, wet savannas, or sandy shores, showing a marked preference for wet habitats with acid soil in which nitrogen and other nutrients are deficient or unavailable. The flycatcher (*Drosophyllum*) of the western Mediterranean region is an exception to the wet-habitat rule; this coarse, wiry sundew grows on dry, gravelly (quartz) hills, where, nevertheless, the soil is acidic.

In North America, the sundew (*Drosera*) is one of the first plants to invade newly disturbed habitats such as roadside ditches and abandoned logging trails. The bright red rosettes often cover the ground. Many of the species thrive best in habitats where sphagnum is growing. Several species of *Drosera* are often found in the same habitat. *Drosera anglica* and *D. rotundifolia* occupy swamps but always in the parts of the swamp most deficient in salts. Most *Drosera* species grow in poor soils. The soil of a pine forest, for example, contains some 27 times more nitrogen than a *Drosera* habitat. The sundew is among the earliest appearing inhabitants of raw peat surfaces, which are a nutrient-poor habitat. Too much calcium in the soil may be toxic to *Drosera* plants. The poor-soil generalization does not apply necessarily to all of the many species of *Drosera* in the Southern Hemisphere; in fact, at least one species of southern Australia (*D. whittakeri*) grows on wooded slopes among general vegetation.

Venus's-flytrap thrives in a habitat transitional between wet evergreen-shrub bog (pocosin) and dry sandy longleaf-pine savanna on the Atlantic Coastal Plain of the United States. The plants tend to grow along the edges of wet depressions and pools, often in company with pitcher plants of the genus *Sarracenia*, sundews, and butterworts (*Pinguicula*). Occasional burning helps to maintain this limited pineland in the scrubby, semi-savanna condition. Thus fires, far from being the enemy of the flytrap, actually may be required for its continued existence.

Aldrovanda grows in shallow quiet water between the stems of such marsh plants as cattails (*Typha*), reeds (*Phragmites*), and wild rice (*Zizania*).

Carnivory, the adaptation for digesting animal prey, is the most important aspect of the ecology of the species in this order; it has enabled the plants to occupy otherwise unavailable niches.

FORM AND FUNCTION

The *Nepenthes* plant consists of a creeping rhizome from which arises a coarse, leafy stem that climbs over trees and other vegetation by means of its modified leaves, which may attain a length of three to ten feet (one to three metres). The expanded, tongue-shaped or round blade of the thick, glossy leaf narrows to a long tendril that twines around other plants and is always coiled except in the short upright or creeping species of the genus. The tendril has enormous strength and, in some species (*e.g.*, *N. rafflesiana*), may support as much as 13 pounds (six kilograms) of weight without breaking. The tendril finally becomes transformed at its tip into a pitcher that always is held upright and cannot function otherwise. The pitchers vary considerably in form even on the same plant; they may be tubular, cylindrical, urn-shaped, funnel-shaped, ovoid, goblet-shaped, or globose. In most species, but noticeably in the cylindrical ones, the upper one-third of the pitcher, corresponding to the inner waxy zone, is somewhat constricted. Pitchers range from the size of a thimble to that of a pint jar or larger (up to 20 inches, or 50 centimetres), but commonly they are four to six inches (ten to 15 centimetres) long. The colour usually varies, even on the same plant, from yellow green to dark green with all degrees of red marking, depending on age, light exposure, and soil conditions; sometimes, however, the pitchers are a uniform pale green or deep red. When red occurs on the rim (lip), it forms stripes. The rim of the pitcher is fluted, and the corrugations strengthen the lip and help to keep the mouth from collapsing. This corrugated structure, known as the peristome, is a conspicuous feature of nearly all species. An immobile lid (operculum), formed by an outgrowth of the leaf, may overhang the mouth and help to keep out rain, or it may be small, narrow, and turned back. The under surface of the lid and the corrugations of the lip are supplied copiously with nectar glands except in a few species.

Specialized structure of pitcher plant leaves

The small greenish or claret-coloured flowers of *Nepenthes* are borne in clusters at the tips of stems opposite leaves; as few as 15 to 20 and as many as several hundred flowers may be produced in one inflorescence. The flowers are noteworthy chiefly because they are unisexual, and the male and female flowers, unlike those of other carnivorous plants, are found on different plants (*i.e.*, *Nepenthes* is dioecious).

Drosera species vary from a few inches to three or more feet in height. The smallest often are hidden among the mosses in a sphagnum bog. Among the North American species, which are herbaceous and stemless, there are three main leaf forms: oval or round (*D. rotundifolia*); spoon-, club-, or strap-shaped (*D. intermedia*); and threadlike or wirelike (*D. filiformis*). The leaves of the wide-ranging common sundew resemble tiny mittens or baseball catcher's gloves. The well-known sundews of the Northern Hemisphere usually produce one to 20 erect flowers on a single, leafless flower stalk that is six to eight inches (15 to 20 centimetres) long or occasionally up to a foot (30 centimetres) or more long. The flower, measuring an inch or less across, is bisexual and regular (radially symmetrical); its five petals are white to pink or even deep red, the colour depending on the species. Some species of *Drosera* from the Southern Hemisphere bear their flowers on leafy stems.

Flowers of the sundew

The Venus's-flytrap has a single flowering scape (leafless stalk) up to a foot high. The two to 15 bisexual white flowers measure about one inch across and are similar to those of *Drosera*. The leaf is divided into a blade and a prominently winged petiole (stalk), narrowing at the base of the blade. The blade consists of two identical semicircular lobes united along the middle by a thick midrib and standing at an angle of about 50° to each other; the lobes constitute the hinged trap. The outer margin of each lobe is provided with a comb of long bristles, about 13 in number, that interlock like fingers when the trap closes. The leaf is from two to six inches (five to 15 centimetres) long and about an inch or two across. The plants are bright red when growing in strong sunlight, but green if in shade.

EVOLUTION AND CLASSIFICATION

Evolution. The fossil record of the order is extremely limited and does little to illuminate the evolutionary history. Speculations on the phylogenetic relationships, which have been based on comparative studies of the modern species of the order, have resulted in divergent

views. Although there is no common view on the origin of carnivory among the flowering plants, authorities now agree that the carnivorous plants represent several more or less unrelated lines of evolution.

Phylogenists who accept the concept of the order Nepenthales as defined here, comprising the families Droseraceae and Nepenthaceae, believe that it probably evolved from the order Saxifragales. Most authorities now are convinced on the basis of floral morphology that the family Droseraceae is closely related to the Saxifragaceae, especially that part of the family sometimes segregated as the separate family Parnassiaceae.

Traditionally, the families Droseraceae and Nepenthaceae were thought, on the basis of leaf morphology, to form a natural group with the Sarraceniaceae (New World pitcher plants), because of the obvious vegetative transitions between the two pitcher-plant families (Sarraceniaceae and Nepenthaceae). Some authorities still hold to this view, choosing to place more weight on the evidence from leaf morphology than from floral morphology. At issue, primarily, is the evolutionary position of the Nepenthaceae, about which there is little agreement. The family Droseraceae clearly is more advanced than the Sarraceniaceae, and the two should not be placed in the same order (see SARRACENIALES). The members of the family Nepenthaceae are closely knit and clearly have evolved from a common ancestor. One line of phylogenetic reasoning places the Nepenthaceae in an order by itself that stands between the evolutionary positions of the Droseraceae and Sarraceniaceae but somewhat closer to the latter; another interpretation has placed Nepenthaceae in the order Aristolochiales (*q.v.*; a group that includes the pitcher-like Dutchman's pipe). Evidence from pollen and ovule morphology, however, now indicates a close affinity between the Nepenthaceae and the Droseraceae and at the same time casts doubt on the supposed affinities of the Old World pitcher plants with the Aristolochiales or Sarraceniales.

Differing opinions on the evolutionary position of pitcher plants

Classification. *Distinguishing taxonomic features.* The Nepenthales is distinguished from other orders chiefly by the characteristics of the distinctive insect-trapping leaves and, to a lesser extent, by features of the inflorescence and flower, particularly pollen features. The main characteristics for separating the two quite distinct families are the habit and size of plant; form and arrangement of leaves; presence of unisexual or bisexual flowers; presence or absence of differentiated petals; number of carpels (ovule-bearing segments of the pistil, or female structure); number, form, and fusion of styles (narrow, upper part of pistil); and number and fusion of stamens (male pollen-producing structures).

Annotated classification. The classification presented here departs from the traditional one and places the Droseraceae and the Nepenthaceae in an order by themselves, apart from the Sarraceniales. Whatever the degree of their affinity may be, these two families superficially do not show much morphological similarity. To the casual observer their chief similarity is functional—the carnivory of their leaves.

ORDER NEPENTHALES

Plants stemmed or stemless, annual or perennial, herbaceous or somewhat shrubby, with alternate leaves specialized in various ways for trapping insects and other tiny animals. Flowers unisexual or bisexual, radially symmetrical, with sepals only or sepals and petals. Stamens few to many, free or more or less fused. Pistil 1, positioned above the other flower parts (superior), with 3 to 5 fused carpels (ovule-bearing segments), the ovules few to numerous. Fruit usually a capsule. Seeds small, few to numerous. Two families, 5 genera, and about 180 species distributed worldwide; concentrations of species occur in Borneo (*Nepenthes*) and Australia (*Drosera*).

Family Droseraceae (sundew family)

Annual or usually perennial, glandular-hairy, stemless herbs or rarely subshrubs. Leaves usually in basal rosettes, both surfaces (except in *Dionaea*) generally covered with sticky, gland-tipped hairs and sensitive tentacles that enmesh small insects. Flowers bisexual, mostly with 5 sepals and 5 petals. Stamens 5 to many, free or nearly so, in whorls of 5. Ovary 1-chambered (occasionally 3- to 5-chambered), with 3 to 5 carpels; styles 3 to 5, free, often divided. Fruit a capsule. Seeds 3 to many, spindle-shaped. Four genera (*Aldrovanda, Dionaea, Drosera,* and *Drosophyllum*) and about 100 species, ranging throughout the world from temperate to tropical regions.

Family Nepenthaceae (pitcher-plant family)

Perennial, herbaceous or usually shrubby, stemmed plants, often climbing by their leaves, anchored in the soil or growing as epiphytes upon other plants, often forming vinelike lianas. Leaves with a winged or expanded portion followed by a constricted, often coiled tendril terminated by hanging but upright, cylindrical or urn-shaped, often highly coloured, insect-trapping, pitcher-shaped structures with a lid (operculum). Flowers unisexual, with usually 4 distinct, nectar-producing sepals (in 2 whorls of 2 each). Petals absent. Male flowers with 4 to 24 stamens fused into a column. Female flowers with single pistil that has a 3- or 4-carpelled and 3- or 4-chambered ovary; style 1, short to absent, with 4 stigmas. Capsule leathery. Seeds numerous, with long terminal wings, very small. One genus (*Nepenthes*) with about 80 species distributed in the tropics from northeast India to Australia and New Caledonia; concentrated in Borneo and Sumatra and reaching also to the Seychelles (1 species) and Madagascar (1 species).

Critical appraisal. The many species of the family Nepenthaceae, despite their sometimes striking variation, are, by comparison with other plants, so morphologically homogeneous that they have always been placed in the single genus *Nepenthes*; the cohesiveness of the family never has been challenged seriously. The family Droseraceae, with several strikingly different types of traps, is by contrast a heterogeneous family of four vegetatively distinct genera, which, however, show a close affinity to each other on the basis of floral morphology. Some authorities have treated the bizarre Venus's-flytrap (*Dionaea muscipula*) as a separate, monotypic (single species) family, Dionaeaceae, although this view is defensible only if vegetative morphology is stressed at the expense of flower structure.

The question of the closeness of relationship between the Old World pitcher plants (family Nepenthaceae) and the New World pitcher plants (order Sarraceniales) will remain unresolved until more is known about the evolution of the pitchered leaves in *Nepenthes*, on the one hand, and *Heliamphora* (family Sarraceniaceae), on the other hand. New worldwide monographic studies are needed to determine the number of species in the large genera *Drosera* and *Nepenthes*.

Neptune

Neptune, symbol ♆ in astronomy, is the eighth planet from the Sun and, until Pluto was discovered in 1930, was the outermost known planet in the solar system. Its mean distance from the Sun is almost exactly 30 astronomical units (1 a.u. = the mean distance of the Earth from the Sun). Neptune will, in fact, be the most distant planet from the Sun for about two decades after 1979, when Pluto will be near its point of closest approach to the Sun, inside Neptune's orbit.

Neptune, being only as bright as a star of the eighth magnitude, is invisible without optical aid. The image it forms in a telescope of moderate aperture shows a sensible disk of a slightly greenish hue and about 2″.3 in diameter. Physical data for Neptune are given in Table 1.

Table 1: Physical Data for Neptune

Mean distance from Sun	$4{,}486.10^6$ km (30.1 a.u.)
Eccentricity of orbit	0.011857
Inclination of orbit to ecliptic	1° 46′ 34″
Sidereal period of revolution	$60190^d.0$ (164.8 years)
Rotation period	$15^h.8$
Albedo	0.84
Mean synodic period	$367^d.49$
Mean orbital velocity	5.44 km/sec
Mean daily motion	0° .005981
Inclination of equator to ecliptic	28° 48′
Mass (Earth = 1)	17.46
Diameter (including atmosphere)	50950 km
Density	1.54 gm/cc
Apparent magnitude	+7.8
Satellites	2

Discovery. The detection of Neptune through its action upon Uranus is one of the fascinating stories in the history of astronomy, and a striking example of the precision of the theory of planetary motions. Before its actual discovery by the English astronomer Sir William Herschel in 1781, Uranus had been observed as a fixed star on at least 17 other occasions, first by the English astronomer John Flamsteed in 1690. The French astronomer Alexis Bouvard, in 1820, constructed tables of the motions of Jupiter, Saturn, and Uranus; the observed positions of Jupiter and Saturn were represented satisfactorily but he found it impossible to do this for Uranus. During the next two decades there was continued divergence between the theory of perturbations, describing how the known planets should alter slightly one another's motions, and the observations. The idea of an ultra-Uranian planet occurred to Bouvard, the German astronomer and mathematician Friedrich Wilhelm Bessel, the U.S. astronomer William Joseph Hussey, and others. At Mannheim, the German astronomer Friedrich Bernhard Gottfried Nicolai decided that a planet beyond Uranus could account for the apparent inconsistency between older and more recent observations of Halley's Comet.

Bessel, in 1842, announced his intention of investigating the problem of the motion of Uranus. Unfortunately, he died before much had been done. Meanwhile an English astronomer, John Couch Adams and a French astronomer, Urbain-Jean-Joseph Le Verrier, were also tackling the problem energetically.

Adams, at St. John's College, Cambridge, began serious work in 1843 and by September, 1845, had communicated his results to the English astronomer James Challis at Cambridge, and the following month to the Astronomer Royal, Sir George Biddell Airy. Adams said that his calculations would account for the irregularities in the motion of Uranus by the action of an exterior planet whose orbital elements were tabulated. The position of the exterior planet, as derived from Adams' work, was later found to be so close to the true value that two evenings of assiduous searching should have been sufficient to locate it. Adams also demonstrated that the observations of Uranus from 1780 onwards were in good agreement with his theory. Instead of looking for the unknown planet, however, Airy did no more than to ask, in a reply, whether the assumed perturbations would also explain the known error in the calculated distance of Uranus from the Sun.

Meanwhile Le Verrier in France, working on similar lines had published the results of his thorough mathematical investigations in a communication to the French Academy of Sciences on November 10, 1845. A second memoir was presented by Le Verrier on June 1, 1846.

The close agreement between the elements found by the two investigators is clear from the tabulated values (see Table 2) and led Airy to suggest to Challis, on July 9, 1846, that a search for the unknown planet should be made with the Northumberland telescope, then at Cambridge Observatory. Challis commenced on July 29, sweeping each region twice, so that a comparison of the two sets of observations would then reveal the unknown planet by its motion. It subsequently transpired that Challis observed the planet on August 4 but failed to compare his observations with those of the previous night.

Table 2: Orbital Data According to Le Verrier and Adams

elements	Le Verrier	Adams	
		hypothesis I	hypothesis II
Semimajor axis (a.u.)	36.154	38.38	37.27
Eccentricity	0.1076	0.16103	0.12062
Longitude of perihelion	284° 45′	315° 57′	299° 11′
Mean longitude	318° 47′	325° 08′	323° 02′
Epoch	1847, Jan. 1	1846, Oct. 1	1846, Oct. 1

On August 31, Le Verrier's final paper was presented to the French Academy and on September 18 he wrote to the German astronomer Johann Gottfried Galle at Berlin suggesting that he should search for the planet, with the hope of distinguishing it from a star by its disklike appearance. On September 23 the planet was located at the first attempt by Galle and the German astronomer Heinrich Louis d'Arrest, not by its disklike appearance but by the absence of an observed starlike body from one of the new star charts prepared at the observatory.

Controversy over the credit for Neptune's discovery

The question whether Le Verrier should receive the sole credit was warmly discussed by French and British astronomers; Adams and Le Verrier took no part in the controversy. Arago went so far as to suggest that the new planet should be named Le Verrier, but this was received with such little favour outside France that he withdrew it, proposing Neptune instead.

The mathematical methods employed in the solution of the problem and, in particular, the choice of the value of the semimajor axis of the orbit have been questioned. At the date of its discovery Neptune was only 1° from the place predicted by Le Verrier and about 2½° from the place predicted by Adams. However, it has since been shown that it was fortunate that the search was made around the middle of the 19th century, because if the orbit worked out by Adams had been used for a search in 1770, then Neptune would have been nearly 30° from its predicted place, and not much less if Le Verrier's orbit had been used. Figure 1 shows how sharply the true and predicted places would have diverged after 1850–60. Recent work on the orbit of Neptune has provided a new value for the mass of Pluto; the revised values for six defining quantities (elements) of the closest elliptic orbit are given in Table 3.

Appearance. The great distance and relative faintness of Neptune make it exceedingly difficult for any details to be observed, even with large telescopes. Limb darkening, or dimming of the image near its edge, is pronounced. A few markings have been noted, but these are so vague that it has not been possible to determine a rotation period from such observations.

Neptune is seen by light reflected from the Sun and its slight greenish hue is due to absorption of the red, orange, and yellow solar rays by its extensive atmosphere. Strong absorption bands in the infrared region of the spectrum were identified in 1932 as being due to methane (CH_4); some unidentified bands at a wavelength of about 7500

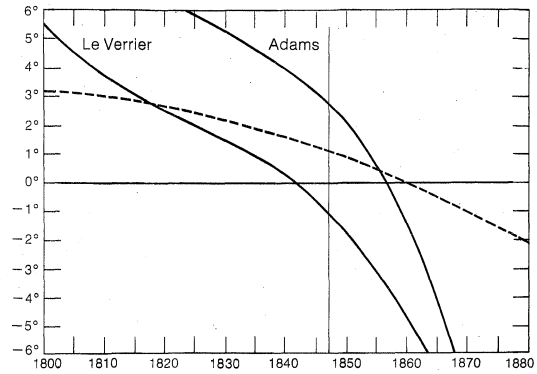

Figure 1: Curves of amounts by which orbits of Adams, Le Verrier, and circular-orbit solution (dashed curve) differ from true position of Neptune. The vertical marks the date of discovery, 1846 (see text).
From R.A. Lyttleton, *Mysteries of the Solar System* (1968); Clarendon Press, Oxford

angstroms, near the deep red end of the visible spectrum, were found by the U.S. astronomer Gerard Peter Kuiper in 1949. It is inferred, though not observed, that the most abundant gases in the atmosphere are hydrogen and helium. A temperature of −205° C has been derived for the atmosphere, and this is in fair agreement with measurements at the Nançay Radio Observatory in France, which gave an upper limit to the disk temperature of −223° C. Observations with the 43-metre (140-foot) radio telescope at the National Radio Astronomy Observatory, Green Bank, West Virginia, indicate that Neptune emits radio waves as if its black-body disk temperature were −193° C ±40° C. For such measurements the planets are considered black bodies in the physicist's sense of the term, meaning they freely absorb and emit radiation of all wavelengths. As the indicated temperature for Neptune is higher than that expected for a planet at Neptune's distance from the Sun, these measures suggest the retention of solar heat under some layer of Neptune's atmosphere (as by the glass panels of a greenhouse), or, another possibility, a strong source of internal heating.

Temperature of Neptune

Table 3: Elements of Neptune's Orbit

Mean anomaly	133° 44' 09".783
Perihelion	270° 03' 30".833
Ascending node	131° 16' 41".893
Inclination	1° 46' 33".651
Eccentricity	0.0118570458
Semimajor axis	29.9871290465

Constitution. The constitution of the planet can only be obtained from theoretical considerations, since the extensive cloudy atmosphere precludes direct observation. Its physical constitution is probably similar to those of Jupiter, Saturn, and Uranus. It has been calculated that there is a rocky core about 20,000 kilometres (12,000 miles) in diameter enveloped in an ice layer 10,000 kilometres (roughly 6,000 miles) thick, with a gaseous envelope 3,000 kilometres (roughly 2,000 miles) deep.

Rotation. In 1928, a rotation period now generally accepted of $15^h{\cdot}8 \pm 1^h{\cdot}0$ was obtained from spectroscopic observations. Light from the portion of the rotating planet moving toward the observer is shifted toward the blue end of the spectrum, while light from the receding part of the surface is reddened. Photographic and visual observations indicated periodic variations in brightness, attributed to rotation, but photoelectric observations have shown no evidence of variation of brightness. The degree of flattening at the poles, caused by the planet's rapid spin, is estimated to be $\frac{1}{50}$. This means the equatorial diameter is about 1,000 kilometres longer than the polar diameter.

Diameter. The U.S. astronomer Edward Emerson Barnard, in 1899, used a filar micrometer—in which two wires or threads are aligned with the edges of the planet's image—to measure the angular diameter directly. The planet's distance being known, the linear diameter was determined as 52,900 kilometres (32,900 miles). The value is still used in astronomical ephemerides today. G.P. Kuiper at the McDonald Observatory in 1949, obtained a value of 44,600 kilometres (27,700 miles). In 1953, a double-image micrometer measurement by the U.S. astronomer Henri Camichel yielded a value of 45,000 kilometres (28,000 miles). These two latter results were in good agreement but differ noticeably from the value given by Barnard. Limb darkening may introduce some uncertainty in the angular measures and a change of only 0".1 in angular measure is equal to a linear change of about 2,000 kilometres (1,200 miles).

Measurements of Neptune's occultation

Successful efforts have been made to derive the diameter from observation of the occultation of a star (its disappearance and reappearance behind the moving planet) from several different places on the Earth. Because of the slow motion and small angular size of the planet such occultations are quite rare. A comparison of the ephemeris of the planet with star catalogs was performed annually from 1952 onward, but the first predicted occultation did not occur until April 7, 1968. Fortunately, the event was successfully observed photoelectrically at observatories in Australia, New Zealand, and Japan (see Figure 2).

From G. Taylor, *Monthly Notices of the Royal Astronomical Society* (1970)

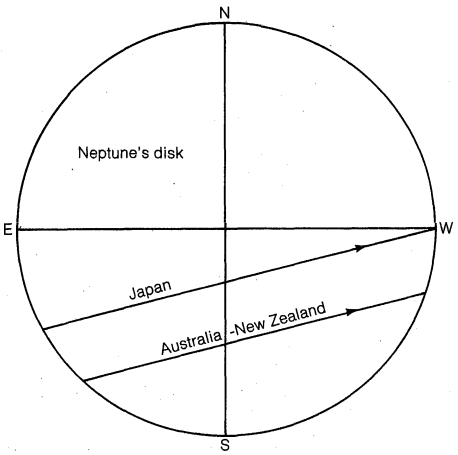

Figure 2: Tracks of star BD-17° 4388 behind disk of Neptune on April 7, 1968. The star was obscured for about 45 minutes for Japanese observers, about 40 as seen from Australia and New Zealand. At the time, the planet's distance from Earth was 2,700,000,000 miles (4,300,000,000 kilometres).

Observations from these countries were highly consistent with each other and an analysis of them yielded two main results: (1) an extremely accurate position of the centre of Neptune relative to the occulted star (the difference in declination at the time of conjunction being determined to an accuracy of better than 0".01); and (2) a new value for the diameter of the planet. Two solutions were made, one assuming Neptune to be a sphere, the other assuming it to be an oblate spheroid. There was little to choose between the two solutions, the value using an oblate spheroid having only a slightly smaller standard deviation. The value quoted for the equatorial diameter of the oblate spheroid was 50,950 kilometres ± 170 kilometres (which included an extra 110 kilometres as a correction for the deflection of light in a gravitational field). This value corresponded to the height at which the first photoelectrically detectable dimming of light occurred and in this sense could be taken as the upper limit of the atmosphere.

With this value for the diameter, the density is 1.54 g/cm^3, close to the value currently given for Uranus, namely 1.56 g/cm^3.

Satellites. Neptune has two satellites, Triton and Nereid. Triton, the larger and brighter of the two was discovered visually by W. Lassell, using a 60-centimetre (24-inch) telescope at Liverpool, England, in 1846, within a month of the discovery of the planet itself. It was originally assumed that Triton revolved around Neptune in the same direction as the planet's rotation, implying that Nep-

tune's north pole pointed south of the ecliptic, like that of Uranus (in those days no retrograde satellites were known). In 1928, however, careful spectroscopic work at Lick Observatory, California, showed that Neptune rotated in the direct sense unlike Uranus; so Triton moved round Neptune in the retrograde direction, opposite to that of Neptune's spin. The orbit of Triton is circular and was seen edge-on from the Earth in 1953. The apparent diameter of Triton has been measured as 0″.173 at a distance of 30·1 a.u. Nereid was discovered photographically by G.P. Kuiper in 1949, using the 208-centimetre (82-inch) McDonald telescope in Texas. The value of the diameter is only an estimate based on its apparent magnitude and an assumed albedo (the fraction of light reflected from the surface).

Discovery of Nereid

Table 4: Satellite Data

	Triton	Nereid
Apparent magnitude	13.5	18.7
Mean distance from Neptune (km)	355,000	5,562,000
Mean sidereal period	$5^d.877$	$359^d.881$
Inclination of orbit to Neptune's equator	159° .9	27° .7
Eccentricity of orbit	0.000	0.749
Diameter (km)	3,700	300
Reciprocal mass (Neptune = 1)	750	?
Density (water = 1)	5.1	?

The orbital plane of a satellite around a spherical planet would be fixed in direction, apart from an extremely slow change produced by the action of the Sun. As the plane of Triton's orbit is changing noticeably with time it may be deduced that Neptune is not spherical but is an oblate spheroid, flattened at the poles, indicating rapid rotation. The degree of flattening thus obtained is $\frac{1}{50}$.

A mathematical investigation of the orbits of the satellites has led to the suggestion that Triton could have been drawn in from a highly elliptical or even parabolic orbit, and that this may have caused the high eccentricity of Nereid's orbit. According to these calculations, Triton is getting nearer to Neptune and is expected to approach and collide with the planet or, more likely, to disintegrate at a close approach and form a ring system.

Searches for other satellites indicate that any other satellite in the range 16″–10″ from the planet would have to be fainter than a photographic magnitude of 22·5 to remain undetected. Farther out the limit is altered to magnitude 19 or 20. Closer than 10″ to the planet the limit is brighter because of the glare of Neptune itself.

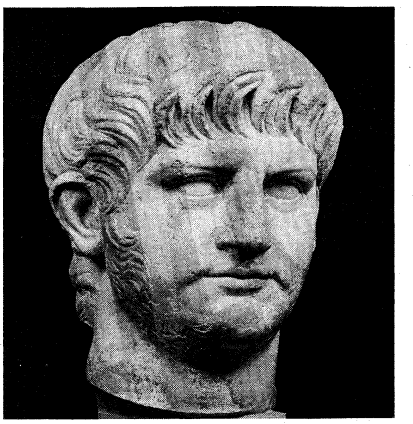
NEWCOMB, *Investigation of the Orbit of Neptune* (1866); R.L. DUNCOMBE, W.J. KLEPCZYNSKI, and P.K. SEIDELMANN, "Orbit of Neptune and the Mass of Pluto," *Astron. J.*, 73: 830–835 (1968); R.A. LYTTLETON, *Mysteries of the Solar System* (1968), with a chapter on the history of the discovery and a discussion of the orbits; G.E. TAYLOR, "The Occultation of B.D.-17° 4388 by Neptune on 1968 April 7," *Mon. Not. R. Astr. Soc.*, 147:27–33 (1970), gives a new value for the diameter of the planet.

(G.E.T.)

Nero

History has branded the Roman emperor Nero with the reputation of being a monster of cruelty and has also credited him, on doubtful evidence, with the burning of Rome and the first persecution of the Christians. His appalling family background, stained as it was with incest and murder, no doubt accounted for his instability of character. This displayed itself in the unbounded vanity that caused him to nurse artistic and histrionic pretensions that seriously undermined his imperial dignity and helped to bring about his early death and, with it, the extinction of the Julio-Claudian line, which had descended from Julius Caesar. Proclaimed when he was not yet 17, he was the first boy emperor.

Nero was born Lucius Domitius Ahenobarbus in AD 37 in Rome. His father died in about AD 40, and Nero was



Nero, portrait bust by an unknown artist. In the Museo Nazionale Romano, Rome.
Anderson—Alinari

brought up by his mother, Agrippina the Younger, a great-granddaughter of the emperor Augustus. After poisoning her second husband, Agrippina incestuously became the wife of her uncle, the emperor Claudius, and persuaded him to favour Nero for the succession, over the rightful claim of his own son Britannicus, and to marry his daughter Octavia to Nero. Having already helped to bring about the murder of Valeria Messalina, her predecessor as the wife of Claudius, in 48 and ceaselessly pursuing her intrigues to bring Nero to power, Agrippina eliminated her opponents among Claudius' palace advisers, probably had Claudius himself poisoned in 54, and completed her work with the poisoning of Britannicus in 55. Earlier, Nero had passed his childhood under the menace of the mentally deranged emperor Caligula (Gaius Caesar), his mother's brother, until Caligula was murdered and succeeded by Claudius.

Agrippina's intrigues

Promising start. Brought up in this kind of atmosphere, Nero might well have begun to behave like a monster upon his accession as emperor in 54 but, in fact, behaved quite otherwise. When he was required to sign a death warrant for the first time, he cried "Why did they teach me how to write?" The testimony of his contemporaries depicts Nero at this time as a handsome young man of fine presence but with soft, weak features and a restless spirit, entirely under the influence of his terrifying mother, whom he censured and feared while he adored her. His first speech to the Senate was universally praised as heralding a new Golden Age. Up to the year 59 his biographers cite only acts of generosity and clemency on his account. Indeed, the measures he instigated were those of a wise and virtuous man: he forbade contests in the circus involving bloodshed, banned capital punishment, reduced taxes, and accorded permission to slaves to bring civil complaints against unjust masters. He pardoned writers of epigrams against him and even those who plotted against him, and secret trials were few. More independence was granted to the Senate. The law of treason was dormant: Claudius had put 40 senators to death, but, between the murders instigated by Agrippina in 54 and the year 62, there were no like incidents in Nero's reign. He inaugurated competitions in poetry, in the theatre, and in athletics as counter-attractions to gladiatorial combats. He saw to it that assistance was provided to cities that had suffered disaster and at the request of the Jewish historian Josephus gave aid to the Jews. In all this, he was pursuing an intention that the philosopher Seneca, his old tutor and now his adviser, considered as mad—to remain innocent of any crime.

Artistic pretensions and religious mania. Although it must be admitted that his nocturnal rioting in the streets was a scandal as early as 56, the emergence of real brutality in Nero can be fixed in the 35-month period between the putting to death of his mother at his orders in 59 and his similar treatment of his wife Octavia in June 62. He was led to the murder of Agrippina by her insanity and her fury at seeing her son slip out of her control, to the murder of Octavia by his having fallen in love with Pop-

Affair with Poppaea

paea Sabina, the young wife of the senator (and later emperor) Otho, and by his fear that his repudiated wife was fomenting disaffection at court and among the populace. He married Poppaea in 62, but she died in 65, and he subsequently married the patrician lady Statilia Messalina.

Nero gave rein to inordinate artistic pretensions. He fancied himself not only as a poet but also as a charioteer and lyre player, and in 59 or 60 began to give public performances; later he appeared on the stage, and the theatre furnished him with the pretext to assume every kind of role. He dreamed of abandoning the empire in order to fulfill his poetical and musical gifts, saying "They would adore in me what I am." But this puerile ambition did not suffice, and another, more dangerous inspiration took hold of him: "No one has known all that a prince could do," he said, desiring now to create God. This form of insanity was nevertheless in keeping with the messianic spirit of the age: all peoples—Jews, Greeks, Syrians, Romans, and even Indians and Chinese—were waiting for the new god. From about 63 or 64 Nero was drawn to preachers of novel cults, to Zoroastrian mages, esoteric Judaists, to such men as the Gnostic magician Simon Magus, the Neopythagorean sage Apollonius of Tyana, and perhaps even to St. Paul, who is depicted in a fresco from the Palatine Chapel conversing with the Emperor. His predecessors Caligula and Claudius had shown interest in Eastern religions, but Nero was to go further than they did. Obsessed by the mystery-religion symbols of the sea and the fish, he became a devotee of the Syrian virgin-mother Atargatis, to whom the fish was sacred, then of the virgin-mother Juno-Canathos; the ecstasy that seized him in the Temple of Vesta in 64 showed that there was no limit to his bizarre delirium. Taking advantage of the fire that ravaged Rome in that year, he had the city reconstructed in the Greek style and built the most prodigious palace that a man had ever consecrated to the new god—the fabulous Golden House, which, had it been finished, would have covered a third of Rome. During the fire Nero was at his villa at Antium 35 miles (56 kilometres) from Rome and therefore cannot be held responsible for the burning of the city. Nor, despite the apocryphal additions made centuries later to the *Annals* of the Roman historian Tacitus and to the *Nero* of Suetonius, the Roman biographer and antiquarian, should he be charged with the first persecution of the Christians, because there were then so few Christians in Rome. Paul had just arrived in the city, and the Jews were anxious to learn from the Apostle the nature of this new sect, proof enough that no one had yet told them about it. Nero corresponded with Tiridates, the Armenian prince, and learned the religion of Mithra from him. He gave himself up to debauches and vice but also imposed the wearing of the white toga and had the floral festivals of the Field of Mars transformed into sacred proceedings.

The Golden House

The approaching end. The imperial government had had some success in the east. Their general, Gnaeus Domitius Corbulo, was able to impose an advantageous settlement on Armenia, which had long chafed under Roman suzerainty. Rome now recognized the Armenian ruler Tiridates, but he was compelled to come to Rome to receive his crown from Nero. This secured Armenia as a buffer state against Parthia, Rome's implacable foe in the east. Nevertheless, the provinces were increasingly uneasy, for they were oppressed by exactions to cover the imperial court's extravagance. A revolt in Britain was headed by Queen Boudicca (Boadicea) in 60 or 61, and an insurrection in Judaea lasted from 66 to 70. Nero had many antagonists by this time. The great conspiracy of the Piso family in 65 reveals the diversity of his enemies —senators, knights, officers, and philosophers. The Emperor did not give way to panic; the slaves kept him out of danger by warning him of plots hatching among their masters. And he did not altogether abandon his lenient attitude. Out of 41 conspirators, only 18 died (including Seneca and the poet Lucan), either by order or from fear; the others were exiled or pardoned. At the end of the year 66 he undertook a long visit to Greece, the "country of the gods," which was to keep him away from Rome for 15 months, and during his absence he entrusted the consulate to one of his freedmen. He freed Greek cities in honour of their glorious past, suppressed the pagan gods, and went everywhere garbed as an ascetic, barefoot and with flowing hair. He returned to Rome to establish there the worship of Apollo in his manifestation as the dolphin god, to free slaves, and in his own way to instruct the young nobles, to distribute money among the people, and to surround himself with "priests of the sea" (followers of Neptune).

Visit to Greece

In the four months following his return (from February to June of 68) these delirious actions aroused the enmity not only of the Christian Jews, who called him the Antichrist, but also of the Senate and the patricians, whom he insulted openly, and especially the great Roman families who had been dispossessed by him. Even the soldiers of the legions were scandalized to see the descendant of Caesar publicly act the parts of ancient Greek heroes and re-create in Greek fashion the legend of a saviour born of a virgin-mother (Canathos). "I have seen him on stage," Gaius Julius Vindex, the legate who rebelled against him, was to say, "playing pregnant women and slaves about to be executed."

At the news of revolts brewing throughout the empire —that of the provincial governor Servius Sulpieius Galba in Spain, the rebellion of Vindex at Lyons in Gaul (France), and others on the eastern frontier—Nero only laughed. Instead of taking action, he composed hymns and had hydraulic organs made. Arming his priestesses with light shields, he said "I have only to appear and sing to have peace once more in Gaul." Meanwhile, the legions made Galba emperor, and the Senate condemned Nero to die a slave's death: on a cross and under the whip. The Praetorian Guard, his palace guard, abandoned him, and his freedmen left to embark on the ships he kept in readiness at Ostia, the port of Rome. He was obliged to flee the city. According to Suetonius, he stabbed himself in the throat with a dagger, and his Christian mistress Acte buried him piously in a white sheet in conformity with his wishes. According to another version (recounted by Tacitus and almost certainly fiction) he reached the Greek islands, where the following year (69) the governor of Cythnos (modern Kíthnos) recognized him in the guise of a red-haired prophet and leader of the poor, had him arrested, and executed the sentence passed by the Senate.

Abandonment and suicide

The emperors Otho and Aulus Vitellius honoured his memory, and the people adored images of Nero for 20 years. The historians Plutarch and Josephus protested against the "calumnies that soiled his memory," but all in vain. Trajan and subsequent Roman emperors execrated his memory, destroyed his works, including the Golden House, as well as the many works in which Lucan, Plutarch, Rusticus, and many other writers commemorated the period of his reign. Under these emperors, Tacitus, Suetonius, and later Dio Cassius wrote the biographies of Nero known today. Lastly, the Christian Church, triumphant under the emperor Constantine I the Great, furthered the legend of Nero as a monster and even added to it in the 15th century by drawing upon the apocrypha of Sulpicius Severus, a Christian ascetic and historian of the early 5th century, to transform Nero into Antichrist, the first executioner of Christians.

BIBLIOGRAPHY. Up to the last century the only accepted sources for Neronian history were the *Annals* and the *Histories* (Book I) of TACITUS, the *Lives of the Caesars* by SUETONIUS, and the *Roman History* of DIO CASSIUS. The monstrous image given of the Roman emperor by these tendentious works was the only one known to all of the dramatists and novelists, from RACINE'S *Brittannicus* to DUMAS' *Acté* and the celebrated *Quo Vadis* of SIENKIEWICZ. The discovery of Nero's oration announcing to the Greek cities their liberation opened the first breach in the legend: MAURICE HOLLEAUX, *Discours prononcé par Néron à Corinthe en rendant aux Grecs la liberté, 28 November 67 J.C.* (1889). A number of Italian studies then appeared questioning the traditional stories about Nero and the burning of Rome, and the first persecution of the Christians. ARTHUR WEIGALL in *Nero, Emperor of Rome* (1930, reprinted 1950), proposed a less sanguinary—and almost amiable—portrait of the Roman emperor. Among the most recent contributions to the rehabilitation of the fifth

emperor of Rome are GEORGES ROUX, *Néron* (1962); GILBERT CHARLES-PICARD, *Auguste et Néron* (1962; Eng. trans., 1966); and JEAN-CHARLES PICHON, *Saint Neron* (1961), republished with commentary, under the title *Néron et le mystère des origines chrétiennes* (1971).

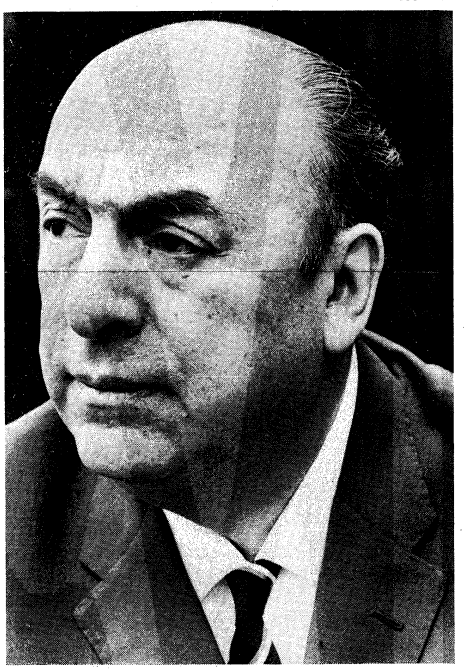
(J.-C.P.)

Neruda, Pablo

One of the most original and fertile poets to write in Spanish this century, Pablo Neruda successfully combined a literary career with a constant concern for the social problems of his time. He has been referred to as "the poet of enslaved humanity." He was awarded the Lenin Prize for Peace, and the Nobel Prize for Literature in 1971, during which time he served as the Chilean ambassador in France.

Neruda was born on July 12, 1904, in Parral, a small town in central Chile, the son of José del Carmen Reyes, a railway worker, and Rosa Basoalto. He was christened Neftalí Ricardo Reyes. His mother died within a month of Neruda's birth, and two years later the family moved to the "new lands" of the south and settled in Temuco, where his father remarried. The boy came to love his stepmother as if she had been his real mother. "In this frontier—or 'far west'—of my country, I was born to life, land, poetry, and rain," Neruda later wrote.

Camera Press—Pix



Neruda.

In 1910 he entered the Temuco Boys' School and completed his secondary schooling in 1920. He began writing poetry when he was ten; some of it was later published (under a pseudonym in order not to annoy his father) in student publications. In 1920 he began using the name Pablo Neruda, which he was legally to adopt in 1946.

When he was 12, Neruda met Gabriela Mistral, the famous Chilean poet who introduced him to the great classic writers who were to influence his choice of career and his political development. He became a militant anarchist and translated the work of Jean Grave, the outstanding theorist of Peter Kropotkin's "anarchist communism."

In 1921 Neruda left Temuco for the capital, Santiago: his immediate goal was to receive his degree in French from the teachers' college, but he found himself devoting more time to his poetry than to his studies. The romantic provincial student invaded the literary life of the Chilean capital with his poet's cape (which had been his father's railroad cape) over his shoulders and wearing a wide sombrero. In October of that year, he won first prize in the Federation of Chilean Students poetry contest with his "La canción de la fiesta," and he began publication of his literary works in the federation's magazine, *Claridad*.

Early poetry

In 1923 his first book, *Crepusculario*, was published at his own expense and financed by selling what furniture he had and the watch his father had given him. The following year he found a publisher for what was to become his most widely read book: *Veinte poemas de amor y una canción desesperada* (1924; *Twenty Love Poems and a Song of Despair*, 1969). The work achieved immediate success and has retained its popularity over the years. Neruda himself was surprised that these poems, written with such pain, have brought consolation to new lovers. "By some miracle which I do not understand, this tormented book has opened the road to happiness for many, many people."

At 20, and with two books published, Neruda became one of the best known Chilean poets. He abandoned his French studies and devoted himself entirely to poetry. He wrote *Tentativa del hombre infinito* ("Attempt of the Infinite Man"); *Anillos* ("Rings"), in collaboration with Tomás Lago; and *El hondero entusiasta* ("The Enthusiastic Slingshooter").

In 1927 he was named honorary consul in Rangoon, Burma, and for the next five years he represented his country in Asia. From Rangoon he went to Colombo, Ceylon, Batavia (modern Jakarta), Java—where he married his first wife, a Dutch girl, Maria Haagenar—and Singapore. He attended the "Pan Hindu" Congress in Calcutta. His books recalling these trips are full of pleasant anecdotes—moving, but sometimes pathetic; his life at the time was one of loneliness, relieved only by his romance with a Burmese girl, Jossie Bliss. It was during these years in South Asia that he wrote *Residencia en la tierra* (*Residence on Earth*). In 1933 he was named Chilean consul in Buenos Aires, where he began a friendship with the Spanish poet, Federico García Lorca, who was visiting the city. The following year he was transferred to Barcelona, and later to Madrid, where he was married again, this time to Delia del Carril.

Friendship with García Lorca

With the same impact he had made on his own country's literary life, he entered the European world in which he and his poetry quickly became known. The Spanish poets welcomed him in *Homenaje a Pablo Neruda* ("Homage to Pablo Neruda"), carrying the signatures of representatives of Spain's intelligentsia.

These years of poetic development were interrupted suddenly by the outbreak of the Spanish Civil War in 1936. The execution of his friend García Lorca, the imprisonment of Miguel Hernández, "the blood in the streets," all contributed to the maturing of the Chilean poet's political attitudes. He was to say, "The world has changed, and my poetry has changed. One drop of blood falling on these lines will remain alive in them, indelible like love." He wrote *España en el corazón* ("Spain in the Heart"), which was published during the Civil War in the Republican front lines.

Neruda returned to Chile in 1938 with a group of Spanish refugees. Shortly thereafter, his government sent him to Mexico, where he entered a phase of intense poetic production—much of it determined or inspired by World War II in Europe, and especially by the heroic defense of Stalingrad against the German onslaught. Mexican mural painting also influenced his work at this time.

In 1943 he returned to Chile by sea, receiving a tremendous welcome in every country along the Pacific coast. In 1945 he was elected senator and for the next three years devoted as much time to the problems of his country as he did to his literary career. His political activity was halted, however, when the Chilean government moved to the right. Neruda, a Communist, was forced along with other leftists into hiding. These years of clandestine living proved to be fruitful ones for his writings. He wrote *Canto general* ("General Song"), one of the greatest epic poems written on the American continent. In February 1948 he left Chile, crossing the southern part of the Andes Mountains on horseback and in April attended the Congress of Supporters of Peace in Paris. In June 1949 he visited the Soviet Union for the first time to attend the 150th birthday celebration of Aleksan-

Diplomatic appointment

dr Pushkin. He then visited other parts of Europe and once again went to Mexico. In 1952, after the order to arrest leftist writers and political figures had been withdrawn, he returned to Chile. He married his third wife, a Chilean, Matilde Urrutia.

Although his permanent residence was the Isla Negra on the Pacific, he travelled constantly, visiting, among other places, Cuba in 1960 and the United States in 1966. His poetry was translated into almost every language. He built a house called La Chascona in Santiago on the side of San Cristóbal hill and another in Valparaíso called La Sebastiana. The three houses were notable for their taste and for their collections of ships' figureheads and varied objects collected during his travels.

Political activities

In essence, the poetry of Neruda represents constant change, the kind any man experiences during his lifetime. In his youth, the lyric and erotic *Crepusculario* and *Veinte poemas de amor y una canción desesperada* gave way to the more spiritual *Tentativa del hombre infinito* and *El hondero entusiasta*. Withdrawing from the external world and its creative stimuli into the domain of his inner self, he produced the towering and enigmatic work *Residencia en la tierra*. With this work, he broke with traditional form and created a highly personalized poetic technique, which has become known as *nerudismo*. The poetry he wrote during the Spanish Civil War moved toward a greater realism and awareness of the affairs of the outside world. This accusatory and reality-oriented poetry was followed by the imposing epic *Canto general*, but this grander style was in turn rejected for the more simple themes of a poetry of social criticism.

The variety of his themes and techniques did not decrease *as* he grew older. Love was once again central to *Cien sonetos de amor*, humour to *Estravagario*, and *Memorial de Isla Negra* was a nostalgic autobiography.

Neruda himself confessed that "I will keep on writing a large cyclical poem which has not yet ended because it will only end with the word at the final instant of my life." That life came to an end in Santiago on September 23, 1973.

MAJOR WORKS

POEMS: "La canción de la fiesta" (1921); *Crepusculario* (1923); *Veinte poemas de amor y una canción desesperada* (1924); *El habitante y su esperanza* (1925); *Tentativa del hombre infinito* (1926); *Anillos* (1926); *El hondero entusiasta* (1933); *Residencia en la tierra, 1925–1931* (1933); *Residencia en la tierra, 1925–1935* (1935); *Tercera residencia, 1935–1945* (1947); *Canto general* (1950); *Los versos del Capitán* (1952); *Las uvas y el viento* (1954); *Odas elementales* (1954); *Nuevas odas elementales* (1956); *Tercer libro de las odas* (1957); *Estravagario* (1958); *Navegaciones y regresos* (1959); *Cien sonetos de amor* (1959); *Cantos ceremoniales* (1961); *Plenos poderes* (1962); *Memorial de Isla Negra* (1964); *La barcarola* (1967); *Las manos del dia* (1968); *La espada encendida* (1970); *Las piedras del cielo* (1970).

TRANSLATIONS: *Residence on Earth and Other Poems* (1946); *The Man Who Told His Love* (1959); *Selected Poems of Pablo Neruda* (1961); *The Elementary Odes of Pablo Neruda* (1961), a selection; *The Heights of Macchu Picchu* (1966); *We Are Many* (1967), a selection; *Twenty Poems of Pablo Neruda* (1967); *Pablo Neruda: A New Decade*, ed. by Ben Belitt (1969); *Twenty Love Poems and a Song of Despair* (1969); *Selected Poems*, ed. by N. Tarn (1970).

BIBLIOGRAPHY. The first critical survey of the work of Pablo Neruda was that of AMADO ALONSO, *Poesía y estilo en Pablo Neruda* (1940), which covers his early work and deals in particular with *Residencia en la tierra*. In 1957, two critical works on Neruda appeared—one, by the poet MARIO JORGE DE LLELIS, *Pablo Neruda*; and the other by ROBERTO SALAMA, *Para una crítica a Pablo Neruda*. The Chilean critic RAUL SILVA CASTRO, who deals with the works of Neruda from his childhood on, published a study of Neruda's work, *Pablo Neruda* (1964). MARGARITA AGUIRRE, *Genio y figura de Pablo Neruda* (1964), is the first biography of the man, complete with chronology and details of his life; also published as *Las vidas de Pablo Neruda* (1967), an expanded version with photographs. The excellent Uruguayan critic EMIR RODRIGUEZ MONEGAL has published one of the most interesting books about Neruda: *El viajero inmóvil* (1966). HERMAN LOYOLA, *Ser y morir en Pablo Neruda, 1918–1945* (1967), contains good material relevant to Neruda's childhood and adolescence. Neruda himself published an autobiography in the magazine *O Cruceiro Internacional* (1962); it appeared in 10 consecutive issues and has never been reproduced, even though it is of tremendous value. The second edition of the *Obras completas* of Neruda, under the direction of MARGARITA AGUIRRE, was published in 1968 in two volumes. It contains two of the best collections of studies of Neruda's work, that of HERNAN LOYOLA and that of ALFONSO ESCUDERO; these constitute the best of all that has been published about the author. The Pablo Neruda Foundation, located at the University of Chile, holds both Neruda's library (valuable for its incunabula, first editions, and manuscripts of famous writers) and his collection of shells, which he donated.

(M.Ag.)

Nerve Impulse

Nerve impulses are electrical units of information; carried rapidly by nerve fibres throughout the bodies of multicellular animals, nerve impulses consist of brief (about one-thousandth of a second) electrical events, called action potentials, which occur across the membrane of a nerve fibre in response to a stimulus. Because an action potential travels as a wave of excitation along a nerve fibre, it also may be called a propagated potential. An action potential is conducted along a nerve fibre at speeds that range from one to 100 metres per second, depending on the properties of the fibre and its environment. The characteristics of an action potential are independent of the way in which it is initiated, although the frequency of action potentials conducted along a nerve fibre may vary. A nerve impulse is transmitted from one nerve cell to another at a junction called a synapse; nerve fibres that innervate muscles transmit impulses at regions of contact called neuromuscular junctions.

Impulses normally travel in only one direction, sometimes called the orthodromic direction, along a fibre. If, however, a nerve fibre is stimulated artificially by an electric shock, the fibre will conduct impulses in the opposite, or antidromic, direction. Both orthodromic and antidromic impulses are conducted at the same velocity. If electric shocks are used to stimulate two nerve impulses conducted in opposite directions along a nerve fibre, both impulses stop at the point at which they collide; nerve fibres, therefore, are not two-way communication lines. One-way conduction of impulses along nerve fibres is the basis for their classification according to function. Impulses that arise in sense organs (*e.g.*, eyes) and provide sensory information to the central nervous system (brain and spinal cord) are said to travel in afferent, or sensory, nerve fibres. Impulses that arise in the central nervous system and travel to effector organs (*e.g.*, muscle fibres) are said to travel in efferent, or motor, nerve fibres. Impulses in sensory nerve fibres, therefore, are conducted toward the central nervous system; those in motor nerve fibres, away from it. Action potentials, detectable in nerve fibres when they are conducting information (Figure 1), are not peculiar to nerve tissue; they play an important role in many muscle fibres and also occur in certain excitable plant cells.

This article includes the following topics: the structure

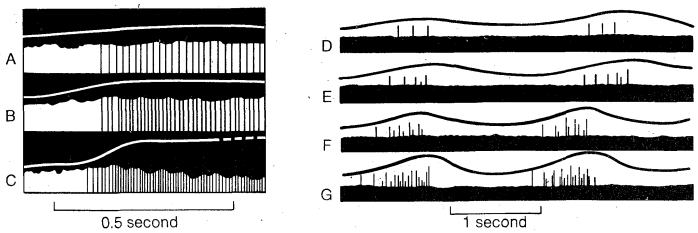

Figure 1: *Electrical impulses in the respiratory nerves of a cat.* (A-C) Sensory impulses traveling from the lungs to the brain in the vagus nerve. White lines indicate the degree of inflation of the lungs. The impulses, recorded with external electrodes from a strand of the nerve trunk, appear as black vertical lines. The deflections produced by the impulses are shown downward and the frequency of the impulses rises as the distension of the lungs is increased. (D-G) Motor impulses traveling to the diaphragm in the phrenic nerve. Upper tracing indicates the respiratory movement; impulses are shown below as upward deflections. One fibre carries the impulses in (D), two in (E) and (F), and three in (G).

of nerve cells, the general features of a nerve impulse, the way in which an action potential originates and is conducted as a result of electric currents it generates, the mechanisms involved in transmitting impulses between cells, and ways by which the nerve impulse is studied.

THE NEURON

Nerve fibres, which are extensions of nerve cells, or neurons, may vary in length from a fraction of a millimetre to a metre or more in a large mammal. Many fibres generally comprise the large nerves found outside the central nervous system and the fibre tracts inside. At the termination of fibre tracts, individual fibres separate and ramify, either to supply effector organs (*e.g.*, muscle fibres) or sense organs (*e.g.*, eyes) or to contact other nerve cells (see NERVES AND NERVOUS SYSTEMS).

Structural features. A neuron (Figure 2A) is a specialized cell consisting of a cell body and fibres. The internal medium (cytoplasm) of a cell body, which may range in diameter from five to 100 microns (one micron equals $\frac{1}{1,000}$ millimetre), contains a nucleus, within which is a smaller structure called a nucleolus, and various other components; *e.g.*, mitochondria, lysosomes, a Golgi apparatus, and Nissl's granules. The nerve fibres extending from nerve-cell bodies are either axons or dendrites; an axon carries nerve impulses away from the cell body; dendrites carry information to it. Both may contain very small fibres called neurofibrils and neurotubules. A nerve cell usually has a single axon, which extends from a raised region known as the axon hillock, and numerous dendrites, which extend from many points on the surface of the cell body. The axon, often the largest nerve-cell fibre, may branch many times, transmitting impulses onward to other nerve cells or conducting impulses to effector cells. In certain nerve cells, particularly sensory neurons, the principal fibre is a dendrite, which transmits impulses from distant sense organs to a cell body located near the central nervous system. The number of fibres extending from nerve cells is used to classify them; *i.e.*, a cell with many dendrites is termed multipolar, a cell with but one dendrite and one axon is termed bipolar (*e.g.*, as found in the retina of the eye, in ganglia of the middle ear, in the olfactory mucous membranes of the nose), and a cell with a single fibre is termed unipolar (*e.g.*, sensory neurons of spinal ganglia).

Axons and dendrites

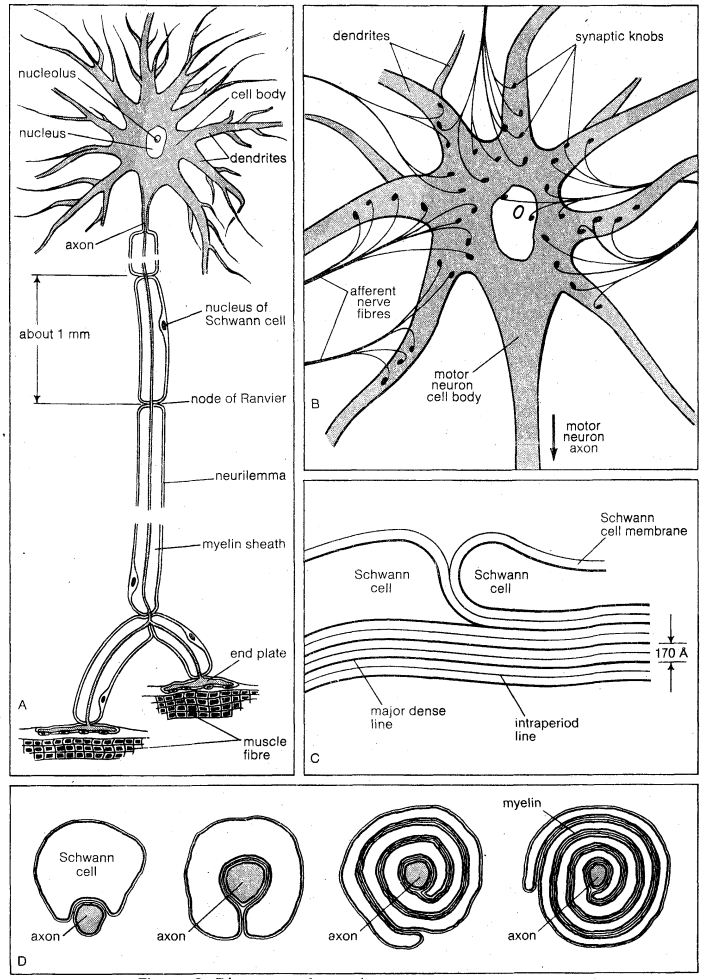

Figure 2: *Diagrams of vertebrate neurons.*
(A) Main features of a myelinated motor neuron. (B) Termination of afferent nerve fibre axons. (C) Outer edge of myelin sheath in transverse section. (D) Stages in formation of myelin sheath.

Myelin. Nerve fibres generally are surrounded by special cells, called Schwann cells, which form a membranous sheath, the neurilemma. The specialized Schwann cells of the large nerve fibres of vertebrates (also prawns and shrimps) wind many times around the fibre to form a multilayered deposit, called myelin, which consists of fatty, or lipid, membranes. Nerve fibres with these lipid-rich membranes are said to be myelinated; those without them, unmyelinated. The myelin in myelinated nerve fibres acts as an insulator, thereby hastening conduction of nerve impulses along them. Gaps occur in the Schwann-cell layer of myelinated fibres at intervals of approximately a millimetre; the gaps, called nodes of Ranvier, result in direct exposure of the nerve-fibre surface to the extracellular space. Although the small nerve fibres of vertebrates (*i.e.*, those with a diameter of less than about one micron) and the nerve fibres in most invertebrates have Schwann cells surrounding the fibres, they lack multiple membranous layers and, thus, are unmyelinated fibres. Nerve-cell bodies lack myelin but are surrounded by supporting cells, known as glia, in the central nervous systems of vertebrates; in invertebrates, the nerve fibres may lack obvious association with specialized supporting cells.

Nodes of Ranvier

The electron microscope reveals the myelin sheath as a repetitive array of dark lines, known as major dense lines, which alternate with less dense lines, called intraperiod lines (Figure 2C). Various stages involved in the formation of the myelin sheath from Schwann cells may be seen in Figure 2D. Myelin is composed of a variety of fatty materials (*e.g.*, cholesterol, cerebrosides, sphingomyelin, and sphingophospholipids), protein, and water. The layer-like character and the orientation of the molecules in myelin enable it to affect the passage of light unequally in different directions; *i.e.*, myelin is birefringent. The myelin sheath is lost at the site of nerve-fibre termination; that is, at sense organs, at effector organs, or against cell bodies and dendrites of other nerve cells (Figure 2B).

Synaptic vesicles. A functional connection between two nerve cells, which allows nerve impulses to be transmitted onward from one cell to the next, is known as a synapse. At a synapse, a nerve-fibre ending swells to form a small, often buttonlike structure covered with the cell membrane; it contains large numbers of small vesicles, called presynaptic vesicles, each about 500 angstrom units in diameter (one angstrom unit [Å] is 10^{-7} millimetre). The fibre, called a presynaptic fibre, is separated from the next fibre, called a postsynaptic fibre, by a space (synaptic cleft) 150 to 200 Å wide. Presynaptic and postsynaptic fibres so close to each other that their membranes appear to fuse are known as tight junctions.

Regeneration. The ability to conduct impulses does not depend on the integrity of a whole nerve cell. Nerve fibres separated from their cell bodies, for example, may retain the ability to be excited for hours or days, even though they begin to degenerate within a short time. The myelin sheath and the nerve fibre eventually swell and disintegrate. The cell body may survive after removal of its largest axon or dendrite, although the Nissl granules disappear for a time. Fibres of neurons outside the central nervous system may regenerate by growth outward from the cell body; this regeneration process, which may restore nerve function, proceeds in man at the rate of about one to two millimetres per day.

CHARACTERISTICS OF ARTIFICIALLY STIMULATED NERVE FIBRES

Effects of stimulation. *All-or-none law.* Although nerve fibres may be excited artificially by any of several methods (*e.g.*, chemicals, mechanical methods), electrical stimulation is the most convenient, the most easily controlled, and the least damaging. A brief electrical shock applied as a stimulus to a nerve fibre must be of a certain strength, called the threshold, in order to excite the fibre and to initiate an action potential. Increases in shock strength above the threshold do not affect either the size or the time course of an action potential; this phenomenon, called the all-or-none law, occurs because the nerve impulse, like the firing of a line of gunpowder, derives its energy locally and not from the initial stimulatory process. For the same reason the action potential does not diminish in size as it is conducted along a nerve fibre; *i.e.*, conduction of a nerve impulse is without decrement. If something is applied at one region of a nerve fibre to modify, but not extinguish, an action potential, the modification affects the action potential only in the region of application, not along the entire fibre.

Concept of threshold

In nerve trunks containing many individual fibres, the compound action potential is graded, because the thresholds of the individual fibres vary; that is, a minimal shock stimulates one fibre, and increases in shock strength cause additional fibres to respond, until all are stimulated, after which the response is independent of increasing shock strength.

Tetanus. Repeated stimuli applied to a nerve fibre, called a tetanus, results in repeated action potentials and the fibre is able to respond to such stimuli for long time intervals without becoming fatigued. The nerve is unlike the junction between a nerve fibre and a muscle fibre in this respect; *i.e.*, the junction generally fatigues more readily than do nerve fibres. If a nerve fibre is stimulated rapidly and repeatedly, the threshold of excitation increases after the first shock; with extremely frequent stimuli (about 1,000 per second), however, some stimuli fail to cause an action potential, indicating that there is a limit to the rate at which nerve fibres can conduct information.

Refractory periods. After an effective stimulus, a nerve fibre is briefly unable to respond to a second stimulus, regardless of its strength; termed the absolute refractory period, this interval lasts about half a millisecond in large mammalian nerve fibres. The absolute refractory period is followed by the relative refractory period, during which the threshold of excitation is abnormally high. Strong electrical shocks are needed to stimulate the nerve during the relative refractory period, and the action potential of a nerve fibre stimulated at this time is small and conducted less rapidly than usual. Later excitability changes are related to small electrical changes (afterpotentials) that occur in a fibre following the action potential.

Latent addition. Although a subthreshold shock applied to a nerve fibre does not stimulate a conducted action potential, it affects the fibre; that is, two stimuli, inadequate if given independently, may, if given in succession, stimulate the fibre by the process known as latent addition. Subthreshold shocks closely approximating the threshold strength cause localized electrical changes in the fibre that are difficult to distinguish from the stimulating current. The indication of the stimulating current on graphic recordings of an artificially induced nerve impulse is known as shock artifact; useful as an initial time marker, it is caused by a slight leakage of charge between the stimulating apparatus and the recording device (see Figure 4C, D). A large shock artifact occurs close to the stimulating electrodes.

Shock artifact

Strength–duration curve. The excitability of a nerve fibre in relation to previously applied stimuli reveals limitations of the rate at which information can be conducted. The conditions required for excitation of a nerve fibre by a single shock, on the other hand, have been studied in attempts to clarify the mechanisms involved in excitation. Usually, the action potential originates at the cathode (negative electrode) as a shock is applied; occasionally, particularly with nervous tissue in poor condition, the action potential begins when current flow ceases, and the anode (positive electrode) is the site of excitation, the effect being called anodal break excitation.

When very brief shocks are applied to a nerve fibre, a minimal quantity of charge must pass to stimulate the fibre. Its amount depends on conditions such as the properties of the fibre and the position of the stimulating electrodes. Indeed, very high frequency currents, in which little charge flows, can be applied to tissues to heat them and to stop bleeding. The minimal current strength needed to stimulate a fibre, regardless of the time it flows, is called the rheobase. When a current stronger than the rheobase passes through a fibre, it flows for a certain time interval, known as the utilization time, before the fibre is excited. A graphic representation of steady current against the time required for that current to excite a fibre is called a strength-duration curve (Figure 3A). Such curves are used to calculate the time required for a current twice as large as the rheobase to cause excitation. This time, known as the chronaxie, has been determined for many types of nervous tissue. Strength-duration curves have the form expected if excitation of a nerve fibre requires a specific change in voltage across a leaky condenser; that is, a change in voltage to a fixed value must be reached in a fibre that accumulates and holds electrical charge but is not perfectly insulated, so that some charge is lost through leakage. Other evidence indicates that the cell membrane acts as a leaky condenser in nerve fibres.

Chronaxie

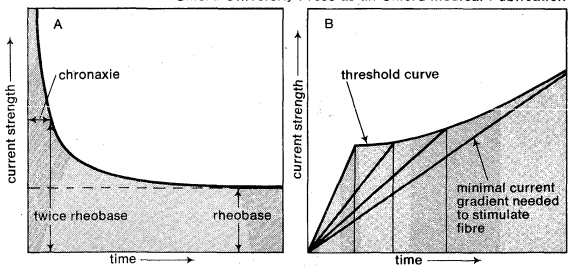

Figure 3: *Requirements for electrical stimulation.*
(A) Strength–duration curve showing threshold conditions.
(B) Illustrates threshold requirements for currents that increase steadily with time. Ordinate is current strength, abscissa is time. Triangular constructions show time course of some currents that achieve threshold conditions (see text).

When slowly increasing, instead of steady, currents are used to excite a nerve fibre, large currents are required before the fibre responds; indeed, if the rate of increase of current strength is sufficiently low, the nerve fibre will never be stimulated, regardless of the final current strength (Figure 3B). The lack of responsiveness of excitable tissue to slowly increasing currents occurs because it adapts to the current, a characteristic called accommodation.

NATURE OF THE NERVE IMPULSE

The nerve impulse or action potential can be detected as it passes electrical connections placed outside the nerve fibre. It then appears as a brief, small, electrically negative wave passing the electrical connections. A much larger electrical charge is noted if one connection is in-

side the fibre; it is then found that the inside of the fibre is electrically negative when it is resting but briefly becomes electrically positive as the action potential passes the electrical connection.

These potentials principally originate from the unequal distribution of ions (charged particles) across the cell membrane. Positively charged potassium ions occur in high concentration within the nerve cell; positively charged sodium ions are in high concentration outside. The ions tend to diffuse away from the regions where they are concentrated.

In the resting state, the membrane allows potassium ions to move out from the cell fairly readily; the membrane is said to be selectively permeable to potassium ions. Because positively charged potassium ions move out of the cell, the contents of the resting cell are electrically negative. The outward movement of potassium ions stops when the electrical potential of the cell is sufficiently negative to overcome the tendency of the remaining potassium to diffuse outward. The size of the electrical potentials generated in this way can be calculated when the concentrations of the ions on either side of the membrane are known (see also MEMBRANE, BIOLOGICAL).

When very small steady changes in the resting potential of a membrane are measured, the membrane behaves as a simple resistance to the flow of current. The nerve fibre acts as an electric circuit equivalent to that of a submarine cable or core conductor; that is, the nerve fibre may be considered as having a core of cytoplasm, which is a good conductor of electricity, surrounded by a membrane, which is a poor conductor and spreads the current along the fibre. Mathematical descriptions of the distribution of weak currents in nerve fibres and their associated voltage displacements are based on these assumptions and give an account of such phenomena.

The core-conductor theory. Although a core-conductor circuit, in which the membrane acts as a simple resistance, can not explain the events that occur during an action potential, it does provide the basis for a well-established theory of the way in which an action potential is conducted. Where the action potential occurs in a nerve fibre, the inside of the fibre is positively charged, and currents flow outward from this zone. The properties of an unmyelinated fibre (*i.e.*, a well-conducting cytoplasm, or core, surrounded by a poorly conducting membrane), ensure the spread of current from the excited region into neighbouring regions of the fibre; the current spreads outward through the membrane in advance of and behind the zone occupied by the action potential. Immediately behind the action potential is a region in which the membrane is in a refractory condition; that is, it cannot be stimulated. The theory, known as the local-circuit theory, states that the local currents ahead of the action potential excite the membrane (Figure 4A), causing the continuous, forward spread of the action potential in unmyelinated nerve fibres.

Saltatory theory

Although the local-circuit theory also applies to myelinated nerve fibres (those surrounded by layers of fatty membranes containing myelin), the process, according to the saltatory theory, is slightly modified. Myelin, a good insulator, covers an entire fibre, with the exception of the gaps (nodes of Ranvier); moreover, only small quantities of charge are stored in the myelinated regions between nodes. Local currents through the fibre membrane occur ahead of an action potential only at a node (Figure 4B). Conduction of an action potential in myelinated fibres, therefore, is a discontinuous process, the active region jumping from one node to the next, thereby hastening conduction.

It follows from the local-circuit theory that the velocity of conduction of an impulse increases if electrical resistance outside or inside the fibre decreases. In unmyelinated fibres, for example, conduction velocity varies directly with the square root of the fibre diameter; in myelinated fibres, it varies with the diameter of the fibre. The relationship between fibre size and velocity of conduction causes a dispersion of impulses when a stimulus is given to a nerve trunk containing fibres with different diameters. As the action potentials are recorded progressively farther from the point of stimulation, fibre types become recognizable; *i.e.*, the action potentials of larger and, therefore, faster conducting fibres reach a given point in the nerve trunk sooner than those of smaller, hence slower conducting, ones.

Arrows show direction of electric currents at a given moment in time. (C, D) Two action potentials recorded across the membrane of a giant squid nerve fibre. In D, the fibre contents were replaced by a solution containing potassium sulfate.

Electrical events. *The resting potential.* Electrodes, usually silver wires coated with silver chloride, arranged to make indirect contact (through a salt solution) with nervous tissue, are used to detect both the action potential associated with excitation and the potential, called a resting potential, that occurs between the inside and the outside of the resting cell. The resting potential is most easily detected after a nerve has been crushed. The crushed region of a nerve is electrically negative with respect to an intact zone, and this, the injury potential, is a representation of the resting potential across the membrane of a nerve fibre. Crushing damages the fibre membranes, exposing the fibre contents to the electrode. The injury potential is less than the value of the resting potential because the fluid in the region between the electrodes reduces the measurement. Techniques other than crushing are used to measure accurately the resting potential of nerves. In one technique, used with giant nerve fibres, long electrodes, consisting of fine glass tubes containing salt solution and wires, are manipulated inside the fibre. In another technique, small electrodes, made from glass capillaries with a very small tip diameter and filled with salt solution, are pushed inward through the side of a fibre or nerve-cell body without causing excessive damage.

The resting potential for nerve fibres and several other types of electrically excitable cells lies in the range of 60 to 95 millivolts, with the inside of the cell negatively charged. If the inside of a cell becomes more electronegative (*i.e.*, if the potential is increased over that of the resting potential), the membrane or the cell is said to be hyperpolarized. If the inside of the cell becomes less negative (*i.e.*, the potential is decreased below that of the resting potential), the process is called depolarization. The action potential occurs as a brief depolarization when the inside of the fibre becomes positively charged. Small potential changes (afterpotentials) often occur after an action potential, before the resting potential recurs; the slow decrease in potential, which sometimes occurs at

the end of the action potential, is termed a negative afterpotential, and subsequent hyperpolarization of the membrane is termed a positive afterpotential. Both positive and negative afterpotentials depend upon previous activity in the fibre and, at least in vertebrate nerve fibres, may cause the increase in threshold that follows the relative refractory period.

The ionic theory. This theory accounts for the origins of the resting and action potentials. The resting cell membrane is relatively permeable to positively charged potassium ions, which tend to diffuse outward from the cell contents, where they occur in rather high concentration. They leave the cell contents negatively charged, thus giving rise to the resting potential. During an action potential (Figure 4C), the inside of a cell becomes electrically positive to the extent of 30–60 millivolts, so that the charge is reversed from that found in the resting nerve cell; an excited membrane does not become permeable to all ions, however, even though a decrease in membrane resistance accompanies the action potential.

The sodium hypothesis

The observation that excitable tissues generally require sodium ions led two nerve cell physiologists, A.L. Hodgkin and Sir Bernard Katz, to postulate that an excited membrane becomes highly permeable to positively charged sodium ions. These are found in small concentration inside fibres; the positive charge inside a cell during an action potential is caused by the entry of sodium ions. Calculations similar to those used to determine resting potentials, but dependent on sodium-ion concentrations rather than those of potassium, can be used to predict fairly accurately the potential (in millivolts) across a membrane at the peak of an action potential. The selectivity of the membrane for sodium ions is not perfect, however, and nerve fibres do not become quite so positive internally as calculations indicate. In accord with the sodium hypothesis, nerve fibres commonly cannot be excited if sodium is removed from the region outside the membrane; however, certain ions (*e.g.*, lithium ions), most of which do not normally occur in significant concentrations in tissues, may substitute for sodium ions, another indication that the increase in membrane permeability is not completely selective for sodium ions.

The sodium hypothesis has been used to predict the increase in the sodium-ion content of nerve fibres following stimulation. The charge required to alter the voltage across a cell membrane by the amount observed during an action potential, about 120 millivolts, can be determined, and the numbers of sodium ions required to carry this charge can then be calculated. In the squid nerve, the number of sodium ions that enter the cell exceeds calculated values by a factor of three, so that sodium ions can account for the change in potential across a stimulated membrane.

Role of potassium ions

If the entry of sodium ions into a fibre were not balanced by the exit of some other ion of similar charge, an action potential could not decline from its peak value and return to the resting potential. The falling phase of the action potential is caused by movement of potassium ions out of the nerve fibre. In squid nerve fibres, stimulation results in a loss of potassium ions from the cell approximately equal to the entry of sodium ions. For a short time after the peak of an action potential the permeability of the membrane to potassium ions is very high, and they are able to cross the membrane barrier and to leave the cell more easily than are those in a resting fibre. In an isolated giant nerve fibre from a squid, the period of high potassium permeability allows the membrane potential to enter a positive phase, or positive afterpotential. The increase in membrane permeability to potassium ions, which occurs whenever a nerve fibre is depolarized (*i.e.*, the resting potential decreased), develops after a brief delay; it is responsible for the phenomenon known as delayed rectification, and depolarization maintained at any point in a nerve fibre causes a large outward flow of charge, which is almost entirely potassium ions.

The nerve-cell membrane has the dominant role in the potentials observed in nerve fibres. Schwann cells, which play a minor role, may provide a weak barrier to ions traversing the membrane; *e.g.*, the potassium ions leaving a stimulated nerve fibre. In repeatedly stimulated nerve fibres, potassium ions can temporarily accumulate in a cleft between the Schwann cells and the fibre membrane, thereby reducing the potassium-ion concentration gradient across the membrane. This depolarizing effect of external potassium ions can contribute to afterpotentials in these nerve fibres.

According to the ionic theory, therefore, the changes that occur in nerve fibres during an action potential involve a transient increase in the membrane permeability to sodium ions, which allows them to enter the fibre and, thus, reverse the charge of the inside of the cell (from negative to positive), followed by an increase in the membrane permeability to potassium ions, which allows a charge approximately equivalent to that brought into the cell (as sodium ions) to leave in the form of potassium ions.

Maintenance of ionic concentration gradients. The ionic theory requires that the sodium and potassium ions, which move in response to concentration gradients (*i.e.*, from regions of high concentration to regions of low concentration) during an action potential, must be restored to their original locations if the nerve fibre is to function continuously. The mechanism by which the concentration gradients are restored, called the sodium pump, or the sodium transport system, maintains ionic concentration gradients in many types of cells and indirectly maintains the resting potential across nerve-cell membranes.

Role of the sodium pump

The function of the sodium pump is energy-dependent; *i.e.*, it utilizes energy-rich compounds formed during metabolism, especially adenosine triphosphate (ATP). The energy released from an ATP molecule is used to transport several sodium ions across the cell membrane and out of the cell. The removal of sodium ions is tightly coupled to an uptake of potassium ions into the fibre. The ratio of the number of sodium ions removed from a fibre to the number of potassium ions taken up is probably less than 2:1. Because the number of sodium ions that leave a nerve fibre is greater than the number of potassium ions that enter, the sodium pump establishes an electric current that aids in helping keep the inside of the cell negative. Potentials that originate in the action of the sodium pump are quickly abolished by anything that disrupts metabolism (and the formation of ATP); the resting potential, however, which is dependent on concentration gradients of ions across the membrane, is not destroyed unless the gradients are lost by leakage of ions across the cell membrane.

Two separate mechanisms involved in ionic movements, therefore, occur in the cell membrane: one is concerned with permeability changes accompanying the action potential, during which ions move in response to concentration gradients and electrical potential; the second is concerned with the movements of ions against those gradients.

Accompanying phenomena. The action potential, the most easily detectable aspect of the nerve impulse, is accompanied by other phenomena. A minute quantity of heat, sufficient to raise the temperature of a nerve by only a few millionths of a degree centigrade, is liberated at about the time of the action potential. This initial heat arises from a brief heat pulse, which is liberated at about the time of the rising phase of the action potential, and much of it is reabsorbed as the action potential subsides. The small initial heat, therefore, is the net result of two much larger positive and negative phases of heat production. According to the local-circuit theory for the spread of the action potential, heat should be given off from the local-circuit currents. If, however, the currents arise, as the ionic theory suggests, from the movement of ions in response to concentration gradients, movement would be accompanied by a cooling that would match the heat given off. A better explanation for the positive and negative parts of the initial heat may be that they arise from changes in the cell membrane during an action potential.

Liberation of heat

The initial heat production is followed by a slower and more extensive heat production, known as the recovery

heat, which probably arises from the energy released during metabolic reactions that help to restore the ionic concentration gradients to the resting state. The recovery heat is accompanied by an increase in the rate of oxygen consumption by the nerve cell. Immense technical difficulties are involved in attempts to detect and follow the minute and rapid temperature changes that accompany the nerve impulse.

The action potential is accompanied by a transient change in the birefringence of the nerve; *i.e.*, its ability to affect the passage of light. The effect is extremely small, and the measured light changes in intensity only slightly. The change occurs in or near the cell membrane, and experiments with the voltage-clamp technique (see below *The voltage-clamp technique*) have provided evidence that the phenomenon is associated with the voltage differences across the membrane rather than with membrane currents. Complicated changes that cause scattering of light also accompany the nerve impulse, some are transient, others long-lived; a tetanus, for example, produces a relatively easy to detect and prolonged change in the optical properties of a nerve fibre. Another optical effect involves certain fluorescent dyes, which adsorb onto the fibres and increase in fluorescence when the nerve is stimulated. Optical methods eventually may be refined so as to provide a more convenient method of monitoring impulses in nerves than electrical methods.

TRANSMISSION OF THE NERVE IMPULSE

The conduction of an impulse along a nerve fibre is an electrical process; at the end of a fibre, however, the impulse is transmitted to a neighbouring cell by a chemical mechanism. According to the chemical theory of nerve transmission, the arrival of an impulse at the end of a nerve fibre causes the release of a chemical compound that excites the neighbouring cell. Although several chemical transmitter compounds exist, only a few have been identified; *e.g.*, acetylcholine, gamma-aminobutyric acid. The mechanism of nerve-impulse transmission has been studied particularly at the neuromuscular junction, the point at which a nerve affects a muscle fibre, and at the synapse between motor nerve cells in the spinal cord and other nerve cells.

General features. The impulse in a nerve fibre leading to a synapse (presynaptic fibre) initiates a response in a fibre leading away from the synapse (postsynaptic fibre) after a delay of a fraction of a millisecond. The delay arises because of the electrical discontinuity in transmission; *i.e.*, the intervention of a nonelectrical mechanism. In addition, impulses are transmitted in one direction only across a synapse. The action potential initiated in the postsynaptic cell is preceded by an electrical change called an endplate potential (EPP) at the neuromuscular junction and an excitatory postsynaptic potential (EPSP) at the synapse between nerve cells. Since the full time course of the preliminary change may be masked by the action potential, which occurs when depolarization of the membrane reaches the threshold for excitation, it is studied either by activating only a few synapses on a nerve-cell body or after certain drugs have been applied to a neuromuscular junction. Curare, for example, which diminishes the size of the endplate potential at a vertebrate neuromuscular junction without changing its time course, acts by making the junction insensitive to the chemical transmitter (acetylcholine), thereby preventing the endplate potential from attaining the threshold required to initiate an action potential in the muscle fibre.

Summation and facilitation

Both the EPP (endplate potential) and the EPSP (excitatory postsynaptic potential) differ from the action potential in being capable of summation; *i.e.*, the arrival of a second impulse at a presynaptic nerve terminal shortly after the first is added to it, so that the size of the synaptic potential increases with the number of impulses. One practical consequence of summation is that a graded response is achieved in the relatively inexcitable crustacean muscle fibre by summation of endplate potentials. Successive impulses in the presynaptic fibre occasionally yield successively larger endplate or postsynaptic potentials, a phenomenon known as facilitation. Facilitation arises in part from the release of larger quantities of transmitter substance by successive impulses and, together with summation, plays an important role in the central nervous system. An action potential occurs in the postsynaptic fibre when the transmitter substance is present in quantities sufficient to cause adequate depolarization of the nerve-cell membrane amounting often to about ten millivolts.

In the central nervous system, many thousands of presynaptic fibres may make functional contact with the cell body and dendrites of a single neuron (postsynaptic cell), thereby influencing its response. Incoming impulses must be synchronized in order to excite a postsynaptic fibre to its threshold before it is stimulated to give an action potential. The additive properties of synaptic potentials permit the elaborate integrative action that occurs in the nervous system.

The active process. *Role of the transmitter substance.* The endplate potential (EPP), like the excitatory postsynaptic potential (EPSP), is relatively long lasting; developing in frog muscle in about one millisecond and lasting for about 20 milliseconds, it spreads decrementally (*i.e.*, the size of the potential decreases as it travels from the point of origin) for a short distance. The initial stages represent only the active process of the EPP. The active process is an increase in the ability of the postsynaptic membrane to conduct electricity and is caused by the chemical transmitter. In contrast to the action potential, during which the cell contents become positively charged, however, the active process involves a decrease in the resting potential of the postsynaptic fibre membrane (*i.e.*, the membrane is depolarized) to a potential that approaches zero but does not become positive. The potential arises because the membrane of the postsynaptic fibre undergoes a nonselective and simultaneous increase in permeability to both sodium and potassium ions in the presence of the transmitter.

Fate of the transmitter

The junction between excitable cells is commonly the site of enzymes (organic catalysts) that function in the rapid destruction of the chemical transmitter, thereby ensuring its brief action; postsynaptic potentials are prolonged and enhanced, therefore, if the enzyme is poisoned. This information has medical applications; conditions in which the quantity of transmitter released is too low, for example, may be alleviated by drugs that reduce the activity of the enzyme. Drugs such as prostigmine, eserine, and Tensilon act by interfering with the activity of the enzyme, called cholinesterase, that breaks down acetylcholine at the neuromuscular junction; certain nerve gases act in a similar way. Other substances act differently at the neuromuscular junction; *e.g.*, botulinum toxin prevents the release of acetylcholine, and hemicholinium interferes with its synthesis.

Miniature potentials. One muscle endplate releases a few million acetylcholine molecules for each impulse. The resting synaptic region of a postsynaptic fibre shows miniature potentials, which have properties similar to postsynaptic potentials resulting from stimulation of presynaptic fibres. The miniature potentials, which occur randomly, are not the effects of single transmitter molecules; rather, they occur as a result of leakage of packets of transmitter molecules from the resting presynaptic nerve fibre. Each packet contains thousands of transmitter molecules. The packets probably represent the contents of the small sacs, or vesicles, known to occur at the ends of presynaptic nerve fibres. The frequency of miniature potentials increases when the presynaptic fibre is depolarized. The concentration of ions such as calcium and magnesium at the junction influences the release of packets of transmitter substance from depolarized nerve terminals. Calcium is necessary for their release; magnesium has an opposing action.

Inhibitory postsynaptic potentials. The stimulation of certain presynaptic fibres causes an increase in the threshold of excitation of postsynaptic cells rather than their excitation; synapses and neuromuscular junctions at which this occurs are said to be inhibitory. Changes in membrane potentials, known as inhibitory postsynaptic po-

tentials (IPSP's), which follow stimulation of a presynaptic fibre, hyperpolarize (*i.e.*, increase the resting potential of) the postsynaptic cell membrane, thus making more difficult the stimulation of an action potential. During an IPSP, the postsynaptic membrane often becomes selectively permeable to negatively charged particles (anions), and chloride ions enter the cell, their negative charges causing the increase in membrane potential.

The transmitter substance at inhibitory neuromuscular junctions is probably, in crustaceans, a compound called gamma-amino-butyric acid. In other animals, it has not been identified with certainty. It is likely that acetylcholine is an excitatory transmitter at certain synapses in vertebrates and mollusks and an inhibitory transmitter at other molluscan synapses. Glutamic acid may be the excitatory agent at some crustacean neuromuscular junctions; acetylcholine is important at many parasympathetic nerve endings, noradrenaline or adrenaline at sympathetic ones.

Electrical transmission. At certain synapses, where there is electrical, rather than chemical, transmission of the impulse, no synaptic delay occurs, and vesicles may not be present in presynaptic fibres; in addition, presynaptic and postsynaptic cell membranes generally are close to each other or fused. Electrical transmission of impulses occurs in the giant nerve fibres of earthworms, and, unlike most synapses, the junctions transmit impulses in either direction. The ciliary ganglion of the chick also permits action currents to spread in both directions. An excitatory synapse in the abdominal nerve cord of the crayfish depends upon electrical transmission but operates only in one direction; the synaptic contact allows currents to flow from the presynaptic to the postsynaptic fibre but not in the reverse direction. An example of electrical transmission in an inhibitory synapse is the Mauthner neuron of the goldfish, in which action currents, derived from adjacent nerve cells, are channelled into a specialized region, the axon cap, of the Mauthner cell and leave the cell in distant, nonsynaptic regions. The entering current hyperpolarizes the synaptic zone, raising the local threshold to excitation.

STUDY OF THE NERVE IMPULSE

The voltage-clamp technique. Applied by the Nobel Prize winners A.L. Hodgkin and A.F. Huxley, the technique known as the voltage clamp is used to measure currents flowing across a nerve-fibre membrane relative to the voltage across the membrane. First used on the giant nerve fibres of squid, the technique involves the insertion of two long wire electrodes along the fibre, so that a uniform potential may be maintained across a substantial length of the fibre membrane. One electrode is used to measure the voltage inside the nerve fibre, the second to introduce electrical current that can flow across the fibre membrane. When the membrane potential is changed to a new steady value by the flow of current across the fibre, the current crossing a specific membrane region is measured with two appropriately placed electrodes outside the fibre. This procedure was used to establish the time course and strength of currents flowing through the nerve membrane at known voltages and to characterize the ionic flow across the membrane.

Phases of membrane current

If a nerve fibre is suddenly depolarized (*i.e.*, resting potential decreased) by more than 20 millivolts, three phases of current may be measured. The first phase is a very brief surge of outward-flowing current, the result of the discharge of the stored charge in the membrane; this is called the displacement current. A second and transient phase follows, in which current flows inward through the cell membrane if the depolarization does not exceed 110 millivolts; otherwise, the transient current flows outward. After this transient current, a third phase of persistent outward current flow develops. The transient current in the second phase, which, over a large range of depolarization, flows in a direction contrary to the voltage gradient, is caused by sodium ions moving into the cell. The persistent current evoked by depolarization in phase three arises principally from the movement of potassium ions outward from the fibre. The phenomena that occur during voltage-clamp experiments with squid nerves also occur in other nerve fibres.

Applications

A set of equations for membrane conductances and ionic equilibrium potentials has been developed to describe the electrical phenomena in nerves. Although derived from observations made under the restricted conditions of the voltage clamp, these equations account for both the form and the velocity of the normal action potential in the squid nerve. In addition, they anticipate the positive phase following the action potential; they predict a well-defined threshold depolarization for excitation and the all-or-none response; and they account for the movements of both sodium and potassium ions that accompany each nerve impulse. The rate constants for changes in the ability of membranes to allow the passage of ions are temperature dependent, increasing threefold for a 10° increase in temperature; this property accounts for the marked temperature dependence of the action potential, which is of shorter duration as temperatures increase. Other phenomena that can be described from the equations relating to the voltage clamp include refractory period, anode break excitation, and subthreshold responses. The equations do not account for afterpotentials, apart from the positive phase seen in squid nerve fibres, or for phenomena associated with the sodium pump.

The voltage-clamp technique is valuable for providing information about many factors that affect nerve conduction. Calcium and magnesium ions, for example, affect the electrical properties of nerve fibres. Removal of calcium ions from the environment of a nerve fibre often leads to spontaneous activity and the voltage clamp indicates that the effects of calcium-ion deficiency are equivalent to a reduction of the resting potential. Magnesium ions have a calcium-like action but are less effective. One hypothesis of the effect of calcium ions is that they adhere to the outer surface of the cell, producing local potential gradients in the membrane, but they may have a more important role in nerve conduction. Calcium ions enter excited fibres faster than resting ones, and action potentials have been reported in axons placed in a sodium-free but calcium-rich environment. Voltage-clamp techniques show that local anesthetics, which reversibly block the conduction of nerve impulses, reduce the ability of the nerve membrane to conduct ionic currents. Of particular interest is tetrodotoxin, a powerful poison extracted from the puffer fish; in minute concentrations, this poison blocks nerve conduction by lowering the conductance of the membrane for sodium currents. Tetrodotoxin, reversible in its action on isolated nerve fibres, has no effect when applied inside a fibre. The separate characters of sodium and potassium current suggests that there may be zones in which each current is conducted.

Artificial and simplified membranes. The successful description of the nerve impulse in terms of the ionic theory has led to attempts to explain the chemical basis for the action potential in terms of structural models. One possibility involves a class of complex lipid molecules, called phospholipids, that are found in membranes. It has been postulated that these molecules, which contain electric charges, might change their positions in the membrane as a result of the electrical changes occurring during an action potential; in this way, they could provide a route through the membrane for sodium ions during depolarization (resting potential decrease) that later changes to a path allowing the entry of potassium ions. Thin membranes, approximately two phospholipid molecules in width, have been synthesized in attempts to construct membranes similar in structure to natural ones. Artificial membranes, or bilayers, have high electrical resistance and do not alone give action potentials; however, their resistance can be lowered by the addition of various small molecules. Of interest is a specific type of antibiotic, of which valinomycin is an example, that increases the permeability of both bilayers and cell membranes to potassium rather than sodium ions. Other compounds also cause bilayers and cell membranes to undergo phenomena reminiscent of those found in nerve fibres.

Possible role of phospholipids

Another method used to study the nerve impulse involves removal of the cytoplasm from squid giant nerve fibres; the cytoplasm is squeezed out of the fibre as toothpaste might be squeezed from a tube, and the fibre, including the membrane, is then filled with an artificial solution. If a potassium salt solution is used, the nerve fibres can conduct many impulses over several hours (Figure 4D); the bulk of the cytoplasm, therefore, apparently has little significance in the conduction of the nerve impulse, although the nature of the salt solution within the fibre determines whether or not the fibre is excitable. The action and resting potentials are abolished if identical solutions are used both inside and outside the fibre.

Nerves and Nervous Systems

All living organisms are able to react to external and internal changes in their environments. Some nonliving things can also react to changes; mercury in a thermometer expands as the temperature rises, and a photographic emulsion becomes chemically different when exposed to light. But the reactions of living forms differ from these relatively mechanical responses in that they tend to preserve the integrity, well-being, or status quo of the living organism. An animal, for example, tends to avoid excessive heat, which is harmful to it. A plant bends toward the light, which is necessary for its photosynthetic processes. In such manner do the reactions of living organisms increase the chances of survival of both the individual and the species. Dealt with in this article are coordinative activities based on the responsiveness of cells generally and on the reactions of nerve cells in particular. The integrative system of plants is dealt with generally, by way of comparison; details of plant coordination are covered in the article STEREOTYPED RESPONSES. For the entire complement of man's nervous coordination see the article NERVOUS SYSTEM, HUMAN.

This article is divided into the following sections:

I. General features
II. Nervous coordination
  Intracellular coordination
  Organelle systems
  Nervous systems
    The neuron, or nerve cell
    The transmission of the nerve impulse
III. Invertebrate nervous systems
  The earliest nervous systems
  Diffuse nervous systems
    Nerve net
    Simple radial systems
  Centralized nervous systems
    Complex radial systems
    Simple bilateral systems
    Moderately cephalized systems
    Complexly compartmentalized systems
IV. The vertebrate nervous system
  The central nervous system
    The brain and its components
    The spinal cord
    The brain coverings, cavities, and cerebrospinal fluid
    Neuroglia: non-nervous tissue
  The peripheral nervous system
    Cranial nerves
    Spinal nerves
    Sensory and motor fibres
    The autonomic nervous system
  Embryonic development of the vertebrate nervous system
    Development of the spinal cord and its nerves
    Development of the brain and its nerves
  Evolution of the vertebrate nervous system
    The primitive condition
    Encephalization
    Dominance of the cerebrum
V. Biodynamics of the vertebrate nervous system
  Controls exerted on the nervous system
    Intrinsic control
    Extrinsic influences
  Interaction between nervous and endocrine systems
    The neurosecretory cell and the concept of neurosecretion
    Neuroendocrine interactions

I. General features

The simplest type of living response is the direct one-to-one stimulus-response reaction. The change in the environment is the stimulus; the reaction of the organism to it is the response. In the case of single-celled organisms the response is the result of a property of the cell fluid (cytoplasm) called irritability. In protistan organisms, such as algae, protozoans, and fungi, simple responses in which the organism moves toward or away from the stimulus are termed taxes (singular: taxis). In larger and more complicated organisms, those in which response involves the synchronization and integration of events in different parts of the body, a control mechanism, or "controller," is located between the stimulus and the response. In multicellular organisms, the controller consists of two basic mechanisms by which integration is achieved—chemical regulation and nervous regulation.

Integrative mechanisms

In chemical regulation, substances called hormones are produced by definite groups of cells and are either diffused or carried by the blood to other areas of the body where they act on so-called target cells, influencing metabolism or inducing synthesis of other substances. The changes resulting from hormonal action are expressed in the organism as influences on, or alterations in, form, growth, reproduction, and behaviour patterns.

Plants respond to a variety of external stimuli by utilizing hormones as controllers in a stimulus–response system. Directional responses of movement are known as tropisms and are called positive when the movement is toward the stimulus and negative when it is away from the stimulus. When a seed germinates, the growing stem turns upward toward the light; the roots turn downward away from the light. Thus, the stem shows positive phototropism and negative geotropism, while the roots show negative phototropism and positive geotropism. In this example, light and gravity are the stimuli, and directional growth, which results in movement, is the response. The controllers are certain hormones synthesized by cells in the tips of the plant stems. These hormones, known as auxins, diffuse through the tissues beneath the tip and concentrate toward the shade side, causing elongation of these cells and, thus, a bending of the tip toward the light. The end result is that the growing part of the plant is maintained in an optimal condition with respect to light.

In animals, in addition to chemical regulation via the endocrine system, there is another integrative system called the nervous system. A nervous system can be de-

fined as an organized group of cells specialized for the conduction of an impulse—an excited state—from a sensory receptor through a nerve network to an effector, the site at which the response occurs. The controller in this type of stimulus-response system is a specialized cell called a neuron. In contrast to the endocrine system, the actions of the nervous system are generally extremely rapid, short acting, and precise, involving point-to-point transmission between cells.

Conduction of impulses

Organisms that possess a nervous system are, therefore, capable of much more complex behaviour than are organisms that lack one. The nervous system, being specialized for the conduction of impulses, allows rapid responses to stimuli from the environment. Many of the responses mediated by the nervous system are directed toward preserving the status quo, or homeostasis, of the animal. Stimuli that tend to displace or disrupt some part of the organism call forth a response that results in reduction of the adverse effects and a return to a more normal condition. Organisms with a nervous system are also capable of a second group of functions that initiate a variety of behaviour patterns. Animals, thereby, may go through periods of exploratory or appetitive behaviour, nest building, and migration. Although these activities are beneficial to the survival of the species, they are not always performed by the individual in response to a particular need or stimulus. Finally, learned behaviour can be superimposed on both the homeostatic and initiating functions of the nervous system.

II. Nervous coordination

INTRACELLULAR COORDINATION

All living cells have the property of irritability, or responsiveness to environmental stimuli, which can affect the cell in different ways, producing, for example, electrical, chemical, or mechanical changes. These changes are expressed as a response, which may be the release of secretory products by gland cells, the contraction of muscle cells, the bending of a plant-stem cell, and the beating of whiplike "hairs," or cilia, by ciliated cells.

The responsiveness of a single cell can be illustrated by the behaviour of the relatively simple protozoan amoeba, a single-celled organism.

Responsiveness of amoebas

Unlike some other protozoans, an amoeba lacks highly developed structures that function in the reception of stimuli and the production or conduction of the response. The amoeba behaves as though it had a nervous system, however, because the general responsiveness of its cytoplasm serves the functions of a nervous system. An excitation produced by a stimulus is conducted to other parts of the cell and evokes a response by the animal. An amoeba will move to a region of a certain level of light. It will be attracted by chemicals given off by foods and exhibit a feeding response. It will also withdraw from a region with noxious chemicals and show an avoidance reaction upon contacting other objects.

ORGANELLE SYSTEMS

In more complex protozoans, however, the specialized cellular structures, or organelles, that serve these functions include receptors such as stiff sensory bristles in ciliates and the light-sensitive eyespots of flagellates. Effectors that enable a protozoan to respond to stimuli include cilia (slender hairlike projections from the cell surface), flagella (greatly elongated whiplike cilia), and other organelles associated with drawing in food or with locomotion. Protozoa also have subcellular cytoplasmic filaments that, like muscle tissue, are contractile. The vigorous contraction of the stalked protozoan *Vorticella*, for example, is the result of contraction of a threadlike structure (myoneme) in the stalk.

Although Protozoa clearly have specialized receptors and effectors, it is not certain that there are special conducting systems between the two. In a ciliate such as *Paramecium*, the beating of the cilia—which propels it along—is not random, but coordinated. Beating of the cilia begins at one end of the animal and moves in regularly spaced waves to the other end, suggesting that coordinating influences are conducted longitudinally. A system of fibrils connecting the bodies in which the cilia are rooted could provide conducting paths for the waves, but coordination of the cilia could also take place without such a system. Each cilium could respond to a stimulus carried over the cell surface from an adjacent cilium, in which case, coordination would be the result of a chain reaction from cilium to cilium.

The best evidence that formed structures are responsible for coordination comes from another ciliate, *Euplotes*, which has a specialized band of ciliary rows (membranelles) and widely separated tufts of cilia (cirri). By means of the coordinated action of these structures, *Euplotes* is capable of several complicated movements in addition to swimming (*e.g.*, sharp turns, moving backward, spinning). The five cirri at the rear are connected to the anterior end in an area known as the motorium. The fibres of the motorium apparently provide coordination between the cirri and the membranelles. The membranelles, cirri, and motorium constitute a neuromotor system.

NERVOUS SYSTEMS

As has already been indicated, the basic pattern of nervous coordination in animals is the organization of the stimulus–response system into receptor, adjustor (or controller), and effector units. External stimuli are received by the receptor cells, which, in most cases, are neurons. (In a few instances, a receptor is a nonnervous sensory epithelial cell, such as a hair cell of the inner ear or a taste cell, which stimulates adjacent neurons.) The stimulus is modified, or transduced, into an electrical impulse in the receptor cell. This incoming excitation, or afferent impulse, then passes along an extension, or axon, of the receptor to an adjustor, or association neuron. All neurons are capable of conducting an impulse, which is a brief change in the electrical charge on the cell membrane. Such an impulse can be transmitted, without loss in strength, many times along an axon until the message, or input, reaches another neuron, which in turn is excited. The adjustor neuron selects, interprets, or modifies the input from the receptor and sends off an outgoing, or efferent, impulse to an efferent, or motor, neuron. The efferent neuron, in turn, makes contact with an effector such as a muscle or gland, which produces a response.

In the simplest arrangement, the receptor–adjustor–effector units form a functional group known as the reflex arc. Sensory cells carry afferent impulses to a central adjustor or internuncial neuron, which makes contact with a motor neuron. The motor neuron carries efferent impulses to the effector, which produces the response. Three types of neurons are involved in this reflex arc; a two-neuron arc, in which the receptor makes contact directly with the motor neuron, is possible but probably not of widespread occurrence. Simple reflexes are prompt, short-lived, automatic, and involve only a part of the body. Examples of simple reflexes are the contraction of a muscle in response to stretch, blinking of the eye when the cornea is touched, and salivation at the sight of food. Reflexes of this type are usually involved in preserving homeostasis.

Adjustor neurons of complex nervous systems

The differences between simple and complex nervous systems lie not in the basic units but in their arrangement. In higher nervous systems, there are more adjustor neurons concentrated in the central nervous system (brain and spinal cord) that mediate the impulses between afferent and efferent neurons. Sensory impulses from particular receptors travel over specific pathways to the central nervous system. Within the central nervous system, though, the impulse can travel over multiple pathways formed by numerous adjustor neurons. Theoretically, the impulse can be distributed to any of the efferent motor neurons and produce a response in any of the effectors. It is also possible for many kinds of stimuli to produce the same response. Man, for example, walks in response to a variety of stimuli. The connections of the adjustor neurons in the central nervous system make possible all the special pathways between the receptive areas and the final common pathways.

As a result of the integrative action of the adjustors, the behaviour of the organism is more than the simple sum of its reflexes; it is a unitary, integrated whole that exhibits coordination between many individual reflexes. Reflexes can occur in a complicated series or sequence producing elaborate behaviour patterns. Behaviour in such cases is characterized not by inherited, stereotyped responses but by flexibility and adaptibility to circumstances. Many automatic, unconditioned reflexes can be modified by or adapted to new stimuli. The remarkable experiments of the Russian physiologist Pavlov, for example, showed that if an animal salivates at the sight of food while another stimulus, such as the sound of a bell, occurs simultaneously, the sound alone can induce salivation after several trials. This response, known as a conditioned reflex, is a form of learning. The animal's behaviour is no longer limited by fixed, inherited reflex arcs but can be modified by experience and exposure to an unlimited number of stimuli. The most evolved nervous systems are capable of even higher associative functions: of other forms of learning, of thinking, and of memory. The complex manipulation of the signals necessary for these functions depends to a great extent on the number and intricacy of the arrangement of the adjustors.

The neuron, or nerve cell. In multicellular organisms, the diffuse general irritability of single cells does not permit adequate coordination between widely separated regions of the body. Instead, specialized cells have evolved to channel and focus that irritability. These cells —known as neurons—are specialized for the reception of stimuli, conduction of excitation, and transmission of the signal to other cells.

A nerve cell consists of a cell body and cell processes (Figure 1). There is a great variety of neuron types, depending on size, shape, number of processes, and function. The cell body is composed of a more or less centralized nucleus and the surrounding cytoplasm. The nerve cell processes are of two types: short, multiple processes are dendrites and a single, long process is an axon. Neurons with one process are called unipolar and are especially common in invertebrates. If the process originating from the cell body gives rise to two branches running in opposite directions, the cell is said to be pseudo-unipolar. Bipolar cells have two separate processes. Some vertebrate sensory cells are bipolar, such as neurons in the retina of the eye and in the inner ear. Multipolar cells have more than two processes—a single axon and two or more dendrites. Multipolar neurons, which are the predominant type in the vertebrate central nervous system, can be further subdivided into two types: neurons with a large cell body and an extremely long axon—up to three feet—and neurons with a small cell body and a short axon.

Functionally, nerve cells can be classified as sensory, associative (internuncial), or motor. A sensory neuron is a nerve cell specialized for the reception of stimuli. A nerve cell that carries impulses to the effector organs is a motor nerve cell, or motoneuron. The internuncial nerve cell, or interneuron, is an adjustor or integrator; it receives the excitations arising from a receptor cell but distributes, inhibits, combines, and modifies this information before passing it on to a motor neuron.

Functional classification of neurons

From *Biological Sciences Curriculum Study, Biological Science: An Inquiry into Life*, 2nd ed. (1968); Harcourt Brace Jovanovich

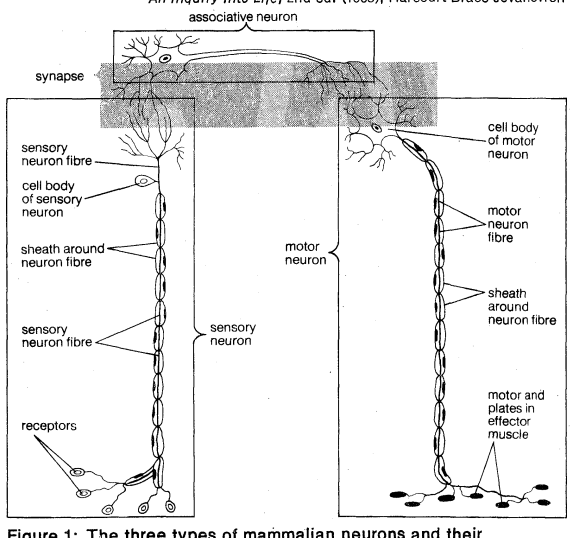

Figure 1: The three types of mammalian neurons and their relationships in a reflex arc (see text).

The cell body. Despite the great varieties of neurons, there are certain similarities in structure among the different types. The nucleus is a large, round body centrally situated in the cytoplasm and enclosed in a nuclear envelope. The nucleus contains a smaller body known as the nucleolus and dispersed material called chromatin. In addition to the usual cell components, such as mitochondria and the Golgi apparatus, the cytoplasm of the nerve cell contains special organelles, such as the Nissl bodies and neurofibrils, all of which are evident in nerve cells when they are stained with the appropriate chemicals and viewed under an ordinary optical microscope. Viewed with the greater magnifying power of the electron microscope, however, the Nissl bodies are a delicate channel-like system—the endoplasmic reticulum—which pervades the cell with flattened membranous cisterns and attached particles called ribosomes. Two types of delicate threads in the cytoplasm extend into the nerve processes—tiny neurofilaments and larger tubules known as neurotubules, or microtubules.

Large neurons often contain large bodies of golden-brown pigment. These structures, known as lipofuscin pigment granules, seem to be a by-product of nerve-cell metabolism; they become more abundant as the cell ages. Brown or black melanin granules are also sometimes present, as are lysosomes (granular bodies containing certain enzymes) and varying amounts of nutrients such as lipids and glycogen.

The nerve processes. Each neuron gives rise to a single axon, which arises from a conical elevation known as the axon hillock. The hillock and the axon cytoplasm, or axoplasm, can be distinguished from other regions of the cytoplasm by the lack of Nissl bodies. The axon contains mitochondria, neurofilaments, microtubules, and elongated channels of smooth endoplasmic reticulum. Along its course, the axon may give off collateral branches, which divide into even smaller branches. The main branch forms an extensive terminal brush, the telodendrion, which forms either a connection (synapse) with another neuron or with an effector such as a muscle fibre or a gland cell.

The nerve cell gives rise to one or, more commonly, several dendrites. The dendrites, usually short and confined to the vicinity of the cell body, branch repeatedly and sometimes form elaborate "trees," which increase enormously the receptive surface of the neuron. The farthest (distal) branches contain tiny spines, thorns, or knoblike gemmules upon which axons of other neurons converge. In internal structure, dendrites represent extensions of the neuronal cytoplasm. Unlike axons, they contain Nissl bodies.

The dendrites receive nerve impulses from the axons of other neurons terminating on them. In this way a single neuron may receive messages from a great many neurons. It has been estimated that there may be 200,000 axon terminals on the elaborate dendritic tree of a single Purkinje cell, a flask-shaped cell in the cerebellum of the brain. Thus, the dendritic tree plays a major role in integrating information received from different sources. The impulses travelling over the axons to the dendrites excite or inhibit electrical activity in localized regions of the dendrite membrane. The graded changes in electrical potential in the dendrite raise or lower the ability of the neuron to generate a nerve impulse. The impulse arises in the initial segment of the axon, is conducted to the axon terminal, and is then transmitted to other neurons or to effector cells.

The dendrite tree

The nerve cell body comprises only a small portion of the total cell mass, the major portion being the processes. The cell body maintains the cytoplasm of the processes by means of axoplasmic flow, which proceeds at a rate of

about one millimetre (0.04 inch) per day. Some structures within the axoplasm, however, such as vesicles, move at a greater rate.

The nerve fibre. The nerve fibre consists of the axon and covering or sheath cells (Figure 2). In the peripheral nerves, which extend into appendages, the sheath is

Thomas L. Lentz

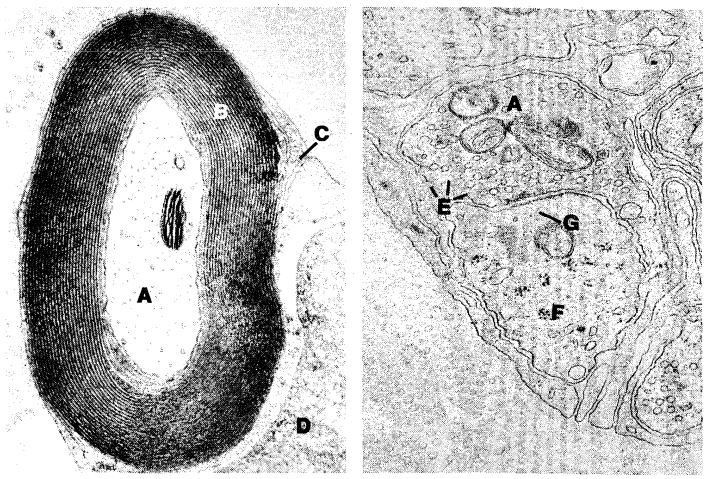

Figure 2: (Left) Electron micrograph of myelin sheath around nerve axon showing (A) nerve axon, (B) myelin sheath, (C) Schwann cell membrane, and (D) Schwann cell nucleus. formed by so-called Schwann cells; in nerves of the central nervous system, the covering is formed by cells called oligodendroglia. In addition, some axons are enclosed by a fatty (lipoidal) covering, the myelin sheath, formed by Schwann cells or oligodendroglia. Nerves with a myelin sheath are called myelinated nerves; those lacking a sheath are unmyelinated. Myelin is responsible for the white colour of the nerves, brain, and spinal cord.

Interruptions of myelin at intervals along a nerve fibre are known as the nodes of Ranvier. These nodes represent points of discontinuity between individual Schwann cells arranged along the nerve fibre. In these regions, the axon is covered only by fingerlike extensions of the Schwann cells. Oblique lines running across the nerve fibre within Schwann cell segments, known as incisures of Schmidt-Lanterman, are formed by separations of myelin layers.

Each nerve fibre—myelinated or unmyelinated—is enclosed in a delicate connective-tissue covering called the endoneurium. Bundles of nerve fibres are surrounded by a more extensive layer of connective tissue, the perineurium. Finally, the entire peripheral nerve trunk is encapsulated by another connective sheath, the epineurium.

In nerve conduction, the myelin sheath acts as an insulator that prevents the impulse from jumping to adjacent axons. The nerve impulse is a wave of excitation, called the action potential, that is formed by an electrical change, or depolarization, of the membrane of the axon and passes down the nerve fibre. In unmyelinated nerves, conduction is a smooth and continuous process. In myelinated nerves, however, the impulse travels by means of jumps (saltatory conduction) between the nodes of Ranvier, a more rapid process than the continuous conduction in unmyelinated nerves.

Speed of conduction in the nerve fibre depends on the size of the axon and the thickness of the myelin sheath. Nerve fibres can be grouped into three main classes: A, B, and C fibres. The A fibres are myelinated, one to 20 microns (one $\mu = 0.001$ millimetre) in diameter, and are the fastest, conducting impulses at a rate of five to 120 metres (16 to 400 feet) per second; B fibres have a thinner myelin sheath, a diameter up to three microns, and conduct impulses at a rate of three to 15 metres (ten to 50 feet) per second; C fibres are the smallest, often less than one micron across, are unmyelinated, and conduct impulses slowly, at a rate of 0.6 to two metres (two to seven feet) per second.

Degeneration and regeneration of neurons. A nerve cell body lost because of injury or disease cannot be replaced. If, however, a nerve fibre is injured, cut, or crushed, the nerve cell body undergoes a series of changes preparatory to replacing the fibre. Beyond the point of injury, the axon and its myelin sheath die after a succession of changes called Wallerian degeneration. The neurilemma, however, persists as a hollow tube. The cell body and fibre closest (proximal) to the injury undergo changes called retrograde degeneration. The axon and myelin degenerate up to the first node of Ranvier, while in the cell body, the Nissl substance disperses. If the nerve fibre is injured very near the cell body, the neuron may die; if the cell body survives, however, regeneration of the peripheral fibre begins. (Although axons in the central nervous system attempt to regenerate, they seem unable to make connections across a wound gap.)

Tiny sprouts appear at the proximal end of the nerve fibre. The dilated ends of these sprouts are known as growth cones or end bulbs. Advancing sprouts, which enter the wound along with Schwann cells and connective-tissue cells called fibroblasts, then invade the persisting neurilemmal tube of the distal stump and grow down this pathway. Growth occurs at a rate of two to four millimetres (0.08 to 0.16 inch) per day; thus, a long nerve may require months to regenerate completely. Once it reaches its termination, it connects with the end organ, and normal function is restored. During this process, the axon increases in diameter, and the myelin sheath is reformed.

Rate of nerve regeneration

The transmission of the nerve impulse. In simple reflex arcs, as well as in complicated multineuron pathways, impulses must be transmitted from nerve cell to nerve cell over minute gaps called synapses. A synapse is formed by the termination of an axon on the dendrites (axodendritic synapse), the cell body (axosomatic synapse), or the axon (axoaxonic synapse) of an adjacent nerve cell, or postsynaptic cell. Some neurons have only a few synapses, but others, like the Purkinje cell, may have hundreds of thousands. Each synapse represents a connection with another neuron that has information to convey. Each neuron represents a centre in which all this information is integrated and sent along as a nerve impulse to still other neurons.

Near the termination of the axon, the myelin sheath, if present, ends, and the axon ends in a dilated bulb. The bulb usually contains a few mitochondria and many small sacs called synaptic vesicles (Figure 2). At the synapse the axon ending is separated from the postsynaptic neuron by a microscopic space called the synaptic cleft. Each neuron, therefore, is a discrete cellular unit anatomically separate from all other neurons.

Transmission of the nerve impulse can be either chemical or electrical, but chemical synapses are by far the more numerous. In chemical transmission, a specific chemical is synthesized by the nerve cell, stored at the axon terminal, and released at the appropriate time, affecting the postsynaptic cell. These chemical neurotransmitters are stored in the synaptic vesicles. Neurons in which the transmitter is the chemical acetylcholine are said to be cholinergic; neurons utilizing norepinephrine as the transmitter are known as adrenergic.

Upon arrival of an impulse at the nerve ending, the neurotransmitter is released from the synaptic vesicles. The transmitter diffuses across the synaptic cleft and produces a change in permeability of the postsynaptic membrane. The change results in an electrical change in the postsynaptic cell. The effect on the postsynaptic neuron may be excitatory or inhibitory. After the neurotransmitter is liberated, it is destroyed by enzymes so that its effect is localized and of short duration.

In electrical synapses, the arriving nerve impulse passes directly from the presynaptic to the postsynaptic element, whose membranes are very closely apposed, with only the tiniest gap separating them. This close apposition probably accounts for the low resistance between cells at these points, which allows the impulse to travel directly from cell to cell. In both chemical and electrical synapses, transmission is polarized; that is, it can pass in only one

direction across the synapse. (See the article NERVE IMPULSE for the biochemistry and biophysics of nervous conduction.)

III. Invertebrate nervous systems

THE EARLIEST NERVOUS SYSTEMS

Interest in the evolutionary origin of the nervous system has arisen primarily from the need to reduce the extremely complex nervous system of man and other higher animals to its simplest characteristics. Knowledge of the nature of the earliest nervous system might reveal the basic underlying mechanisms of nervous function in all nervous systems.

Among several theories about the manner in which the nerve cell arose, one of the earliest proposed that all the components of the nervous arc—the receptor, conductor, and effector—were originally contained in a single cell type. This cell, called a neuromuscular cell, then gave rise to separate nerve and muscle cells. This theory, however, has not been widely accepted because true neuromuscular cells have not been identified with certainty in any existing animal.

A more widely accepted view of the origin of the nervous system suggests that effectors evolved first. Sponges, for example, are considered to represent the state in evolution when muscle, an effector, is present in the absence of nerve cells. The next stage was the appearance of receptors, or sensory cells, which terminated on muscle cells. This stage constitutes a receptor–effector system. Finally, another nerve cell—the adjustor, or central organ—appeared between the receptor and effector, forming the receptor–adjustor–effector system that is found in higher invertebrates and vertebrates.

The origin of nerve cells

Nerve cells are thought to have arisen from the epidermis, or body covering, because they occur in this layer in some of the simple invertebrates and because nervous tissue develops from the outer layer (ectoderm) in the embryo. The cell that gave rise to neurons could have been excitable and conductile to the extent that many non-nervous cells and protozoans are. Being epithelial, this pre-nervous cell may also have been capable of secretory activity. Being excitable, the cell could respond to environmental stimuli. By the appearance of long cytoplasmic processes, the conductive properties of the cell could have become better developed. Finally, if the secretory capabilities of the cell were directed to the production of active substances that, when released, affected other cells, such as muscle, a means of transmission would be available. This primitive nerve cell, then, could have fulfilled the criteria necessary in any nerve cell —excitability, conductivity, and transmissibility.

The nerve cell probably appeared first in some primitive multicellular animal that was ancestral to more complicated invertebrates. In view of the functions performed by a nervous system, it is apparent that an organism possessing such a system would have a considerable advantage over those lacking one. The organism would be capable of more complex behaviour, expressed perhaps in better abilities to feed or to detect and escape from its enemies.

DIFFUSE NERVOUS SYSTEMS

Among the invertebrates in general, the least complex nervous systems are found in forms that are small, relatively simple in structure or uncomplicated in behaviour. Of the two general types of nervous systems—diffuse and centralized—the diffuse system is the original and most primitive type. It is found in the coelenterates (*e.g.*, hydroids, jellyfishes, sea anemones, corals) and in the ctenophores, or comb jellies. The even more primitive sponges have scattered cells with neural characteristics, but it is not certain whether these cells constitute a true nervous system. In the diffuse systems, nerve cells are distributed throughout the organism, usually beneath the outer epidermal layer. Large concentrations of nerve cells (*e.g.*, a brain) are not found in these animals, but there may be small local concentrations called ganglia.

Nerve net. The common hydroid *Hydra* has a nervous system that consists entirely of a nerve net—a meshlike system of individual and separate nerve cells and fibres dispersed over the organism but more concentrated near the "mouth" (Figure 3A). This widespread arrangement of fibres allows diffuse conduction of nervous excitation over a large number of available pathways, so that, if a hydra is split longitudinally but left connected by a small piece of body wall, stimulation of one side will result in contraction of both sides. In most higher animals, by contrast, interruption of specific nerves blocks responses to stimuli, because there are no alternate conducting pathways.

Several cell types comprise the nervous system of *Hydra*. Most of the nerve cells are found in the outer epithelial layer. Ganglion cells, situated at the base of the epidermis, are spindle shaped and have long processes. Sensory cells are elongated and oriented perpendicular to the surface of the animal; the outward extensions such as cilia act as sensory receptors, while inward extensions join the network at the base of the epithelial cells. Some of the nerve cells of *Hydra* are capable of secretion and are known as neurosecretory cells. Neurosensory cells are deeply situated ganglion cells with cilia reaching the body surface.

Simple radial systems. The nervous system of coelenterates, which corresponds to the radially symmetrical bodies of these animals, is distributed over the surface as a nerve net. In sea anemones the neurons are more highly concentrated near the mouth. Although local concentration of neurons reaches its highest degree in the jellyfish, the concentration is not sufficient to be considered a central nervous system. The jellyfish of the class Hydrozoa have two circular thickenings of the nerve net near the margin of the bell. These thickenings constitute the nerve rings. From the nerve rings, other thickenings of the net extend inward toward the mouth. In jellyfish of the class Scyphozoa there are no marginal rings, but ganglion cells are concentrated into usually eight marginal ganglia. The marginal ganglia occur near marginal bodies, or rhopalia, which are complex sensory structures that may include sensory or olfactory pits; sensory tentacles; a statocyst, or equilibrium organ; and photoreceptor organs, or ocelli.

Nerve nets

The marginal bodies initiate the rhythmic pulsation by which the jellyfish swims. Rapid conduction over the nerve net excites all the musculature of the bell nearly simultaneously.

CENTRALIZED NERVOUS SYSTEMS

One of the most prominent trends in the evolution of the nervous system is the centralization of nervous elements. In echinoderms (*e.g.*, starfishes, sea cucumbers, sea lilies) the nervous system is sufficiently concentrated to be called a central nervous system, but there is no true brain. In the platyhelminthes, or flatworms, and most higher invertebrates, however, there is an anterior collection of nerve cells, or a brain, and a longitudinal nerve cord. In the simpler types, the central nervous system is not distinctly separated from the peripheral nervous system, whereas in more advanced types, the nervous system is increasingly concentrated in the cephalic, or head, end of the animal.

Complex radial systems. A complex radial nervous system is found in the echinoderms, which, like the coelenterates, have a radial type of body construction. In fact, the nervous system of echinoderms shares some primitive characteristics with that of coelenterates, but also shows some advanced features. The major components of the nervous system are a nerve ring around the mouth, radial nerves extending into the arms, and a nerve network, or plexus, beneath the body covering. The radial nerves and nerve ring constitute the central nervous system of echinoderms. These are actually just thickened regions of the subepidermal plexus that contain both nerve cells and fibres. Specialized sensory organs are not common in these animals, although many starfishes have eyespots and sensory tentacles at the tip of each arm. The junction of each radial nerve with the circumoral nerve ring acts as a centre for the coordinated movement of the arms.

Simple bilateral systems. The flatworms were the first invertebrates to exhibit bilateral symmetry and also the first to develop a central nervous system with a brain (Figure 3B). The nervous system of a free-living flatworm such as *Planaria* consists of a brain, longitudinal nerve cords, and peripheral nerve plexuses. Located in the anterior portion of the animal, the brain is composed of two cephalic ganglia joined by a broad connection called a commissure. Longitudinal nerve cords, usually three to five pairs, extend posteriorly from the brain; they are connected by transverse commissures, and smaller, lateral nerves extend from the cords. The lateral nerves give rise to the peripheral nerve plexuses. The submuscular nerve plexus, consisting of sensory cells, ganglion cells, and their processes, is situated in the loose tissue (mesenchyme) below the subepidermal musculature. A much finer subepidermal plexus is located at the bases of the epithelial cells above the muscular layer.

Sensory receptors in *Planaria*

Planaria are richly supplied with sensory receptors. Single sensory cells in the nerve plexuses are widely scattered over the animal. Sensory organs also are present and include ciliated pits and grooves, auricles, the frontal organ, statocyst, and eyes. The ciliated pits and grooves contain chemical receptors (chemoreceptors), which permit the animal to detect food. The statocyst is responsible for balancing and such reactions as rising to the surface of the water or sinking. The eyes, or ocelli, may occur as a pair situated anteriorly or may be scattered abundantly over the head region depending on the species. Short optic nerves connect the eyes with the brain.

Moderately cephalized systems. Basic similarities in the nervous systems of the annelid worms, mollusks, and arthropods include an anteriorly situated brain, connectives running from the brain around the esophagus and joining paired longitudinal cords, and ventral nerve cords with ganglia along their length. The trend toward greater centralization and cephalization of nervous functions is continued within these groups, reaching its peak in the higher mollusks and arthropods.

Annelids. The brain of most annelids, terrestrial earthworms and the leeches, is relatively simple in structure. The earthworm brain is a bilobed mass lying above the pharynx in the third body segment (Figure 3C). Sensory nerves leave the brain and run forward into the prostomium (extreme anterior end) and first segment. The brain of the active, predatory polychaetes is more complicated. In some, the brain can be divided into a forebrain, midbrain, and hindbrain; a single pair of circumesophageal or circumpharyngeal connectives leave the brain, surround the anterior gut, and connect with the ventral nerve cord.

The most primitive annelids have a pair of ventral nerve cords joined by transverse connectives; the more advanced forms have the cords fused to form a single cord. A ganglionic swelling of the cord is found in each body segment, with the most anterior ganglion, the subpharyngeal ganglion, being the most prominent. Two to five pairs of lateral nerves leave each ganglion to innervate the body wall of that segment. Separate ganglia supply the leglike parapodia of polychaetes. A subepidermal nerve plexus occurs over the whole body. Another plexus, called the enteric, stomodaeal, or sympathetic system, is found in the wall of the gut.

Giant axons, usually few in number, are found running the length of the cord. They may belong to one cell or be composed of many neurons. These axons are capable of vary rapid conduction of impulses to the segmental muscles; their main function is to permit the worm to contract very rapidly as a defense against predators.

The usual slow crawling movements of worms are mediated by a series of reflex arcs. During crawling, the contraction of muscles in one segment stimulates stretch receptors in the muscle. Impulses are carried over sensory nerves to the cord, causing motor neurons to send impulses to the longitudinal muscles, which then contract. The longitudinal pull activates stretch receptors in the following segment, and a wave of contraction moves along the worm.

Some of the annelids, especially the active polychaetes, are richly supplied with sensory organs. The most highly developed eyes consist of a retina, a vitreous body, a lens, and an outer cornea. Optic nerves leave the eye and enter the brain. Spiral organs are light sensitive regions on the surfaces of the antennae. Nuchal organs are ciliated sensory pits, or slits, located on the head; they contain chemoreceptors necessary for the detection of food. Other ciliated sense organs include the dorsal and lateral organs, which are found on the trunk segments. Statocysts, necessary for orientation of the worm in burrowing, are located in the head.

Simple mollusks. The nervous systems of the lower mollusks (snails, slugs, and bivalves such as clams and mussels) conform to the basic annelid plan but are modified to conform with the unusual anatomy of these animals. In snails, a pair of cerebral ganglia constitutes the brain, which overlies the esophagus. Nerves leave the brain anteriorly to supply the eyes, tentacles, and a pair of buccal ganglia. These last ganglia, also called the stomatogastric head ganglia, innervate the pharynx, salivary glands, and a plexus on the esophagus and stomach. Other nerve cords—the pedal cords—leave the cerebral ganglia ventrally and terminate in a pair of pedal ganglia, which innervate the foot muscles. Another pair of nerve cords—the visceral cords—leave the brain and run posteriorly to the visceral ganglia. The pleural ganglion, supplying the mantle, or fleshy lining of the shell, and the parietal ganglion, innervating the lateral body wall and mantle, are located along the visceral nerves. Intestinal ganglia connected with the pleural ganglia innervate the gills, osphradium (a chemical sense organ), and mantle. Because of the torsion that occurred during the evolutionary history of the snails, some components of the nervous system are twisted and located in asymmetrical positions. In addition, there has been some migration forward and fusion of ganglia. Sense organs of snails include eyes, tentacles, statocysts, and osphradia.

Modified nervous system of snails

In the bivalves, a cerebropleural ganglion is situated on either side of the esophagus. An upper pair of nerve cords leaves these ganglia and runs posteriorly to the visceroparietal (visceral) ganglia. The visceral ganglia supply the mantle, adductor muscles (which close the shell), and internal organs. A second pair of nerve cords runs ventrally to the pedal ganglia. Most of the sense organs are found at the edge of the mantle. In the scallop, for example, the eyes are set in a row. They are well developed and consist of a cornea, lens, and a retina, in which the photoreceptor cells are directed away from the source of light (an arrangement much like that in the vertebrate retina).

Complexly compartmentalized systems. *Complex mollusks.* The highest degree of development of the invertebrate nervous system is attained by the cephalopods (squids, cuttlefishes, and octopuses) among the mollusks and by the insects and spiders among the arthropods. Although the basic plan of these nervous systems is similar to that of the annelids, there are several advances. First, there is a high degree of cephalization, with nervous functions concentrated in the head region of the animal. In addition, ganglia are fused and further forward, and nerve cells, less abundant in the peripheral nervous system, are situated in the brain or ganglia so that the nerve cords consist only of nerve fibres. Finally, control and coordination of specific functions, such as locomotion and feeding, are compartmentalized in particular parts of the nervous system.

The complex nervous system of the cephalopods is correlated with the active movement and predatory habits of these animals. Most of the ganglia typical of mollusks are concentrated or fused in a brain that encircles the esophagus. Nerves extend from the brain to ganglia at the base of the arms or tentacles and from the ganglia the length of the arms. A pair of large pallial nerves connects the brain with a pair of stellate ganglia on the inner surface of the mantle. The stomatogastric ganglia supply nerves to the digestive tract.

A great variety of body functions are centralized in the brain and compartmentalized to specific brain regions. These activities may be local, simple, and uncoordinated with other regions or may be extensive, complex, and

coordinated, involving large groups of muscles. The highest centres of the cephalopod brain are the associative areas, concerned with discrimination between objects, learning, and memory.

Giant-fibre system of the squid

The giant-fibre system—also seen in earthworms and insects—is very well developed in the squid. The diameter of giant fibres is many times greater than the diameter of most other nerve fibres. Giant neurons in the brain send fibres to the retractor muscles of the head and the funnel or to the stellate ganglion. Fibres from the stellate ganglion fuse to form giant fibres that innervate the mantle. Because of their large size, these fibres are capable of rapid conduction that, in turn, permits extremely rapid movement.

The eyes of cephalopods are especially well developed and bear close structural resemblance to the vertebrate eye. The eye fits into a socket of cartilaginous plates separate from the cartilages that protect the brain, and external muscles permit its movement. A transparent cornea covers the surface of the eye and can be focussed for both near and far objects. There is a pupil formed by an iris diaphragm, which can regulate the amount of light reaching the retina. The retina contains light-sensitive cells that differ from those in the vertebrate eye in being directed toward the source of light. The axons of the photoreceptors, or rod cells, form the optic nerves, which terminate in the extremely large optic lobes of the brain.

Arthropods. The other complex compartmentalized nervous system is found in arthropods. The arthropodan brain consists of three main regions: the protocerebrum, deutocerebrum, and tritocerebrum (Figure 3D). The anterior protocerebrum, which receives the nerves of the eyes and other organs forward, contains centres or neuropils such as the optic centres and bodies known as corpora pedunculata. The neuropils function as integrative systems for the anterior sense organs, especially the eyes, and in control of movement; they also are the centres for the initiation of complex behaviour. The deutocerebrum contains the association centres for the first antennae. The posterior tritocerebrum contains association neuropils for the second antennae (of crustaceans) and gives rise to nerves that innervate the mouthparts and the anterior digestive canal. The latter comprise the stomatogastric system, which regulates the intake of food and the movement of the gut necessary for digestion. This system bears a resemblance to the vertebrate autonomic system (see below).

The ventral nerve cord, connected to the brain by the circumesophageal connectives, is basically composed of a double row of ganglia connected longitudinally by connectives and transversely by commissures. Different groups of arthropods exhibit different degrees of fusion of the ganglia. In insects, the first ganglion, the subesophageal, is formed by fusion of three pairs of ganglia; it sends nerves to the mouthparts and to the salivary glands. The segmental ganglia in the thorax and abdomen provide nerves to the appendages, dorsal muscles, sense organs, and heart. Insects have three pairs of thoracic ganglia and up to ten abdominal ganglia.

Giant-fibre systems—found in most arthropods with an elongated abdomen, such as shrimps, lobsters, and scorpions—take part in reflexes in which there is a tail flick or a jumping movement serving as a rapid means of escape.

The most common sensory receptors in arthropods are the cuticular hairs, many of which are mechanoreceptors, sensitive to touch, vibration, water currents, or sound waves; some hairs are chemoreceptors, which detect odours or chemicals in the water. Hairs situated near the joints are stimulated by body movements and thus provide a sense of the position of the joint or appendage during locomotion or flight. Many sensory cells and organs are concentrated in the antennae, and a statocyst is found at the base of each antenna.

The most highly developed organ for sound reception is the tympanal organ of grasshoppers, crickets, and cicadas. It consists of modified parts of the cuticle (the tympanum), to which are attached mechanoreceptor sensory neurons. Sound waves that produce vibrations in the tympanum are detected by the nerve cells.

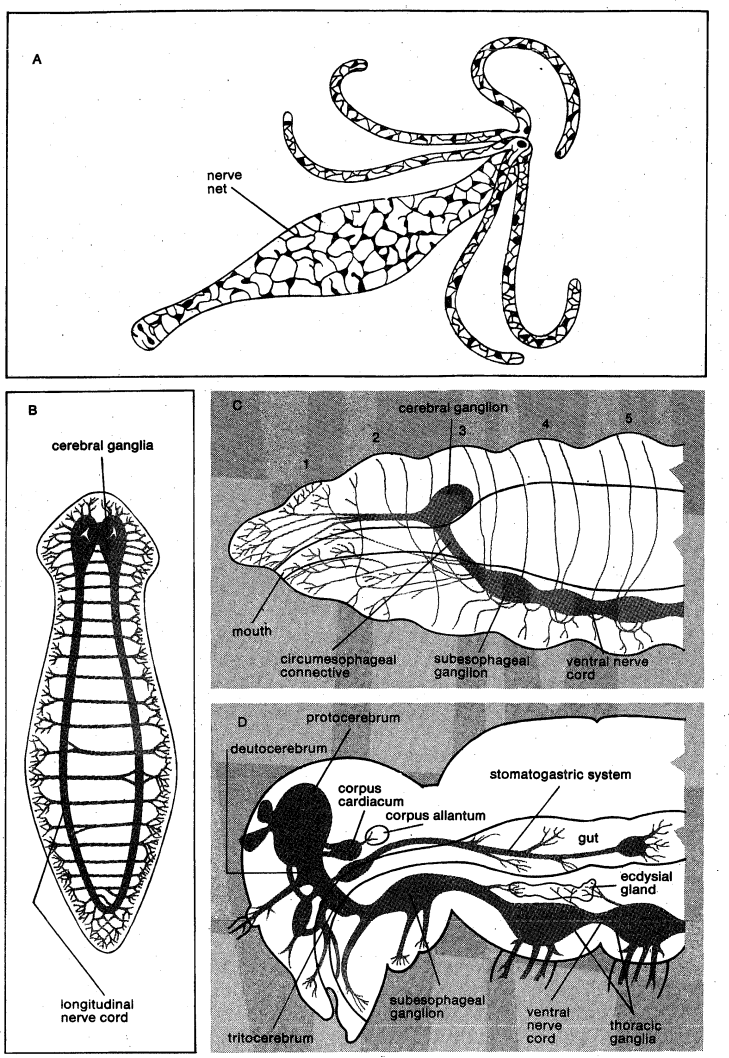

Figure 3: *Invertebrate nervous systems.*
(A) The nerve net of *Hydra*. (B) Central nervous system of a flatworm, composed of a brain (cerebral ganglia) and longitudinal nerve cords; (C) annelid, moderately cephalized with a brain, ventral nerve cord, and ventral ganglia; and (D) arthropod, highly cephalized and compartmentalized.

Spiders have several pairs of simple eyes with cup-shaped retinas. Crustaceans and insects, however, have a pair of well-developed compound eyes, each consisting of a large number of visual units called ommatidia. Each ommatidium contains six to eight sensory receptors arranged under a cornea and refractile cone and is surrounded by pigment cells, which adjust the intensity of light. Each ommatidium can act as a separate eye, capable of responding to its own visual field. Such an arrangement seems particularly well suited for detecting movement across a wide visual field.

Neurosecretory cells in crustaceans and arthropods

Neurosecretory cells, which have been identified in all the major invertebrate groups, reach their highest degree of development in the crustaceans and arthropods. The principal system of insects consists of neurosecretory cells in the protocerebrum of the brain. The axons of these cells form nerves that innervate structures called corpora cardiaca, situated just posterior to the brain. A corpus cardiacum is an organ in which neurosecretory products are stored in the nerve terminals for later release into the vascular system.

The neurosecretory cells of the protocerebrum manufacture a hormone called ecdysiotropin, or brain hormone. Sensory nerve impulses reaching the brain regulate the release of the hormone from the nerve endings into the blood within the corpora cardiaca. The hormone then stimulates a non-neural endocrine gland, the ecdysial gland, located in the thorax. The ecdysial glands in turn release a hormone, ecdysone, which initiates molting dur-

ing larval development and also stimulates differentiation into adult tissues. Another hormone, however, the juvenile hormone, keeps tissue in a juvenile or larval form. This hormone is released by the corpora allata, another pair of non-neural endocrine glands, located behind the corpora cardiaca. The successive life stages in insect development are, therefore, determined by the varying levels of ecdysone and juvenile hormone (see HORMONE; ENDOCRINE SYSTEMS).

IV. The vertebrate nervous system

The nervous system of vertebrates has two main divisions: the central nervous system, consisting of the brain and spinal cord, and the peripheral nervous system, which in man includes 12 pairs of cranial nerves and 31 pairs of spinal nerves, and the autonomic, or involuntary, nervous system. Because the arrangement of nerve cells and their fibres is so complex, it is helpful to understand some basic terms used in describing the vertebrate nervous system.

Anatomical structures such as the nervous system are described according to their position. In four-legged animals, the upper (back) surface is called dorsal and the lower (belly) surface ventral. The terms anterior, cranial, cephalic, or rostral refer to the head end of the body; posterior, or caudal, to the tail end. In man, since he stands erect, the situation is more complicated: dorsal becomes equivalent to posterior, and ventral is the same as anterior; cranial is often called superior, and caudal inferior. Objects near the middle plane of the body are medial and those farther away are lateral. Proximal refers to structures nearest the central bulk of a structure and distal to ones away from it. In referring to another structure, if it is located on the same side of the body, it is known as ipsilateral; if it is on the opposite side, it is contralateral.

Nerve cell bodies, or neurons, are often gathered into localized masses. In the peripheral nervous system these accumulations are called ganglia; in the central nervous system they are called nuclei. Portions of the central nervous system in which neurons predominate are called gray matter; areas in which myelinated nerves dominate are called white matter. Efferent, or motor, nerve fibres carry impulses away from the central nervous system; afferent, or sensory, fibres carry impulses toward the central nervous system. Visceral fibres innervate the viscera such as the heart and intestine, and somatic fibres innervate the body-wall structures such as skin and muscle. In the central nervous system, the nerve fibres are organized in bundles called tracts, or fasciculi. Ascending tracts carry impulses along the spinal cord toward the brain, and descending tracts carry them from the brain or higher regions in the spinal cord to lower regions. The tracts are often named according to their origin and termination; for example, the corticospinal tract consists of fibres running from the cerebral cortex in the brain to the spinal cord.

The account given here applies generally to the nervous system of mammals and particularly to that of the primates, including apes, monkeys, and men.

THE CENTRAL NERVOUS SYSTEM

The brain and its components. The brain is the greatly enlarged anterior portion of the central nervous system. It is enclosed within the cranial cavity of the skull and enveloped by membranes known as the meninges. Within the brain itself are cavities called ventricles, containing cerebrospinal fluid. The brain is divided into two major regions, the telencephalon (cerebral hemispheres) and the brainstem. The cerebral hemispheres include the cerebral cortex and basal ganglia. The brainstem is further subdivided into the diencephalon (thalamus and hypothalamus), mesencephalon (midbrain), metencephalon (pons and cerebellum), and the myelencephalon (medulla oblongata); the cerebellum lies behind the medulla and pons.

Major regions of the brain

Cerebrum. The two cerebral hemispheres make up the largest portion of the brain. Each hemisphere consists of an outer pallium, or cerebral mantle, and the deeply situated basal ganglia. The pallium is composed of an outer layer of gray matter, the cerebral cortex, consisting of the cell bodies of neurons, and an internal mass of white matter comprised of nerve fibres.

The surface of the hemispheres is wrinkled and convoluted by shallow furrows, or sulci; the ridges between the sulci are convolutions, or gyri. Deeper furrows are known as fissures. A deep longitudinal fissure incompletely separates the two hemispheres into right and left halves. At the base of the fissure, the hemispheres are joined by the corpus callosum, a broad band of nerve fibres. The two major grooves on the lateral surface of the brain are the lateral fissure (fissure of Sylvius), which starts at the base of the brain and extends upward and backward on the lateral surface, and the central sulcus (sulcus of Rolando), which runs from the middle of the dorsal border of the hemisphere downward almost to the lateral fissure.

The hemispheres are divided into lobes that have specific functions. The frontal lobe extends from the front of the brain to the central sulcus. The parietal lobe is the region behind the central sulcus and above the lateral sulcus. The temporal lobe lies below the lateral sulcus. The occipital lobe lies at the back of the brain, posterior to the temporal and parietal lobes. A fifth lobe, the insula, lies buried in the lateral sulcus. The olfactory lobe, or rhinencephalon, forms the lower (inferior) surface of the cerebrum.

The cells in the cerebral cortex are arranged indistinctly in six layers, from outside inward: molecular (I), external granular (II), external pyramidal (III), internal granular (IV), internal pyramidal (V), and fusiform (VI).

Each half of the cerebral cortex can also be divided into several regions depending on the distribution of afferent fibres or the origin of efferent fibres that connect with the deeper nerve centres. On this basis, the major functional regions of the cortex are the primary motor area, primary somesthetic area, primary visual area, primary auditory area, and the association areas.

The primary motor area is located on the anterior wall of the central sulcus and adjacent portions of the precentral gyrus of the frontal lobe. This region of the cortex controls the skeletal muscles on the opposite side of the body. The impulses travel over the corticospinal paths to the motor neurons of the spinal cord. The corticospinal tracts are formed by the axons of the Betz cells, giant pyramidal cells in layer V. The different parts of the body are represented in specific regions of the motor cortex, so that stimulation of a particular region of the cortex results in a particular movement.

General sensations from the skin, muscles, joints, and tendons reach the cortex by way of the thalamus. The fibres project to the somesthetic area located in the postcentral gyrus of the parietal lobe. The sensory cortex contains a pattern of localization of parts of the body similar to that in the motor cortex. Lesions of this area interfere with sensory perception but do not abolish it because some important sensations (*e.g.*, pain) enter consciousness at the level of the thalamus.

The primary visual area is located in the calcarine fissure of the occipital cortex. This region receives fibres carrying visual impulses from the lateral geniculate body; damage produces defects in vision. The primary auditory area is in the transverse temporal gyrus, which lies buried in the floor of the lateral cerebral fissure and receives auditory impulses from the medial geniculate body; injury can cause mild deafness.

Association areas of the cortex

Association areas, connected with the various motor and sensory areas, occupy a large portion of the cortex in higher vertebrates and are especially dominant among higher primates such as man. Association areas situated near the primary sensory areas are necessary to formulate sensory stimuli into images and to comprehend their meaning. Objects come to be associated with a constellation of past experiences, or memories. When sensory impulses excite these memories, the object is recognized. Before performing complex voluntary movements, there must first be a mental formulation of the plan, an idea.

The idea is transferred by association fibres to the motor area so that the movement can be executed. Complex sensory and motor associative mechanisms also underlie the comprehension of language.

The large remaining part of the frontal lobe, in front of the motor areas, is the prefrontal cortex, or frontal association area. Much of the prefrontal cortex is connected to the thalamus, which in turn has connections with autonomic centres in the hypothalamus. The frontal lobes also receive association fibres from other regions of the cortex. This region of the brain is responsible for certain aspects of higher intellectual functions and emotional behaviour in man.

Located on the inferior surface of the brain, the rhinencephalon is concerned primarily with the sensation of smell and the reception and integration of olfactory impulses (the rhinencephalon also includes the limbic system described below). The olfactory portion of the rhinencephalon includes the olfactory nerves, bulbs, tracts, and parts of the pyriform lobe. These regions of the brain constitute the paleopallium, which, in lower vertebrates, is very prominent.

A complex of structures forms the limbic system, or visceral portion of the brain. The limbic system consists of the limbic lobe, parts of the temporal and frontal cortex adjacent to the lateral sulcus, some thalamic and hypothalamic nuclei, and parts of the basal ganglia. The limbic lobe is formed by gyri surrounding the anterior end of the brainstem and corpus callosum. Parts of the limbic lobe, the hippocampus, and dentate gyrus constitute another old—in terms of evolution—part of the cerebral cortex, the archipallium. There are complicated interconnections between structures of the limbic system and with other parts of the brain; one major connection is the fornix, running from the hippocampus to the hypothalamus. The limbic system, through its connections with the cortex and hypothalamus, is thought to play a major role in the emotional responses to either hypothalamic activity or to higher thought processes and appears to be involved in reactions of fear, rage, or aggression and in sexual behaviour.

Deep within the cerebral hemispheres are masses of gray matter forming the basal ganglia, which regulate movement. These include the caudate nucleus, putamen, globus pallidus, and amygdaloid nuclear complex. Only the last named nucleus is part of the limbic system. The other nuclei form the corpus striatum, which constitutes the extrapyramidal system (distinguished from the pyramidal system originating in the motor areas of the cerebral cortex). Fibres from the corpus striatum run to the thalamus and subthalamus.

Diencephalon. The diencephalon is the most anterior end of the brainstem. Although small, it is a complex and important part of the nervous system, being composed of the thalamus, geniculate bodies, hypothalamus, subthalamus, and epithalamus.

The thalamus: an integration centre

The thalamus, an ovoid mass of gray matter lying on either side of the third ventricle, is composed of several groups of nuclei connected with other parts of the brain. The subcortical nuclei receive fibres from the major sensory systems and connect only with subcortical structures such as the hypothalamus and basal ganglia. Another group of nuclei, the cortical relay nuclei, receive fibres from the sensory tracts and also from the cerebellum, reticular system, and basal ganglia. Fibres from these nuclei project to the cerebral cortex. The association nuclei do not receive fibres from the sensory systems but are connected with other nuclei in the diencephalon and project to the association areas of the cerebral cortex. The thalamus is a major sensory integration centre, receiving all sensory impulses except the olfactory ones. It also seems to play a major role in the regulation of the state of consciousness, alertness, and attention and is responsible for some of the emotional experiences that accompany sensory perception.

The geniculate bodies are two pairs of small swellings on the lateral surfaces of the thalamus. The optic tracts, collections of nerve fibres from the retina of the eyes, transmit visual impulses to the lateral geniculate bodies, which then relay them to the visual cortex. The medial geniculate bodies receive auditory impulses via parts of the midbrain and relay them to the temporal lobe of the cerebral cortex.

The hypothalamus lies below the thalamus and forms the floor of the third ventricle. On the ventral surface of the brain are the crossing of the optic tracts (the optic chiasma), a slight eminence called the tuber cinereum, the infundibulum (a stalk connecting the tuber cinereum with the neural lobe, or pars nervosa, of the pituitary), and a pair of small swellings called the mammillary bodies. Although small, the hypothalamus has extensive and complex fibre connections. It receives fibres from olfactory nuclei, thalamus, hippocampus, amygdala, frontal lobe, and midbrain. From the hypothalamus, tracts proceed to the thalamus, tegmentum of the midbrain, autonomic centres and reticular formation of the brainstem, and neural lobe of the pituitary. The hypothalamus has important functions related to temperature regulation, water balance, and glandular secretion. Some of these functions are controlled through the connections with the pituitary; others are mediated through control of autonomic activity. If the external temperature drops, for example, the posterior hypothalamus initiates activities necessary to prevent heat loss (*e.g.*, constriction of blood vessels) and, under more extreme conditions, initiates muscular and metabolic activities that actually increase heat production (*e.g.*, shivering, oxidation of body resources). If the external temperature rises, activities that increase heat loss (*e.g.*, sweating and dilation of blood vessels) are initiated. Another regulatory activity of the hypothalamus is control of food intake by interaction of a feeding centre, which produces a desire to eat, and a satiety centre, which decreases the appetite. Finally, through its connections with the autonomic nervous system, the hypothalamus is a principal centre of emotional expression.

The subthalamus lies between midbrain and the thalamus. It receives connections from the basal ganglia. The epithalamus, which forms the roof of the diencephalon, has a curious small outgrowth, the pineal body (epiphysis), connected to it. The functions of the pineal body are obscure, but it is thought to be an endocrine gland that influences sexual function. It may be responsible for the sexual cycles associated with seasonal light changes such as occur in birds and small mammals. In lower vertebrates, it contains light-sensitive cells.

Possible functions of the pineal body

Midbrain. The midbrain, or mesencephalon, is the shortest portion of the brainstem. It is divided into three parts: the tectum, or quadrigeminal plate; the crura cerebri; and the tegmentum. The crura cerebri and tegmentum together comprise the cerebral peduncles, two large projections that contain fibres passing between the cerebral cortex and lower levels of the central nervous system. The two parts of the peduncles—crura cerebri and tegmentum—are separated by a black coloured nucleus known as the substantia nigra. A red nucleus is found in the raised part of the tegmentum and, giving rise to the rubrospinal tract, is part of the reticular formation of the brainstem. Fibres of the superior cerebellar peduncles enter the tegmentum. The cavity of the midbrain, the cerebral aqueduct, is surrounded by the central gray substance formed of the nuclei of two nerves that participate in eyeball movement, the trochlear and oculomotor nerves, and a portion of the trigeminal nucleus.

The quadrigeminal plate contains four rounded elevations called the corpora quadrigemina. The two higher projections are the superior colliculi, which receive fibres from the optic nerves and serve as reflex centres for eye movements and blinking. The lower pair—the inferior colliculi—are auditory reflex centres and receive fibres from the lateral lemnisci, bands of nerve fibres on either side of the peduncles. Cells in the nuclei of the tectum send fibres to motor neurons in the brainstem by way of the tectobulbar tracts and to the spinal cord by way of the tectospinal tracts.

Pons. The pons is an oblong-shaped mass located just ahead of the medulla. The middle cerebellar peduncles leave the lateral aspect of the pons, and the superior

cerebellar peduncles enter the cerebellum from the dorsal aspect. The abducens nerve—another nerve that influences the eyeball movement—leaves the ventral surface of the pons. The trigeminal nerve arises from the lateral surface; the facial and acoustic nerves emerge from the angle formed by the pons, medulla, and cerebellum.

The pons is divided into a dorsal portion known as the tegmentum and a ventral, or basilar, portion. The dorsal portion of the pons contains the forward extension of the reticular formation from the medulla. It also contains the motor nuclei of the facial, abducens, and trigeminal nerves, the main sensory and spinal nuclei of the trigeminal nerve, and the vestibular and cochlear nuclei of the acoustic nerve. The trapezoid body and the lateral lemniscus, which goes to the midbrain, are formed by fibres from the cochlear nuclei.

Fibres leaving the four vestibular nuclei extend into the cerebellum. Other fibres form a tract called the medial longitudinal fasciculus, through which branches descend through the medulla to the spinal cord; others ascend and end in the nuclei of the muscles of the eyeball. Still other fibres from the nuclei give rise to the two vestibulospinal tracts. The vestibular nuclei are thus important relay centres for coordinating movements of the eyes, neck, and body and for maintaining equilibrium, posture, and muscle tone.

The basilar portion of the pons consists of transverse and longitudinal fibres between which are the pontine, or pontile, nuclei. The longitudinal tracts are the corticospinal, corticobulbar, and corticopontine tracts. The transverse tracts, formed by the axons of nerve cells in the pontine nuclei, cross to the opposite side and form the middle cerebellar peduncle. The cells of the pontine nuclei receive terminations from the corticopontine tract and thus act as a relay station between the cerebral cortex and cerebellum.

Cerebellum. The cerebellum is divided into two large lateral portions, the cerebellar hemispheres, and a narrow middle portion called, because of its "tangled worm" appearance, the vermis. Three lobes can be distinguished on each hemisphere. The flocculonodular lobe in the posterior lower region consists of paired bumps, called flocculi, and the nodulus, or lower part of the vermis. The anterior lobe comprises that part of the cerebellum lying anterior to the primary sulcus. The posterior lobe, located between the other two lobes, constitutes the main part of the cerebellum. The flocculonodular node is part of the vestibular system involved in equilibrium. In terms of evolution, it is the oldest part of the cerebellum and is called the archicerebellum. The anterior lobe receives most of the proprioceptive impulses (originating in muscles and tendons) from the spinocerebellar pathway and regulates muscle tone. It is also an old part of the cerebellum and is called the paleocerebellum. The posterior lobe is the most recent development of the cerebellum—the neocerebellum—and is most prominent in primates and man. This portion of the cerebellum is involved in the coordination of fine, skilled movements.

"Old" and "new" parts of the cerebellum

The cerebellum, like the cerebrum, consists of a superficial mantle of gray matter and an inner mass of white matter. The surface of the cerebellum has a large number of sulci and fissures between narrow ridges called folia, or gyri. The cortex of gray matter has an outer molecular layer with many nerve cell processes, a single row of very large neurons (Purkinje cells), and an inner granular layer with many small nerve cells. Deep within the white matter are four pairs of cerebellar nuclei—the fastigial, globose, emboliform, and dentate—which act as relay stations between the cerebellar cortex and other parts of the brain.

The cerebellum is attached to the brainstem by the cerebellar peduncles, which are composed of large numbers of nerve fibres entering and leaving the cerebellum. These fibres connect the cerebellum with the cerebral cortex, brainstem, cranial nerve nuclei, and the spinal cord. The superior cerebellar peduncle, or brachium conjunctivum, contains most of the fibres leaving the cerebellum. These fibres arise from the dentate and other cerebellar nuclei and extend to the red nucleus, thalamus, and reticular formation. The middle cerebellar peduncle, or brachium pontis, consists entirely of fibres from the nuclei embedded in the pons. The inferior cerebellar peduncle, or restiform body, contains one efferent tract, which runs from the fastigial nucleus to the vestibular nuclei. It also contains several groups of afferent fibres that arise from the vestibular nerve and nuclei, inferior olivary nuclei, gracile and cuneate nuclei, and the posterior spinocerebellar tract from the spinal cord.

Conscious perception does not occur in the cerebellum nor can the coordinative functions of the cerebellum be voluntarily modified. In order to control or modify muscular activity, the cerebellum must receive information about position and movement. It is informed of the commands being issued by the cerebral cortex over the cortico-ponto-cerebellar pathway, of the status of the muscles and joints of the body over the spinocerebellar tracts, and of other sensory events from the skin, eyes, and ears.

Within the cerebellar cortex, the sensory signals are evaluated and appropriate corrections are made for any mistakes or inaccuracies of muscle activity. Nerve impulses are dispatched from the Purkinje cells to the cerebellar nuclei, from which there are several routes over which impulses reach the voluntary motor system to modify muscular movements.

Medulla oblongata. The medulla, the lower part of the brainstem, extends from the pons to join the spinal cord at the opening (foramen magnum) at the base of the skull. On its ventral surface, the corticospinal tracts can be seen as two longitudinal ridges on either side of the anterior median fissure. Such cranial nerves as the hypoglossal, glossopharyngeal, vagus, and accessory emerge from the lateral surface of the medulla. The dorsal, anterior surface of the medulla is formed by the thin roof of the fourth ventricle, alongside of which are the prominent inferior cerebellar peduncles.

Internally, many of the long fibre tracts of the spinal cord extend into the medulla. They may pass through directly or change their positions; their complete course and function are described along with the spinal cord (below). In the lower region of the medulla, the ventral pyramidal tracts form a prominent crossing (decussation) of the fibres to opposite sides. Dorsally, the fasciculi gracilis and cuneatus from the spinal cord terminate in the nuclei gracilis and cuneatus. The fibres of the cells in these nuclei arch downward as the internal arcuate fibres and cross the midline as the decussation of the medial lemniscus. The medial lemniscus travels up the brainstem and terminates in the thalamus.

In the upper half of the medulla, the inferior olivary nucleus in the ventrolateral region is a convoluted band of gray matter receiving fibres from the cerebral cortex and other higher structures and from the spino-olivary tract. From the olive (a prominence on each side of the medulla nearest the pons) fibres join the spinocerebellar fibres in the inferior cerebellar peduncle and proceed to the cerebellum. On the dorsal part of the medulla are the origins of three cranial nerves: the nucleus of the hypoglossal nerve, supplying the muscles of the tongue; the dorsal motor nucleus of the vagus nerve, supplying the viscera (heart, lungs, intestines); and the vestibular nuclei, receiving sensory fibres from the vestibular division of the acoustic nerve. Laterally, the solitary tract and nucleus convey taste impulses from several nerves. The spinal trigeminal tract and nucleus, which extends from higher levels into the lower portion of the medulla, convey sensory impulses from the face. The nucleus ambiguous supplies fibres via several nerves that innervate the muscles of the throat and voice box.

Around the central canal of the medulla is a diffuse network of cells and fibres called the reticular formation. It contains a respiratory centre, which controls the rhythmic respiratory movements. Other cells in the reticular formation control blood pressure, heart activity, and intestinal movements.

The reticular formation

The spinal cord. The spinal cord with its coverings lies loosely within the vertebral canal of the backbone. It extends from the foramen magnum at the base of the skull to the lower border of the first verterbra of the

lumbar section. The spinal cord is roughly cylindrical in shape, though somewhat flattened. The swollen regions of the cord that innervate the appendages are known as the cervical and lumbar enlargements. Below the lumbar enlargement, the cord tapers in a cone called the conus medullaris. From the conus, a slender non-nervous filament, the filum terminale, runs downward and attaches to the tailbone, or coccyx. The spinal nerves are formed by fusion of dorsal and ventral roots, which originate from the spinal cord. The spinal nerves pass through the openings between the vertebrae. Since the vertebral column is longer than the spinal cord, the spinal nerves must run downward at an angle to the cord to reach their corresponding intervertebral openings. In the lumbar and sacral regions, the roots of the spinal nerves extend past the end of the spinal cord in a bundle of nerve fibres called the cauda equina because of its fancied resemblance to a horse's tail.

There are a number of longitudinal grooves, or furrows, on the surface of the cord (Figure 4). A deep anterior, or ventral, median fissure and a shallow posterior, or dorsal, median sulcus divide the cord into equal right and left halves except in the midpoint, where the two halves are joined by tracts that cross. The posterolateral and anterolateral sulci are located more laterally. Dorsal roots of the spinal nerves enter the cord at the posterolateral sulcus and the ventral roots leave at the anterolateral sulcus. In the cervical and upper thoracic portions of the cord, the posterior intermediate sulcus runs between the median and posterolateral sulci.

Spinal columns. The spinal cord consists of centrally placed gray matter surrounded by white matter. The gray matter, which contains nerve cell bodies, unmyelinated nerve fibres, dendrites, and terminal branches, roughly has the form of a butterfly or the letter H. The crossbar is the gray commissure, in the centre of which runs the central canal of the spinal cord. The gray substance extending dorsally (posteriorly) from the commissure is called the dorsal, or posterior, column, or horn; that extending ventrally (anteriorly) is the ventral, or anterior, column, or horn. Between the dorsal and ventral horns is a slight lateral projection of gray matter known as the lateral horn. The cells of the gray matter can be divided into two major columns, motor and receptor. The motor neurons are situated in the ventral and lateral gray columns and give rise to the ventral roots of the spinal nerves. Large motor neurons in the ventral horn supply the voluntary skeletal muscle, and smaller neurons give rise to efferent fibres that innervate the sensory endings in muscles (neuromuscular spindles). The motor cells of the lateral column give rise to the preganglionic fibres, which leave the cord via the ventral root and terminate in the sympathetic ganglia of the thoracic, lumbar, and sacral portions of the autonomic system. The receptor part of the spinal cord is in the dorsal columns, where many fibres of the dorsal root (sensory) cells terminate. These cells—the central, internuncial, commissural, or association neurons—are confined to the central nervous system. Most of their fibres divide in the shape of a T as they enter the white matter and form ascending and descending branches. When the fibres remain on the same side of the spinal cord, the cells are known as association, or ipsilateral, column cells. If the axons cross to the other side of the spinal cord, the cells are called contralateral, or commissural, cells. The most prominent group of cells in the dorsal column is the nucleus dorsalis, or Clarke's column, which sends fibres into the dorsal spinocerebellar tract. The substantia gelatinosa is the chief associative centre for incoming impulses.

The funiculi of the white matter

The white matter is divided into three main columns known as funiculi. The dorsal funiculus lies between the dorsal median septum and the dorsal lateral sulcus. The lateral funiculus is situated between the dorsal lateral sulcus and ventral lateral sulcus. The region between the ventral lateral sulcus and ventral median fissure is the ventral funiculus. The white matter in the two halves of the spinal cord is joined by the ventral white commissure, which lies directly in front of the ventral gray commissure.

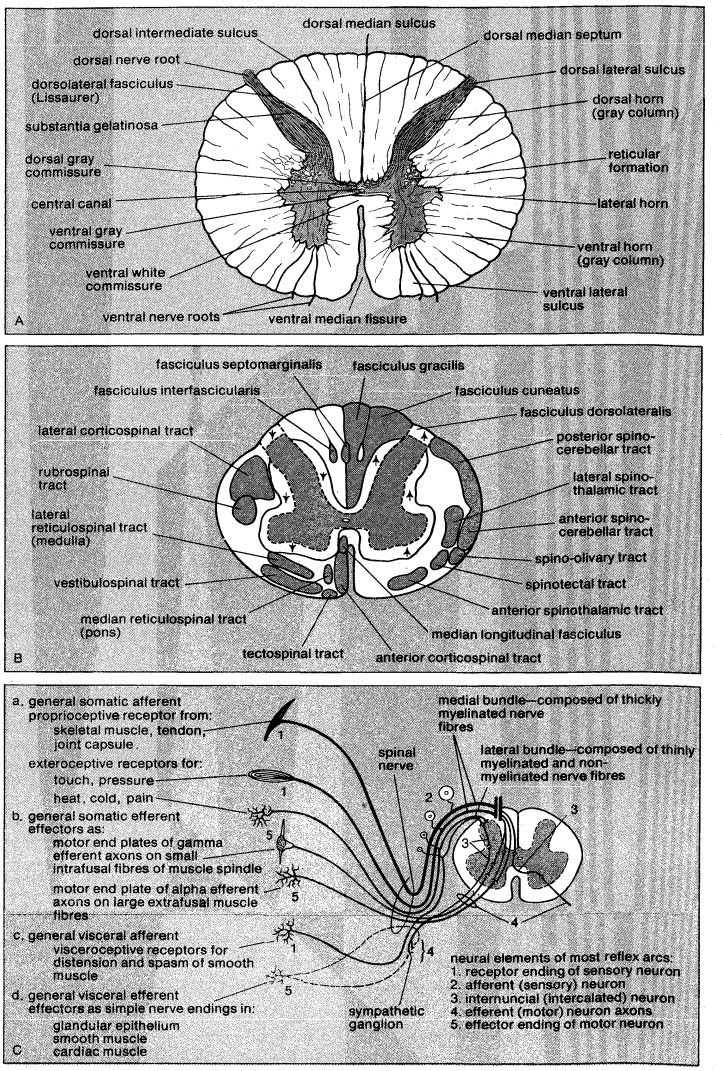

Figure 4: (A) Transverse section of the mammalian spinal cord in the midthoracic region. (B) (Left) Descending and (right) ascending pathways of the spinal cord. (C) Functional components of a spinal nerve. Receptor and effector endings and reflex connections in the spinal cord are shown.

Spinal tracts. Within the dorsal, lateral, and ventral columns, the nerve fibres are organized in specific bundles called tracts, or fasciculi. The fasciculi connect different levels of the spinal cord or connect the spinal cord with the brain. The tracts are called descending or ascending depending on the direction in which the nerve fibres run within them. The descending tracts, formed by the fibres of nerve cells located in the brain, end near motor neurons in the ventral horns of the spinal cord and so are mainly associated with motor activities. The ascending tracts, which originate from neurons in the receptor region of the spinal cord gray matter, carry to the brain impulses related to sensation. Other (intersegmental) tracts carry fibres involved in certain reflex activity.

The corticospinal, or pyramidal, tracts are the largest and most important of the descending tracts. They consist of nerve fibres of pyramidal cells in the cerebral motor cortex. At the level of the medulla, some of the fibres cross to the opposite side and form the lateral corticospinal tract. The uncrossed fibres continue as the ventral corticospinal tract. The fibres of the pyramidal tracts terminate on motor cells in the ventral horn and carry the impulses for voluntary motor and skilled activities.

The rubrospinal tract in the lateral funiculus arises from the contralateral red nucleus of the midbrain. The fibres end on neurons in the ventral horn and carry impulses that control muscle tone in certain muscle groups.

The two vestibulospinal tracts (medial and lateral) in the ventral funiculus originate from the vestibular nuclei at the junction of the medulla and pons. Impulses are carried to this area from the internal ear over the vestibular nerve. The fibres of these tracts terminate on lower motor neurons in the ventral horns. These tracts are involved in balance reflexes that maintain equilibrium.

The reticulospinal tracts (lateral and medial) descend in the ventral funiculus. They arise in the reticular substance of the medulla and pons. Some of the fibres end on the preganglionic neurons of the lateral gray columns and carry impulses related to several autonomic activities such as temperature and respiratory regulation. Other fibres act on certain motor neurons to influence muscle tone.

The tectospinal tracts descend from neurons of the contralateral superior colliculus—an optic relay centre—and mediate postural reflexes, especially of the head and upper extremity, in response to visual stimuli. Fibres of the olivospinal tract arise from the inferior olive of the medulla and help coordinate movements of the head and upper extremity.

Descending autonomic pathways

The pathways just described eventually terminate on ventral horn cells that innervate the voluntary striated muscles. The spinal cord also contains descending autonomic pathways for the innervation of visceral structures such as smooth muscle, heart muscle, and glandular tissue. Many of these fibres originate in the hypothalamus. The pathways are diffuse and located mainly in the ventral and ventrolateral portions of the white matter. The fibres terminate on preganglionic cells in the lateral gray column.

The largest ascending tracts to the cerebral cortex are found in the dorsal white columns. These pathways are the fasciculus gracilis and the fasciculus cuneatus, which are formed by the ascending branches of the central processes of the dorsal root ganglion cells. The fasciculus gracilis contains long ascending root fibres from the sacral, lumbar, and lower thoracic ganglia. The fasciculus cuneatus contains fibres from the upper thoracic and cervical ganglia. All these fibres terminate on neurons in the nucleus gracilis and nucleus cuneatus in the medulla. The axons of these latter neurons then cross the midline, travel upward in the medial lemniscus, and end in the ventral dorsolateral nucleus of the thalamus. From the thalamus, neurons in turn send axons to the sensory areas of the cerebral cortex. The fibres in the dorsal columns carry impulses from tactile receptors necessary for the ability to detect the size, shape, and texture of objects by feeling them. In addition to tactile impulses, these tracts carry the proprioceptive impulses that convey information concerning the movements of limbs and the position of different parts of the body.

Axons of neurons in the dorsal horn cross in the anterior white commissure and turn upward in the contralateral ventral spinothalamic tract. The fibres terminate on cells of the ventral dorsolateral nucleus of the thalamus, from which the impulses are relayed to the cerebral cortex. The ventral spinothalamic tract carries the impulses of simple or light touch.

The central processes of pain and temperature receptors enter the zone of Lissauer (dorsolateral fasciculus) and ascend or descend one or two segments before ending on cells in the substantia gelatinosa and dorsal gray matter. The axons of these cells cross in the anterior white commissure and ascend in the opposite lateral funiculus as the lateral spinothalamic tract to the ventral dorsolateral nucleus of the thalamus, from which fibres extend to the cortex.

The uncrossed posterior spinocerebellar tract arises from the cells of Clarke's column (dorsal nucleus) of the dorsal horn. Its fibres enter the cerebellum by way of the inferior cerebellar peduncle and terminate in the cortex of the cerebellum. This tract relays impulses from stretch, touch, and pressure receptors, information utilized in the coordination of posture and movement of individual limb muscles. Other axons from the dorsal horn cross in the ventral white commissure and join uncrossed fibres in the ventral spinocerebellar tract. These fibres, which enter the cerebellum in the superior cerebellar peduncle, also convey information concerning movement and posture.

Besides these major ascending pathways, several other ascending fibre systems are found in the spinal cord. These include the spino-olivary tract to the inferior olivary nucleus, spinoreticular fibres to the brainstem reticular formation, the spinotectal tract to the superior colliculus, a spinovestibular system to the lateral vestibular nucleus, spinopontine fibres to the pontine nuclei, and a spinocortical tract to the cerebral cortex.

Intersegmental tracts

Intersegmental tracts connect different levels of the spinal cord. In the majority of reflex arcs, there is at least one central, or internuncial, neuron between afferent and efferent neurons. The internuncial neuron may then send its axons to motor cells of the same segment or to higher and lower segments. Commissural cells send axons to the white matter of the opposite side of the spinal cord. All these nerve fibres, which may be ascending or descending, crossed or uncrossed, begin and end in the spinal cord and connect its various levels. They constitute the proprius bundles (fasciculi proprii), spinospinal, or fundamental columns of the spinal cord, and are found in all the funiculi of the white matter immediately outside the gray matter.

In addition to the proprius bundles, there are some systems associated with the major conduction pathways. The dorsal root neurons whose ascending branches form the fasciculus gracilis and fasciculus cuneatus tracts also have descending branches, which are involved in intersegmental reflexes. In the cervical and thoracic cord, these descending fibres form a small bundle, known both as the fasciculus interfascicularis and as the comma tract of Schultze, located in the dorsal funiculus. In the lumbar region, the fibres descend in the septomarginal fasciculus, situated in the middle of the dorsal median septum.

The brain coverings, cavities, and cerebrospinal fluid. *Meninges.* The spinal cord and brain are tightly covered by three connective tissue envelopes, the meninges: the outer layer is the dura mater, the middle layer the arachnoid, and the inner the pia mater.

The dura mater is tough, dense, and firm. The dura mater of the brain has two layers: a thin inner layer and a thicker outer layer that serves as the covering (periosteum) for the inner surface of the cranial bones. In the spinal cord the vertebrae have their own coverings, and, while the dura is separated from the vertebral periosteum by the epidural space, it is connected to the spinal cord on each side by a series of ligaments. The nerve roots emerging from the cord penetrate and become invested by the dura.

The arachnoid is a thin, delicate membrane devoid of blood vessels. From its inner surface, numerous strands connect to the pia mater across the subarachnoid space. The dura and arachnoid pass over the sulci and fissures on the surface of the brain and spinal cord without dipping into them. The pia mater, however, is a thin membrane that closely adheres to the surface of the brain and spinal cord, following each crevice. The pia contains a large number of blood vessels.

Ventricles. The central nervous system begins its development as a hollow tube. The cavity persists in the adult as the central canal of the spinal cord and the ventricles of the brain. There are two large lateral ventricles in the cerebral hemispheres. The third ventricle lies in the thalamic region and is connected to the lateral ventricles through openings called the interventricular foramina (foramina of Monro). The cerebral aqueduct (aqueduct of Sylvius) connects the third ventricle with the fourth ventricle in the pons and medulla. The central canal of the spinal cord extends from the fourth ventricle.

Cerebrospinal fluids. All these interconnected spaces —the ventricles, central canal, and subarachnoid spaces —are lined with a cellular layer called the ependyma and filled with cerebrospinal fluid, a clear, colorless, noncellular fluid that bathes the interior of the brain and spinal cord and cushions against any jarring shocks. It might also provide a pathway for certain substances to reach the intercellular spaces of the brain and for others to be carried away.

Sources of cerebrospinal fluid

There is constant production, circulation, and resorption of cerebrospinal fluid. The principal sources are the choroid plexuses, membranes found in part of the wall of the lateral ventricles and in the roof of the third and fourth ventricles. They are formed by vascular pia mater pushing the ependyma into the ventricles. Fluid from the lateral ventricles passes through the foramina of Monro into the third ventricle. More fluid is added here and passes through the aqueduct of Sylvius to the fourth ventricle, where additional fluid is added. From the fourth ventricle, it reaches the subarachnoid space on the surface of the nervous system by passing through medial (foramen of Magendie) and lateral (foramina of Luschka) openings. At these regions, the subarachnoid space is very wide forming dilated cisterns. The largest is the cisterna cerebellomedullaris (cisterna magna) between the cerebellum and medulla. The apertures of the fourth ventricle open into this cavity. From the cisterns, the cerebrospinal fluid diffuses into the subarachnoid spaces around the brain and spinal cord, most of it absorbed by pia–arachnoid extensions (villi) or granulations (Pacchionian bodies) into venous sinuses of the dura.

Neuroglia: non-nervous tissue. Although the number of nerve cells in the central nervous system is enormous, there is an even greater number of non-nervous cells called glial, or neuroglial cells (comprising the neuroglia), which intermingle with the nerve cells in the central nervous system. There are three types of glial cells: astrocytes, oligodendrocytes, and microglia. Besides glial cells, the ependyma and the so-called satellite cells on the surface of neurons in peripheral ganglia belong to the non-nervous tissues of the central nervous system. The Schwann cells of peripheral nerves could be considered as peripheral neuroglia.

The astrocytes are the largest and most numerous of the glial elements, with long branching processes that invest the nerve cells and provide much of the packing material of the nervous system. They provide structural support to nerve cells, may help regulate the transfer of substances from blood capillaries to the nerve tissue, and may prevent the spread of impulses into improper channels. The oligodendrocytes are smaller than the astrocytes and have fewer processes. They are aligned in columns along the nerve fibres and are believed to form the myelin sheaths in the central nervous system. The satellite cells on the surface of some neurons appear to be a type of oligodendrocyte.

The microglial cells are smaller than the other glial cells and are found between nerve cells and along blood vessels. They are considered to be the scavengers of the nervous system, moving about under conditions of inflammation or injury and removing particles and debris in the manner of phagocytes in the blood.

THE PERIPHERAL NERVOUS SYSTEM

Nerve fibres classified by function and innervation

Nerve fibres can be classified according to their function and the regions they innervate. Nerve fibres innervating the body wall structures are designated as somatic; those innervating the internal organs are called visceral. Sensory fibres, which carry impulses to the central nervous system, are called afferent; motor fibres, carrying impulses away from the brain or spinal cord, are efferent. General somatic afferent fibres carry exteroceptive sensory impulses (of pain, temperature, touch, pressure) from the skin and connective tissue and proprioceptive sensory impulses (stretch, position) from the muscles, tendons, and joints. General visceral afferent fibres carry sensory impulses from the visceral organs including the blood vessels. Special somatic afferent fibres carry impulses from the sense organs such as the eye and the ear. Special visceral afferent fibres convey the impulses for smell and taste. Somatic efferent fibres carry impulses to skeletal muscle. General visceral efferent fibres innervate smooth muscle, the heart, and glands. Special visceral efferent fibres innervate the muscles of mastication, facial muscles, and muscles of the pharynx and larynx.

On the basis of anatomical origin nerves are classified as cranial, when their roots arise in the brain, or spinal, when their roots originate in the spinal cord.

Cranial nerves. The 12 pairs of cranial nerves, named from studies of man and other mammals (see NERVOUS SYSTEM, HUMAN), are organized similarly in all vertebrates with minor differences. These nerves are the olfactory (I), optic (II), oculomotor (III), trochlear (IV), trigeminal (V), abducens (VI), facial (VII), acoustic (VIII), glossopharyngeal (IX), vagus (X), accessory (XI), and hypoglossal (XII). All 12 nerves are found in reptiles, birds, and mammals. In fish and amphibians the first ten are present, and the eleventh is part of the tenth nerve. In addition, all vertebrates have an anterior nerve, the terminal, which supplies the olfactory organs. The terminal nerve is rudimentary in primates.

The cranial nerves can be grouped into several functional categories. Special somatic sensory fibres are carried by nerve I (smell), nerve II (vision), and the cochlear (hearing) and vestibular (equilibrium) divisions of nerve VIII. In fish and aquatic amphibians, sensations of water movement are carried in lateral line nerves. The special visceral sense of taste is conveyed by nerves VII, IX, and X. These sense of smell is often classified also as special visceral because it is associated with the visceral function of digestion. Some cranial nerves innervate the voluntary muscles derived from the embryonic somites. These nerves, called general somatic efferent, supply the muscles of the eyeball (nerves III, IV, and VI) and the muscles that move the tongue (nerve XII). These nerves also carry proprioceptive (locational) impulses from these muscles. Several cranial nerves innervate the branchiomeric (gill) arches of fish and the derivatives of the arches in higher vertebrates. The nerves supplying these structures have mixed motor and sensory components and include nerves V (first arch, the jaws), VII (second arch, the hyoid arch), IX (third arch), and X and XI (other arches). Sensations from the face (touch, pain, temperature, proprioception) are carried in general somatic afferent fibres of nerve V. General visceral afferent fibres in nerves VII, IX and X carry sensations from visceral organs, including the heart and intestines. Special visceral efferent (motor) fibres supply the muscles of the gill arches in fish and amphibians. In higher vertebrates they innervate the muscles of chewing (nerve V), facial expression (nerve VII), pharyngeal muscles of swallowing and laryngeal muscles of the vocal cords (nerves IX and X), and some muscles of the neck (nerve XI). Several of the cranial nerves have general visceral efferent (parasympathetic motor) fibres of the autonomic nervous system. Fibres in nerve III supply the muscles for focussing the eye and constricting the pupil. The lacrimal (tear) gland is controlled by nerve V and the salivary glands by nerves VII and IX. The thoracic viscera (heart, lungs, esophagus, glands, intestine) are supplied by the vagus (X) with a small contribution from nerve XI.

The primitive hypothetical vertebrate may have exhibited a segmental pattern of peripheral nerves associated with the brain similar to the arrangement in the spinal cord. The evolution of cranial nerves, however, did not involve a union of dorsal and ventral roots as in the spinal cord. Instead, one or another root dropped out. In the primitive situation, the dorsal root contained visceral motor fibres as well as sensory fibres, while the ventral roots were somatic motor in character. Thus, the cranial nerves of primates that are largely somatic motor (III, IV, VI, and XII) represent original ventral roots. The branchiomeric nerves with sensory and visceral motor components represent dorsal root nerves (V, VII, IX, X and XI).

Spinal nerves. A spinal nerve arises from each segment of the spinal cord. The number of spinal nerves varies from ten pairs, in some tailless amphibians, to over 500 pairs, in snakes. The nerves are named for the level of emergence from the spinal cord, as cervical (neck region), thoracic (chest region), lumbar and sacral (lower back region), and coccygeal (tailbone).

Each spinal nerve is formed by two roots, a dorsal sensory and a ventral motor root, which arise from the spinal cord. In the most primitive vertebrates, the roots remain as distinct nerves. In all other vertebrates, the

dorsal and ventral roots fuse to form the spinal nerve, which passes through an opening (foramen) in the vertebra. The sensory ganglion, a cluster of cell bodies of the sensory neurons, is situated on the dorsal root.

The dorsal roots contain general somatic afferent fibres (sensory fibres from muscle, skin, and other somatic structures) and general visceral afferent fibres (from visceral structures like the intestine). The ventral roots contain somatic efferent fibres, the motor fibres innervating somatic structures, and the general visceral efferent fibres that are preganglionic axons for the autonomic system.

After a short distance the spinal nerve branches into four divisions called rami: dorsal ramus, ventral ramus, ramus communicans, and meningeal ramus. The dorsal ramus innervates the muscles and skin of the back. The large ventral ramus supplies the ventrolateral portion of the body wall and the extremities. The small meningeal branch re-enters the intervertebral foramen and supplies the meninges and vertebral column. The ramus communicans joins the sympathetic ganglion. The general visceral efferent fibres leave the spinal nerve through the white portion (myelinated nerves) of the ramus communicans. Postganglionic general visceral efferent fibres from the sympathetic ganglion join the spinal nerve over the gray ramus (unmyelinated fibres). The general visceral afferent fibres reach the spinal nerve via the white ramus.

When, during development, the embryonic segments migrate to their adult positions—reflecting roughly the changes that occurred during evolution—the spinal nerves migrate with them, resulting in the intermixing and crossing of adjacent nerve trunks in certain areas.

Role of vertebrate plexuses

In many vertebrates, collections of nerves (plexuses) emerge at areas of concentration along the spinal cord. The cervical plexus emerges in the neck region and provides nerves that supply many muscles in the neck and chest as well as the diaphragm. The brachial plexus supplies nerves to the upper extremities—shoulder, forelimb, and hands. The thoracic spinal nerves follow more regularly and do not collect in a plexus. They innervate the muscles of the back, ribs, and abdomen. The lumbosacral plexus innervates the hindlimbs and feet primarily, and the pudendal and coccygeal plexuses supply nerves to the anus and to the genital organs.

Sensory and motor fibres. The spinal nerves as well as the peripheral branches are composed of sensory and motor nerve fibres. The cell bodies of the sensory neurons are located in the sensory ganglia of the dorsal roots. Each sensory neuron has a single process that leaves the cell body and then branches into two. One branch enters the dorsal horn of the spinal cord, and the other runs to the periphery and ends in the sensory receptor organs. The cell bodies of the motor neurons are found in the ventral horn of the spinal cord. From there, axons run into the ventral root, join the spinal nerve, and finally innervate the skeletal muscles of the body.

Receptors can be grouped in three categories on the basis of the origin of the impulse: exteroceptors, proprioceptors, and interoceptors. The exteroceptors receive stimuli from the surface of the body; they carry the sensations of touch, pressure, skin pain and temperature, smell, sight, and sound. The proprioceptors receive sensations from the joints, muscles, and tendons. Exteroceptors and proprioceptors constitute somatic receptors. The interoceptors carry stimuli from the internal organs and are classified as viscероceptors; they carry the sensations associated with digestion, excretion, sex, deep pain, and circulation. (For a detailed account of the reception of sensation see SENSORY RECEPTION; specific receptors and their function are considered in MECHANORECEPTION; PHOTORECEPTION; and SOUND RECEPTION.)

The autonomic nervous system. Smooth muscle (digestive tract and internal organs), heart muscle, and glandular tissues of the body receive their innervation from the autonomic, visceral, or vegetative, nervous system. The reactions of the visceral organs are to a great extent involuntary and unconscious and are controlled by visceral efferent neurons. These same organs also have visceral afferent nerves, which initiate visceral reflexes. The cell bodies of these sensory nerves are located in the dorsal root ganglia. Descending impulses from the cerebral cortex and brainstem as well as impulses from somatic sensory nerves also influence autonomic activity.

Types of neurons of efferent pathways

The efferent pathways of the autonomic nervous system involve two different neurons. The first, or preganglionic, neuron is situated in the brain or spinal cord. The preganglionic cell sends its axon to an autonomic ganglion where it synapses with a postganglionic cell, which in turn innervates the visceral organs.

There are three major outflows of preganglionic fibres from the central nervous system to the autonomic ganglia. The cranial outflow consists of fibres within some of the cranial nerves. The thoracolumbar outflow leaves the spinal cord in the thoracic and upper two lumbar nerves. The sacral outflow passes through the second, third, and fourth sacral nerves. The autonomic nervous system consists of the thoracolumbar division, which comprises the sympathetic system, and the cranial and sacral divisions, which together form the craniosacral, or parasympathetic, system.

The sympathetic division. The preganglionic fibres of the sympathetic division originate from neurons in the intermediolateral gray column of the spinal cord, leave the cord in the ventral roots, and pass to the sympathetic trunks, where some terminate. The sympathetic trunks are chains of ganglia close along either side of the spinal cord from the base of the skull to the coccyx.

Other preganglionic fibres from the spinal cord pass through the sympathetic ganglia as splanchnic nerves and end on the prevertebral, or collateral, ganglia, which are situated near the visceral branches of the aorta.

The actions of the sympathetic nervous system on visceral structures include dilation of the pupil of the eye, acceleration of the heart rate, increased force of contraction of the heart, and dilation of the coronary arteries. The blood vessels of the viscera and skin are constricted, blood pressure rises, and blood supply to the muscles, lungs, heart, and brain is increased. Respiration increases, and the bronchioles of the lung become dilated. Gastrointestinal motility is decreased, and secretion of the salivary and gastrointestinal glands is inhibited. The secretion of sweat glands is increased. The urinary and rectal sphincters contract. Thus, the sympathetic nervous system prepares the body for intense muscular activity necessary in offense and defense (the fight-or-flight reaction). Pain, exposure to cold, or strong emotions, such as rage or fear, evoke sympathetic activity that mobilizes the body resources for violent reactions. At the same time, the peaceful activities of the visceral structures are suspended.

The effects of the sympathetic nervous system are augmented by the medulla of the adrenal gland, whose cells, when stimulated, release epinephrine and norepinephrine into the bloodstream, thereby increasing the effects of impulses in the postganglionic sympathetic fibres and producing generalized rather than localized responses.

The parasympathetic division. In contrast to the sympathetic system, the preganglionic fibres of the parasympathetic system are long and terminate on ganglia located within or very near the organs they innervate. The postganglionic fibres, however, are very short.

The actions of the parasympathetic nervous system are largely antagonistic to those of the sympathetic. The parasympathetic neurons constrict the pupil of the eye, decrease the heart rate, stimulate the flow of saliva and gastric juice, and stimulate the peristaltic movements of the gastrointestinal tract. They relax the sphincters of the bladder and rectum and contract the muscles in the wall of the bladder allowing the body to rid itself of wastes. Thus, the parasympathetic system is concerned with restoring and conserving bodily energy and resting vital organs. Digestion and absorption of nutrients is promoted and the heart given longer periods of rest.

EMBRYONIC DEVELOPMENT OF THE VERTEBRATE NERVOUS SYSTEM

Development of the spinal cord and its nerves. The nervous system develops from the outer cell layer (ecto-

derm) of the early embryo (Figure 5). The ectoderm along the dorsal side of the embryo near a structure called the notochord becomes thickened to form the neural plate, which is broader over the anterior, or cranial, end. The neural plate soon folds in (invaginates) to form a shallow neural groove whose flanks are then called neural folds. The neural groove deepens while the neural folds approach each other over the groove and fuse to form the neural tube. Fusion occurs first over the future cervical region and then continues both headward and tailward. When fusion is completed, the central nervous system is represented by a closed tube with an expanded cranial portion, the future brain, and a narrow caudal portion, which becomes the spinal cord.

Formation of the neural tube

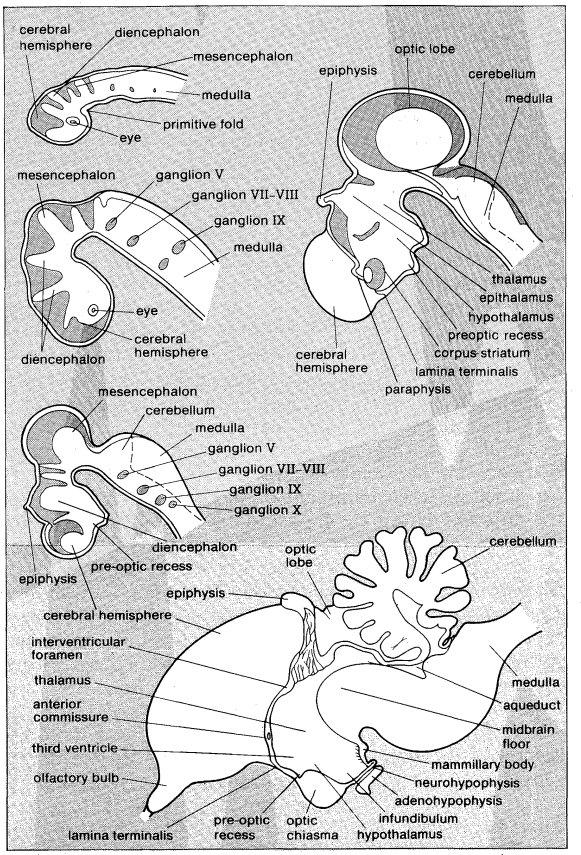

Figure 5: Stages in the early development of the chick brain and cranial nerves.

The lateral margins of the neural plate contain cells that will give rise to the neural crest. When the neural folds fuse, these cells come to lie between the ectoderm and the neural tube and later migrate to the sides of the neural tube. The neural crest gives rise to the sensory cells of the peripheral nervous system, peripheral cells of the autonomic nervous system, cells of the adrenal medulla, Schwann cells of peripheral nerves, pigment cells, and the pia mater and arachnoid membranes.

Undifferentiated stem cells, or germinal cells of the neuroepithelium, give rise to the neurons, neuroglia, and ependyma of the central nervous system. These dividing cells differentiate into medulloblasts and spongioblasts. The spongioblasts develop into ependymal cells and astrocytes. The medulloblasts give rise to astrocytes, oligodendroglia, and neuroblasts. The neuroblasts develop processes and become the neurons of the gray matter. The microglia are of middle layer (mesodermal) origin, perhaps developing from loosely-packed mesenchymal cells accompanying the blood vessels that grow into the central nervous system.

When the neural tube has closed, the spinal cord has thick lateral walls and thin roof and floor plates. A longitudinal groove, the sulcus limitans, running laterally on each side of the neural tube, divides it into ventral (motor) and dorsal (sensory) areas. Part of the lateral wall, called the mantle layer, represents the gray matter of the spinal cord. It thickens ventrally to form the basal plates, which will become the ventral horns of the adult spinal cord. Dorsal thickenings, or alar plates, will become the dorsal horns. The central cavity is reduced in size by fusion of its dorsal portion to form the posterior median septum. The ventral part of the cavity persists as the central canal of the spinal cord. The anterior median fissure is formed by an invagination in the floor plate. As cells differentiate in the mantle layer, they send their fibres into the marginal layer, which will become the white matter. At this point the neural tube has the basic configuration of the adult spinal cord.

The developing neuroblasts in the basal lamina of the developing cord send out processes that reach the developing muscle cells within the embryonic muscle blocks called myotomes. The fibres innervating each myotome are grouped in a bundle forming the ventral root. The neural crest cells give rise to the neuroblasts, which form the sensory ganglia. The proximal processes of these cells grow toward the spinal cord and form the dorsal root while the distal processes unite with the ventral root to form the spinal nerve. Neural-crest cells migrate along the outgrowing nerve processes and form the neurilemmal sheaths. Schwann cells form the myelin sheath present on some nerves. The sympathetic ganglia develop from neural-crest cells and from cells migrating from the spinal cord along the ventral roots. Some of the cells migrate further to form the prevertebral ganglia and the terminal autonomic ganglia in the walls of the viscera.

Development of the brain and its nerves. By the time the neural tube closes, three primary brain vesicles are apparent, the farthest forward being the prosencephalon, or forebrain, from which neural components of the eyes (optic vesicles) extend laterally. The intermediate dilation is the mesencephalon, or midbrain. The caudal dilation is the rhombencephalon, or hindbrain. The mesencephalon persists in the adult as the midbrain. The prosencephalon, however, gives rise forward to the telencephalon, or endbrain, and to a more caudal portion, the diencephalon. The telencephalon develops into the cerebral hemispheres, while the diencephalon carries the optic vesicles and includes the thalamus and hypothalamus. The rhombencephalon develops into the metencephalon and myelencephalon. The metencephalon becomes the pons and cerebellum, while the myelencephalon forms the medulla.

The three primary brain vesicles

The midbrain is separated from the hindbrain by a bend called the cephalic flexure. Farther back a cervical flexure appears at the junction of the brain and the spinal cord, and later a pontine flexure appears in a direction opposite to the cephalic and cervical flexures. Only the cephalic flexure persists in the adult, with the result that the cerebral hemispheres and diencephalon are folded downward at an angle to the rest of the brain axis.

The nerves develop in different ways. The olfactory nerve is formed by the axons of olfactory cells derived from neuroblasts in the nasal epithelium. The optic nerve arises from the stalk of the optic vesicle. The other nerves are formed according to their functional components. Fibres with a motor function arise from several nuclei appearing within the basal plate; sensory elements are derived from ganglia formed from neural-crest cells and in some cases from special ectodermal thickenings called placodes.

Although developing muscle cells of the embryo are capable of contracting spontaneously (myogenic activity) before they are innervated, as soon as a nerve fibre reaches the muscle cell, contraction occurs only in response to nerve impulses (neurogenic activity). At that time reflexes can take place in which the muscles respond to sensory stimulation. As the neurons differentiate and assume their functional capacities, tract systems are laid down so that the influences of higher centres are superimposed on the simple spinal reflexes. The tracts begin to function at the time the nerves become myelinated. At birth, reflex mechanisms controlling vital activities such

as respiration, suckling, and swallowing are well established. Control of movements by the cerebral cortex is not completed until the pyramidal tracts become myelinated after birth. After birth, cell division in the central nervous system stops and nerve cells that are lost thereafter cannot be replaced.

EVOLUTION OF THE VERTEBRATE NERVOUS SYSTEM

The primitive condition. The vertebrates constitute an advanced subdivision of the phylum Chordata. All chordates at some time in their life history have a rodlike bar called the notochord running the length of the body. Lower chordates (acorn worms, tunicates, and amphioxus), which lack a vertebral column, illustrate the most primitive features of the chordate nervous system. In these animals, the nerve cord is a rather uniform-appearing dorsally placed tube with a hollow cavity, which corresponds roughly to the spinal cord of the vertebrates, suggesting that the spinal cord is the most primitive component of the central nervous system (Figure 6).

The notochord

In amphioxus and in the lowest vertebrates such as lampreys, the sensory fibres and motor fibres leave the cord in dorsal and ventral roots to supply the adjacent body segments (myotomes). The dorsal and ventral roots remain separate nerves, and arise at alternate positions along the cord. In lower fishes, there is still alternation of dorsal and ventral roots, but the roots unite in a single spinal nerve. In higher vertebrates the two roots unite in a single spinal nerve and leave the cord at the same level, one above the other. Each spinal nerve supplies a single myotome. When appendages (fins, wings, arms, and legs) develop from several myotomes, the nerves continue to supply their original segments and branches of the spinal nerves become interwoven to form plexuses.

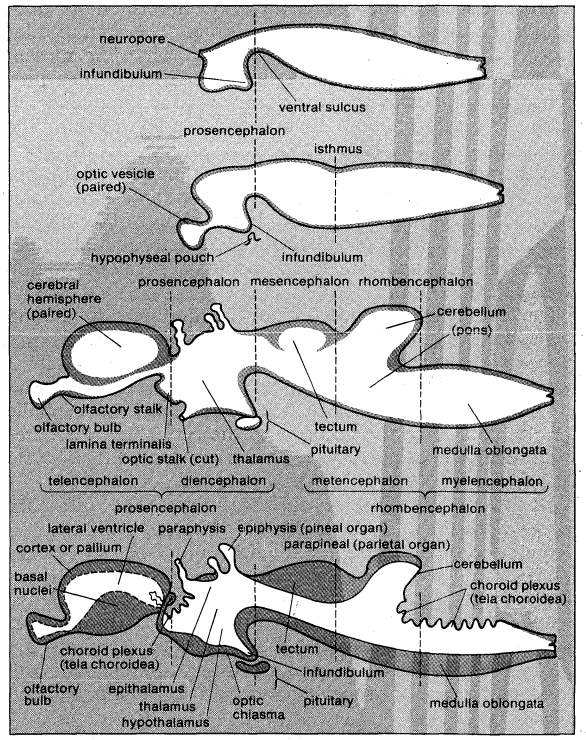

Figure 6: Development of principal vertebrate brain divisions.

The brain of vertebrates developed by the accumulation of nerve cells at the cephalic end of the nerve cord. At first, this diffuse collection of nerve cells regulated the reflex activity of spinal motor neurons. These cells are comparable to the reticular formation occupying the brainstem of higher vertebrates. The brainstem, thus, is the oldest portion of the brain in terms of evolution.

Encephalization. Early in the evolution of vertebrates, a special sensory system became associated with each major part of the brain: the olfactory organs with the forebrain, the eye with the midbrain, and ear and related organs with the hindbrain. Each of the three sections, furthermore, developed dorsal outgrowths of gray matter forming, respectively, the cerebrum, midbrain roof, or tectum, and cerebellum. With these developments, the three-part brainstem was then transformed into a brain of five regions: telencephalon, diencephalon, mesencephalon, metencephalon, and myelencephalon. The addition of these nerve centres to the primitive brainstem allowed greater coordination and association between the sensory and motor fibres.

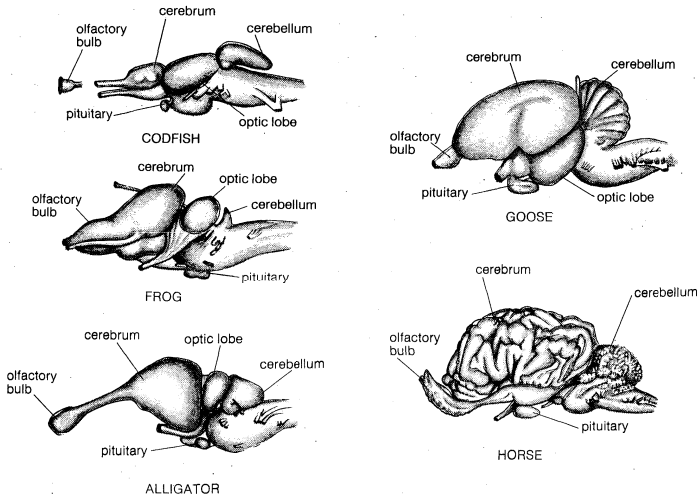

Figure 7: Representative series of vertebrate brains illustrating the evolutionary development of the brain.

From *Biological Sciences Curriculum Study Green Version High School Biology*, 2nd ed. (1968); Rand McNally & Co.

In tracing the development of the parts of the brain in the different vertebrate classes, some general features are apparent (Figure 7). There is a correlation between the size of a particular part of the brain and its importance in the life of the animal in question. Some neural structures (*e.g.*, olfactory bulb) have considerable size and importance in lower forms but are less conspicuous in higher forms. Progressing from the lowest to highest forms, there is a gradual cephalic shift of function from the lower brainstem to the higher cerebral cortex.

The hindbrain is comparable to an enlarged, anterior section of the spinal cord. In the gray matter are dorsal sensory and ventral motor columns similar to those present in the cord. The longitudinal continuity of these columns is preserved in the lower vertebrates, but in higher vertebrates the columns break up into discrete nuclei that serve some of the cranial nerves. The hindbrain exerts control over the spinal motor neurons through the reticular formation. Fish and tailed amphibians, in addition, have a pair of giant cells called the cells of Mauthner, which exert some control over the local spinal-cord reflexes responsible for the rhythmic swimming undulations of these animals.

The hindbrain is the area of reception of one of the main sensory systems, the acoustico-lateralis system, which consists of the ear (hearing and equilibrium) and the lateral-line organs (vibration and pressure). The latter, situated in rows along the head and body, are retained in fish but disappear in the land vertebrates.

Origin of cerebellum

The cerebellum originated as a specialized part of the acoustico-lateralis area. The oldest part of the cerebellum —the archicerebellum—is concerned with equilibrium and connected with the inner ear and the lateral-line system. The anterior lobe of the cerebellum represents the paleocerebellum, an area that regulates equilibrium and muscle tone; it constitutes the main mass of the cerebellum in fish, reptiles, and birds. In mammals, the development of the cerebral cortex and its connections with the cerebellum are correlated with the appearance of the large cerebellar hemispheres. This new part of the cerebellum, or neocerebellum, coordinates skilled movements initiated at cortical levels. In mammals a great mass of fibres connects the brainstem to the cerebellum; this re-

gion forms the pons, which, together with the cerebellum, constitutes the metencephalon. The caudal part of the hindbrain remains as the medulla (myelencephalon).

The midbrain (mesencephalon) and diencephalon comprise the anterior portion of the brainstem. Sensory and motor nuclei for cranial nerves extend from the hindbrain to the midbrain. The roof of the midbrain, or tectum, developed as the primary visual centre. The optic lobes, especially prominent in fish and birds, are a part of this area. In fish and amphibians, the tectum is the major centre of the nervous system and wields the greatest influence on body activity. While this area is still significant in reptiles and birds, it is supplanted in importance by the cerebral hemispheres. In mammals, the midbrain is greatly reduced in importance. Instead, most of the optic sensations are relayed to the cerebral cortex. With development of the cerebral cortex, the thalamus becomes less significant as an association area and more important as a relay centre for sensory impulses. Centres for visceral sensations and visceral motor responses become established in the hypothalamus.

Dominance of the cerebrum. Ascending the vertebrate scale, the cerebral hemispheres become more and more important as association centres (Figure 8). The cerebral hemispheres begin their development as paired

From A. Romer, *The Vertebrate Body*, 3rd ed. (1962); W.B. Saunders Company, Philadelphia

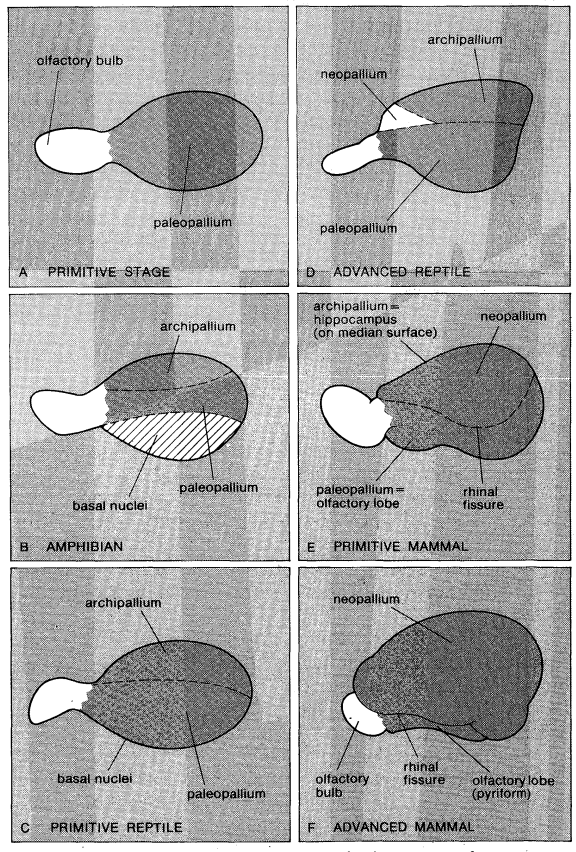

Figure 8: Differentiation of the cerebrum in the course of evolution.

The cerebral hemispheres as olfactory lobes

outgrowths of the forebrain and serve as centres of olfactory reception. In the lowest vertebrates, the forebrain is divided into the olfactory bulb—where the olfactory nerve fibres end—and the cerebral hemisphere. The hemisphere at this time, referred to as the paleopallium, is merely an olfactory lobe serving as an association area for olfactory impulses. The olfactory lobes are very prominent in animals such as amphibians, but in birds and primates in which sense of smell is less important, the lobes are reduced in extent. In amphibians, the hemispheres consist of three parts: the paleopallium (olfactory lobe), archipallium, and basal nuclei. These areas of gray matter are located deep to the surface. All three areas receive olfactory stimuli and discharge impulses to the brainstem. The archipallium is a correlation centre and forerunner of the mammalian hippocampus. The basal nuclei are equivalent to the corpus striatum and function as association areas with connections with the thalamus. In primitive reptiles, the basal nuclei have moved to the inner part of the hemisphere, whereas the other areas of gray matter have moved toward the surface. In advanced reptiles, a new association centre, the neopallium, appears between paleopallium and archipallium. In birds, there is nothing corresponding to the neopallium, but the basal ganglia (corpus striatum) are enormously expanded. In mammals, the neopallium becomes greatly enlarged to exceed all the other parts of the brain in size. This region assumes more and more of the higher types of neural activity in correlation, association, and learning. At first, the neopallium expands to envelop the other brain structures. The archipallium becomes folded into a small area on the median part of the hemispheres, where it remains as the hippocampus. The paleopallium (olfactory lobes) constitute a small ventral region on the hemisphere, the pyriform lobe. The corpus striatum (old basal nuclei) becomes a central part of the hemisphere. Further expansion of the neopallium in primates and man causes extensive folding and results in a very convoluted surface of the brain.

V. Biodynamics of the vertebrate nervous system

CONTROLS EXERTED ON THE NERVOUS SYSTEM

Intrinsic control. In the normal animal, a variety of influences constantly impinge on the nervous system and affect its activity. Stimuli from many external sources travelling over sensory fibres affect the activity of central neurons. Other external influences reaching the nervous system through the bloodstream may act directly on nerve cells. In addition, there are nervous activities not immediately referable to external sources but apparently arising within the nervous system itself. The number and diversity of influences on neural activity might be expected to elicit a variety of conflicting reflexes and behaviour patterns. What is remarkable about the normal nervous system, though, is that from moment to moment it sorts out various activities and arrives at a singular action.

Regulation in the nervous system is achieved by means of its integrative capabilities, which allow the nervous system to regulate its output in response to its input. Integration takes place at different levels within the nervous system. First, it can occur at the level of the neuron, which has several forms of activity that can be coupled, permitting the output of the neuron to be a complex function of its input. The input may either decrease the probability of output (inhibition) or increase it (excitation).

Secondly, integration occurs between organized groups of neurons. The central nervous system contains many specific fibre tracts and groups of neurons that are connected in different ways. One input system may lead to the integrative group of neurons, and one output line leads away. Several input lines may converge on one output, or several outputs can diverge from one input. Associative components, or interneurons, may be situated along the afferent or efferent pathways. The interconnections between these pathways allow for limitless processing of the nerve impulses. The systems can interact through excitatory or inhibitory tendencies or through alteration of frequency of impulses to transform the nervous signal. These influences are finally exerted on the motor neurons to the skeletal muscles and to the visceral structures; the motor neuron, thus, serves as the last neural link, or final common pathway.

Unification of behaviour

The highest orders of integration occur at the level of the organism and can be deduced from the study of behaviour. At any one time, the behaviour of an organism shows a singleness of purpose. Alternative courses of action are excluded in favour of unified behaviour. This function of focussing behaviour is carried out by the reticular activating system, a part of the reticular formation in the central core of the brainstem. The reticular activating system is responsible for arousal, wakefulness, and alertness of the cerebral cortex, permitting the cortex

to carry out its special functions of sensation, volition, and thought. It focusses action and unifies efforts by confining the direction of attention and galvanizing the specific system into action.

Extrinsic influences. Besides stimuli that reach the central nervous system over afferent nerves, many other extrinsic factors influence the nerve cells directly. These influences include nutrients, metabolites (chemical products of metabolism), hormones, and drugs. Most of these substances reach the nervous system through the bloodstream. First, though, they must cross the blood–brain barrier, which plays a major role in maintaining the environment necessary for proper functioning of neurons. Some substances, such as particulate materials, certain dyes, pigments, metals, large molecules, and bacteria, cannot enter the spaces between cells in the brain, although they can move between the cells in other tissues of the body. The actual barrier to these materials seems to be the brain capillaries, which are different physiologically from other capillaries.

The brain has an enormous oxygen requirement, necessary for the utilization of the sugar glucose, its major source of fuel. Therefore, any conditions that reduce the oxygen supply or lower the level of glucose in the blood affect the nervous system and may lead to seizures and coma.

Since the functioning of neurons depends in part on the movement of ions, it is not surprising that disturbances of ion levels will affect the nervous system.

The nutritional and metabolic state of the body also affects the nervous system. Deficiencies of the B vitamins have the most serious effect on the nervous system, causing widespread degeneration of peripheral nerves, damage to neurons in the brain, and degeneration of spinal cord tracts.

The physical state of the body, of course, plays a major role in the functioning of the nervous system. The well-being of the nervous system depends on the proper functioning of other organ systems including the circulatory, respiratory, digestive, and excretory systems. Disease, malfunction, or aging of any of these other systems may adversely affect the nervous system by failing to provide necessary oxygen and energy supplies, to maintain the proper environment for nervous activity, and to remove toxic wastes. Neurons are lost progressively as an organism ages, but because these cells do not divide after birth, there is no capacity for replacement.

The varied effects of drugs

Many drugs have an effect on the nervous system resulting in changes in behaviour, perception, thought, emotions, and other activities of the nervous system. These drugs—called neuropharmacological agents—may exert their influence by acting directly on nerve cells or by affecting the neurotransmitters. Since neurotransmitters are responsible for the exchange of information between nerve cells, any drugs that influence the synthesis or breakdown of these transmitters or that mimic their effects will have an influence on nervous activity. Drugs that have the same effects as acetylcholine are known as cholinergic drugs; they include agents that inhibit acetylcholinesterase, the enzyme that destroys acetylcholine. Other drugs, such as atropine and curare, block the effects of acetylcholine. Drugs that have the same effects as norepinephrine and epinephrine are called adrenergic drugs. Adrenergic blocking agents (*e.g.*, ergotamine) inhibit the effects of norepinephrine and epinephrine and, thus, oppose the effects of sympathetic stimulation.

A number of drugs seem to exert their major effects on the central nervous system. Some, such as alcohol, have a depressant effect on the nervous system through depression of the autonomic circulatory and respiratory centres in the brainstem. Barbiturates, like alcohol, depress the higher cerebral centres first and with increasing doses affect lower subcortical structures. Drugs such as opium and morphine appear to elevate the pain threshold and to alter the reaction to pain. These drugs are also addictive and have depressive effects on the central nervous system. Anesthetics cause central nervous depression ultimately leading to unconsciousness. Some of their effects seem to be exerted on the reticular activating system, which maintains wakefulness. Other drugs elevate mood and stimulate behaviour and are useful in the treatment of depressive states.

Tranquillizers are drugs that reduce anxiety and agitation without clouding the consciousness. These agents exert their action on subcortical structures including the reticular system, hypothalamus, and limbic system. Some drugs are capable of producing changes in perception, thinking, and emotion, causing hallucinations, illusions, and delusions. These drugs, called hallucinogens, include among them lysergic acid diethylamide (LSD) and related compounds.

INTERACTION BETWEEN NERVOUS AND ENDOCRINE SYSTEMS

The neurosecretory cell and the concept of neurosecretion. A special class of neurons called neurosecretory cells have been identified in all groups of higher animals. These cells engage in secretory activity to a degree above and beyond that observed in ordinary nerve cells. They have features characteristic of both neurons and endocrine cells. Like ordinary neurons, they respond to stimuli, they conduct action potentials, and they contain synaptic vesicles. Like endocrine cells, they produce hormonal substances (neurohormones) that act over a distance. These secretory products, however, are usually proteins or polypeptides, unlike the neurotransmitter substances produced by ordinary nerve cells.

Neurohormones

These neurohormones are synthesized in the cell body of the neurosecretory neuron and packaged in neurosecretory granules. The neurosecretory granules travel from the cell body down the axon and are stored in the nerve terminal. Neurosecretory cell terminals are situated near blood vessels; the combinations of neurosecretory cells with vascular channels are known as neurohemal organs. The corpus cardiacum of insects and the posterior lobe of the pituitary of mammals are examples of such storage depots. Upon appropriate stimulation, the neurosecretory cells release their secretory products into the vascular system. The neurohormones then travel in the blood and affect distant structures such as endocrine glands or other tissues.

Neuroendocrine interactions. The functional significance of the neurosecretory cell is that it acts as a mediator between the nervous and endocrine systems. The nervous system is involved in point-to-point transmission of signals with very short duration (fractions of a second). The endocrine system, on the other hand, is concerned with much slower and more diffuse transmission of messages. The significance of the neurosecretory cell is that it alone serves as a singular channel between the nervous and endocrine systems, receiving messages in neural language and transmitting this information in endocrine language.

In all cases afferent stimuli are channelled to the neurosecretory cells and influence the release of neurohormones. Certain neurosecretory hormones are actually factors that effect the release of other hormones by the anterior pituitary. Five of these factors cause the release of specific anterior pituitary hormones (follicle-stimulating hormone, luteinizing hormone, growth hormone, adrenocorticotropic hormone, and thyroid-stimulating hormone), and one inhibits the release of a hormone (luteotropic hormone, or prolactin). These hormones in turn act on their respective endocrine glands. The endocrine organs then release hormones that influence the target organs and tissues. Other neurosecretory hormones directly affect their target organs.

Neurosecretory cell bodies located in certain nuclei of the hypothalamus send axons to the neural lobe of the posterior pituitary and terminate near blood vessels. These neurosecretory cells elaborate two hormones, vasopressin, or antidiuretic hormone, and oxytocin. Vasopressin produces a generalized constriction of blood vessels, producing a rise in blood pressure. It also stimulates the kidney tubules to retain water and lose salt in the urine. Oxytocin causes contraction of the uterus and the flow of milk from cells in the mammary gland (see also the article ENDOCRINE SYSTEMS).

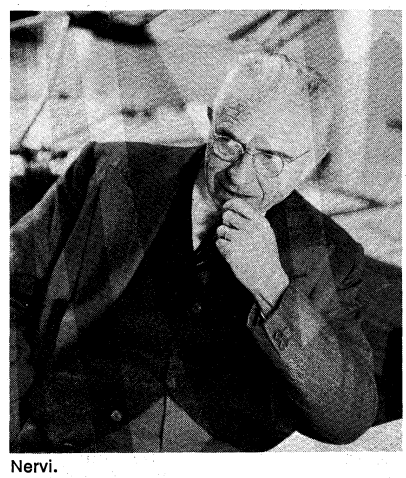
Nervi, Pier Luigi

An Italian engineer-architect, Pier Luigi Nervi is the paradigm of the master builder of modern times. His work expresses a comprehensive understanding and knowledge of design, structure, and construction techniques with a profound understanding of social and economic processes. His audacious, imaginative structures typically are built of reinforced concrete, either cast in place or prefabricated on the site, in forms that span immense distances efficiently and with surpassing beauty. Although his initial interest in building was as a structural engineer and he never designed primarily for aesthetic effect, his works were soon recognized as having transcended engineering and achieved the status of architecture of the higher order.

Henri Cartier-Bresson—Magnum



Nervi.

Nervi was born in Sondrio, Italy, on June 21, 1891. He graduated from the University of Bologna in 1913 and soon afterward World War I began. Nervi served as a lieutenant in the Corps of Engineers of the Italian Army and, after the war, worked as an engineer in Bologna and Florence. In 1926–27 he designed his first significant work, a cinema in Naples, and followed it with the municipal stadium (Berta Stadium) in Florence, built in 1930–32.

Formation of Nervi and Bartoli firm

In 1932 Nervi and a cousin in Rome formed the contracting firm of Nervi and Bartoli, with which he would remain through the rest of his career. In 1935 the Italian Air Force held a competition for a series of hangars to be built throughout Italy. Nervi conceived them as concrete vaults, with huge spans, that could be constructed at low cost, and he won the commission. Between 1935 and 1941 he built hangars in Obertello, Orvieto, and Torre del Lago. All of these structures were destroyed during World War II.

Each of these early structures showed the growth of conceptual design that resulted from Nervi's ceaseless search for new solutions to structural problems. His creativity was not confined to the design of buildings; during World War II, he attempted to construct vessels for the Italian Navy made of concrete, but the project was not completed. After the war, he did succeed in building a 165-ton, motor-powered, concrete sailboat, with a hull 1.4 inches (3.6 centimetres) thick. It was named "Irene" for his wife. Subsequently he built a 38-foot (11.6-metre) ketch, the "Nennele," with a hull only a half inch (1 centimetre) thick. For both of these vessels, he employed ferrocemento, a material of his own invention, composed of dense concrete, heavily reinforced with evenly distributed steel mesh that gives it both lightness and strength.

This material was vital in Nervi's design for a complex he built for the Turin Exhibition in 1949–50. It is a prefabricated structure in the form of a corrugated cylindrical arch, spanning 309 feet (93 metres), based on modular components of glass and ferrocemento. Without the structural properties of this material, the entire conception of the complex would not have been feasible. In this, as in his other works, there is an intimate relationship between conception and execution.

A close relationship is evident between Nervi's work and his austere life. Both have been called humble but full of passion, economical of means, yet extremely warm. His solutions to building problems have always been direct, transmitting to the ground the stresses developed within the structures through the shortest path. His works have been relatively unaffected by the changes in taste that have accompanied the advent of new forms in architecture. As a professor at the University of Rome from

1947, Nervi taught that a designer can develop truthful solutions in three ways: by understanding the pure harmony of the laws of the physical world that regulate the equilibrium of forces and the resistance of materials; by honestly interpreting the essential factors of each problem; and by rejecting the limitations of the solutions of the past.

Design of UNESCO headquarters

In 1950, when UNESCO decided to build its new headquarters in Paris, Nervi was one of the architects selected to design it. The Hungarian-born U.S. architect Marcel Breuer, one of his collaborators, described Nervi's participation in the project as "a continuous search for a system: a system of geometric rhythm," and later he said of the man: "If there is a notion that arrogance and reckless irresponsibility are the very attributes of genius, a notion that to be a genius means not to be quite human, there is Nervi to disprove this notion."

In 1955, in association with a group of architects, Nervi helped design the first skyscraper in Italy, the Pirelli Building in Milan; it was the first office building to use a long-span structure—80 feet (25 metres). Although architects and engineers in the United States had long experience in the design and construction of skyscrapers, they had invariably designed them around frameworks consisting of series of smaller spans. For the Pirelli Building, Nervi used experimental models—as he often had—which he tested in the famous laboratory at Bergamo. His second skyscraper was built in Montreal, again in collaboration, and his third was Australia Square (1962–69; Sydney), a cylindrical tower of 50 stories. At the time, this was the highest concrete structure in the world. In 1957 and 1958–60, for the 1960 Rome Olympic Games, Nervi designed two sport palaces.

Work in the U.S.

His first building in the United States was commissioned by the Port of New York Authority: the George Washington Bridge Bus Terminal, in Manhattan, built in 1961–62. Subsequently he designed a precast, vaulted Field House for Dartmouth College in New Hampshire (1961–62) and, in collaboration with Pietro Belluschi, the Cathedral of San Francisco, four vertical-warped surfaces dramatically enclosing the vertical space of the main nave. In 1961 Harvard University appointed Nervi to the Charles Eliot Norton Chair of Poetry and awarded him, in 1963, an honorary degree; he later received the Gold Medal from the American Institute of Architects in recognition of his work.

After years of intense practice in Italy and abroad, Nervi was obliged to diminish his activities as a builder in the late 1960s. Assisted by two of his sons, Antonio, a structural engineer, and Mario, an architect, he began to confine his activities largely to designs. An increasing number of his projects now were done in association with foreign architects.

Although Nervi's primary concern has never been aesthetic, many of his works, nonetheless, reach the realm of poetry. Nervi's buildings achieve remarkable expressive force, as in the geometry of the slabs in the Gatti wool factory (1953), in Rome, and the mezzanine of the Palace of Labour, in Turin. Through his use of interpenetrating planes, of folded and bent plates, and of warping surfaces, Nervi has introduced a new three-dimensional vocabulary into architectural design. He reminded architects that "materials, statics, the technology of construction, economic efficiency and functional needs, are the vocabulary of the architectural speech."

Nervi's contribution has been compared to that of another builder whose work revolutionized architecture—Joseph Paxton, who built the Crystal Palace for the International Exhibition of 1851 in London. In both instances, highly rational and innovative structures resulted from a continuous process of devoted search and development, with an emphasis on modular construction, prefabrication, and extreme physical and visual lightness.

MAJOR WORKS

Berta Stadium, Florence (1930–32); Hangar for the Italian Air Force, Orvieto (1936); Exhibition Hall, Turin, Italy; (Salone B, 1948–49; Salone C, 1950); Kursaal Beach Casino roof, Ostia, Italy (1950); Sala delle feste delle terme, Chianciano, Italy (1952); UNESCO Headquarters, Paris—with Marcel Breuer and Bernard Zehruss (1953–58); Pirelli Building, Milan (1955–59); Palazzetto dello Sport, Rome (1957); Flaminio Stadium, Rome (1958–59); Palazzo del Lavoro (Palace of Labor), Turin, Italy; (1961); George Washington Bridge Bus Terminal, New York (1961-62); Place Victoria, Montreal (1962–65); Cathedral of San Francisco (1970); Coliseum, Richmond, Virginia (1971); Auditorium, Vatican City (1971).

BOYD, "Australia Square," *ibid.*, 130: 26–35 (1969), a description of an office building by Nervi in Sidney, Australia.

(E.F.C.)

Nervous System, Human

Man's nervous system, like those of other vertebrates, includes such neural structures as the brain, spinal cord, and nerves; these serve to receive stimuli (input), to process and store their effects, and to generate behaviour (output). Abnormal development or injury in the human nervous system can lead to difficulties that range from the grossest defects (*e.g.*, crippling, idiocy, and death) to the subtlest psychiatric symptoms (*e.g.*, transient irritability, suspiciousness, and forgetfulness).

The intimate and overriding role of neural tissues in the functions of all animals, including human beings, is reflected in many other articles, including NERVE IMPULSE; NERVES AND NERVOUS SYSTEMS; and NERVOUS SYSTEM DISEASES.

This article is divided into the following sections:

I. Fundamental considerations
- Origin and development
- Characteristic structures
- Nerve degeneration and regeneration

II. The central nervous system
- The brain
- The spinal cord

III. The peripheral nervous system
- Cranial nerves
- Spinal nerves

IV. The autonomic nervous system
- General organization and function
- Levels of structural organization
- Early development
- Comparative features
- Autonomic transmission
- General and integrative functions of the autonomic nervous system levels
- Pathophysiology

I. Fundamental considerations

ORIGIN AND DEVELOPMENT

The human nervous system appears to have emerged from millions of years of prevertebrate and lower vertebrate evolution. Neural elements that have survived the evolutionary process tend to be those that enhanced the survival of successions of organisms during this long period. Several aspects of evolutionary significance may be inferred from the developing human embryo.

The origin of both the human nervous system and part of the skin from the ectoderm (the outer layer of cells of the early, ball-shaped embryo) may be related to the eventual location of most sensory structures on or close to the body surface where they can receive stimulation from the external environment. The earliest nerve cell, or neuron, to evolve was probably a combined receptor (re-

ceiving environmental stimuli) and motor unit (producing muscle or gland responses). Such primordial types of neuron are still to be found in living sponges. In subsequent evolutionary stages, specialized receptor neurons and the effector (motor) nerve cells seem to have emerged, such sequences of cells being observable in living sea anemones. In more highly evolved stages, greater complexity derives from the interposition (intercalation) of one or more nerve cells between the receptor and effector neurons. These intercalated cells (interneurons, or internuncial neurons) are organized in circuits of various degrees of complexity as in the central nervous system (brain and spinal cord). In this theoretical reconstruction of evolution, the primordial nervous system, composed of neurons on the body surface, evolves into a central nervous system that interacts with the external environment through the peripheral nerves.

Neurons in primitive life forms

In early embryonic stages, the presumptive neural part of the ectoderm in man and other vertebrates detaches from the part destined to become skin, sinks beneath the surface, and becomes surrounded by another embryonic layer (mesoderm). During subsequent development of the embryo, many sensory neurons differentiate and grow until their receptor fibres terminate in or near such ectodermally derived structures as the outer skin (epidermis) and the mucous membranes of the eye, ear, and nose.

All known vertebrates, including the most primitive known fossils (the ancient ancestors of jawless, eel-like fishes), have complex nervous systems. Study of inner skull surfaces (cranial endocasts) of many fossil vertebrate remains indicates that in all of them the brains and cranial nerves are built on a basically similar plan, which includes a specialized brain (encephalization). The vertebrate nervous system is bilaterally symmetrical, most neural structures being repeated on the left and right sides of the body.

Differentiation

The human nervous system begins to differentiate structurally and to show clear signs of function early during prenatal life (see also EMBRYOLOGY, HUMAN). By 18 days after fertilization, the ectoderm thickens along the future dorsal (backside) midline of the body to form the neural plate, and, slightly later, the primordial eye, ear, and nose differentiate. The neural plate elongates, and its lateral edges rise to form the neural folds, which, in turn, extend and unite the midline to close off the neural tube from which the central nervous system develops. The space within the neural tube becomes the cavities (ventricles) of the brain and the central canal of the spinal cord. This developmental sequence produces the dorsally located, hollow central nervous system unique to vertebrates. Continuing to differentiate, the neural tube detaches from the skin ectoderm and sinks beneath the surface. During this process, an ectodermal column of cells on each side differentiates, becoming the neural crests that segregate into future parts (*e.g.*, dorsal-root ganglia) of the spinal nerves. The cephalic (head) end of the tube differentiates into primary brain vesicles called the forebrain, midbrain, and hindbrain. This is the morphological status of the nervous system at the end of the first month of pregnancy.

The cells of the central nervous system originate from the matrix (ependymal) layer of the neural tube—that is, the layer of cells that lines the cavity of the neural tube. The matrix cells differentiate and proliferate into specialized cells (neuroblasts), the progenitors of the neurons of the central nervous system, and other cells (glioblasts) from which associated non-neural cells, called glia, develop. With few exceptions, the neuroblasts, glioblasts, and their derived cells do not divide and multiply (as do most other cells) once they migrate from the matrix layer into the gray and white matter of the nervous system.

Prenatal brain growth

During prenatal life, the slender primordial brain of the neural-tube stage gradually differentiates into the globular-shaped brain by middle fetal life. During this interval the brain continues to grow differentially in size and to bend at three major flexures. The main outlines of the form of the brain are recognizable by the end of the third fetal month. Its typically adult size and shape, however, are not attained until early puberty.

The early development of the "contorted" brain from the neural-tube stage is the product of the formation of three flexures (midbrain, pons, and cervical); the differential enlargement of various regions, especially the cerebrum and cerebellum; the growth of the cerebral hemispheres over and at the sides of the midbrain and cerebellum; and the formation of convolutions ("valleys" called sulci and "hills" called gyri) in the cerebral cortex and of folia (leaflike gyri) in the cerebellar cortex. The forebrain differentiates into such structures (described in greater detail below) as the cerebral cortex, corpus callosum, lateral and third ventricles, basal ganglia, thalamus, and hypothalamus; the midbrain becomes the cerebral peduncles, superior and inferior colliculi, and cerebral aqueduct; and the hindbrain generates the cerebellum, pons, medulla, and fourth ventricle. Such deeper valleys as the central and calcarine sulci are discernible by the fifth fetal month, and every major gyrus and sulcus is normally present by the seventh. The minor sulci and gyri are not fully formed until after birth. The relative size and proportions of the brain and its parts are basically similar to those in the adult brain by two years after birth.

The nervous system exhibits observable activity within the second prenatal month. Seven weeks after fertilization, the head draws away from a stimulus applied to the upper lip. Many reflexes of the head, trunk, and extremities can be evoked from the embryo during the third month of pregnancy.

Postnatal growth of the brain

The postnatal growth of the human brain is rapid and massive, especially during the first two years. The typical brain weighs 350 grams (about 0.8 pound) in the full-term infant at birth, 1,000 grams (2.2 pounds) at the end of the first year, and about 1,300 grams (2.9 pounds) at puberty. This increase is mainly attributable to growth of pre-existing neurons, new glial cells, and myelination (development of fatty insulating sheaths on neuron fibres). This unique threefold growth of the brain during the first year may be interpreted as an adaptation that is essential to man's survival as a species with a large brain. Birth occurs at a developmental stage when the infant is not so helpless that it is unable to survive, yet is still small enough to pass through the bony opening of the maternal pelvis; if the brain were much larger (enough to support intelligent behaviour), normal delivery might not be possible.

The neurons and the non-neural glial cells of the central nervous system differentiate at various times during the development of the individual. With a few uncertain exceptions, all neurons have differentiated from the matrix layer of the neural tube before birth. This effectively means that a person is born with as many neurons as he will ever have (perhaps 10,000,000,000 in the brain cortex alone), losing the potential function of more and more of them from then on. According to one estimate, an average of approximately 50,000 neurons atrophy or deteriorate each day from ages 20 to 70. In a healthy person, in 50 years, less than 10 percent of the original neuronal complement is out of action. Indeed, by age 75, the weight of the brain typically is reduced from its maximum at maturity by about one-tenth; the flow of blood through the brain drops by about one-fifth; and the functional taste buds in the mouth are about two-thirds gone (see also AGING, HUMAN).

The early maturation of neurons makes the first years of life crucial to the level of intelligence that is exhibited at the adult stage. Impairment of normal development of neurons in childhood may result in irreversible abnormality. Thus, severe mental retardation in a genetic disorder called phenylketonuria (PKU) results from a specific enzyme deficiency that prevents sufferers from normally metabolizing the amino acid phenylalanine. Young children with PKU who are fed on a phenylalanine-deficient diet often are able to escape the consequences of this inborn defect. Because neural tissues incorporate amino acids, however, young children reared on diets that are too low in protein fail to develop normal brain structures. The intelligence of many hundreds of millions of the world's potentially normal children may continue to be

impaired as long as so many (about 60 percent) of them suffer protein-deficient diets.

Development of the spinal cord and spinal nerves

The spinal cord and spinal nerves develop from the neural tube and neural crest. Neuroblasts migrate from the matrix layer of the neural tube and differentiate into the neurons of the spinal cord. Some parts (cell bodies and dendrites; see below) of these neurons remain within the gray matter. Other parts, the axons (fibrils or axis cylinders), differentiate, grow, and terminate in a variety of centres within the spinal cord and brain. From some spinal neurons, axons, the basic elements of white matter, elongate, pass out of the spinal cord, and form spinal nerves before terminating in such structures as voluntary muscles (*e.g.*, those that move the limbs). Some neuroblasts migrate from the spinal cord to differentiate into neurons of the sympathetic nervous system (which involves the spinal nerves of the midspine from chest to lower back). Spongioblasts (*i.e.*, glioblasts) migrate from the matrix layer and differentiate into different kinds of glial cells (astroglia and oligodendroglia) found in both white and gray matter.

The neuroblasts within the neural crest differentiate into sensory relay assemblies of neurons (ganglionic cells) in the spinal nerves. Each of these ganglionic cells has a peripheral fibril that extends to a sensory receptor (*e.g.*, in the skin) and a central axon that terminates in the gray matter of the spinal cord. Other crest cells differentiate into such specialized structures as the neurilemma cells, which generate the myelin sheaths that insulate many nerve fibres. Mesodermal cells develop into connective tissue that supports the nerves and into blood vessels that nourish the nerves.

Mechanisms by which genetic influences regulate the formation of the complex patterns within the nervous system remain poorly understood. The axons of motor neurons (*e.g.*, those that activate muscles) grow out of the spinal cord through the primordial ventral roots of the spinal nerves that leave the cord, terminate in the somite or other mesodermal elements, and make connections (synapses) with primordial muscle cells (myoblasts). When the myoblast migrates to its final location, it pulls, or tows, its elongating axon along. The axons of other neurons and of neurilemma cells follow the path taken by the initial outgrowths of axons. In this way peripheral nerves, essentially bundles of axons (neuron fibrils), differentiate and develop. Innervation of all myoblasts tends to be ensured by a process in which myoblasts without neural supply seem to attract growing nerves while those already supplied tend to reject excessive synapses (hyperinnervation). In computer language, nerve development may be programmed by peripheral structures such as myoblasts.

CHARACTERISTIC STRUCTURES

The neuron is the basic structural and functional unit of the circuits and networks of the human nervous system. Each of the more than 15,000,000,000 neurons within the system has synaptic contacts with other neurons, and each acts as integrator, conductor, and transmitter of coded neural information (*e.g.*, as electrical impulses). Some neurons innervate muscle and glandular cells. Non-neural surrounding (interstitial) cells are in intimate contact with the entire neuron including its fibril processes (axons and dendrites). In a sense interstitial elements (called oligodendroglia, astroglia, neurilemma cells, satellite cells, and ependymal cells) are intercalated between the neurons and the blood vessels, extracellular fluids, and connective tissue cells. Except for a few small sites in the entire system, each neuron is effectively enveloped by these supporting, nourishing cells. The connective tissue in the nervous system is similar in structure and function to that in the rest of the body including microglia, or histiocytes, which serve as scavenger cells capable of ingesting bits of degenerating or waste matter in the nervous system. The extracellular fluids in the vicinity of the neurons and their processes contain electrolytes such as salt; thus the composition of these fluids has significant electrical and metabolic effects on the activity of the neuron as an information processor and signaller. The central nervous system is bathed in cerebrospinal fluid, both inside its cavities and outside in the subarachnoid space formed by membranes (meninges) that envelop the brain and spinal cord (see also CEREBROSPINAL FLUID).

Structure of neurons

Neurons. As seen with a microscope, a typical neuron includes a cell body (soma), thin threadlike processes called dendrites, and an axon. Any neuron has metabolic, or trophic, receptive, conductile, and transmissive functions associated with different parts of the cell.

The trophic structure is the cell body, containing the nucleus—the metabolic centre essential to the life of the neuron—as well as other cytoplasmic substructures within the cell. One or more dendritic processes receive and carry neural information into the cell body, and the axon conducts impulses away from the cell body to the terminal dendrites. The latter may chemically link and communicate (synapse) with the cell body of another neuron or with a gland cell or muscle cell at the motor end plate. Depending on their location in the body, receptive dendrites may receive stimuli directly from the environment (*e.g.*, pressure on the skin) or from other neurons through synaptic contacts; in most neurons the dendrites and remainder of the cell body function as the receptive segment of the cell. The conductile segment (typically the axon) is specialized for the transport of neural impulses from the receptive segment to the transmissive portion of the cell. The presynaptic transmissive segment (the short, terminal axonal portion) contains in vesicles chemical substances, called neurosecretions, which pass into a tiny gap (synaptic cleft) to exert a chemical influence on the next cell in the chain.

Nerve cells vary in shape and range in length from a fraction of an inch (*e.g.*, small neurons in the brain) to several feet in tall persons (*e.g.*, sensory neurons extending from the big toe into the central nervous system). In an elephant or whale, neurons can be appropriately longer. Not all nerve cells have the same microscopic appearance. Sensory receptor neurons, for example, may incorporate distinctively different structures. Thus there are non-neural onion-like capsules (pacinian corpuscles) capping some of the receptors in the skin, whereas, in the eye, there are retinal rods and cones, highly specialized nerve cells that are selectively responsive to different kinds of light (see also SENSORY RECEPTION, HUMAN; EYE AND VISION, HUMAN).

The entire neuron including all its processes is bounded by a thin plasma membrane that is selectively permeable to different chemical substances, barring some and permitting others to pass through. This process is crucial to the maintenance of the resting electrical potential of the neuron and to the neural impulses the cell generates.

Other elements of the cell body

In addition to the nucleus, the cell body contains such substructures as Nissl substance, Golgi apparatus, mitochondria, and neuroplasm (see also CELL AND CELL DIVISION). The Nissl substance appears as particles ranging in size from discrete clumps to dustlike bits that function (along with the nucleolus of the nucleus) in producing proteins required for the renewal of protoplasm. Neurons are such prodigious synthesizers of protein that they can replace one-third of their protein content each day. Neuronal protein may flow from the cell down the axon (axoplasmic flow) at the rate of three to 20 millimetres (0.1 to 0.8 inch) each day. The Golgi apparatus, visible only with special staining methods, is a fine network of cytoplasmic organelles associated with the secretory process. The mitochondria are the powerhouses of the cell, utilizing the energy-rich chemical adenosine triphosphate (ATP) for the neuron's metabolic activities (see also METABOLISM). The neuroplasm is the amorphous, flowing cellular protoplasm (cytoplasm); it normally contains a high concentration of potassium and other substances critical to the production of the nerve impulse and other metabolic activities of the neuron. The branching dendrites of the cell body contain their own complement of Nissl substance, mitochondria, and neuroplasm and range from a fraction of a millimetre to generally no more than a few millimetres in length.

The axon also shows mitochondria and neuroplasm but is without Nissl substance. It originates from the cell

body as the conical axon hillock and tapers to a small diameter in what is called the initial segment. The initial segment is considered to be the focal structure that acts as an all-or-none "gate" or "valve" for the neural impulse; at any rate, the neuron either generates all the electrical impulse it can, or it sends out none. The axon ends in terminal dendrites with knobs (boutons terminaux) at their tips. Each knob synapses to transmit excitatory or inhibitory influences to another cell.

Synapses

Synapses, or synaptic junctions, between neurons are specialized complexes where communication occurs between an axonal ending of one cell and a dendrite (axodendritic synapse), cell body (axosomatic synapse), or axon (axo-axonic synapse) of another. An axon and its branches may terminate in only a few or as many as thousands of synapses (a thousand may be an average). In turn, the cell body of one neuron may receive synaptic contacts from several hundred to more than 20,000 other neurons. The synapse consists of a presynaptic portion, an extremely narrow gap called the synaptic cleft, and a postsynaptic portion. The presynaptic knoblike portion shows vesicles that contain the precursor chemicals of the transmitter substance (*e.g.*, acetylcholine, norepinephrine) released at that synapse. The plasma membranes of the two adjacent cells are respectively called the presynaptic and the postsynaptic membrane at the synaptic cleft (about one millionth of an inch). Following the arrival of the all-or-none impulse, transmitter substances are released across the presynaptic membrane into the synaptic cleft to combine chemically with receptor sites in the postsynaptic membrane, evoking physiological response in the next cell in the chain.

Peripheral nerves. Peripheral nerves (*i.e.*, those serving parts in or near the body surface) are bundles of axons extending side by side, crudely analogous to coaxial cables. Each axon is comparable to one wire among the many in a cable, and the neurilemma cells and thin connective-tissue layer encapsulating each axon can be likened to the insulation around the wire. Nerve axons are bound together in subgroups (fascicles and groups of fascicles); all of these are enveloped by a covering of connective tissues to form the entire nerve. Many individual axons are covered by a myelin sheath, a complex of fatty materials and proteins that is the product of the layers of the plasma membrane and of the neurilemma (Schwann) cells. Other axons, which are surrounded by neurilemma cells but without myelin, are called unmyelinated fibres. The myelin sheath is a segmented, sausage-like layer interrupted at regular intervals by indentations called nodes of Ranvier. One neurilemma cell forms the myelin sheath for each internode (between two nodes of Ranvier). There is a direct relation between the internodal length and the speed of neural conduction: the longer the internodes, the greater the conduction speed of the impulse. Myelin improves the signalling efficiency of a nerve fibre; in effect, the impulse hops along the plump sheath from node to node in a process called saltatory conduction. The axons of unmyelinated fibres are encapsulated by neurilemma cells that do not produce myelin; these fine, small-diameter fibres have relatively slow speeds of conduction.

Other neurilemma cells—called satellite cells—encapsulate the cell bodies of sensory ganglia of the cranial and peripheral nerves and of the ganglia of the autonomic nervous system to be discussed later.

Cells of the central nervous system. In the central nervous system, neuroglial (glia) cells outnumber neurons five to ten times. Except for blood vessels and small phagocytic (scavenger) glial cells (microglia), connective tissue is sparse in the central nervous system. Extracellular fluid is present in the spaces (interstices) among the cells and nerve fibres. Oligodendroglia in the gray matter surround the cell bodies of neurons, whereas, in the white matter of the central nervous system, these glial cells produce the myelin sheaths of the axons. These glial cells are equivalent to the satellite, or neurilemmal, cells of the peripheral nervous system. Nodes of Ranvier and internodes are present in myelinated neurons of the central nervous system. Astroglia are cells that are intercalated between blood capillaries and neurons. Processes from these glial cells are in intimate contact with about 85 percent of the capillary surface; other processes are in close synaptic contact with cell bodies of neurons. Interrelations among neurons, blood vessels, glial cells, and extracellular fluid serve to maintain concentrations of chemical substances essential to the neuron's resting potential and all-or-none impulse. They also provide the basis for a kind of blood–brain barrier, a mechanism through which many substances (which readily pass from the blood into other tissues of the body) enter numerous parts of the central nervous system much more slowly and in lower concentration. Some antibiotics, for example, move so poorly from the bloodstream into the cerebrospinal fluid that they are not always a good choice for treating certain infections of the nervous system.

Physiological interrelations among neurons and surrounding tissues

NERVE DEGENERATION AND REGENERATION

An injured neuron exhibits metabolic changes that tend to repair the cell and restore its function. When a peripheral nerve is cut (transected), Nissl substance in each damaged neuron breaks up (a process called chromatolysis), the cell body swells, and the nucleus is displaced to the side of the cell body. In the nerve segment distal to the cut (*i.e.*, the part now disconnected from the central nervous system), the axon and the myelin sheath of each neuron fragment and are subsequently lost in favour of a continuous band of new neurilemma cells. Such so-called degenerative responses appear actually to be initial steps toward new growth, or regeneration. The cell body increases the rate at which it produces protein, which, in turn, flows down the axon to support the sprouting of several new branches at the reconstituting cut end. These growing tips elongate, invade the distal stump, and follow the bands of neurilemma cells, optimally at a rate of about four millimetres per day. Eventually the regenerating tips reach the sensory nerve receptors and motor endings.

Functionally effective regeneration, however, does not occur invariably. Each regenerating axon may send out many new branches that may become associated with different neurilemma bands. Each band, in turn, may act as a scaffold that guides a number of regenerating fibres. The eventually surviving axons are those that grow to terminate in the same kind of nerve endings that were theirs before the injury (*e.g.*, touch fibre to a touch ending in the skin). Those fibres that fail to form such appropriate functional connections eventually degenerate, while successful fibres remyelinate. Although peripheral nerves often can regenerate, transected axons in the central nervous system show regenerative changes but rarely form effective new synapses. In general, then, such injured neurons in the brain or spinal cord can be given up as functionally lost.

Sometimes an uninjured axon may sprout a branch from a node of Ranvier (collateral regeneration). This sprout invades and grows down a neurilemma band of a nearby injured nerve fibre. Thus a healthy neuron may incorporate the severed end of a damaged nerve cell and return that ending to full function. Successful collateral nerve regeneration occurs in both the peripheral and the central nervous systems. (C.R.N.)

II. The central nervous system

The human central nervous system consists of a brain, its connected spinal cord, and their associated membranes, fluids, and blood vessels. The central nervous systems of all vertebrates are similar in structure and function, but there is generally an increase in relative size and complexity as the phylogenetic scale is ascended. The comparative anatomy and physiology of nervous systems of all animals, as well as the nomenclature regarding anatomical structures of the nervous system and their position, are dealt with in the article NERVES AND NERVOUS SYSTEMS. Most aspects of the central nervous system of man are almost identical to those of other primates, dealt with rather extensively in the previously mentioned article.

The normal human brain, a unified, balanced, symmet-

rical, and harmonious organ of specialized and unique function, is endowed with considerably more potential than is realizable in the course of one person's lifetime. The continuity of personality throughout life hinges most directly upon the brain. An individual may lose almost any other part of his body—a kidney, his stomach, half his liver—or exchange his heart for another without losing his identity; his brain, however, seems to be where he "lives" as a legally and psychologically unique individual. If complete nerve regeneration were possible, and if parts of all severed nerves could be matched, there could still, in actuality, be no such procedure as a "brain transplant" —it would be a matter of a body transplant. A "well" brain would acquire another body in which to be housed.

The delicate brain and its spinal cord are provided with specially evolved, intricate protective and nutritive mechanisms of bone, muscle, ligament, and blood vessels, as well as supporting cushions of fluids.

Structure of the skull and spinal column

The human skull that encases the brain is remarkably structured in weight, contour, cavities, depressions, and openings for the exit and entry of nerves carrying an almost infinite variety of motor and sensory messages to and from various organs via other parts of the nervous system. The bony spinal column, extending caudally from the skull, normally comprises 30–33 individual bones (vertebrae) linked together by fine, multiple criss-crossing ligaments and intervertebral cartilage that permit great mobility (except at the lower end, where the column is relatively fixed as it joins the pelvis). The vertebrae are so structured in curves, configurations, and facets as to allow considerable flexibility of movement while still bearing the stress of erect posture and body weight. At the same time the spinal column protects the delicate nervous tissue of the spinal cord running most of its length. The column also has small channels (foramina) that allow for the entry and exit of peripheral nerves (see also SKELETAL SYSTEM, HUMAN).

The lowest part of the brain, the medulla oblongata, is continuous through the foramen magnum, the opening at the base of the skull, with the spinal cord. The brain and spinal cord, as previously mentioned, constitute the central nervous system; the nerves passing to and from the central nervous system form the peripheral nervous system. The human nervous system includes certain nerve centres and nerve fibres that, without conscious knowledge of the processes concerned, control the vital functions of the body, such as circulation of the blood and respiration (Figure 1). This system, called the autonomic nervous system, includes sympathetic and parasympathetic components. These systems will be described later. Through communicating branches the brain can influence organs that are supplied by the autonomic system —*e.g.*, the salivary glands and heart, both of which may be acted on by fear, hunger, and other emotions. Ordinarily, however, the internal organs function without awareness of the processes involved.

THE BRAIN

General structure. The average male brain weighs about three pounds (1,400 grams). It is surrounded by three successive membranes called meninges and protected by the bony skull (neurocranium). The brain (encephalon) is divided into five parts: telencephalon (end brain), diencephalon (interbrain), mesencephalon (midbrain), metencephalon (afterbrain), and myelencephalon (medulla oblongata). The cerebrum comprises the telencephalon, diencephalon, and upper midbrain. The metencephalon is divided into the pons and the cerebellum. The pons is connected to the cerebellum by bridges of nerve fibres called cerebellar peduncles.

Each half of the bilateral telencephalon, called a cerebral hemisphere, consists of an outer gray mantle called the cerebral cortex, a deep mass of gray matter—the basal ganglia—and the white matter located between the two gray structures. The hemispheres are connected by bands of nerve fibres called commissures. The corpus callosum is the largest commissure. The cerebral cortex is characterized by ridges called convolutions or gyri, which are separated by grooves called sulci. The right and left cerebral hemispheres are separated by a midsagitally located, deep, longitudinal fissure.

Two major structures of the diencephalon are the thalamus and the hypothalamus. The brain has a series of cavities, called ventricles, that are filled with cerebrospinal fluid. All of these structures are described in more detail in this article.

Membranes of the brain. The membranes, or meninges, covering the brain are an outer, tough, fibrous layer, the dura mater; a thin, intermediate, weblike tissue, the arachnoid; and a soft, vascular inner covering, the pia mater.

The dura mater. The dura mater lines the cranial cavity. In it are meningeal arteries and veins that serve for the nutrition of the bone. If the dura mater is torn in an injury to the skull, an effusion of blood may occur between the dura mater and the bone, which may, by exerting pressure on the underlying brain, cause paralysis of the opposite side of the body. The inner surface of the membrane is smooth and moist. The dura mater also forms partitions (septa) between the hemispheres of the brain and cerebellum. These septa are folds of the dura mater and consist of two layers, blended where they touch but separated along the attached borders of the septa to form venous channels, or dural sinuses, by which blood and excess of cerebrospinal fluid is drained from the brain into the great veins of the neck, which carry the

Functions of the dura mater

fluid mixture back toward the heart (see also CEREBROSPINAL FLUID).

The secretion from the pituitary gland is also carried away into the general bloodstream by small venules, which open into the neighbouring cavernous and other venous sinuses. Absorption and passage of the cerebrospinal fluid is carried out, to a large extent, by small villous projections of the arachnoid membrane, which extend into the venous sinuses and spaces of the dura mater and are most numerous in the neighbourhood of the sagittal sinus. If this passage is prevented or retarded, the intracranial pressure of the cerebrospinal fluid rises, and one form of hydrocephalus results. After birth the arachnoid villi enlarge to form what are called pacchionian bodies, beginning at about 18 months. Between the dura mater and the subjacent arachnoid membrane is an interval called the subdural space. It contains a small quantity of fluid that serves to lubricate the smooth inner surface of the dura mater.

The arachnoid membrane. Beneath the dura mater is the arachnoid membrane, which, although thin, is not permeable to fluids. It is separated from the pia mater, beneath, by the subarachnoid space. This is traversed by a network of delicate fibrous bands. The meshes of this network are filled by the subarachnoid cerebrospinal fluid; the larger thin-walled cerebral arteries and veins covering the surface of the brain lie in the thin bands of fibrous tissue forming the net. In the lower part of the roof of the fourth ventricle (see below) are three openings in the arachnoid membrane and pia mater: a median, the foramen of Magendie; and two lateral, the foramina of Luschka. These form a communication between the cerebrospinal fluid in the ventricles of the brain and that contained in the subarachnoid space. Obliteration of these openings by meningitis produces an obstructive hydrocephalus, in which the accumulation of fluid is entirely intraventricular.

Openings in the arachnoid

The pia mater. The pia mater is a delicate vascular membrane forming the immediate investment of the brain and dipping down into the fissures between the convolutions. It contains the smaller arterioles and venules that supply the subjacent brain. A large triangular fold of pia mater (velum interpositum) is included in the great transverse fissure lying between the corpus callosum and fornix above and the roof of the third ventricle and thalamus below. This pyramidal fold contains two great blood vessels, the cerebral veins of Galen, which drain the blood from the interior of the brain. Vascular fringes at the margin of the fold project into the lateral ventricles, and similar fringes project from under the surface of the fold into the third ventricle. These fringes are the choroid plexuses of the lateral and third ventricles, and a similar choroid plexus is found in the roof of the fourth ventricle. The fringes are covered by a secretory layer, called the choroidal epithelium, which elaborates and secretes some of the cerebrospinal fluid (see also CEREBROSPINAL FLUID).

Ventricles. Ventricles are cavities containing fluid, situated in the substance of the brain, and lined by a thin membrane, the ependyma. There are four true ventricles: the right and left lateral ventricles, contained in the cerebral hemispheres; the third ventricle, situated in the diencephalon; and the fourth ventricle, located in the pons and medulla (hindbrain). Each lateral ventricle is connected with the third ventricle by a small opening, the interventricular foramen of Monro; and the third ventricle is joined to the fourth by a narrow channel; the cerebral aqueduct of Sylvius in the midbrain. The fourth ventricle communicates below with the central canal of the spinal cord and with the subarachnoid space by the foramina of Magendie and Luschka.

The cerebrospinal fluid contained in the ventricles and subarachnoid space acts as a mechanical support to the brain and spinal cord; it also performs functions similar to those of tissue fluid and lymph in other parts of the body (see TISSUES AND FLUIDS, ANIMAL). The brain floats in the cerebrospinal fluid. Blood is supplied to the brain by two paired arteries: the internal carotid and the vertebral arteries. These are in communication with each other at the base of the brain, where they form the so-called arterial circle of Willis. Venous return is arranged not alongside the arteries, as almost everywhere else in the body, but through a system of dural sinuses that drain blood to the jugular foramen and from there to the internal jugular veins.

Medulla oblongata. The medulla oblongata is situated in the lower and posterior part of the cranial cavity. It appears to be a direct continuation upward of the spinal cord but differs in its arrangement of fibres composing the nerve tracts and in disposition of the gray matter. It contains the vital cardiac, vasomotor, and respiratory

Vital centres within the medulla oblongata

centres. These are situated in the lower part of the medulla. Longitudinal bundles of nerve fibres connect the medulla oblongata with the pons, and two diverging bundles of fibres called the paired inferior cerebellar peduncles join it to the cerebellum.

The principal longitudinal tracts that connect the pons with the medulla are (1) the pyramidal tracts, (2) the medial longitudinal fasciculi, and (3) the medial lemnisci.

Pyramidal tracts. The pyramidal tracts consist of motor fibres, each of which originates from the motor areas of the cerebral cortex and descends through the internal capsule of the cerebrum, midbrain, and pons to the anterior part of the medulla. Here they form two parallel strands (pyramids), one on each side of a median vertical groove. In the lower part of the medulla oblongata, the greater number of the fibres of the pyramidal tract cross over to the opposite side of the spinal cord, where they form a bundle of descending fibres called the crossed pyramidal tract. The few remaining fibres are continued downward on the same side of the cord as the direct pyramidal tract. Eventually these fibres also cross to the opposite side. The crossing of the motor nerve fibres in the medulla oblongata is called the decussation of the pyramids, and, because, with few exceptions, all motor and sensory fibres cross to the opposite side, each cerebral hemisphere influences the muscles of and receives sensory impulses from the opposite side of the body.

Medial longitudinal fasciculi. The medial longitudinal fasciculi are paired tracts of nerve fibres that have their cells of origin in the vestibular nuclei of the brainstem. The fibres end in the motor nuclei of the muscles of the eyes and the descending ones in the nuclei of the neck muscles of the same and the opposite side. By means of these tracts, the position of the eyes and the head can be adjusted to each other and coordinated in such a way that the eyes remain fixed on a given object, regardless of the position of the head.

Medial lemnisci. Each medial lemniscus is a longitudinal tract of ascending sensory fibres lying close to the median plane between the pyramidal tract and the medial longitudinal fasciculus. The fibres of the right and left tracts cross the median plane, forming the sensory decussation. This lies in the medulla above the level of the motor, or pyramidal, decussation.

The sensory impulses coming from the spinal cord end in cell processing stations in the medulla, the gracile and cuneate nuclei. It is from these that fibres (internal arcuate fibres) cross to opposite sides and ascend in the medial lemniscus, which terminates in the thalamus. This lemniscus forms one link, or relay, in the main sensory tract to the cortex.

The olive

Immediately lateral to the pyramidal tract on the anterior aspect of the medulla is an oval swelling, the olive. The olive lies over a folded lamina of gray matter in the substance of the medulla; this is the nucleus of the inferior olive. It is connected with the opposite cerebellar hemisphere by fibres that cross the middle line and reach the cerebellum through the inferior cerebellar peduncle. The nuclei from which the motor fibres of the cranial nerves III through XII originate and those in which the sensory fibres terminate lie in the reticular formation of the medulla and pons. Like the spinal nerves, they are connected by nerve tracts with the opposite hemisphere (for a description of cranial and spinal nerves, see below *The peripheral nervous system*).

Pons. The pons is located between the midbrain and the medulla oblongata. Its posterior surface forms the floor of the upper half of the fourth ventricle. The posterior region of the pons, adjacent to the ventricular surface, is called the tegmentum, while the anterior region is the basilar portion. The tegmentum is part of a continuous structure of the same name extending rostrally (to the front) and caudally (to the rear) to form much of the midbrain and medulla. The basilar portion extends rostrally, as the crura cerebri of the midbrain, and caudally, as the pyramids of the medulla.

In common with the tegmentum of the midbrain and the medulla, the tegmentum of the pons contains nuclei of origin (motor) and of termination (sensory) of some cranial nerves, the tracts of ascending sensory pathways, sone descending motor pathways, and the reticular formation. The nuclei of the cranial nerves include those of the fifth, sixth, seventh, and eighth cranial nerves. The ascending pathways include the spinothalamic tract (pain and temperature from the body), trigeminothalamic tracts (pain, temperature, and touch from the head), medial lemniscus (touch from the body), the medial longitudinal fasciculus (vestibular influences to the nuclei innervating the eye muscles and correlating position of head in space to the direction of gaze; see below), and the lateral lemniscus (hearing). The descending pathways include the corticobulbar fibres, which influence the motor nuclei of the cranial nerves, and the fibres of the extrapyramidal system (see below). The reticular formation is an intricate neuronal network organized into complex ascending pathways, descending pathways, and local neuronal circuits.

The basilar portion of the pons includes: (1) the fibres of the pyramidal tracts, which course longitudinally from the crura of the midbrain, located rostrally, to the pyramids of the medulla; and (2) the fibres of the corticopontine tracts, pontine nuclei, and fibres of the pontocerebellar tracts. The latter group conveys information from the cerebral cortex to the cerebellum. The corticopontine tracts originate in the cerebral cortex and terminate to synapse (interconnect) with pontine nuclei on the same side of the body. The pontine nuclei have fibres that cross over in the basilar portion and course through the middle cerebellar peduncle before terminating in the cerebellum of the opposite side.

Cerebellum. The cerebellum consists of a medial part, known as the vermis, and two lateral hemispheres. Each hemisphere is connected with the brainstem by three

paired stemlike parts (peduncles): (1) the inferior cerebellar peduncle to the medulla; (2) the middle cerebellar peduncle; (3) the superior cerebellar peduncle. The last joins the cerebellum to the midbrain and conveys mostly efferent fibres, one bundle leaving the cerebellum and ascending to the contralateral red nucleus and to the contralateral thalamus, and another bundle going finally to the reticular formation of the medulla oblongata.

The cerebellum receives impulses from the equilibratory organ in the middle ear, from muscle spindles, from the exteroceptors of the skin, from the eye, and from the ear (acoustic organ), as well as from the cerebral cortex. These impulses reach the gray matter of the cortex of the cerebellum and are believed to pass from there to the deep cerebellar nuclei (dentate, emboliform, globose, and fastigial nuclei). From this nuclei a relay of fibres ascends to the opposite red nucleus, thalamus, and brainstem reticular formation (see below). The fastigial nuclei are integrated functionally with the vestibular system. The superficial surface of the cerebellum differs from that of the cerebral hemispheres. In place of convolutions, the vermis and hemispheres of the cerebellum are crossed by numerous transverse fissures, which mark off a series of folds, or folia. The general arrangement of these is seen in a median section through the vermis, which presents a branched appearance called the arbor vitae. The surface of the cerebellar hemispheres and central lobe is subdivided into lobes and lobules by deep fissures.

The cortex of the cerebellum consists of a superficial stratum, the molecular layer; an intermediate layer, which contains the cell bodies of branched Purkinje cells; and an inner deep stratum, the granular layer, which rests upon the central white matter. The latter is formed by medullated nerve fibres, which course to and from the gray matter. The Purkinje cells are large and have extensive connections. The cell bodies are pear-shaped and arranged in a single layer. From the outer end of each cell, processes (projections) branch out in the molecular layer.

Purkinje cells

These processes are the dendrites, and the branching takes place chiefly in a plane at right angles to the longitudinal axis of the folium in which it lies. The dendrites of the Purkinje cells are intersected at right angles by parallel fibres that run in the direction of the folium. These fibres are derived from axons of the granule cells in the inner stratum of the cortex, which pass outward and divide in the molecular layer in a T-shaped manner into right and left branches. The bodies of the Purkinje cells, moreover, are surrounded by a network of fibres that originate from basket cells in the molecular layer; and the Purkinje dendrites are also accompanied by delicate climbing afferent nerve fibres from the white matter.

Although areas of the cerebellar cortex cannot be mapped out by response of particular groups of muscles to electrical stimulation, it is possible on morphological grounds, by means of experimental work and by the tracing of tracts of nerve fibres entering the cerebellum, to locate areas of the cortex according to the fibres that they receive from the particular parts. The cerebellum, relatively large in man, weighs more than the entire spinal cord. It is the great modulator subserving the coordination of groups of muscles. The cerebellum smooths out the actions of these groups by delicately regulating and grading muscle tensions. Cerebellar reactions are unconscious; destruction of the cerebellum entails no loss of sensation or intelligence, although cerebellar disturbance may cause some proprioceptive misperception and poor muscular coordination.

The midbrain. The midbrain (mesencephalon) connects the pons and cerebellum with the cerebrum. It is traversed by the cerebral aqueduct of Sylvius. The part that lies above the aqueduct, called the roof plate or tectum, is subdivided into four rounded swellings. These are the colliculi or corpora quadrigemina. The upper pair of these bodies receive nerve fibres from the retina, which reach them through the optic tracts and from the medial lemniscus. They are an important centre in lower mammals but are of less importance in primates. The lower pair serve as a cell station in the path of the auditory impulses, which commence in the cochlea and terminate in the cerebral cortex of the temporal lobe. The gray matter in the roof of the aqueduct receives an important tract of nerve fibres from the spinal cord, known as the spinotectal tract.

A similar bundle, the spinothalamic tract, also traverses the midbrain. This pathway conveys the more primitive sensations of pain, heat, and cold to the receptive centres in the thalamus. These have been described as protopathic sensations, to distinguish them from the finer and more recently evolved sensations of touch, which have been termed epicritic. The latter ascend in the posterior columns of the spinal cord to the gracile and cuneate nuclei. From these a relay of nerve fibres ascends through the medulla oblongata and, crossing in this to the opposite side of the brain, passes as the medial lemniscus through the pons and midbrain to the thalamus. From the thalamus another relay of fibres carries the sensory impulses to the cerebral cortex of the brain.

Spinotectal and spinothalamic tracts

The most ventral part of the midbrain forms the crura cerebri. These two diverging limbs are composed of nerve fibres coursing from the cerebral cortex to the spinal cord (pyramidal tract) and pons (corticopontine fibres). Behind, or dorsal to, the crura is a lamina of pigmented nerve cells (substantia nigra) that separates the pes pedunculi from the tegmentum. This is traversed by decussating fibres, the greater number being the cerebellar

Figure 5: Medial aspect of the brain.

fibres already mentioned as issuing from the dentate nucleus, travelling by the superior cerebellar peduncle to the midbrain and then crossing to the red nucleus of the opposite side and to the thalamus.

From the red nucleus a tract of nerve fibres descends to the spinal cord, where it forms connections with the motor cells in the gray matter of the anterior horn (see below *Spinal cord*). This is the rubrospinal tract. The red nucleus is also connected with the thalamus, the brainstem reticular formation, and the nucleus of the inferior olive. By means of these connections, it is believed that the cerebral hemispheres control the more reflex movements carried out by the spinal cord, such as balancing movements and the maintenance of posture.

In the tegmental part of the midbrain are also situated the longitudinal association tracts, known as the dorsal and medial longitudinal fasciculi, and the nuclei and roots of origin of the third and fourth cranial nerves and part of the fifth in the gray matter surrounding the cerebral aqueduct of Sylvius.

Cerebral hemispheres. Two of the most distinctive features of the human brain are the large size of the cerebral hemispheres and the high degree of specialization in the microscopic structure of the cerebral cortex. The cerebral hemispheres comprise the cerebral cortex, the lateral ventricles, white matter deep to the cerebral cortex, and the basal ganglia. The surface of each hemisphere is subdivided, for descriptive purposes, into lobes and lobules. Certain sulci and lines that are arbitrarily drawn between these are employed for demarcating the boundaries of these areas. The central sulcus, or sulcus of Rolando, is situated on the lateral surface and separates the frontal from the parietal lobe. The lateral sulcus, or sulcus of Sylvius, marks off the temporal lobe from the parietal and frontal lobes. On the median surface are the callosomarginal and parieto-occipital sulci, which limit the frontal, limbic, parietal, and occipital lobes.

The central, or Rolandic, sulcus marks the posterior limit of the important motor area of the cortex. Electrical stimulation of particular parts of this area produces definite movements of groups of muscles, the action of which is normally initiated and controlled by the part stimulated. Injury to the same part causes paralysis of the corresponding muscles.

The cortex of the occipital lobe, which surrounds the posterior part of the calcarine sulcus, is the visuosensory area for reception of visual impulses from the retina. The visuosensory area is surrounded by a zone that extends on to the outer aspect of the occipital lobe, termed the visuopsychic area.

The middle part of the first temporal gyrus and the adjacent gyri on the lower lip of the fissure of Sylvius are concerned with hearing. The auditory area of the brain receives sensory impulses by way of the auditory radiation from the medial geniculate body of the same side. These, the lower auditory centres, are connected with the opposite ear by means of the lateral lemniscus.

The front part of the hippocampal gyrus, with its hooklike end, the uncus, is the higher cortical centre for the sense of smell. This is the most primitive of the special senses. It is closely associated with the sense of taste and is more highly developed in many other vertebrate animals than in man. That part of the brain that is concerned with the sense of smell and with certain complex emotional responses is called the limbic lobe. There is also a large area behind the central sulcus that extends forward onto the motor area. This is the cutaneous sensory, or tactile, area.

The areas of cerebral cortex lying between the special and cutaneous sensory areas are believed to function as association centres between the different senses and as centres in which the memory of associated sensations is stored. The region in front of the motor cortex (premotor cortex) is connected by association fibres with all the various sensory and motor areas and, more especially, with that part of the adjacent motor area that is concerned with the movements of the eyes. It is therefore believed that this part of the cortex may control skilled movements that are dependent on impulses reaching the brain from the eyes and that require close attention and a knowledge or memory of past experiences—such movements, for instance, as those of the lips and tongue or of the hand, which have given man the powers of speech and of writing. In front of the premotor cortex is the prefrontal cortex, which is somehow involved with such qualities as disposition, outlook on life, drive, personality, planning for the future, and control of activities along ethical standards. If the upper and lower lips of the fissure of Sylvius are separated, a triangular area of submerged cortex called the insula or island of Reil will be exposed.

The basal ganglia

The basal ganglia are the large masses of gray matter embedded in the cerebral hemispheres. They include the caudate and lenticular nuclei; the subthalamic nucleus of the thalamus and the substantia nigra of the midbrain are often included. The lenticular nucleus is divided into the putamen and the globus pallidus. The caudate nucleus and putamen are called the striatum, or neostriatum, while the globus pallidus is also called the paleostriatum or pallidum. The caudate and lenticular nuclei form the corpus striatum. The basal ganglia are integrated through complex neural connections with the cerebral cortex and thalamus. They are involved with the basic regulation of stereotype movements basic to the performance of complex volitional movements. The malfunctioning of the basal ganglia is contributory to a variety of motor disturbances. These include paralysis agitans (Parkinson's disease), athetosis, and choreas. A general term for some of these abnormal movements (called dyskinesias) is cerebral palsy. The precise role of each of these structures in these conditions was not fully understood in the early 1970s. For example, degenerative changes in the globus pallidus and substantia nigra are present in patients with Parkinson's disease; in addition the neostriatum and substantia nigra have reduced amounts of dopamine within them. Paralysis agitans is characterized by rigidity and tremor. In athetosis, the movements are slow and those of the extremities have a wormlike action. Choreas (from the Greek meaning dance) are featured by jerky and brisk movements of the extremities and involuntary twitchings of the facial and neck muscles.

The cerebral cortex is the stratum of gray matter that covers the central white matter of the cerebral hemispheres. It is comprised of nerve cells, nerve fibres, blood vessels, and a supporting tissue, the neuroglia. It exhibits a definite stratification into layers of nerve cells and nerve fibres. In sections of fresh brain, the main strata and various zones are easily recognizable by the unaided eye, and more especially so in the visual cortex, or area striata. These appearances correspond closely with those revealed by microscopic preparations. In recent years it has become apparent that there is also a columnar arrangement of the cells that can easily be seen in properly cut sections.

Although the cerebral cortex is conventionally described as being organized into layers oriented parallel to the surface of the cortex, the basic functional unit is now conceived as being a physiologically defined vertical column extending from the cortical surface to the white matter. These columns are: (1) the terminal regions for fibres (input) that originate in the thalamus and other cortical columns of the same and opposite cerebral hemispheres, and (2) the source of output fibres that terminate in other cortical areas of the same and opposite cerebral hemispheres and in neural centres in the basal ganglia, thalamus, brainstem, and spinal cord. The neurons of the cerebral cortex include: (1) pyramidal cells (cell body in the shape of a pyramid), with axons that extend from the column to the white matter as the output fibres just noted; (2) small cells with short axons that interact with pyramidal cells and other small cells in the immediate vicinity. The axons of the pyramidal cells leave the column of origin, join the white matter, and terminate in other columns by re-entering the cortex, or the gray matter, of other regions of the brain and spinal cord. The axons of the small neurons are integrated into intracortical neuronal circuits that tend to sustain the vertical columnar organization. The complex synapetic connectivity among

these small neurons and the pyramidal neurons is basic to the intricate activity within the cortex. These small neurons are numerous in the cortex of man; hence these neurons are considered to be the "structural expression" of the delicacy of the function of the human brain.

In animals the degree of lamination and differentiation of the nerve cells in the cortex appears to correspond to the stage of evolution attained by the particular species. Thus, the cortex is thicker and more highly evolved in man and the higher types of mammals than it is in lower forms (see NERVES AND NERVOUS SYSTEMS). In the development of the human cortex, stratification begins about the sixth month of fetal life, when the convolutions first appear, and differentiation continues not only during the later months of fetal life but for a considerable period after birth.

The thalamus is strategically located to receive influences from a variety of sources and to send information to the cerebral cortex. In brief, the massive complex of neural processing centres receives input from all sensory systems, with the exception of the olfactory system, and from the basal ganglia, brainstem, and cerebellum, and sends neural influences to the cerebral cortex. The thalamus has a role in the conscious appreciation of sensation; many of the crude sensory modalities (pain, touch, and, possibly, sound detection) are brought to consciousness in this structure. The affect of an individual (*e.g.*, state of contentment and well-being) and the phase of the sleep–wake cycle are largely mediated through the thalamus. The rhythmic brain wave activity as observed in the electroencephalogram is synchronized and integrated in the thalamus and expressed in the cerebral cortex.

The hypothalamus is a small structure, weighing four grams, involved with numerous functional activities associated with the autonomic nervous system. It has crucial roles in influencing the functional activities of the pituitary gland (hypophysis) and in the regulation of water balance through the so-called "thirst centre," of body temperature by maintaining the balance between heat production and heat loss, and of food intake and feeding responses. In addition, the hypothalamus is involved with many objective physical expressions associated with emotion and behaviour; for example, alteration in the heart beat (palpitations), blushing, cold sweat, and tears of sadness. The sleep–wake cycle is influenced by activity of the hypothalamus. A portion of the thalamus, called the subthalamus, is functionally integrated with the basal ganglia.

The brainstem. The brainstem comprises the midbrain, the pons, and the medulla oblongata. The diencephalon—the thalamus and hypothalamus—is often included within the brainstem. The diencephalon and midbrain are referred to as the upper brainstem and the pons and medulla as the lower brainstem. The brainstem is dealt with separately, as a unit, because of its special roles in reflexes, sensory and motor conduction, the regulation of the internal environment of the body, and regulation, or control, of the rest of the nervous system. In man the embryonic central nervous system undergoes differentiation at its interior end into the brain, while the remainder becomes the spinal cord. The original part of this differentiating brain becomes the brainstem. The stem, from its lateral and dorsal aspects, gives off "buds" that develop into the cerebral hemispheres and cerebellum. These overgrow and cover their stalk, so that, when the adult brain is removed from the cranium, nothing of its initial component is seen until, viewed from the underside, a lumpy column about as large as a man's thumb from tip to wrist, and not greatly different in shape, can be distinguished as the brainstem.

The brainstem is interposed between and interconnected with the more differentiated parts of the brain on the one hand and the spinal cord on the other, and it bears certain similarities to each of these structures. By means of its entering and exiting nerves, the spinal cord is concerned largely with gathering sensory impressions from and effecting motor behaviour to what were originally serially arranged segments of skin or muscles of the body. The skin of the head and the muscles of the eyeball and tongue are likewise supplied with nerves from the brainstem. Sensory endings and muscles develop around the nasal, oral, and pharyngeal cavities, and their derivatives are also supplied by brainstem nerves. The specialized sense organs—the ear, eye, and olfactory receptors—which develop in the head, are also innervated by nerves connecting with the brainstem. These nerves of the head are collectively designated as cranial (see below *The peripheral nervous system*).

Ascending pathways from the spinal cord continue upward through the brainstem and are joined there by others, conveying afferent messages to be relayed to the cerebellum or to the cerebral hemispheres. Similarly, from these latter structures descend into the brainstem, in part to terminate in relation to its motor outflows, in part to continue uninterruptedly through it toward motor outflows from the cord, and in part to reach these cranial or spinal outflows indirectly after relay by collections of brainstem neurons. The brainstem therefore resembles the spinal cord, of which it is the rostral continuation, both in supplying nerves to the periphery and in accommodating ascending pathways to, and existing connections from, the cerebral hemispheres and cerebellum.

The development called encephalization, which carried the cerebellum and, to a great degree, the cerebral hemispheres to such heights of structural complexity and functional achievement, led the brainstem also to assume a dominating and integrating role over lower lying outflows from the nervous system—in general, those innervating the viscera, or skeletal structures related to viscera—which preserve the internal environment of the body in a state of optimum activity; in addition, and less clearly perceived, this development also led the brainstem to assume the role of maintaining a state of optimum activ-

ity within the interior of the central nervous system itself, both in the spinal cord below it and in the cerebral hemispheres above.

The functional aspects of the brainstem are as follows:

Brainstem reflexes. A reflex is a relatively invariable and stereotyped response to a specific stimulus. Those reflexes mediated by the brainstem and its cranial nerves are concerned with adjusting the related musculature for optimum performance of the body's distance receptors, the eye and the ear, with orienting parts of the body in spatial relation to the head, and with managing the complicated acts involved in ingesting food.

Reflexes related to the eye and ear

Of the reflexes related to the eye, coordinated deviation of the eyeballs, often combined with turning of the head to perceive some aspect in the field of vision, occurs almost constantly during an individual's waking hours. Alterations for near vision are also frequent and involve contraction both of muscles converging the eyeballs and of intraocular muscles, which alter the curvature of the lens; the latter manoeuvre, called accommodation, serves to focus light rays on the retina. Associated with it is a constriction of the pupil cutting off light from the periphery of the lens, whose shape is not changed as much. The light reflex is a constriction of the pupillary aperture also evoked, as the term implies, by visual stimulation. Its purpose is to reduce excessive illumination of the retina. A so-called Argyll-Robertson pupil (extremely contracted and fixed to light but constricting in accommodation to various distances) is a frequently encountered sign in neural syphilis, for the brainstem path of the light reflex is unusually susceptible to injury by the spirochete of this disease (see also NERVOUS SYSTEM DISEASES).

More intense light evokes a reflex blinking of the lids, but the corneal reflex, a blink caused by stimulation of the cornea by touch or by drying, is more important not only for protection but also because loss of lachrymal secretion by frequent wiping of this structure leads to its injury, the cornea being the last portion of the body surface of terrestrial animals still to require a watery environment (see also EYE AND VISION, HUMAN).

Two reflexes related to the ear are evoked by auditory stimulation. One directs the head toward the source of a sound and appears designed to capture the maximal intensity of sound stimuli. The other, the auditory reflex, involves the two smallest muscles of the body, buried in the middle ear, the tensor tympani and stapedius, whose contractions reduce undue movement of the ossicular chain in response to loud sounds. In its damping action to loud sound, the auditory reflex is analogous to the pupillo-constrictor reflex of the eye to bright light.

Also located in the ear is the vestibular organ, which initiates reflexes involving (1) the muscles that orient the eyeballs in effective positions for vision when the head is moved and (2) muscles of the trunk and extremities that hold the body in a definite spatial relationship to the force of gravity. The most easily examined of these vestibular reflexes is nystagmus, a repetitive deviation of the eyeballs designed to keep them abreast of the rotating head. It may be evoked by spinning in a chair or by irrigating the external ear with hot or cold water, thus creating convection currents in the fluid-filled canals of the vestibular organ, simulating those induced by rotation. Prolonged repetitive stimulation of the balancing part of the vestibular organ, as by the pitching of a ship at sea, evokes a battery of visceral alterations not normally induced by vestibular nerve impulses, accompanied by sensations of nausea and distress—an incapacitating syndrome described as motion sickness (see also EAR AND HEARING, HUMAN).

Reflexes related to food ingestion

Reflexes associated with the nasal and oral cavities are concerned with conveying solid and liquid food into the gastrointestinal tract and with expelling these or other foreign objects from the closely adjacent air passages that they sometimes enter. The first of these objectives is accomplished by the swallowing reflex, in which stimulation of the back of the mouth cavity evokes sequential contractions of the muscles of the lips, jaw, tongue, pharynx, and part of the neck, propelling food or liquid into the esophagus. Ingested material is prevented from regurgitating into the nose, during swallowing, by a tensing of the soft palate and from entering the larynx, by a drawing up of this latter structure beneath the back of the tongue, so that the swallowed material cascades past it (see also DIGESTION, HUMAN). Impairment or absence of swallowing, called dysphagia, from injury to the swallowing reflex arc, is a frequent symptom of poliomyelitic involvement of the brainstem.

Reflexes expelling material from the nasopharynx are of two sorts; those in which the local musculature tries to accomplish this act unaided, as in gagging or choking; and those in which the respiratory musculature is also invoked to contribute a blast of expired air to the process, as in sneezing or coughing. Swelling of the mucosa in allergies or infections of the nasopharynx causes persistent stimulation of its receptor endings bringing about recurrent sneezing or coughing.

Related to these reflexes are vomiting and hiccupping, the latter appearing to be a repeated but ineffective effort to vomit. Both reflexes involve cramplike contractions of the abdominal and thoracic respiratory musculature—particularly the diaphragm—designed to empty the stomach by regurgitation. Because hiccupping is personally annoying and can become painful, the attempt is usually made to stop it by various manoeuvres. In cases of prolonged and intractable hiccupping, surgical crushing of the phrenic nerve, innervating the diaphragm, has sometimes been necessary to relieve an exhausted patient of the annoyance.

Sensory conduction through the brainstem. There are three general aspects of sensation with regard to the brainstem.

First, afferent nerve impulses gathered from all parts of the body and conducted to the cerebral hemispheres are somehow converted there into consciously perceived sensations, in which the intermittent features of nerve conduction fuse into the familiar picture of the world as normally seen and heard. Though the nature of this transmutation is not understood, it is clear that the delivery of afferent impulses to the hemispheres is prerequisite to it. If a receiving area of the hemisphere is destroyed, for example, or if the afferent pathway to it is interrupted at some lower level, the modality of sensation it subserves becomes lost to consciousness. Because paths conducting afferent messages toward the hemispheres are topographically distinct from one another, sensations can be lost singly. It is possible in cases of intractable pain that can no longer be relieved with drugs for the surgeon, by an appropriately placed incision either in the spinal cord or in the brainstem, to interrupt that pathway mediating impulses from pain receptors and thus eliminate pain sensations from consciousness, while preserving other afferent pathways and leaving unaffected the sensations that they mediate.

Next, if the central course of any single sensory pathway is examined, it will be found that its component nerve fibres, mediating impulses from different portions of the receptor field, whether for vision, hearing, pain, or touch, possess a definite spatial relationship to one another. This relationship is preserved in the relay of these impulses from the anterior end of the brainstem to the various sensory areas of the cerebral hemispheres. This orderly arrangement of conducting elements, an obtrusive structural feature of afferent pathways at each level of the central nervous system, may be without functional significance. It seems likely, however, that it underlies the orientation that objects are seen to bear to one another in the field of vision or the orderly relation that sounds of different pitch hold to one another in audition or the sense of localization that normally is attached to painful or tactile impressions.

The "feeling quality" of sensations

Lastly, another general feature of afferent conduction through the brainstem is the "feeling quality" that sensations often possess. Many sensations are perceived with no reaction but indifference, but most individuals can recall some dramatic instance when perception was accompanied by a warm suffusion of pleasure or by a shuddering chill of unpleasantness. Because lesions in or near the anterior end of the brainstem are sometimes followed

by states collectively called the thalamic syndrome, in which the most prosaic sensations are accompanied by intense and unmerited feelings of pleasure or unpleasantness, it has been suggested that this region of the brain is particularly concerned with endowing sensation with these qualities.

Motor conduction through the brainstem. The activity of skeletal musculature, whose contraction holds body parts in position or moves them about, is integrated at both upper and lower levels of the nervous system (the stereotyped contraction of some of the head muscles in cranial reflexes has already been considered). The finer, more labile and adaptive contractions of skeletal muscle, particularly in voluntary movement, are managed by a motor area in the cerebral hemispheres from which the pyramidal tract descends on each side through the brainstem to pass, with crossing, directly to the levels of motor outflow whose discharge it initiates.

A part of this pyramidal projection, concerned with voluntary contraction of the head musculature, terminates in relation to the brainstem cells of origin of the cranial motor nerves and is designated as the corticobulbar system. (The pons and medulla are called the bulb.) Though corticobulbar connections subserve a number of functions, the most important of which is speech, relatively little is known of their neural organization. After corticobular fibres are given off, the remainder of the pyramidal projection descends into the spinal cord for voluntary contraction of the muscles of the body, in particular those manipulating the distal portions of the extremities. Injury to the motor area of the hemispheres or to its descending pyramidal tract, as frequently occurs at the junction of the brainstem and hemispheres in a stroke or apoplectic attack, is followed by a paralysis of voluntary movement.

Not all of the cerebral influences upon movement are exerted over the pyramidal tract, however. A significant part reach lower outflows over a series of shorter paths, some of the constituent relays of which are provided by collections of brainstem neurons. Because this group of motor connections lies outside the pyramidal projection, it is called the extrapyramidal system. This latter system is able to initiate contraction of a postural nature, involving chiefly muscles of the trunk or proximal parts of the extremities. It serves also in managing grosser types of movements, such as those of progression. One of the major functions of the extrapyramidal system is, however, that of modifying activity initiated from other neural sources and already in progress. Because different components of this system respectively augment or reduce motion, their injury is followed either by depression or exaggeration of motor activity. Other symptoms that may be present following an injury to a component of extrapyramidal system are those of involuntary movement, such as tremor.

The extrapyramidal system

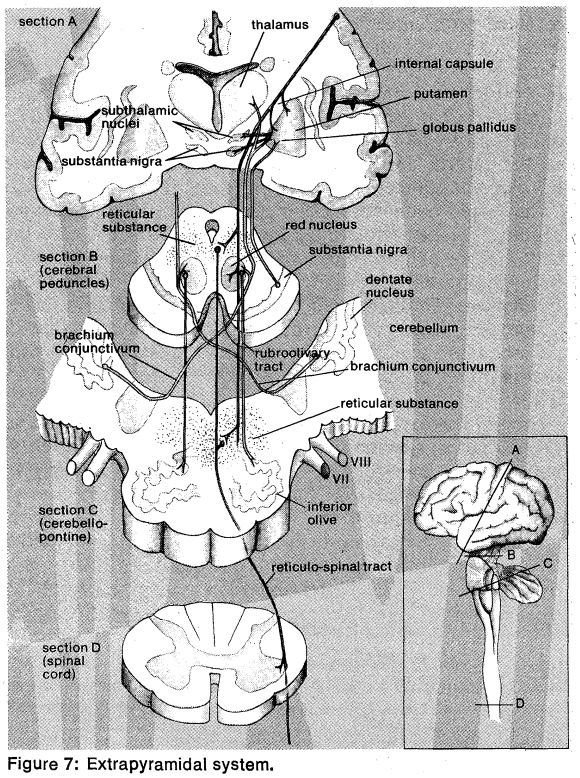

Figure 7: Extrapyramidal system.

Important modulating influences on motion are also exerted by the cerebellum and are mediated by connections passing either upward, via the brainstem, to the cerebral hemispheres or downward, over brainstem relays, which are apparently identical with those of the extrapyramidal system, to lower motor outflows. The brainstem thus plays an important part in motor conduction both from the cerebral hemispheres and from the cerebellum.

Regulation of the internal environment. In serving local reflexes and providing relays for pathways to and from other levels, the brainstem is analogous to the spinal cord. In exerting a dominating and regulating influence over collections of lower outflows concerned with certain general functions of the body, it resembles the cerebral hemispheres. The hemispheres are broadly involved with preserving optimum relations of the body with the external world, and, to a degree, the brainstem is comparably concerned with managing a number of the processes that maintain the internal environment of the body in an optimum condition. Parts of the brainstem so concerned are its anterior and posterior extremities.

The hypothalamus of the upper brainstem, overlies the pituitary, or master gland of the endocrine system. It has connections with this gland that control the liberation of pituitary hormones and so exert widespread influences throughout the body. A second group of efferent connections from the hypothalamus descends, with relays to the spinal cord to terminate in relation both to outflows for skeletal muscle and, in larger part, to outflows of the autonomic nervous system, innervating smooth muscle and exocrine glands throughout the body. By exciting parts of the autonomic system in varying combinations, or throwing the whole system into activity at once, this second outflow from the hypothalamus may likewise alter body states profoundly.

Innervation of the posterior pituitary

Variations in the osmotic tension of blood circulating through the hypothalamus cause its neurons to innervate the neurohypophysis (posterior pituitary) and to elaborate and to secrete that gland's hormones. One of these, antidiuretic in action, passes in the bloodstream to the kidney, where it facilitates the reabsorption of water from the kidney tubules. About 170 litres of water filter from man's blood every 24 hours and start down the kidney tubules toward the bladder. With the aid of a normal complement of an antidiuretic hormone from the neurohypophysis, about 169 litres of this water are reabsorbed into the bloodstream before leaving the kidney, and only the remaining litre, conveying waste materials in solution, continues to the bladder and thence voided as urine.

If the hypothalamus is injured, or if its path to the pituitary is interrupted, the neurohypophysis becomes paralyzed and atrophic, so that the secretion of its antidiuretic hormone fails. Reabsorption of body water from the kidney is then incomplete, and in record cases as many as 40 litres may be lost daily and passed as urine, so that, were not a compensating quantity of water drunk, the body would rapidly become dehydrated. This disturbing syndrome is called diabetes insipidus. Administration of an extracted antidiuretic hormone constitutes a specific therapy (see also ENDOCRINE SYSTEM, HUMAN; ENDOCRINE SYSTEM DISEASES AND DISORDERS; HORMONE).

Although the secretion of the anterior lobe of the pituitary appears to be somewhat more autonomous, appropriate injury to the anterior brainstem causes deficiency in production of gonadotropic hormones, with consequent atrophy of the sex glands, regression of secondary sexual characteristics, and loss of potency. Brainstem in-

juries causing deficiencies in the sexual sphere are often associated with the development of pronounced obesity, the combined disorder referred to clinically as adiposogenital dystrophy, or Fröhlich's syndrome. A contrasting disturbance, the precocious onset of puberty, which may result from involvement of the anterior brainstem, depends on either overactivity of the mechanism just considered or malfunction of the pineal gland, connected with the dorsal, rather than the ventral, aspect of the brainstem.

The anterior brainstem is also involved in the increased secretion of the adrenocorticotropic hormone (ACTH) from the anterior lobe of the pituitary in response to stress stimulation. Regulation of the adrenal cortex thus appears to be under the control of the brain. Stress stimuli have been found to cause increased discharge of the anterior brainstem, and direct stimulation of this structure has been shown to increase ACTH secretion. Conversely, after injury to the anterior brainstem, stress is no longer capable of leading to increased pituitary–adrenal activity.

Relationship of the anterior brainstem with the autonomic nervous system

By way of its connections with autonomic outflows, the anterior brainstem is similarly able to regulate or widely alter conditions in the interior of the body. Excitation of this neural part evokes a mass discharge of the sympathetic portion of the autonomic system, with rise in blood pressure, increase in heart rate, cessation of gastrointestinal peristalsis, erection of hair, sweating, and other changes brought about by emotional excitement known as the fight or flight reaction.

Many of the changes just mentioned are also those that are employed in preserving a relatively stable internal body temperature in the face of wide variations in environmental conditions. Heat, produced in the body by oxidative reactions, is conserved by peripheral vasoconstriction (and erection of the hair in fur-bearing animals), reducing the body's irradiation; when necessary, heat conservation is also augmented by shivering. It is dispelled by increased irradiation, consequent to peripheral vasodilation, and by the evaporation of an increased sweat secretion. These opposing processes (heat retention and heat release) are regulated by two antagonistic thermal mechanisms in the anterior part of the brainstem, influenced by alterations in the temperature of the blood circulating through the brainstem.

These neural systems by which the brainstem preserves a constant body temperature may sometimes undergo derangement. Circulating toxins or breakdown products, incident to infection, paralyze that neural mechanism dispelling body heat and periodically excite the other, initiating heat production and conservation. The affected individual then shivers and exhibits peripheral vasoconstriction, and, although he subjectively experiences a chill, his internal temperature rises to fever height. Elevated body temperature together with increase in the count of white blood cells, enemies of foreign agents in the body, thus constitute the two most reliable diagnostic signs of infections.

The lower brainstem is concerned with managing internal processes, even more vital in nature, that clear the blood of carbon dioxide, provide it with a fresh supply of oxygen, and circulate it through the body (see also RESPIRATION, HUMAN).

Neural control of respiration

The contraction of the thoracic and abdominal musculature, which expands the chest cavity, permitting air to flow into the lungs, is initiated by lower brainstem neurons, the efferent fibres of which descend to the spinal outflows of the inspiratory muscles. These brainstem neurons are constantly being excited by a multiplicity of factors associated with oxygen deficiency in the circulation. The rhythmicity of respiration is affected by the periodic prevention of inspiration, both by inhibitory afferent impulses initiated by lung stretch during inspiration and conveyed to the lower brainstem by cranial afferent nerves and by central inspiratory–inhibitory or expiratory connections. In respiration more forceful than that of ordinary quiet breathing, the active contraction of expiratory muscles is added to the relaxation of inspiratory muscles in expelling air.

Though the motor nerve supply to the respiratory muscles proceeds entirely from the cord, spinal neural levels are, by themselves, incapable of maintaining respiration. Participation of the brainstem mechanisms is essential for this activity.

The lower brainstem also contains regulating collections of neurons whose efferent fibres influence outflows (from both the brainstem and spinal cord) concerned with the rate of heartbeat and those (from the cord alone) that innervate smooth muscle in the walls of arterial blood vessels. Contraction of the latter maintains an optimum pressure in the circulatory system, enabling blood to be conveyed to all parts of the body.

Two receptor organs, informing the lower brainstem of both the pressure and the chemical composition of circulating blood (via cranial afferent nerves), play an important part in the regulation of cardiovascular activity. The first of these is strategically located in the arch of the aorta, where it can test the blood leaving the heart and starting on its way to all parts of the body. Because the body apparently is particularly concerned with maintaining an optimum circulation through the cerebral hemispheres of the brain, another, similar receptor is found in the wall of the internal carotid arteries, which supply blood to these structures. Injury to the brainstem cardiovascular mechanism or interruption of its connections to autonomic outflows is followed by vasomotor collapse and fall of blood pressure. Resultant circulatory disturbances, if unrelieved, are fatal.

Regulation of the central nervous system. The brainstem plays an important role in maintaining an optimum state of activity within the interior of the central nervous system. Injury to the rostral brainstem is followed by deterioration of function of the cerebral hemispheres; injury to more caudal parts of the stem results in impairment of activity within the spinal cord.

Results of injury to the anterior brainstem

The conscious perception of sensation, the voluntary control of motion, and other features that characterize the activity of the cerebral hemispheres in what is called the waking state are somehow dependent upon the functional integrity of the upper brainstem. Injury to this region is followed by states varying in intensity from somnolence to coma. In the most severe states, though the patient's respiration and circulation are preserved, and he may be nourished and kept free of infection for years, he has no more rapport with the external world than a vegetable. The electroencephalogram (EEG) has revealed pronounced differences in the spontaneous electrical activity of the cerebral cortex in wakefulness and sleep. In sleep the electrical record is composed largely of high, slow waves and is described as being synchronized. During wakefulness, in contrast, the EEG is made up of low-voltage, fast activity. Direct stimulation of the central core of the brainstem will reproduce the normal waking record.

Many side connections or collateral branches from ascending sensory paths have been shown to turn into the central core of the brainstem and to exert their arousing influences indirectly by modifying its activity. Structurally, the portion of the brainstem involved is reticular (like a network), and research has identified the existence of an ascending reticular activating system concerned with regulation of the background activity of the cerebral cortex.

Though the lower brainstem's influence upon the spinal cord is not as specific and is abetted by both the cerebral hemispheres and the cerebellum, it is important in preserving the normal function of this part of the nervous system. Transection of the cord from the brain, even at thoracic levels, leaving respiratory and vasomotor activity unimpaired, is followed, in the isolated cord segments, by a specifically neural depression called spinal shock. In this condition, spinal reflexes for a period can no longer be evoked by afferent stimulation and, even when recovered, may exhibit abnormality. Though other factors may be concerned, spinal shock depends in part upon loss of excitatory influences descending to the cord over pyramidal and extrapyramidal connections, to the latter of which the brainstem makes contributions.

In addition to exerting ascending influences upon the cerebral cortex, the central reticular formation of the brainstem has been shown to give rise to descending connections to motor outflows from the spinal cord. The more cephalic of these augment or facilitate spinal motor discharge, while the more caudal region exerts an inhibitory or reducing action. An imbalance in these extrapyramidal motor connections is thought to be responsible for spasticity, in which condition inhibitory influences are no longer active, while facilitatory ones are preserved and exert an augmented effect since they are no longer opposed. The involuntary movements of other types of extrapyramidal disease may also have their basis in malfunction of these descending connections from the brainstem.

Oxygen requirements of the brain

Nutrition of the brain. The oxygen requirement of the brain, even at rest, is high. The human brain comprises only about 2 percent of the total body weight, yet it uses approximately 25 percent of all the oxygen taken up by the body under conditions of complete mental and physical rest. The purpose underlying the oxygen consumption by the brain undoubtedly is the same as in any other living system, viz., to provide energy to be used in doing work. Yet, as Otto Warburg, a pioneer in studies of brain metabolism, pointed out in 1912, nerve cells do no work that is measurable in mechanical or chemical units, since they do not contract, move, divide, or grow. Nevertheless, the brain obviously needs oxygen, as indicated by (1) its extraordinarily high oxygen consumption; (2) its vulnerability to deprivation of oxygen; and (3) the fact that functional activity of the brain runs parallel to its oxygen consumption, exhibiting cerebral depression from such conditions as anesthesia, diabetic coma, insulin shock, and brain tumors.

The foodstuffs and oxygen necessary to meet the requirements of the brain can reach it only by way of the blood. An increase in the functional activity of any organ entails a simultaneous increase in the amount of blood that it receives. It is noteworthy, however, that the way in which this compensation is brought about differs markedly among organs. In the case of the skeletal muscles, for example, increased activity is associated with both an increase in the amount of blood expelled by the heart and a widening of the blood vessels supplying the exercising muscles, brought about largely via the brainstem. In the salivary glands, increased secretion of saliva is elicited by nerve impulses carried by special nerves, and these impulses also cause dilation of the blood vessels supplying the gland. In the brain, however, although nerves are known to be able to mediate either constriction or dilation of blood vessels, these effects are much weaker than those in other tissues, and nerve control appears to play no important part in the normal regulation of the cerebral circulation. It is likely that the blood vessels of the brain possess the unusual property of tending to constrict if left to themselves and that this tendency is constantly opposed by the dilating action of the products of cell metabolism either arising in the brain itself or carried to it in the blood from other tissues. Any increase or decrease in the oxygen consumption of the brain would then be associated with a corresponding change in the calibre of its blood vessels and, consequently, in the volume of blood flowing through them, because the amount of vessel-dilating material had changed. Increase or decrease in the concentration of material such as this in the blood reaching the brain would have similar effects on cerebral blood flow.

Mechanism of brain-blood-flow action

The evidence in favour of this conception is of two main types: (1) all the characteristic products of nerve metabolism tested (increased carbon dioxide, decreased oxygen, acids, potassium salts, acetylcholine, phosphates, heat) have been found to dilate cerebral blood vessels; and (2) increase in the carbon dioxide or decrease in the oxygen content of the blood reaching the brain (by inhalation of appropriate gas mixtures) causes dilation of cerebral blood vessels and increase in cerebral blood flow, while decrease in carbon dioxide (by overbreathing) or increase in oxygen has the opposite effect. It is probable that the ordinary adjustments of the cerebral circulation to the changing requirements of the brain do not necessitate corresponding changes in the general circulation. When the latter is depressed by such influences as hemorrhage, shock, or drugs, cerebral blood flow will follow this change, apparently quite passively. When the general circulation is stimulated (as by blood transfusions or drugs), cerebral blood flow will be increased. No constricting or dilating drugs have been shown to be able to produce a change in cerebral blood flow that is contrary to changes in the general blood pressure, and in this respect the cerebral circulation is unique. Even the coronary vessels in the heart, which resemble the cerebrals in being obedient to changes in general blood pressure and in lacking important control by vasoconstrictor or vasodilator nerves, can be strongly constricted by an extract of the posterior lobe of the pituitary gland, but administration of the extract has no direct effect on the cerebral circulation. Spasm of cerebral vessels has long been suspected to be the cause of certain conditions, such as convulsions, temporary depression or loss of consciousness, memory, or speech, and transitory disturbances of vision, but the cause of the spasm, or indeed the fact of its occurrence, has not been clearly demonstrated. The only factor shown to be capable of causing an important degree of constriction of cerebral vessels is hyperventilation, which can produce mental confusion, or even complete unconsciousness, in normal persons and can elicit a typical convulsion in persons with latent epilepsy. Diminution in cerebral blood flow produced by constriction of cerebral vessels may be partly the cause of these conditions.

Factors affecting cerebral blood pressure

The commonest and most important derangements of the cerebral circulation are produced by either a decrease in the arterial blood pressure or an impediment to flow in the cerebral vessels themselves. The former can be caused by an appropriate decrease in any of the three main factors concerned in the regulation of blood pressure, namely, efficiency of the heart, resistance of the blood vessels, and volume or viscosity of the circulating blood. The latter may be caused by obstruction of cerebral arteries by a clot carried by the blood (embolism) from another part of the body (usually the heart), by formation of a clot in a cerebral artery or vein (thrombosis), or by actual rupture, with hemorrhage into the brain substance. In all such cases the part of the brain supplied by the involved vessel or vessels loses its functions, and, from the consequent symptoms, it is usually possible to locate the lesion with considerable precision. The loss of function is a result of the fact that the distribution of the arteries in the brain does not overlap significantly. Therefore, there is no alternative source of supply of blood when one terminal artery is occluded, and the tissue supplied loses its function because it undergoes degeneration.

Another source of interference with the cerebral circulation lies in the peculiar location of the brain inside a rigid container, the skull. Because the container is practically indistensible, an increase in the volume of any of the cranial contents will lead to an increase in pressure involving all of them and will be reflected in an increase in pressure of the cerebrospinal fluid. This pressure operates on the blood vessels, as well as on other cranial contents, and, when it rises to a level higher than the pressure inside the vessels, the latter collapse and flow of blood through them ceases. A change of this type in the vessels supplying the vasomotor centre in the brainstem causes increased activity there and thus brings about a rise in blood pressure. When the rise is sufficient to overcome the abnormal pressure on the outside of the vessels, flow of blood through them is restored. Thus the arterial blood pressure characteristically rises in cases of high intracranial pressure whether the latter depends on an intracranial hemorrhage or a tumour, on interference with drainage of the cerebrospinal fluid, on swelling of the brain itself (as in uremia or eclampsia), or on inflammatory disease (encephalitis, meningitis). If this rise in blood pressure did not occur, all functions of the brain would cease as soon as the cerebrospinal pressure exceeded the normal pressure in the cerebral veins and capillar-

ies, and death would occur from respiratory failure and circulatory collapse.

Anatomical arrangements of cerebral circulation

The anatomical arrangements are among the unusual features of the cerebral circulation. Instead of depending on a single artery to supply most of the blood and a single vein to carry it back to the heart, the brain gets its blood from four major arteries and is drained by three separate sets of veins. Any two of the arteries and any one of the veins could meet the needs of the brain if time were given for adjustment, and even one artery is enough to supply the vital centres of the brainstem and thus prevent failure of circulation and respiration. The arteries (the two internal carotids and the two vertebrals) join at the base of the brain to form a circle (the circle of Willis) from which arterial branches are given off to course either through the brain substance or over its surface in the pia mater. The carotid arteries run in the neck and can be occluded by deep pressure, but the vertebrals arise in the chest and soon enter the vertebral column, where they are protected from pressure or injury short of disruption of the spine itself. The cerebral veins follow the arteries; they do not meet in a circle, however, but in a number of wide thin-walled sinuses from which blood leaves by way of the two large internal jugular veins, in a variable network of veins located at the base of the skull, and in large sinuses found inside the vertebral canal. Even if the entire venous return from the upper portion of the body is obstructed (as by thrombosis of the superior vena cava), there is no serious impediment to the drainage of the cerebral circulations.

Weight of the brain. The weight of the human brain varies with age, stature, body weight, sex, and race. It is also influenced by congestion of the blood vessels, degenerative changes, and atrophy. At birth the brain weighs approximately 380 grams (about 13 ounces) and is 12.4 percent of the body weight. The entire brain, with the pia-arachnoid, of an adult male weighs approximately 1,400 grams (about three pounds); that of a female, 1,260 grams (44.6 ounces). The average stature and body weight of the female, however, are less than those of the male, and, when these facts are considered, the size and weight of the brain in the two sexes are approximately equal. The influence of age on brain weight is considerable. The growth of the brain is rapid during the first three years but slightly less so up to the seventh year, when it is almost its full weight. After this the increase is very gradual, its prime weight usually attained in males by the 20th year and in females somewhat earlier. From this period onward, in both sexes, there is a continuous diminution in the average brain weight of approximately one gram per year.

Tall persons have heavier brains than short persons, but, relative to their height, short persons have larger heads and brains than tall persons. Many men of conspicuous ability have had brains of large size, but averages calculated from groups—*e.g.*, scholarship winners and persons of average and below average ability—show statistically that there is only a slight correlation between head size and intelligence.

THE SPINAL CORD

The spinal cord in man is the elongated cylindrical portion of the central nervous system located in the upper two-thirds of the vertebral canal of the vertebral column. Spinal nerves and many of the reflexes stemming from spinal connections are described in detail below in the major sections on the peripheral and autonomic nervous systems.

As with the brain, the spinal cord of man closely resembles that of other higher animals, particularly the primates. Additional detail may be found in the article NERVES AND NERVOUS SYSTEMS.

Anatomy. The spinal cord is about 45 centimetres (18 inches) long. It extends from just above the first cervical vertebra (atlas) at the base of the skull to the level of the first or second lumbar vertebra, where it is known as the conus medullaris. Small groups of nerve fibres attached to the spinal cord unite to form the segmental series of dorsal and ventral roots. One dorsal root and one ventral root combine in the region of an opening, the intervertebral foramen, between the two vertebrae to form one of the 31 pairs of spinal nerves. The dorsal roots contain the nerve fibres that transmit sensory impulses from the body to the spinal cord, whereas the ventral roots are composed of the motor fibres that transmit nerve impulses from the cord to the muscles and glands.

Dorsal and ventral roots

The spinal cord does not occupy the entire length of the vertebral canal because the vertebral column continues to grow after the cord has reached its full length. Since the column is longer than the cord, the nerve filaments of each dorsal root leave the cord above the site where the root enters each intervertebral foramen.

Each thoracic, lumbar, sacral, and coccygeal spinal nerve is named from the vertebra that is just above its exit from the vertebral column. Since there are 12 thoracic vertebrae, five lumbar vertebrae, five fused sacral vertebrae and one (to three) vestigial coccygeal vertebra, there are 12 thoracic, five lumbar, five sacral, and one coccygeal spinal nerves.

There are eight cervical nerves, although only seven cervical vertebrae, because, in addition to a nerve passing below each cervical vertebra, one exists above the first cervical vertebra. The long roots of the lower third of the vertebral canal below the conus medullaris form a structure called the cauda equina ("horse's tail").

Meninges. The cord is enveloped by three coverings, the meninges. From within outward, as with the brain, they are the pia mater, arachnoid, and dura mater. These meninges are continuous with comparable layers surrounding the brain. The pia mater is closely attached to the spinal cord and contains the many blood vessels that supply the cord. The pia mater continues as a strand in the middle of the cauda equina known as the filum terminale, which extends to the coccyx.

The arachnoid layer is connected to the pia mater by delicate strands. The region between the two layers is the subarachnoid space, which is filled with the cerebrospinal fluid. Formed mainly in the brain, the fluid cushions the spinal cord. In the region below the conus medullaris, the arachnoid forms a cul-de-sac—containing the cauda equina and cerebrospinal fluid—into which lumbar puncture needles may be inserted to withdraw cerebrospinal fluid for diagnostic examination and to inject spinal anesthetics. This procedure avoids damage to the spinal cord, and injury to the spinal roots is slight.

The outer dura mater is a tough fibrous tissue surrounding the cord and continuous with the sheaths of the spinal roots and spinal nerves. It extends caudally to the lower sacral region, where it is reduced to a strand, the filum durae matris spinalis, attached to the coccyx. A thin subdural space is located between the dura mater and the arachnoid. Between the dura mater and the vertebral column is the epidural space, which contains many blood vessels, especially veins, and fat. A hypodermic needle may be inserted into this space in the lower sacral region for the injection of certain anesthetics (caudal anesthesia).

Cervical and lumbosacral enlargements. The spinal cord has two enlargements: the cervical enlargement and the lumbosacral enlargement. These regions are large because these segments are involved in the innervation of the upper and lower extremities, respectively. The fifth through eighth cervical segments and the first thoracic segment comprise the cervical enlargement. The spinal nerves arising from the cervical enlargement form the brachial plexus.

Cross section. In cross section the spinal cord consists of an H-shaped gray matter surrounded by white matter. The gray matter is made up of cell bodies of nerve cells (the part of the cell containing the nucleus and other constituents) and nerve fibres that are oriented in the cross-sectional plane because the fibres enter and leave the gray matter from the white matter and spinal roots. The white matter consists of nerve fibres that are oriented parallel to the long axis of the spinal cord. These fibres ascend to and descend from the brain and other levels of the spinal cord. The whiteness is caused by the fatty sheath (myelin sheath) that surrounds many of the fibres.

The gray and the white matter of the cord

Some non-neural neuroglia cells are scattered throughout both the gray and the white matter. The arms of the H that extend dorsally (toward the back of the body) are called dorsal or sensory horns, while the ventrally (toward the front) directed arms are called ventral or motor horns. The crossbar of the H is the gray commissure and the intermediate gray. The gray matter is largest in the regions of the cervical and lumbosacral enlargements because of their relation to the innervation of the limbs. In the middle of the gray commissure is the small central canal, which is continuous with the ventricles of the brain. The gray matter has been subdivided by Rexed into nine lamina, counting from dorsal to ventral. The incoming sensory impulses end in lamina four, five, and six. In lamina six end the proprioceptive messages; in lamina five, the protopathic messages; and in lamina four, the epicritic messages. The white matter is subdivided into three columns: the dorsal column, between the dorsal horns; the ventral column, between the ventral horns; and the lateral columns, at the sides of the gray matter.

Anatomical and functional organization of the spinal cord. The functional anatomy of the spinal cord may be visualized by describing the orientation of the nerve cells of the spinal reflex arcs. The withdrawal of the hand upon touching a hot stove before it is felt is an example of a spinal reflex. The heat stimulates the terminal endings of the thermal neurons in the hand. The resulting impulses are transmitted by the fibres of these neurons through the peripheral nerves and dorsal roots into the dorsal horn. Each sensory nerve cell has its cell body in a dorsal-root ganglion. Thus each nerve cell is a unit structure extending from its peripheral ending in the hand to its termination in the gray matter of the spinal cord.

In the dorsal horn the nerve fibres have synapses (interconnections) with one or more other neurons. The second nerve cells in the arc are called interneurons (internuncial or intercalated neurons); each has a cell body in the gray matter. Some interneurons send axons into the ventral horn and form synapses with the motor cells whose cell bodies are in this horn. The axons of the motor cells reach the voluntary muscles via the ventral roots and peripheral nerves. In short, an exteroceptive stimulus transmitted by a nerve goes to the spinal cord via a dorsal root into the gray matter, then to an interneuron, and finally to the motor cell and the voluntary muscle via the ventral root and the peripheral nerve. This is known as a three-neuron reflex. If the interneuron is not involved, only two cells are in the series, and it is thus a two-neuron reflex.

In the knee-jerk reflex, the sensory cells synapse directly with the motor neurons in the gray matter; it is, therefore, a two-neuron reflex. The interneuron may cross over from the dorsal horn of one side to the ventral horn of the opposite side and synapse with motor cells. This is one means of coordinating one side with the other. An intersegmental reflex is a mechanism relaying impulses to higher and lower spinal cord levels to coordinate large areas of the body. The fibres of such interneurons leave the gray matter and go up, down, or both (fibres may divide into two or more branches) to other spinal levels in that part of the white matter called the fasciculus proprius and re-enter the gray matter to synapse with motor cells.

The white matter of the spinal cord contains nerve fibres that transmit most of the nerve impulses from the body (below the head) to the brain and from the brain to the body. Microscopic examination of the white matter does not give visible evidence of functional subdivisions. On the basis of numerous experimental data, however, and examinations of spinal cords from persons with spinal injuries, the white matter can be partitioned into functional regions called tracts or pathways. A tract, or fasciculus, is a collection of nerve fibres having the same origin, function, and termination. Those fibres transmitting impulses toward the brain form sensory, or ascending, tracts; those transmitting impulses from the brain form motor, or descending, tracts.

Pathways of sensation. So-called epicritic sensations are transmitted by the fibres in the dorsal columns. They include position sense, pressure sense, vibratory sense, sense of movement, and stereognosis. Position sense is the quality that enables a person to know where the parts of his body are in space when his eyes are closed; pressure sense is the quality of sensation that results from a deformation of the skin and may, thus, be called deep touch; vibratory sense is experienced when the stem of a vibrating tuning fork is placed in contact with a bone; and stereognosis, or two-point discrimination, is the faculty of perceiving the weight, form, and shape of objects and of distinguishing the distance between two touch stimuli. Epicritic senations

These senses are transmitted by fibres that pass from the peripheral nerves and dorsal roots into the dorsal horn of the spinal cord. These fibres with their cell bodies in the dorsal-root ganglia have several branches in the gray matter. The shorter branches (collateral fibres) are utilized in the spinal reflex arcs. The main axon continues into the dorsal column to ascend to the lower medulla of the brain. Two interesting features are that (1) a fibre in the dorsal column is a part of the same neuron that was stimulated in the body, and (2) this fibre ascends on the same side of the spinal cord as it enters; *i.e.*, it does not cross the midline of the cord.

As a consequence, the sense of position of the toes, for example, is carried by nerve cells that extend from the toes to the medulla oblongata without a synapse. In addition, injury to the dorsal column on one side of the cord will result in the impairment of the proprioceptive senses on the same side of the body below the level of injury. Each half of the dorsal column is divided into a fasciculus gracilis and a fasciculus cuneatus. The epicritic impulses from the lower half of the body, including the lower extremities, are carried in the fasciculus gracilis, while those from the upper half of the body, including the upper extremities (but excluding the head) are carried in the fasciculus cuneatus.

Some light-touch sensations (*e.g.*, gentle brushing of skin by cotton) are transmitted by fibres in the dorsal column. In the medulla the fibres of each half of the dorsal column synapse with neurons in the nucleus gracilis and nucleus cuneatus. The neurons of these nuclei cross over to the opposite side of the medulla, pass upward as the medial lemniscus, and terminate in the thalamus, from which they relay to the cerebral cortex.

Pain and temperature sensations are transmitted by another pathway (see also SENSORY RECEPTION, HUMAN). The fibres from the periphery, in common with other sensory fibres, enter the dorsal horn of the spinal cord, where their terminal branches establish reflex connections with other neurons. At the spinal level, at which the fibres enter the cord, they synapse with dorsal-horn neurons. Some of these cells are interneurons in the reflex arcs. Other neurons of the dorsal horn have axons that cross the midline to the opposite side through the ventral white commissure (ventral to the gray commissure) to join the lateral spinothalamic tract in the lateral columns. This tract contains more fibres as it ascends in the spinal cord, the new fibres being added from each spinal level. The spinothalamic tract's name is based on the fact that the fibres of the pathway originate in the dorsal horn of the spinal cord and terminate in the thalamus on the opposite side of the brain. Crude pain and awareness of touch may be brought to consciousness in the thalamus. Impulses from the thalamus are relayed to the cerebral cortex. Pain and temperature sensations

In addition to the light-touch fibres of the dorsal column noted above, some light-touch impulses take a different pathway. After entering the dorsal horn, the axons transmitting light touch synapse with neurons whose axons cross the midline to join the ventral spinothalamic tract in the ventral column.

The symptoms resulting from injury to the spinal cord are a consequence of the course of these pathways. If the right half of the spinal cord is cut at a midthoracic level, for example, conscious proprioception would be lost on the right side of the body below the level of the lesion of the fasciculus gracilis (right abdomen and the right

lower extremity). Pain and temperature sensations would be lost on the left side of the body below the level of the lesion of the lateral spinothalamic tract. Because of the dual course of their fibres, light touch would be diminished, but not necessarily lost, below the level of the lesion. Perception of sensations from regions above the cut would be unimpaired.

Some unconscious proprioceptive impulses relay from the gray matter of the cord via the spinocerebellar tracts of the same and opposite sides and terminate in the cerebellum.

The precise course of the pathways for sensations from the viscera (heart, intestinal tract, kidney, and so forth) through the white matter of the cord is not known.

Motor pathways. In the ventral horn of the gray matter are large motor cells whose axons pass through the ventral roots to the spinal nerves. These neurons, which innervate the voluntary muscles, are called lower motor neurons; if they become nonfunctional, as in poliomyelitis, the muscles are deprived of their nervous stimulation and do not contract. These muscles waste away (atrophy) and do not respond to stimulation (areflexia). This paralytic condition is known as a lower motor neuron paralysis.

Lower motor neurons

The lower motor neuron cells are stimulated and influenced by neurons of the spinal reflex arcs and by the descending motor tracts of the white matter. These descending tracts from the brain may synapse directly with the motor cells, but usually interneurons of the gray matter are interposed between the descending tracts and the lower motor neurons.

Collectively the descending motor tracts from the brain are known as upper motor neurons. Their cell bodies are in the brain and their axons pass through the brainstem and white matter of the spinal cord before terminating in the gray matter of the spinal cord. Two major subdivisions of these motor tracts are recognized: the pyramidal tracts, which are phylogenetically recent, and the phylogenetically old extrapyramidal tracts.

The lateral pyramidal tract, or lateral corticospinal tract, arises in the cerebral cortex of the opposite side and crosses over just as its fibres enter the spinal cord. The direct pyramidal tract, or ventral corticospinal tract, originates in the cerebral cortex and crosses over in the spinal cord. The extrapyramidal tracts include the motor tracts that arise in regions of the brain other than the cerebral cortex. These tracts do, however, receive neural influences from the cerebral cortex as well as from other parts of the brain.

The extrapyramidal tracts include (1) the vestibulospinal tract, which transmits impulses from the vestibular (balance) mechanisms of the inner ear; (2) the reticulospinal tracts, which arise from the medulla and pons; (3) the medial longitudinal fasciculus, a collection of fibres from several regions of the brainstem; and (4) the rubrospinal tract from the red nucleus in the midbrain.

Spastic paralysis

When a number of these motor tracts are damaged, an upper neuron paralysis may result. This contrasts with the lower motor neuron paralysis previously mentioned. Here the reflexes are exaggerated; there is loss of voluntary motion; and the extremities become spastic. The condition, called spastic paralysis, results because the muscles are under control of a spinal cord that still mediates spinal reflex arcs but is deprived of its normal innervation from the brain. Spastic paralysis resulting from an injury of the spinal cord is observed on the same side of the body as the lesion.

The complexity of the nervous system may be illustrated by spinal reflex arcs innervating the voluntary muscles. In probably all muscles (since all muscles have not been investigated) there are small fibres arranged in bundles of two to eight fibres that receive their motor innervation from small neurons in the anterior horn and that are endowed with sensory fibres. These fibres go through the spinal ganglia, where their cell bodies are situated, to the posterior horn (lamina six), where they make direct contact with the motor cells in the anterior horn. These motor cells stimulate the voluntary muscles to contract. When the voluntary muscles contract sufficiently, the sensory endings in the tendons are stimulated to send impulses via sensory fibres through the dorsal root back to the spinal cord to inhibit the motor cells of the ventral horn. In brief, the sensory endings in the muscle and tendon have a critical role in muscle activity.

Autonomic nervous system. The autonomic nervous system will be considered in detail in a later section. Briefly, it is concerned with the motor innervation of glands, blood vessels, and the viscera, and it has neurons in the gray matter. The nerve cells of the sympathetic division of this system have their cell bodies in the lateral part of the intermediate gray, known as the intermediolateral cell column, of the thoracic and upper lumbar levels. Their axons leave the spinal cord through the ventral roots. The nerve cells of the spinal part of the parasympathetic division of this system have their cell bodies scattered in the gray matter of the midsacral levels. Their axons leave the spinal cord through the ventral roots. The sympathetic nervous system assists the body in meeting emergencies and stress. This includes increasing the rate and force of the heartbeat, the dilation of the bronchial tubes of the lungs, and the inhibition of the motility and the secretory activity of the digestive system. The parasympathetic system contributes to the conservation of bodily energy. This includes decreasing the rate and force of the heartbeat, the constriction of the bronchial tubes, and the stimulation of the motility and secretory activity of the digestive system.

Intermediolateral cell column

Physiology. *The reflex.* The simplest complete reaction of the nervous system is a reflex. There are many reflexes that are extremely complex, being built up of a number of simpler reflexes combined. A reflex is a reaction started by the environment acting as a stimulus upon some nerve that communicates the excitement to other nerves by connections with them in the central nervous system. The excitement so generated and transmitted finally travels outward from the central nervous system by one or more of the efferent nerves and through these reaches muscles or galnds, producing in them its final effect. The muscles and glands are from this point of view termed effector organs. The reaction is therefore "reflected" from the central nervous system. The nerve structures that include its trajectory are spoken of as a nervous arc.

The whole purpose of the central nervous system is to bring afferent neurons into touch with efferent neurons. The whole purpose of reflex arcs is to bind one part of the organism to another part in such a way that what the environment is doing to the organism at one place may appropriately call forth or restrain movement or secretion in the muscles or glands wherever situated in the organism.

Receptor cells. There is one condition for the performance of these reactions that is not provided by the nervous system itself. The afferent neurons are not in most cases so constituted as to be excitable themselves directly by the environment—they cannot, for example, be stimulated by light. Their amenability to the environment, their sensitization to environmental stimuli, is effected by special cells adjunct to their peripheral ends. These cells form organs called receptors. They are delicately adapted to be stimulated by specific agents and are classifiable into various species, so that each species is easily excited by a particular stimulus that is "adequate" for it and is inexcitable or excitable only with difficulty by stimuli of other kinds. Thus in the skin some receptors are adapted for mechanical stimuli (touch) and not for thermal stimuli, while others (cold spots, warm spots) are adapted for thermal stimuli and not for mechanical. As far as it is known, each afferent neuron is connected with receptors of one species only. The receptors thus confer upon the reflex arcs selective excitability. Each arc is tuned to respond to certain stimuli, while other arcs not having that kind of receptor do not respond. The receptors, therefore, while increasing the responsiveness of the organism to the environment, prevent confusion of reactions (incoordination) by limiting to particular stimuli a particular reaction.

Receptors

Proprioceptors. By the conditions just described, the

body's system of neurons is made accessible to the external environment; in addition to those receptors, there are others lying within the mass of the organism itself that are excitable by actions occurring within the organism. These are called proprioceptors. They are distributed principally in the muscles and in structures functionally adjunct to muscle, such as joints, ligaments, and fasciae. The reactions, both passive and active, induced in such motor structures reflexly by environmental stimuli tend, therefore, secondarily to be followed and accompanied by reflex reactions initiated from proprioceptors.

Conduction. The process by which the excitement generated in the afferent neuron travels along the reflex arc is known as conduction. Conduction along afferent and efferent nerves differs in some important respects from that in the nerve centre—*i.e.*, in the piece of the central nervous system connecting the afferent nerve with the efferent nerve. In a nerve trunk the excited state set up by a stimulus travels along its fibres as a wavelike disturbance, called an impulse, at a speed up to 0.5 and 100 metres (1.5–330 feet) per second. An impulse does not alter in intensity or speed as it travels. A nerve trunk when excited at some point along its length transmits the impulse in both directions (*i.e.*, both up and down each fibre) from the point stimulated. This is true whether the fibre is afferent or efferent. The speed of travel of the nervous impulse along the nerve trunk is the same whether the nervous impulse is weak or intense. The nerve trunk shows practically no delay in its response to an effective, even though weak, stimulus, and its response ceases practically at once on cessation of the exciting stimulus. When excited by repeated brief stimuli, the rhythm of the response corresponds closely with that of the stimuli, even when the frequency of the latter is as high as 500 per second. Finally, nerve-trunk conduction is singularly resistant to fatigue, to impoverished blood supply, and to many drugs that powerfully affect reflex actions.

Through the central nervous system the travel of the impulse differs from these features. Its intensity is likely to be altered in transit. Its transit time is much longer than that for a similar length of nerve trunk. Its direction of transmission becomes polarized—*i.e.*, confined to one direction along the nervous path. To a strong stimulus the central reaction, instead of being as brief as an impulse, may endure for a whole second or more. A stimulus not capable of evoking a response from a centre when applied once may, by simple repetition, become effective—a process known as temporal summation.

Conduction in the gray matter differs in these respects from conduction in nerve trunks. In the gray matter each afferent fibre breaks up into branching threadlets that ramify in various directions and terminate in close apposition with other neurons. The point of junction of one neuron with another is called the synapse. The distance between two neurons at the synapse is about 200 Å (angstrom units; 1 Å = 1/10,000,000 millimetre, or about 1/250,000,000 inch). The absence of cytoplasmic continuity between the neurons is the anatomical basis that accounts for the slight delay in the speed of the impulse at the synapse and for the polarization of the direction of the impulse.

Reflex reactions. When the spinal cord is severed at any point, the reflex arcs of the portion of the body below the transection are cut off from the rest of the nervous system above, including the brain. The reflex reactions elicited from the isolated region cannot, therefore, be modified by the action of the higher nervous centres. In the head the local centres are overlaid by higher centres that cannot by any simple severance be separated from them. By studying the powers of the cord behind a complete spinal transection, information has been obtained as to the powers of the purely local, or segmental, reflex mechanisms.

The flexion reflex

The so-called flexion reflex of the limb is one of the most accessible of the local reflex reactions that can be studied by means of an isolated portion of the spinal cord. If the isolated portion serves the leg, the following phenomena are noted. The three main joints of the leg are the hip, the knee, and the ankle. Each of these joints is provided with muscles that flex (bend) it and with others that extend (straighten) it. It is found that reflex mechanisms throw into contraction the flexor muscles of each of these joints. It matters little which of all the various afferent nerves of the limb is stimulated; whichever afferent nerve may be involved, the discharge goes to practically the same muscles, namely, always to the flexors of the joints.

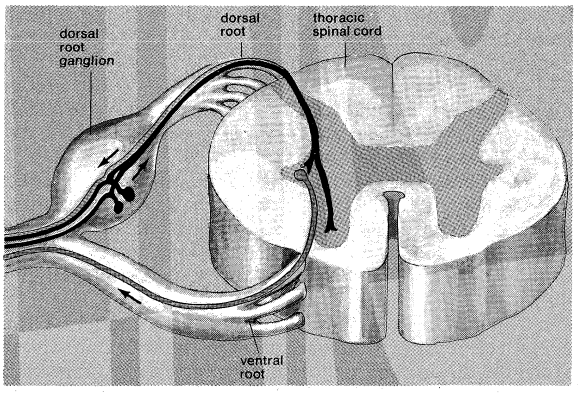

Figure 8: The spinal reflex.

Not only does the reflex action not discharge motor impulses into the nerves of the extensor muscles, but, if the spinal cord happens to be discharging impulses into these nerves when the reflex is evoked, this discharge is suppressed or diminished (inhibited). In this way the latter muscles are prevented from impeding the action of the contracting flexors. This inhibition prevents other reflexes from upsetting, for the time being, the due action of the flexion reflex, for it renders the muscles opposing that reflex less accessible to motor discharge through the spinal cord, whatever the source of that discharge.

A feature of this reflex is its graded intensity. A weak stimulus evokes in the flexor muscles a weak contraction and in the extensor muscles a slight relaxation. In the case of the muscle fibre, any strength of stimulus, if sufficient to excite it at all, totally excites the fibre and evokes its full contraction; and the contraction remains the same, quantitatively, as long as the mechanical and nutritive conditions of the fibre remain constant. With each muscle fibre reacting on this all-or-none principle, and each nerve fibre similarly responding, different amounts of contraction yielded by the muscle in response to different strengths of stimulation to its nerve signify differences in the number of muscle fibres the stimulus excites. In other words, the weaker stimuli excite fewer of the nerve fibres innervating the muscle.

When the tension developed by the muscle reaches the maximum obtainable from it, that fact indicates that all the muscle fibres are then in contraction; when the tension development is less than maximal, some of the muscle fibres are not in action. A stimulus to the nerve that evokes maximal tension from the muscle is one that succeeds in exciting all the nerve fibres innervating the muscle, and any stimulus that evokes less than maximal tension is having some of the nerve fibres idle.

The tension developed by a muscle under reflex excitation falls short of its maximal tension, even when the afferent nerve is stimulated maximally. The reflex activates only a proportion of the total aggregate of the muscle's fibres and, therefore, only a proportion of the spinal motor neurons innervating the muscle. But, within the range of the limit imposed by the maximal number of muscle fibres that it can activate, the grading of the number activated in accordance with the grading of the strength of stimulation of the afferent nerve is delicate, much more so than in the case of the motor nerve itself. The actual fractional proportion of the muscle's total aggregate of motor units that an afferent nerve, maximally stimulated, can activate differs from one afferent nerve to another and for the same afferent nerve under different conditions. The threshold value of stimulus for the reflex

is usually higher than for the contraction of the muscle from the motor nerve.

Spinal reflex action no more regards "muscles" than does a motor centre of the cerebral cortex. Both ignore muscles as entities and have in view only movements. A weak flexion reflex activates a few fibres of each of the several flexor muscles of the limb. The reflex treats a complex composed from some (*i.e.*, those of similar threshold for the particular afferent nerve) motor units of hip flexor, of knee flexor, and of ankle flexor as being functionally more homogeneous than the total group of fibres composing any one of these involved muscles alone.

Reflex inhibition

Reflex inhibition has its seat in the gray matter of the spinal centre. It acts at some point in the reflex arc above from the all-or-none motor unit (motor nerve fibre with its group of muscle fibres). The inhibitory reflex is, like the excitatory, capable of delicate grading; its effect in diminishing or precluding a specific amount of an excitatory reflex is effected entirely by regulating the number of the motor units thrown out of action or kept out of action. Intensity of contraction or of relaxation is thus in both cases simply a question of number of motor units reacting. The reflex centre continues discharging impulses for a certain time after its exciting stimulus has ceased. This after-discharge succeeding a strong stimulus may persist even for several seconds.

Refractory phase. Besides characteristics common to all or many spinal reflexes, certain spinal reflexes have features peculiar to themselves or exhibited by them in degrees not obvious in other reflexes. One of these features is a refractory phase, exemplified by the scratch reflex. In the dog, cat, and many other animals, the hindlimb often performs a rapid scratching movement, the foot being applied to the skin of the shoulder or neck as if to groom the hairy coat in that region. This movement is, in the intact animal, under control of the brain and can be executed or stopped at will. When certain of the higher centres in the brain have been destroyed, this scratching action occurs very readily and in an uncontrolled way. When the spinal cord has been severed in the neck, this scratching movement of the hindlimb can be elicited with regularity as a spinal reflex by merely rubbing, or applying a weak electric current to, the skin of the side of the neck or shoulder.

Mechanism of the scratch reflex

In this reflex the stimulus excites afferent nerves connected with the hairs in the skin, and these convey impulses to the spinal centres in the neck or shoulder segments; these in turn discharge impulses into nerve fibres entirely intraspinal, passing backward along the cord to reach motor centres in the hindlimb region. These motor centres in turn discharge impulses into the muscles of the hindlimb of the same side of the body as the shoulder that is the seat of irritation. The motor discharge is peculiar in that it causes the muscles of the hindlimb to contract rhythmically at a rate of about four contractions per second, and the discharge is peculiar further in that it excites the flexor and extensor muscles of the joints alternately, so that at the hip, for instance, the limb is alternately flexed and extended, each single phase of the movement lasting about an eighth of a second.

This rhythmic discharge remains the same in rate whether the exciting stimulus applied to the skin is continuous or one of many various rates of repetition. Evidently at some point in the reflex arc there is a mechanism that, after reacting to the impulses reaching it, remains for a certain brief part of a second unresponsive, and then becomes once more for a brief period responsive, and so on. This phasic alternation of excitability and inexcitability repeats itself throughout the continuance of the reflex. The phase of inexcitability is called the refractory phase. Its seat lies in the spinal centre. A similar element probably forms part of the coordinating mechanism for many other cyclic reflexes, including those of the stepping of the limbs, the movement of the jaw in mastication, the action of the eyelids in blinking, and perhaps the respiratory movements of the chest and larynx.

Fatigue. Nerve trunks do not tire easily under even the most prolonged stimulation. Reflex actions, on the other hand, tire relatively soon, some being more resistant to fatigue than others. The flexion reflex may be continued for ten minutes at a time. As a reflex tires, the muscular contraction that it causes tends to become less intense and less steady. The relatively rapid onset of fatigue in reflexes is counterbalanced by speedy recovery in repose. A fatigued long-flexion reflex, although weak, tremulous, and irregular, after 30 seconds' rest will recommence with almost the same vigour and steadiness that it had previously.

Reflex postures. Reflex postures are specific reflexes that persist for long periods at a time. The hindlimbs of a spinal frog (one in which the spinal cord has been surgically isolated from the brain) assume an attitude that is reflex, for it ceases on severance of the afferent spinal roots. This attitude is one of flexion at hip, knee, and ankle, resembling the well-known natural posture of the frog as it squats when quiet. Similarly, in the decerebrate mammal certain muscles (*e.g.*, the limb extensors) exhibit a persistent contraction. These tonic reflexes are related to attitudes. In the dog and cat they are exhibited by those muscles whose action antagonizes gravity in postures that are usual in the animal; thus the extensors of the knee and hip and shoulder and elbow are in tonic contraction during standing. The postural contraction is accompanied by electrical "action currents" like those of other contractions, though weak and indicative of self-smothering from the asynchronous rhythms in the contributory fibre groups. The postural contraction of the extensor muscles in the maintenance of the erect posture is traceable to a reflex, called the stretch reflex. A stretch (*e.g.*, by a pull upon the tendon) lengthening the muscle by even so little as 0.5 percent excites reflex contraction of some of its fibres. The passive stretch is a mechanical stimulus to some of the proprioceptive organs (perhaps the muscle spindles) in the muscle. The reflex is therefore unobtainable when the afferent nerve fibres of the muscle itself have been severed. The essential centre for the stretch reflex is spinal, but midbrain and cerebellar centres greatly reinforce it. If the "antigravity" muscles are not checked from yielding by the stretch reflex—which their own passive yield induces in themselves—the head, neck, tail, and jaw droop, and the limbs fold up under their own weight and that of superincumbent parts. Hence the reflexly maintained standing posture is a multiple stretch reflex. Considerable latitude of actual pose is allowed to the individual parts because each muscle involved acts for itself and develops and regulates its own stretch reflex.

The stretch reflex

Characteristic of reflex postural contraction is its continuance for long spells at a time without obvious fatigue. Attempts to reproduce this feature by electrical stimulation of afferent nerves or of the muscle's motor nerve are uniformly unsuccessful. Thus, the suggestion has been made that the postural contraction of muscle is brought about by a process in the muscle fibre different from that of the ordinary contraction so easily studied under electrical stimulation in the laboratory. The explanation has been offered that the postural contraction, although the same process as that of ordinary reflex and other contraction, usually involves relatively few motors units at a time and these, as they fatigue, are replaced by others. The stretch, which is the essential stimulus, is automatically shifted to fresh motor units as soon as those already in operation begin to fatigue.

The eyeballs are organs that employ active postures (the gaze being a posture) throughout the waking day. The proprioception of the neck muscles excites from the cervical spinal cord reflex influences acting on the nerves of the eyeball muscles. For example, turning the neck toward one side excites turning of the eyeballs toward the opposite side. Or again, a clockwise partial rotation of the neck round its long axis excites from the neck proprioceptor a compensatory counterclockwise shifting of the eyeballs. These reflex postures of the eyeballs are sometimes called compensatory because they tend to keep the gaze level despite displacements of the head by the movements of the neck.

When the cord or the medulla and cord of a mammal are surgically isolated from the brain, the animal's com-

posite stretch reflex enables it when placed in the erect posture to maintain that attitude, even for hours at a time; but it is incapable of assuming that posture when laid, for instance, on its side. But, when the midbrain is retained in addition to hindbrain and cord, the animal has that power of righting itself. These righting reflexes are likewise postural and largely evoked by the otolith organs in the vestibular portion of the ear. Although not truly spinal reflexes, their field of nervous operations overruns into the spinal cord.

Interaction between reflexes. At the start of every reflex arc is a receptive neuron extending from the receptive surface to the central nervous system. This neuron forms the only avenue that can be used by impulses generated at its receptive point, regardless of their destination. The neuron is, therefore, a path exclusive to the impulses generated at its own receptive point; receptive points other than its own cannot employ it. A single receptive point may play reflexly upon a considerable number of different effector organs. It may be connected through its reflex path with muscles and glands in many different regions. Nevertheless, all its reflex arcs arise from the one single shank or stem—*i.e.*, from the one afferent neuron that conducts from the receptive point at the periphery into the central nervous system.

Reflex arcs as receptive neurons

But at the termination of every reflex arc is a final neuron, the ultimate conductive link to an effector organ (muscle or gland). This last link in the chain (*e.g.*, the motor neuron) differs, obviously, in one important respect from the first link of the chain. It does not subserve exclusively impulses generated at one single receptive source but receives impulses from many such sources situated in various regions of the body. It is the only path that all impulses, no matter what their source, must travel if they are to act on the muscle fibres to which that path leads.

Therefore, while the receptive neuron forms a private route exclusively serving impulses of one source only, the final or efferent neuron is, so to say, a public path common to impulses arising at any of many sources of reception. A receptive field (*e.g.*, an area of skin) is analyzable into receptive points. One and the same effector organ is in reflex connection not only with many individual points but even with many various receptive fields. Reflexes generated in manifold sense organs can pour their influence into one muscle. Thus a limb muscle is the end point of many reflex arcs arising in various parts of the body. Its motor nerve is a path common to all the reflex arcs that reach that muscle.

Reflexes arcs show, therefore, that the initial neuron of each is a private path belonging exclusively to a single receptive point (or small group of points), that finally the arcs discharge into a path leading to an effector organ, and that their final path is common to all receptive points wherever they may lie in the body, so long as they have connection with the effector organ in question. Before finally converging upon the motor neuron, the arcs converge to some extent. Their private paths join interneuronal paths common in various degrees to groups of private paths. The terminal path may, to distinguish it from interneuronal common paths, be called the final common path. The motor nerve to a muscle is a collection of final common paths.

The final common path

There are certain consequences from this arrangement. One of these is the preclusion of essential qualitative difference between nerve impulses arising in different afferent nerves. If two conductors have a tract in common, there can hardly be essential qualitative difference between their modes of conduction.

A second consequence is that, each receptor being dependent for final communication with its effector organ upon a path not exclusively its own but common to it with certain other receptors, such junction necessitates successive and not simultaneous use of the common path by various receptors using it to different or opposed effect.

In the simultaneous correlation of reflexes, some reflexes combine harmoniously, being reactions that mutually reinforce. These are called allied reflexes, and the neutral arcs that they employ are allied arcs. On the other hand, some reflexes, as mentioned above, are antagonistic one to another and are incompatible. These do not mutually reinforce; instead, one of them inhibits the other.

Allied reflexes. When trains of impulses, travelling by convergent afferent arcs, meet at the same common path (as frequently happens), certain phenomena occur. For example, an afferent path, *A*, discharges into the intraspinal motor neurons of the knee flexor and can activate 75 percent of them. An afferent path, *B*, also discharges into the motor neurons of the same muscle and can activate 75 percent of them. If the muscle is reflexly contracting to *A* with a tension 75 percent of that of the muscle's maximal contraction, and stimulation of *B* is added, the contraction tension will rise to 85 percent of the maximal. The inference is that, for 65 percent of the total motor units of the muscle, the excitation from *A* acts upon the same motor units as would that from *B*. In other words, 65 percent of the total aggregate of the motor units of the muscle are common to *A* and to *B*. The stream of impulses arriving at these common motor units from *B* when *A*'s stream is already activating them leaves their activity unchanged, failing either to increase or to diminish it. *A*'s stream, which is engaging them, precludes *B*'s stream from engaging them. This is called occlusion.

Occlusion

The final common path under the competition of allied arcs is comparable with a telephone line already busy for one subscriber and for that time engaged and unavailable to others. The action of the principle of the final common path may be instanced in regard to allied arcs in the scratch reflex as follows. If, while the scratch reflex is being elicited from a skin point at the shoulder, a second point one centimetre (0.4 inch) from the first point, but also in the receptive field of skin, is stimulated, the stimulation at this second point favours the reaction from the first point. This is clear when the stimulus at each point is of subminimal intensity. The two stimuli, each unable separately to invoke the reflex, do so when both are applied at the same time. The receptive field of a reflex is really the common area of commencement of a number of allied arcs.

Antagonistic reflexes. Not all reflexes connected to one and the same common final path supplement one another. If, for instance, during the scratch reflex, a stimulus is applied to the foot not of the scratching side but of the opposite side, then the left leg, which is executing the scratch reflex in response to stimulation of the left shoulder skin, is cut short in its movement by the stimulation of the right foot, although the stimulus at the shoulder to provoke the scratch movement is maintained unaltered all the time. The stimulus to the right foot will temporarily interrupt a scratch reflex or will cut it short or will delay its onset, depending on the time relations of the stimuli. The inhibition of the scratch reflex occurs sometimes when the contraction of the muscles innervated by the reflex conflicting with it is very slight. There is interference between the two reflexes, and the one is inhibited by the other.

The reflex from the right foot straightens (extends) the opposite leg at the knee; in doing this it causes steady excitation of extensor neurons of that knee and steadily inhibits the flexor neurons. But the scratch reflex causes rhythmic excitation of the flexor neurons. In this conflict the flexor neurons, as a final common path, therefore lie under the influence of two antagonistic reflexes, one of which would excite them to rhythmical discharge four times a second, while the other would continually repress all discharge in them.

In all these forms of interference there is a competition, as it were, between the excitatory stimulus used for the one reflex and the excitatory stimulus for the other. Both stimuli are in progress together, and the one in taking effect precludes the other's taking effect as far as the final common path is concerned.

Competition between stimuli

Again, if, while stimulation of the skin of the shoulder is evoking the scratch reflex, the skin of the hindfoot of the same side is stimulated, the scratching may be arrested. Stimulation of the skin of the hindfoot in a way that has the character of threatening the part with damage (nociceptive stimulus) causes the leg to be flexed, drawing the

foot up by steady maintained contraction of the flexors of the ankle, knee, and hip. Here, therefore, is an arc that discharges into a final path, common to it and to the scratch reflex arc; both these arcs employ the same effector organ, namely, the knee flexor, and employ it by the common medium of the final pathway. But, though the channels for both reflexes discharge into the same final common path, the excitatory flexor effect, specific to each, differs strikingly in the two cases. In the scratch reflex, the flexor effect is an intermittent effect; in the nociceptive flexion reflex, the flexor effect is steady and maintained. The scratch reflex is set aside by that of the nociceptive arc from the homonymous foot. (The term homonymous is used here and below to indicate a common locus or other intimate experimental relationship.)

The stimulation that previously sufficed to provoke the scratch reflex is no longer effective, though it is continued all the time. But, when the stimulation of the foot is discontinued, the scratch reflex returns. In that respect, although there is no enforced inactivity, there is an interference tantamount to, if not the same thing as, inhibition. Though there is no cessation of activity in the motor neuron, one form of activity being impressed upon it is cut short, and another takes its place. A stimulation of the foot, too weak to cause more than a minimal reflex, often will suffice completely to interrupt, cut short, or prevent onset of the scratch reflex.

The whole point of the interference between the homonymous flexion reflex and the scratch reflex is that both employ the same final common pathway to different effect—just as in the interference between the crossed extension reflex and the scratch reflex. The motor neuron to the flexor of the knee being taken as a representative of the final common path, the homonymous flexion reflex inhibits it from discharging. Hence if, while the direct flexion reflex is in progress, the crossed foot is stimulated, the reflex of the knee flexor is inhibited. The crossed extension reflex, therefore, inhibits not only the scratch reflex but also the homonymous flexion reflex.

Further, in all these interferences between reflexes, the direction taken by the inhibition is reversible. Thus the scratch reflex is not only likely to be inhibited by, but is itself able to inhibit, either the homonymous flexion reflex or the crossed extension reflex; likewise, the homonymous flexion reflex is not only capable of being inhibited by the crossed extension reflex but conversely in its turn can inhibit the crossed extension reflex. These interferences are therefore reversible in direction. Certain conditions determine which reflex among two or more competing shall obtain mastery over the final common path and thus obtain expression.

Reversibility of interferences

The intimate nature of the mechanism that thus, by summation or by interference, gives coordination where neurons converge upon a common path is unknown. In the central nervous system of vertebrates, afferent neurons *A* and *B* in their convergence toward and impingement upon another neuron, *Z*, toward which they conduct, do not make any lateral connection directly with one another—at least, there is no clear evidence that they do. It seems, then, that the only structural link between *A* and *B* is neuron *Z* itself. *Z* itself should, therefore, be the field of coalition of *A* and *B* if they transmit allied reflexes.

Factors determining the sequence. The formation of a common path from tributary converging afferent arcs is important; the dominant action of one afferent arc or of a set of allied arcs is subject to supersession by another (afferent arc or set of allied arcs), and the supersession normally occurs without intercurrent confusion.

Whatever may be the nature of the physiological process occurring between the competing reflexes for dominance over the common path, the issue of their competition, namely, the determination of which one of the competing arcs shall, for the time being, reign over the common path, is largely conditioned by four factors: spinal induction, relative fatigue, relative intensity of stimulus, and the functional species of the reflex.

1. *Spinal induction.* This refers to the ability of one spinal reflex to lower the threshold of another. Induction occurs in two forms: immediate and successive. In immediate induction the stimulus that excites a reflex tends by central spread to facilitate and lower the threshold for reflexes allied to that which it particularly excites. There thus tends to be formed a constellation of reflexes that reinforce each other, so that a reflex figure results. If the stimulus shifts, allied arcs are by the induction particularly prepared to be responsive to it or to a similar stimulus.

Immediate induction occurs only between allied reflexes. Its tendency in the competition between afferent arcs is to fortify the reflex just established or, if transition occurs, to favour transition to an allied reflex. Immediate induction seems to obtain with highest intensity at the outset of a reflex, or at least near its commencement.

Successive induction is in several ways the reverse of immediate induction. If the crossed extension reflex of the limb of a spinal dog (one whose spinal cord has been severed from the brain) is elicited at regular intervals, say once a minute, by an electrical stimulus of defined duration and intensity, the resulting reflex movements are repeated each time with almost constant character, amplitude, and duration. If in one of the intervals a strong, prolonged (*e.g.*, 30 seconds) flexion reflex is reduced from the limb yielding the extensor reflex movement, the latter reflex becomes intensified after the intercurrent flexion reflex. The intercalated flexion reflex lowers the threshold for the aftercoming extension reflexes and especially increases their afterdischarge. This effect may endure, progressively diminishing, through four or five minutes, as tested by the extensor reflexes at successive intervals. Now, during the flexion reflex, the extensor arcs were inhibited; after the flexion reflex, they are in this case evidently in a phase of excitability. The phenomenon presents obvious analogy to visual contrast. The aftereffect may ensue with such intensity that simple discontinuance of the stimulus maintaining one reflex is immediately followed by spontaneous appearance of the antagonistic reflex.

The so-called mark-time reflex of the spinal dog is an alternating stepping movement of the hindlimbs that occurs on holding the animal up so that its limbs dangle. The reflex can be inhibited by stimulating the skin of the tail. On cessation of that stimulus, the stepping movement sets in more vigorously and at a quicker rate than before. This afterincrease might be explicable in either of two ways. It might be due to the mere repose of the reflex centre, the repose so recruiting the centre as to strengthen its subsequent action. But a similar period of repose obtained by simply supporting one limb—which causes cessation of the reflex in both limbs, the stimulus being stretch of the hip flexors under gravity—is not followed by afterincrease of the reflex. Or the afterincrease might result from the inhibition being followed by a rebound to superactivity. This latter seems to be the case. The afterincrease occurs even when both hindlimbs are passively lifted from below during the whole duration of the inhibitory stimulus applied to the tail. And the reflex inhibition of the knee extensor by stimulation of the central end of its own nerve is followed by marked rebound to superactivity of the extensor itself. Again, the knee jerk, after being inhibited by stimulation of the hamstring nerve, is more brisk than before the inhibition.

Inhibition followed by superactivity

By virtue of this spinal contrast, therefore, the extension reflex predisposes to, and may actually induce, a flexion reflex, and conversely the flexion reflex predisposes to and may actually induce an extension reflex. This process may play a part in linking reflexes together in alternating sequence.

A reflex movement in its progress must generate a number of further stimuli and throw up a shower of impulses from the moving muscles and joints into the spinal cord. Squeezing of muscles and stimulation of their afferent nerves and those of joints and other structures elicit reflexes. The primary reflex movement might be expected, therefore, of itself to initiate further reflex movement, and that secondarily to initiate further still, and so on. Yet on cessation of the external stimulus to the foot in the flexion reflex, the whole reflex comes to an end, usually at once.

2. *Relative fatigue.* Another condition influencing competition among reflexes of different sources for possession of one and the same final common path is fatigue. A spinal reflex under continuous excitation or frequent repetition becomes weaker, and it may cease altogether. This decline is progressive and takes place earlier in some kinds of reflexes than in others. In the spinal dog, for example, the scratch reflex under ordinary circumstances tires much more rapidly than does the flexion reflex.

3. *Relative intensity of stimulus.* In the transition from one reflex to another, a final common path changes hands and passes from one control to another. A fresh set of afferent arcs becomes dominant on the supersession of one reflex by the next. Of all the conditions determining which one of competing reflexes shall, for the time being, reign over a final common path, the intensity of reaction of the afferent arc itself relative to that of its rivals is probably the most powerful. Other things being equal, an afferent arc that strongly stimulates is more likely to capture the common path than is a weaker one. A stimulus can establish its reflex and inhibit an opposed one only if it has intensity. This explains why, in order to produce examples of spinal inhibition, recourse has so frequently been made to strong stimuli. A strong stimulus will inhibit a reflex in progress although a weak one will fail. In the same way, any condition that raises the excitability and responsiveness of a nervous arc will give it power to inhibit other reflexes, just as it would if it were excited by a strong stimulus.

Crossed reflexes

Crossed reflexes are usually less easy to provoke, less reliable of obtainment, and less intense than are direct reflexes. Consequently, crossed reflexes usually are more easily inhibited and replaced by direct reflexes than are the latter by the former. Thus the crossed stepping reflex is easily replaced by the scratch reflex, though its stimulus may be continued all the time and though the scratch reflex itself is not a very potent reflex. But the reverse can occur with suitably adjusted intensity of stimuli.

Again, in the dog's leg, the flexion reflex when fully developed is accompanied by extension in the opposite leg. This crossed extensor movement, though often vigorous, may be considered as an accessory and weaker part of the whole reflex, of which the prominent part is flexion of the homonymous limb. When the flexion reflex is poorly elicitable—as, for instance, in spinal shock or under fatigue or weak excitation—the crossed extension does not appear. But, where the flexion reflex is well developed, if not merely one foot but both are stimulated simultaneously with stimuli of fairly equal intensity, steady flexion at knee, hip, and ankle occurs in both limbs, and extension in neither. The part of each reflex that affects the opposite side is inhibited by the flexion on its own side. In other words, the more intense part of each reflex obtains possession of the final common paths at the expense of the less intense portion of the reflex. But if the intensity of the stimuli applied to the right and left feet is not balanced closely enough, the crossed extension of the reflex excited by the stronger stimulus is found to exclude even the homonymous flexion that the weaker stimulus would otherwise evoke from the leg to which it is applied.

As was pointed out previously, in a number of cases the transference of control of the final common pathway from one afferent arc to another is reversible. Other factors being equal, the direction of the transference can be easily governed by making the stimulation of one receptor or another the more intense. A factor largely determining whether a reflex will succeed another or not is, therefore, intensity of stimulus.

4. *Functional species of reflex.* The fourth main determinant for the issue of the conflict between rival reflexes is the functional species of the reflexes. Reflexes initiated from a species of receptor apparatus that may be termed nociceptive, or pain receptors, appear to dominate particularly the majority of the final common paths issuing from the spinal cord. In the simpler sensations experienced from various kinds of stimuli applied to the skin, there can be distinguished those of touch, of cold, of warmth, and of pain. The pain ending may be regarded as adapted to a whole group of excitants that have, in relation to the organism, one feature in common, namely, a noxious, or injurious, character.

Domination of the final common path by nociceptive reflexes

Considering the organism's liability to various kinds of mechanical and other damage, in a world beset with dangers amid which the individual and species have to win their way in the struggle for existence, noxious stimuli may be regarded as part of a normal state of affairs. The skin has evolved a specific sense of its own injuries. As psychical adjunct to the reactions of that apparatus, a strong displeasurable effective quality is found in the sensations they evoke. This may be a means for branding upon memory, of however rudimentary a kind, a feeling from past events that have been perilously critical for the existence of the individuals of the species. In other words, if it is admitted that damage to such an exposed sentient organ as the skin must in the evolutionary history of animal life have been sufficiently frequent in relation to its importance, then the existence of a specific set of nerves for skin pain seems to offer no genetic difficulty, any more than does the clotting of blood or innate immunity to certain diseases. That these nerve endings constitute a distinct species is argued by their all evoking not only the same species of sensation but the same species of reflex movement as regards such attitudes as purpose, intensity, and resistance to shock. Their evolution may well have been unaccompanied by evolution of any specialized end organ, since the naked free nerve endings would better suit the wide and peculiar range of stimuli to which reaction is in this case required. A low threshold was not required because the stimuli were all intense, intensity constituting their harmfulness; but response to a wide range of stimuli of different kinds was required, because harm might come in various forms. That responsive range is supplied by the naked nerve itself and would be cramped by the specialization of an end organ. Hence, these nerve endings remained free.

Domination of pain reflexes

In the spinal animal—in which pain is of course nonexistent—the prepotent (dominant) reflexes are excited by stimulation of areas in which pain can be excited most intensely in intact animals and, likewise, by stimuli that are most fitted to excite pain in intact animals. The nervous arcs of pain nerves, broadly speaking, dominate the spinal centres in peculiar degree. Pain is thus the psychical adjunct of an imperative protective reflex. The term pain nerves is not used, however, since no sensation of any kind can be shown to enter into the merely spinal and reflex aspect of the reaction of these nerves. Because the feature common to all this group of stimuli is that they threaten or actually commit damage to the tissue to which they are applied, a convenient term for application to them is nocuous. Thus, the nerves that, from the point of view of sense, are cutaneous pain nerves are, from the point of view of reflex action, conveniently termed nociceptive nerves.

In the competition between reflexes the nociceptive usually dominate. This explains why such stimuli have been used so much to evoke reflexes in the spinal frog and why, judging from them, such importance for the fate of the organism belongs to spinal reflexes.

One and the same skin surface will evoke in the hindlimb of the spinal dog one or other of two diametrically different reflexes depending on whether the mechanical stimulus is a harmful or a harmless touch. A needle prick to the sole of the foot invariably causes the drawing up of the limb: the flexion reflex. A harmless smooth contact, on the other hand, causes extension: the extensor thrust described above. This flexion is therefore a nociceptive reflex. But the scratch reflex—which is so readily evoked by simple light irritation of the skin of the shoulder—is relatively mildly nociceptive. When the scratch reflex and the flexion reflex are in competition for the final neuron common to them, the flexion reflex more easily dispossesses the scratch reflex from the final neuron than does the scratch reflex the flexion reflex. If both reflexes are fresh, and the stimuli used are such that, when employed separately, they evoke their respective reflexes with some intensity, it is the flexion reflex that is usually prepotent. Yet if a strong stimulus suitable for producing the scratch reflex is applied while the flexion reflex is being moder-

ately evoked, the steady flexion is replaced by the rhythmic scratch reflex, and this occurs even though the stimulus for the flexion reflex is maintained unaltered. When the stimulus producing the scratch reflex is discontinued, the flexion reflex reappears as before.

Skin receptors concerned with sex

Besides those receptors that react to direct noxious stimuli, the skin has others concerned with functions of vital importance to the species and bound up with sensations of similarly intensive affective quality—*e.g.*, those concerned with sexual functions. It would seem to be a general rule that reflexes arising in species of receptors that, considered as sense organs, provoke strongly affective sensation prevail (other things being equal) over reflexes of other species when in competition with them for the use of the final common path.

One great function of the tonic reflexes is to maintain habitual attitudes and postures. They form, therefore, a nervous background of active equilibrium. It is obviously advantageous that this equilibrium should be easily upset, so that the animal may respond agilely to the passing events.

Summary of spinal cord physiology. Intensity of stimulation, fatigue and freshness, spinal induction, functional species of reflex—all these physiological factors influence the result of the interaction of reflex arcs at a common path. All resolve themselves ultimately into intensity of reaction. Thus intensity of stimulus means, as a rule, intensity of reaction. Those species of reflex that are habitually prepotent in interaction with others are those that are habitually intense, and those specially impotent in competition are those habitually feeble—*e.g.*, the tonic reflexes of skeletal muscle. The tonic reflexes of attitude are thus easily interfered with and temporarily suppressed by intercurrent reflexes (those set up by passing events), which have the higher intensity.

Causes of variability in reflex reactions

The high variability of reflex reactions from one experiment or observation to another is often attributed to changes in nutrition and local blood supply. Variability, however, seems far more often due to changes produced in the central nervous organ by its own functional conductive activity apart from fatigue. This activity itself causes, from moment to moment, the temporary opening of some connections and the closure of others. The chains of neurons, the conductive lines, have been clearly revealed by the microscope. Anatomical tracing of nerve fibres may be likened to tracing the distribution of blood vessels before the vasomotor mechanism was discovered. (The blood vessels of an organ may be turgid at one time, constricted almost to obliteration at another.) With the conductive network of the nervous system the temporal variations are even greater, for they extend to absolute withdrawal of nervous influence. Under reflex inhibition a skeletal muscle is relaxed to its postmortem length *i.e.*, there may then be no evidence of even a tonic influence on it by its motor neuron.

The final common path is handed from some group of a plus class of afferent arcs to some group of a minus class or of a rhythmic class, and then back once more to one of the previous groups, and so on. The conductive web changes its functional pattern to and fro—within certain limits. It changes its pattern at the entrances to common paths. The changes in its pattern occur there as interactions between rival reflexes: occlusion, substitution by equivalence, inhibition, immediate induction, successive induction, and fatigue are factors. A new stimulus striking the receptive surfaces causes in the central organ a shift of functional pattern of the linkage. The central organ is a vast network whose lines of conduction follow a certain scheme or pattern, but within that pattern the details of connection are, at the entrance to each common path, mutable. The gray matter may be compared with a telephone exchange, where, from moment to moment, though the end points of the system are fixed, the connections between starting points and terminal points are changed to suit passing requirements. To comprehend the exchange at work, it is necessary to add to its purely spatial plan the temporal one—that within certain limits the connections of the lines shift to and fro from minute to minute. An example is the reciprocal innervation of antagonistic muscles: when one muscle of the antagonistic pair is thrown into action, the other is thrown out of action.

Reciprocal innervation

Reciprocal innervation is a widespread case of the general rule that antagonistic reflexes interfere where they discharge into the same final common paths. And that rule is part of the general principle of the mutual interaction of reflexes that impinge upon the same common path: unlike reflexes have successive but not simultaneous use of the common path; like reflexes mutually reinforce each other on their common path. The principle may be expressed teleologically: the common path, although economically subservient for many and various purposes, is adapted to serve but one purpose at a time; hence it is a coordinating mechanism and prevents confusion by restricting the use of the organ to but one action at a time.

In the case of simple antagonistic muscles, and in the instances of simple spinal reflexes, the shifts of conductive pattern due to interaction at the mouths of common paths are of but small extent. The coordination covers, for instance, one limb or a pair of limbs. But the same principle extended to the reaction of the great arcs arising in the proficient receptor organs of the head—*e.g.*, the eye—which deal with wide tracts of musculature as a whole, operates with more multiplex shift and wider ambit. Releasing forces acting on the brain from moment to moment shut out from activity whole regions of the nervous system, as they conversely call vast other regions into play. The resultant singleness of action from moment to moment is a keystone in the construction of the individual, whose unity it is the specific office of the nervous system to perfect. The interference of unlike reflexes and the alliance of like reflexes in their action upon their common paths seem to lie at the very roots of the great psychical processes.

The spinal cord not only accommodates reflexes centring wholly within the cord itself but also supplies conducting paths for nervous reactions initiated by impulses derived from afferent spinal nerves—even those involving mechanisms situated altogether headward of the cord, in the brain. Many of these reactions affect consciousness, occasioning sensations of various kinds.

Besides the paths followed by headward-running impulses, the spinal cord contains paths for impulses passing along it backward from the brain. These paths lie in the lateral and ventrolateral columns of the cord. The fibres of which they are composed cross but little in the cord. Their sources are various; some of them come from the hindbrain and some from the midbrain, and, in man, a large tract of fibres in the lateral column (the crossed pyramidal tract) comes from the cortex of the forebrain. This last tract is the main medium by which impulses initiated by electrical stimulation of the motor cortex reach the motor neurons of the cord and through them influence the activity of the skeletal muscles.

Of the function of the other tracts descending from the brain into the cord little is known except that they excite or inhibit the spinal motor neurons at various levels. How they harmonize with one another in their action or what their purpose in normal life may be is little more than conjecture at present.

III. The peripheral nervous system

The peripheral nervous system is made up of three parts: (1) the cranial nerves, (2) the spinal nerves, and (3) that part of the autonomic (involuntary) nervous system that is outside the brain and spinal cord. The cranial nerves arise from, or are attached to, the brain and enter the skull via openings in the bone, called foramina. These nerves are concerned with the special senses and with the innervation of structures in the head and neck. The spinal nerves, attached segmentally to all regions of the spinal cord, enter and leave the vertebral canal by intervertebral foramina (openings between the vertebrae). These nerves innervate the cutaneous surfaces and muscles of most of the body and the deep structures in the trunk and limbs. The autonomic nervous system is a system of nerve

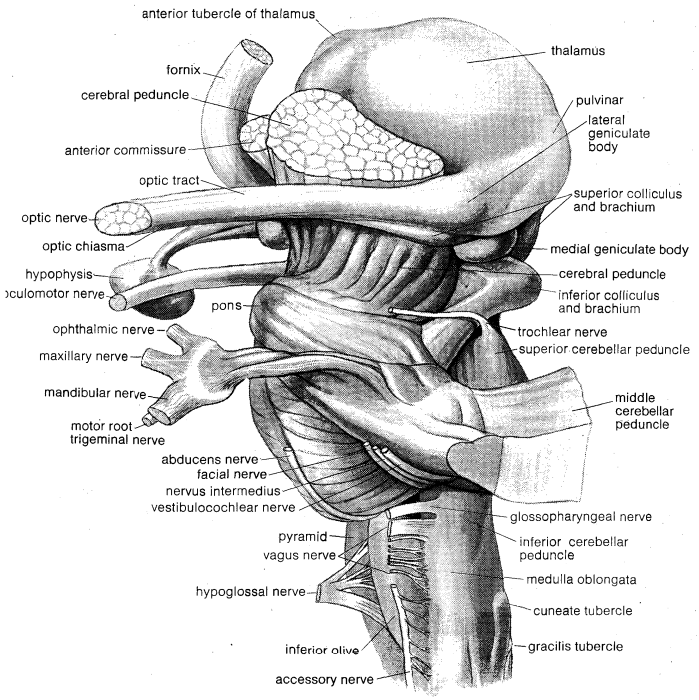

Figure 9: View of the lateral surface of the brainstem and attached cranial nerves.

fibres and masses of nerve cells, called ganglia, arranged in trunks and plexuses; some fibres in this system pass peripherally with certain cranial and spinal nerves even though they subserve separate functions. (The autonomic nervous system is treated as a separate entity in another section of this article.)

The peripheral nervous system has the same essential structure as the central nervous system in that it consists of neurons surrounded by supporting cells (Figure 9). The most striking difference is that the cranial and spinal nerves are composed primarily of axons and dendrites invested by connective tissue sheaths. (Axons carry impulses from a nerve cell body; dendrites, impulses to it.) Cells of the peripheral nervous system lie in spinal, cranial, and autonomic ganglia. Virtually all afferent fibres, both somatic and visceral, have their cell bodies in spinal ganglia or ganglia associated with cranial nerves. Afferent fibres transmit impulses from peripheral receptors into the central nervous system. Autonomic ganglia contain neurons that distribute fibres peripherally that terminate in smooth muscle, heart muscle, and glandular epithelium. These cells give rise to efferent fibres; that is, fibres that convey impulses only to peripheral effector structures. Somatic efferent fibres emerging via spinal and cranial nerves arise from neurons within the spinal cord or brainstem. These fibres pass with peripheral nerve fibres directly to striated, or voluntary, muscles. In a strict sense, they actually are extensions of the central nervous system that link it with peripheral effectors. Autonomic ganglia also receive impulses from cells located within the central nervous system. These fibres, referred to as preganglionic, synapse on (*i.e.*, interconnect with) neurons within the autonomic ganglia. Thus, two neurons are involved in transmitting visceral efferent impulses to peripheral structures. They are: (1) a preganglionic fibre arising in the central nervous system, which synapses upon one or more autonomic ganglion cells, and (2) a postganglionic fibre, projecting peripherally, that arises from a cell in an autonomic ganglion.

Impulses, generated in receptors on body surfaces and within muscles, joints, tendons, and various viscera in response to external and internal stimuli, are conveyed by peripheral nerves to the brain and spinal cord. Receptors, in essence, constitute an elaborate set of transducers capable of converting physical and chemical stimuli (energy) into nerve impulses that are transmitted centrally. The central nervous system exerts its regulating and controlling influences upon striated muscle and viscera by impulses transmitted ultimately by peripheral nerves to effector structures. Virtually the entire input and output of the central nervous system is dependent upon the integrity of the peripheral nervous system. Conversely, the peripheral nervous system could not function as an isolated system.

CRANIAL NERVES

There are 12 pairs of cranial nerves that arise from, or are attached to, the brain. These symmetrically distributed nerves are concerned with the special senses and the innervation of muscles, glands, skin, and the mucous membranes in the head and neck. The vagus nerve is an exception in that it sends fibres to visceral structures in the thorax and abdomen (Figure 10).

Summary of cranial nerve functions

The olfactory and optic nerves, referred to as the first and second cranial nerves, are not actually peripheral nerves but tracts belonging to the central nervous system. The third, fourth, sixth, and 12th cranial nerves are exclusively motor and innervate the extraocular muscles and the muscles of the tongue. The fifth, seventh, ninth, tenth, and 11th cranial nerves innervate muscles derived from the branchial arches. The fifth cranial nerve, the largest of all the true cranial nerves, consists of a large

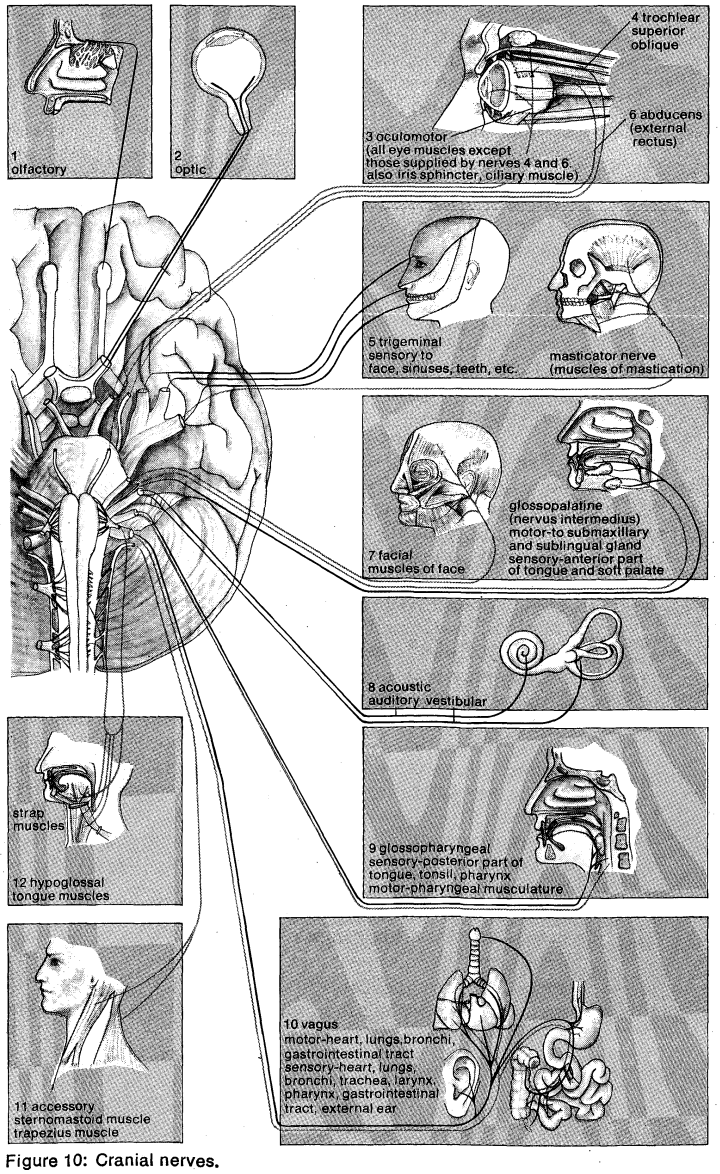

Figure 10: Cranial nerves.

sensory component supplying the face and scalp and a smaller motor component that innervates the muscles of mastication. The seventh, ninth, and tenth cranial nerves contain motor, sensory, and autonomic components. The 11th cranial nerve consists of two parts: (1) a cranial part functionally associated with the vagus nerve, and (2) a spinal part which has a distinctive origin and a separate distribution. The vestibulocochlear nerve (eighth) consists of two parts: the vestibular division concerned with equilibrium and the cochlear division concerned with audition. The first (olfactory), second (optic), eighth (vestibulocochlear), and parts of the seventh, ninth, and tenth (taste) cranial nerves convey impulses concerned with the special senses.

While four functional components of a typical spinal nerve are recognized (*i.e.*, general somatic afferent, general visceral afferent, general somatic efferent, and general visceral efferent), three additional special functional components are represented in the cranial nerves. These additional functional components are designated as: (1) special somatic afferent fibres, (2) special visceral afferent fibres, and (3) special visceral efferent fibres. The special somatic afferent cranial nerves are the optic and the vestibulocochlear nerves. The olfactory nerve and components of the facial, glossopharyngeal, and vagus nerves concerned with taste are classified as special visceral afferent. Motor components of the branchiomeric cranial nerves (*i.e.*, trigeminal, facial, glossopharyngeal, vagus, and accessory) are classified as special visceral efferent because the muscles they innervate are derived from the branchial arches. The oculomotor, the trochlear, the abducens, and the hypoglossal cranial nerves give rise to somatic efferent fibres that innervate muscles derived from somites. These nerves are classified as general somatic efferent cranial nerves. Portions of the oculomotor, facial, glossopharyngeal, and vagus nerves contain preganglionic parasympathetic fibres. These components are designated as general visceral efferent fibres.

Olfactory nerve. The first nerve arises from olfactory neurons scattered among supporting cells in a yellowish-brown patch of specialized epithelium in the upper part of the nasal cavity. Approximately 20 fine, olfactory filaments, not sheathed in myelin, arise from these receptor cells and pass from the nasal cavity into the anterior cranial fossa through foramina in the ethmoid bone. Olfactory filaments, representing the central processes of bipolar cells in the olfactory epithelium, collectively constitute the olfactory nerve. These filaments form a plexus before terminating in the olfactory bulb, a flattened, ovoid body resting on the cribriform plate of the ethmoid bone. Axons of cells in the olfactory bulb form the olfactory tract, which enters the brain.

Olfactory discrimination

The ability of the olfactory receptors, in concert with the brain, to discriminate thousands of different odours is well-known, but the physiological and psychological bases for these discriminations are unknown. Olfactory discrimination does not appear to be based upon morphologically distinct types of receptors. Spatial and temporal factors may play important roles in the neural coding of olfactory responses.

Optic nerve. The second cranial nerve consists of nerve fibres that arise from the ganglion cells of the retina. These fibres converge to form the optic disk, pierce the sclera, and combine to form the optic nerve (see also EYE AND VISION, HUMAN). Optic nerve fibres are axons of connector neurons which receive fibres from receptor neurons. Thus, the optic nerve is regarded as a central nervous system tract. Fibres of the optic nerve lack the neurolemmal sheath common to peripheral nerves, but the optic nerve is surrounded by the three meningeal membranes and a subarachnoid space, the space between the central and innermost layers of the membranes covering the brain and spinal cord. The optic nerves enter the optic canals and pass into the middle cranial fossa, where they form the optic chiasm, or chiasma. The optic chiasm, which lies at the base of the brain immediately in front of the tuber cinereum and infundibulum, is the site of a partial decussation (crossover) of optic nerve fibres. In the optic chiasm, fibres arising from the nasal halves of the retinas cross, while those from the temporal halves of the retinas do not. Thus, each optic tract, the uninterrupted continuation of optic nerve fibres, consists of uncrossed fibres from the temporal half of the ipsilateral retina (*i.e.*, the retina on the same side) and crossed fibres from the nasal half of the opposite retina. Fibres of the optic tract terminate upon cells of the lateral geniculate body, a relay nucleus of the thalamus.

Fibres of the optic nerve convey visual impulses from the retina, which are projected via relays to visual centres in the cerebral cortex. Light reflexes and reflexes resulting in lens accommodation also are mediated by the optic nerves and optic tracts.

Oculomotor nerve. The third cranial nerve is an efferent nerve that consists of two components: (1) general somatic efferent fibres, which innervate all the extraocular muscles except the lateral rectus (lateral straight muscle) and the superior oblique muscles of the eyeball, and (2) general visceral efferent fibres (preganglionic parasympathetic), which pass to the ciliary ganglion. The oculomotor nuclear complex is located ventral to the central gray matter of the midbrain. The complex consists of paired lateral somatic cell columns and an unpaired median cell group called the caudal central nucleus. The lateral somatic cell columns are composed of motor neurons, the fibres of which innervate the superior, medial, and inferior recti muscles and the inferior oblique muscle of the eyeball. The caudal central nucleus gives rise to crossed and uncrossed fibres that innervate the levator palpebrae, the muscle that raises the eyelid. The visceral nuclei of the oculomotor complex arise from small ovoid or spindle-shaped cells located rostral and dorsal to (*i.e.*, in front of and above) the somatic cell columns. These nuclei give rise to preganglionic parasympathetic fibres, which emerge with the somatic fibres and pass to the ciliary ganglion. The ciliary ganglion is a small reddish body, about the size of a pinhead, which lies near the back of the orbit. Preganglionic parasympathetic fibres synapse on cells of this ganglion. The short ciliary nerves arise from the ganglion and, as postganglionic parasympathetic fibres, convey impulses to the ciliary muscle and the sphincter of the iris.

The two components of the oculomotor nerve

Fibres of the oculomotor nerve exit from the brainstem and course forward to enter the lateral wall of the cavernous sinus. Fibres of this nerve enter the bony orbit of the eye via the superior orbital fissure. The nerve divides into superior and inferior branches. The superior branch of the nerve innervates the superior rectus and the levator palpebrae muscles. The inferior branch supplies the medial and inferior recti muscles and the inferior oblique muscle.

The extraocular muscles innervated by the oculomotor nerve serve to elevate the eyelid and move the eye up, down, and toward the midline. Parasympathetic impulses conveyed by the short ciliary nerves cause: (1) contraction of the ciliary body, which effects a thickening of the lens for accommodation, and (2) contractions of the sphincter of the iris, which constricts the pupil.

Trochlear nerve. The fourth nerve supplies motor fibres to the superior oblique muscle of the eyeball. This nerve arises from a small compact cell group in the midbrain. Root fibres of these cells curve dorsolaterally and caudally in the outer margin of the central gray matter and reach the superior medullary velum, where the nerves of the two sides cross (*i.e.*, decussate). The nerves emerge from the dorsal surface of the brainstem just below the inferior colliculus, a rounded eminence on the dorsal surface of the midbrain. This nerve traverses the lateral wall of the cavernous sinus and enters the orbit via the superior orbital fissure.

The superior oblique muscle, which is innervated by the trochlear nerve, turns the eye inward (*i.e.*, intorts) when abducted and depresses the eye when adducted. The trochlear nerve is the only totally crossed cranial nerve and the only one to issue from the dorsal surface of the brainstem.

Trigeminal nerve. The fifth nerve, the largest of the cranial nerves, contains both sensory and motor fibres.

Sensory and motor fibres in the fifth cranial nerve

The sensory division of this nerve conveys tactile sense, pain and thermal sense from the skin of the face and forehead, from the mucous membranes of the nose, nasal sinuses, and mouth, from the teeth, and from large parts of the cranial dura. The sense of deep pressure and movement (kinesthesis) is conveyed by branches of this nerve from the teeth, periodontium, hard palate, and receptors in the temporomandibular joint (articulation or "corner" of the jaw). Additional afferent fibres convey impulses from stretch receptors in the muscles of mastication.

Most, but not all, primary sensory neurons lie in the trigeminal ganglion situated in a dural cavity in the middle fossa of the skull. The ophthalmic, maxillary, and mandibular nerves arise from this ganglion.

Ophthalmic nerve. The ophthalmic nerve passes forward in the wall of the cavernous sinus and divides into three branches, which enter the orbit via the superior orbital fissure. These branches are the lacrimal, frontal, and nasociliary nerves. The lacrimal nerve supplies the lacrimal (tear) gland, the conjunctiva, and the skin of part of the upper eyelid. The frontal nerve passes through the orbital cavity and divides into two branches: the supraorbital nerve supplying the forehead and scalp and the supratrochlear nerve supplying part of the forehead and part of the adjacent upper eyelid. The nasociliary nerve enters the nasal cavity, where branches supply the mucous membrane, nasal septum, and certain areas of skin near the tip of the nose.

Maxillary nerve. The maxillary nerve leaves the middle fossa of the skull via the foramen rotundum and emerges on the face below the eye. The nerve gives off branches to the dura in the middle cranial fossa and to the mucous membranes of the soft and hard palate. The posterior and anterior superior alveolar nerves supply the teeth, gums, and the mucous membrane of the maxillary sinus. The infraorbital nerve, the terminal branch of the maxillary nerve, supplies the skin and conjunctiva of the lower eyelid, the skin on the side of the nose, the cheek, and the upper lip.

Mandibular nerve. The mandibular nerve contains sensory fibres from the trigeminal ganglion and a smaller number of motor fibres, which leave the middle fossa of the skull via the foramen ovale. The motor fibres supply the muscles of mastication. The sensory fibres in the mandibular nerve give rise to the auriculotemporal, lingual, and inferior alveolar nerves. The auriculotemporal nerve gives branches to the mandibular joint, the parotid gland, the upper half of the auricle, and the skin and fascia of the temple and scalp. The lingual nerve supplies the mucous membrane over the sides and dorsum of the anterior two-thirds of the tongue, the floor of the mouth, and the mucosa overlying the sublingual gland. The inferior alveolar nerve distributes branches to the lower teeth, including the incisors. The mental nerve, a cutaneous terminal branch of the inferior alveolar nerve, distributes fibres to the skin of the chin and the lower lip.

Sensory fibres concerned with pain, touch, thermal sense, and some related to pressure sense represent central processes of cells in the trigeminal ganglion. These fibres are distributed to central nuclei that extend throughout most of the lower brainstem. Sensory fibres that convey impulses from stretch receptors in the muscles of mastication, and pressure and kinesthetic sense from the teeth, periodontium, and joint capsules arise from cells within the central nervous system. These cells form the mesencephalic nucleus of the trigeminal nerve, an anomalous group of primary sensory neurons within the brainstem. The motor fibres of the trigeminal nerve arise from typical motor cells in the pontine tegmentum, located in the dorsal part of the pons, one of the basic subdivisions of the brainstem.

Abducens nerve. The sixth cranial nerve contains general somatic efferent fibres that innervate the lateral rectus muscle of the eyeball. The nucleus of the abducens nerve forms a column of typical somatic motor cells in the floor of the fourth ventricle. Root fibres of the abducens nerve emerge from the brainstem at the caudal border of the pons, just lateral to the medullary pyramid. The nerve enters the orbit via the superior orbital fissure and supplies the lateral rectus muscle. This is the cranial nerve most frequently injured. Injury results in horizontal diplopia (double vision) on attempted gaze to the side of the paralyzed muscle.

Facial nerve. The seventh cranial nerve is a mixed nerve containing efferent and afferent components. The largest part of this nerve is the motor component that innervates the muscles of facial expression, the superficial muscles of the scalp and neck, and certain deep muscles. The above component of the facial nerve contains special visceral efferent fibres. The smaller part of the nerve, known as the intermediate (glossopalatine) nerve, contains afferent taste fibres and efferent parasympathetic fibres that convey impulses to the lacrimal gland and certain salivary glands. Cell bodies of afferent fibres are located in the geniculate ganglion.

The motor component of the facial nerve

The motor component of the facial nerve arises from a distinct collection of motor neurons in the ventrolateral pontine tegmentum. Fibres of the nerve emerge from the brainstem at the cerebellopontine angle, formed at the junction of pons, medulla, and cerebellum. The nerve emerges from the skull at the stylomastoid foramen. The mastoid process covers this region in the adult but not in the child. After entering the region of the parotid gland, the nerve breaks up into numerous branches that supply the facial muscles. Temporal branches of the nerve supply the frontalis muscle, the muscles around the eye, and the superior auricular muscles. The lower zygomatic branches supply lower facial muscles including those of the nose and upper lip. Buccal branches supply the buccinator muscle in the cheek, which serves to push food onto the occlusal surfaces of the teeth. A marginal mandibular branch passes between the lower lip and the chin and innervates the muscles surrounding the mouth and those that depress the corner of the mouth. Cervical branches of the facial nerve sweep downward behind the angle of the jaw and supply the platysma muscle, a thin, superficial muscle that extends from the chest over the sides of the neck to the lower jaw.

Special visceral afferent fibres arise from neurons in the geniculate ganglion located at the external genu (bend) of the facial nerve. These fibres convey taste sensation from the anterior two-thirds of the tongue and form part of the intermediate nerve. General visceral efferent fibres (preganglionic parasympathetic) arising from cells of the superior salivatory nucleus in the pons, in part, pass to the lacrimal gland and to nasal and palatine glands. The continuation of the intermediate nerve distal to the geniculate ganglion is known as the chorda tympani nerve. This nerve, containing taste and parasympathetic fibres, separates from the facial nerve and becomes incorporated in the lingual nerve, a branch of the trigeminal nerve. Taste fibres remain intimately associated with the lingual nerve, while the preganglionic parasympathetic fibres synapse upon postganglionic neurons the fibres of which supply the submandibular (submaxillary) and sublingual salivary glands.

Chorda tympani nerve

Lesions of the facial nerve produce a paralysis of facial muscles known as Bell's palsy. Disturbances of taste, salivation, and lacrimation may accompany the facial weakness.

Vestibulocochlear nerve. The eighth nerve is a special somatic afferent cranial nerve consisting of two functionally distinct parts. The vestibular nerve transmits impulses from the labyrinth, a specialized end organ concerned with static and kinetic equilibrium. The cochlear nerve transmits impulses from the cochlear apparatus concerned with audition. Although these nerves run together from the internal auditory meatus to the cerebellopontine angle, where they enter the brainstem, they have distinctive peripheral receptors and central connections (see also EAR AND HEARING, HUMAN).

Vestibular nerve. The vestibular part of the inner ear consists of the three semicircular canals, the utricle, and the saccule. These receptors are concerned with equilibrium and orientation in three-dimensional space. The semicircular canals are arranged at right angles to one another, and one end of each canal has a dilated portion,

the ampulla, containing a transversely oriented ridge. These ridges (cristae ampullaris) are covered by specialized neuroepithelial hair cells, which constitute the vestibular receptor. The utricle and saccule each have a similar patch of sensory epithelium: the macula utriculi and macula sacculi. Hair cells in the maculae are in contact with a gelatinous covering containing small calcareous particles, known as the otoliths.

The cristae of the semicircular canals are stimulated by angular acceleration, which causes movement of the endolymphatic fluid and deflection of hairs in the sensory epithelium. The utricular macula, concerned with static equilibrium, responds to changes in gravitational forces and to linear acceleration. The functional role of the saccule in equilibrium has not been resolved.

The maculae and cristae of the labyrinth are innervated by cells of the vestibular ganglion (ganglion of Scarpa), an aggregation of bipolar cells located in the internal auditory meatus. Peripheral processes of bipolar cells pass to the hair cells of the maculae and cristae. The central processes of these cells form the vestibular nerve the fibres of which pass between the inferior cerebellar peduncle and the spinal trigeminal tract and are distributed to vestibular nuclei in the brainstem.

Cochlear (auditory) nerve. The cochlea is a spiral bony tube with two and three-quarter coils arranged around a central pillar called the modiolus. The coils are referred to as basal, middle, and apical. The cochlea is partitioned by two membranes, the vestibular membrane and the basilar membrane, creating three divisions in all coils. These divisions are the scala vestibuli, the cochlear duct, and the scala tympani. The organ of Corti, the auditory end organ, rests on the basilar membrane in the cochlear duct. This receptor consists of three outer rows of hair cells and one inner row of hair cells, surrounded by supporting cells. A delicate membrane, the tectorial membrane, overhangs the inner half of the spiral organ. Sound waves induce movements of the tympani membrane, which are transmitted via the ear ossicles to the scala vestibuli via the oval window. The endolymph and basilar membrane respond to these waves, which alter relationships between the hair cells of the organ of Corti and the tectorial membrane. Sound waves of different frequencies cause hair cells in different regions of the cochlea to respond. Tones of low frequency cause cells in the apical part of the cochlea to respond, while those of high frequency selectively stimulate cells in the base of the cochlea.

Fibres of the cochlear nerve arise from bipolar neurons situated around the modiolus of the cochlea. The short peripheral processes of these cells end upon the hair cells of the organ of Corti. The central processes of these cells form the cochlear nerve, which enters the brainstem at the cerebellopontine angle.

Glossopharyngeal nerve. The ninth cranial nerve is a mixed nerve, the large afferent component of which supplies the pharynx, part of the tongue, and the carotid sinus and body. A smaller efferent component innervates the stylopharyngeus and middle pharyngeal constrictor muscles and sends preganglionic parasympathetic fibres to the otic ganglion.

Sensory components of the ninth cranial nerve

Sensory components of this nerve arise from two peripheral ganglia: the superior and the inferior. The superior ganglion is small, lies in the jugular foramen, and gives rise to general somatic afferent fibres that supply small cutaneous areas back of the ear; these fibres are carried in the auricular branch of the vagus nerve. The larger inferior ganglion of the glossopharyngeal nerve gives rise to both general and special (taste) visceral afferent fibres. General visceral afferent fibres convey tactile sense, pain, and thermal sense from the mucous membranes of the pharynx, the posterior third of the tongue, the tonsil, and the eustachian tube. A special sensory branch, the carotid sinus nerve, conveys afferent impulses from the carotid sinus and body. The carotid sinus is a dilatation of the common carotid artery and the root of the internal carotid branch. Elevation of carotid arterial pressure initiates afferent impulses in carotid sinus receptors, which are conveyed centrally to vagal nuclei and produce a slowing of the heart rate and a fall in blood pressure. The carotid body, near the branching of the common carotid artery, is a small neurovascular structure that is sensitive to changes in the hydrogen ion concentration of the blood.

Lingual branches of the glossopharyngeal nerve convey taste and general sensation from the posterior third of the tongue.

Preganglionic parasympathetic fibres in the ninth nerve arise from the inferior salivatory nucleus in the medulla and pass via the lesser petrosal nerve and the tympanic branch to the otic ganglion. Postganglionic parasympathetic fibres arising in the otic ganglion pass to the parotid gland and provide its secretomotor and vasomotor supply.

The glossopharyngeal nerve is attached to the lateral surface of the medulla by five or six rootlets. These rootlets lie caudal to those of the facial nerve and are in series with the rootlets of the vagus nerve.

Vagus nerve. The tenth cranial nerve is a mixed nerve containing a large number of parasympathetic fibres that are widely distributed (vagus from the Latin "wandering"). This cranial nerve is unique in that a large part of its fibres are distributed within the thorax and abdomen. The nerve supplies afferent and efferent fibres to the pharynx, larynx, esophagus, stomach, gut, trachea, and lungs. Special fibres of the nerve pass to and from the heart and great vessels. Numerous rootlets of the nerve are attached to the lateral surface of the medulla in series with those of the glossopharyngeal nerve above and the accessory nerve below. The cranial portion of the accessory (11th) nerve contributes efferent fibres to the vagus nerve, most of which pass to the muscles of the larynx. Rootlets of the vagus nerve unite to form a single trunk, which enters the neck via the jugular foramen.

Two ganglia associated with the vagus nerve give rise to afferent fibres. The superior ganglion of the vagus nerve is a small spherical swelling in the root that lies in the jugular foramen. Cells in this ganglion give off general somatic afferent fibres that pass to meningeal and auricular branches. The meningeal branches supply the dura mater of the posterior fossa of the skull. The auricular branch distributes fibres to the skin back of the ear, to the floor of the external auditory meatus, and to the lower part of the tympanic membrane. The inferior ganglion of the vagus nerve, large and spindle-shaped, lies immediately below the jugular foramen. Cells in the inferior ganglion give rise to general visceral afferent fibres and special visceral afferent fibres. The latter convey impulses from taste buds in the region of the epiglottis.

Dorsal motor nucleus of the vagus

Efferent fibres of the vagus nerve arise from cell columns within the medulla. Preganglionic parasympathetic fibres arise from cells of the dorsal motor nucleus of the vagus nerve. This cell column, composed of spindle-shaped cells, lies in the floor of the fourth ventricle dorsolateral to the hypoglossal nucleus. Fibres from the cell column join other fibres of the vagus nerve. Special visceral efferent fibres of the vagus nerve arise from the nucleus ambiguus, a column of typical multipolar motor neurons embedded in the reticular formation. These fibres join other fibres of the vagus nerve and emerge from the lateral surface of the medulla dorsal to the inferior olivary nuclear complex. Fibres arising from the nucleus ambiguus innervate the muscles of the pharynx and larynx. Those that innervate the larynx emerge from the caudal part of the nucleus ambiguus and form the cranial part of the accessory nerve; after joining the spinal part of the accessory nerve, these fibres return to form an integral part of the vagus nerve.

Two branches of the vagus nerve are the pharyngeal and the superior laryngeal nerves. The pharyngeal nerve contains efferent fibres that, along with branches of the glossopharyngeal nerve and sympathetic nerve fibres, form the pharyngeal plexus. Fibres from this plexus supply the muscles of the pharynx and the soft palate. The superior laryngeal nerve divides into a larger internal and a smaller external laryngeal branch. The internal laryngeal nerve supplies the mucous membrane of the larynx, the epiglottis, and the most posterior part of the tongue. The

external laryngeal nerve supplies motor fibres to the inferior constrictor muscle of the pharynx and the cricothyroid muscle.

In the neck the vagus nerve follows a vertical downward course. It enters the thorax on the right side after crossing the subclavian artery; on the left side it crosses between the left common carotid and subclavian arteries. In the thorax the courses of the nerves differ on the two sides. The right vagus nerve continues along the side of the trachea to the root of the lung. The left vagus nerve passes across the aortic arch and then proceeds to the root of the left lung. The vagus nerves form two plexuses: the pulmonary and the esophageal. The pulmonary plexuses are formed behind the root of each lung. From the lower part of the pulmonary plexuses two nerves emerge that reach the esophagus and form the esophageal plexus.

Recurrent laryngeal nerves

The recurrent laryngeal nerves, which supply all of the intrinsic muscles of the larynx except the cricothyroid, pursue different courses on the right and left sides. The right recurrent laryngeal nerve arises in the root of the neck as the vagus nerve crosses the first part of the subclavian artery. This nerve hooks around the artery and passes upward and medially in a groove between the esophagus and the trachea. In this location the nerve lies along the medial side of the right lobe of the thyroid gland. The left recurrent laryngeal nerve separates from the vagus nerve as it crosses the arch of the aorta and, after hooking under the arch, passes upward into the neck in a fashion similar to that of the nerve on the right side.

In the neck both vagus nerves supply cardiac branches, designated as upper and lower cardiac nerves. On the right side both cardiac branches pass downward behind the subclavian artery into the thorax to reach the deep cardiac plexus. On the left side the nerves separate in the thorax; the upper nerve passes near the trachea to join the deep cardiac plexus. The lower nerve passes across the aortic arch to terminate in the superficial cardiac plexus.

In the thorax the vagus nerves form the cardiac, pulmonary, and esophageal plexuses. The cardiac plexus is formed by sympathetic and vagal cardiac branches that meet to produce a large plexus that lies around the great vessels at the base of the heart. The whole plexus is divided into superficial and deep plexuses that distribute fibres to the heart and to the pulmonary plexuses.

The pulmonary plexuses, formed behind the roots of the lung, give off numerous branches which extend into the lungs and are distributed to the bronchi, the pulmonary vessels, and the pleura. The esophagus is supplied by vagal nerve fibres that emerge from the posterior pulmonary plexuses to form the esophageal plexus. Branches of this plexus supply the muscle and mucous membranes in the wall of the esophagus.

From the lower part of the esophageal plexus, anterior and posterior vagal trunks arise and pass into the abdomen. The posterior vagal trunk distributes fibres to the posterior surface of the stomach as well as to the coeliac, splenic, and renal plexuses. The anterior vagal trunk distributes fibres to the lesser curvature of the stomach and branches to the pylorus and the first part of the duodenum. Thus, vagal fibres are distributed directly to the stomach and indirectly to the great autonomic plexuses in the abdomen. Fibres of the vagus nerve extend in the gut as far as the splenic flexure of the colon. These fibres innervate the muscular wall of the gut and provide secretomotor fibres to the glands of the stomach and intestine.

The vagus nerve is the most complex and the most important cranial nerve. Unilateral lesions of the vagus nerve produce ipsilateral paralysis of the soft palate, pharynx, and larynx, which results in hoarseness of the voice and difficulty both in breathing and in swallowing fluids. Vagal cardiac fibres serve to slow the heart rate and probably constrict the coronary vessels, while pulmonary vagal influences constrict the bronchi. Vagal fibres distributed to abdominal viscera stimulate peristalsis and gastrointestinal secretion.

Accessory nerve. The 11th cranial nerve consists of two distinct parts with separate origins and distributions. The cranial part arises from the caudal part of the nucleus ambiguus by several rootlets and emerges below the vagus nerve from the lateral surface of the medulla. These fibres innervate the intrinsic muscles of the larynx and perhaps some muscles of the pharynx. The spinal part of the accessory nerve originates from a cell column in the anterior horn of the spinal cord extending from the fifth (or sixth) cervical segment to the lower part of the medulla. Root fibres from these cells unite to form a common trunk. This common trunk ascends in the spinal canal, enters the skull through the foramen magnum, and joins the cranial part of the accessory nerve. Both parts of the nerve emerge from the skull via the jugular foramen. The cranial part becomes incorporated in the vagus nerve, while the spinal part passes into the neck, where it supplies the sternocleidomastoid and the upper part of the trapezius muscles. The sternocleidomastoid muscle turns the head; the trapezius muscle braces the shoulder and rotates the scapula during elevation of the upper limb.

The two parts of the 11th cranial nerve

Hypoglossal nerve. The 12th cranial nerve is a motor nerve that innervates the muscles of the tongue. The nerve arises from a long column of multipolar motor neurons that occupies the central gray matter of the medulla, which forms the floor of the fourth ventricle. The rootlets of the nerve pierce the dura mater separately and unite to form the hypoglossal nerve in the hypoglossal canal, the bony opening through which the nerve emerges from the skull. At the base of the skull, the nerve is closely associated with the glossopharyngeal, vagus, and accessory nerves. The nerve runs forward and passes into the floor of the mouth, where its fibres are distributed to the hypoglossus, styloglossus, geniohyoid, and genioglossus muscles, and all the intrinsic muscles of the tongue.

The intrinsic muscles of the tongue alter the shape of the tongue, while the extrinsic muscles alter its shape and position. The genioglossus muscle protrudes the tongue. Injury to the hypoglossal nerve results in paralysis of one half of the tongue with loss of muscle tone and substance (atrophy). When the tongue is protruded, it deviates to the side of the injury.

SPINAL NERVES

The spinal nerves are arranged in pairs, with each pair symmetrically attached to the sides of its respective spinal cord segment. Paired spinal nerves are symmetrical in their course and peripheral distribution. There are 31 pairs of spinal nerves, which for descriptive purposes are separated into eight pairs of cervical nerves, 12 pairs of thoracic nerves, five pairs of lumbar nerves, five pairs of sacral nerves, and one pair of coccygeal nerves. The paired coccygeal nerves are rudimentary and occasionally absent. Spinal nerves emerge from the vertebral canal via the intervertebral foramina. The first cervical nerve emerges between the occiput and the atlas, while the eighth cervical nerve exits between the seventh cervical and the first thoracic vertebrae. All thoracic, lumbar, sacral, and coccygeal nerves emerge below the vertebrae of their corresponding number. Spinal nerves vary in size; the largest nerves are those which form the great nerve trunks innervating the lower extremities (Figure 11).

Attachments of spinal nerves to the spinal cord

Origin of spinal nerves. Each spinal nerve is attached to the spinal cord by two nerve roots: (1) a dorsal sensory root (afferent) and (2) a ventral motor root (efferent). The dorsal roots are larger than the ventral roots, contain more fibres, and have fibres of larger diameter. Each dorsal root has interposed in its course an ovoid mass of nerve cells that form the spinal (dorsal root) ganglion. Nerve fibres forming the dorsal root arise from these cells and thus are of peripheral origin. Dorsal root ganglion cells give rise to a single fibre that undergoes a T-shaped bifurcation. One branch of this bifurcation passes peripherally, while the central branch enters the spinal cord. These cells are referred to as unipolar neurons. Central branches of the dorsal root ganglia at first form a single compact bundle, which passes through a sleeve of dura mater and then breaks up into a series of root filaments. These filaments spread vertically in a fanlike manner to enter the spinal cord. Peripheral fibres

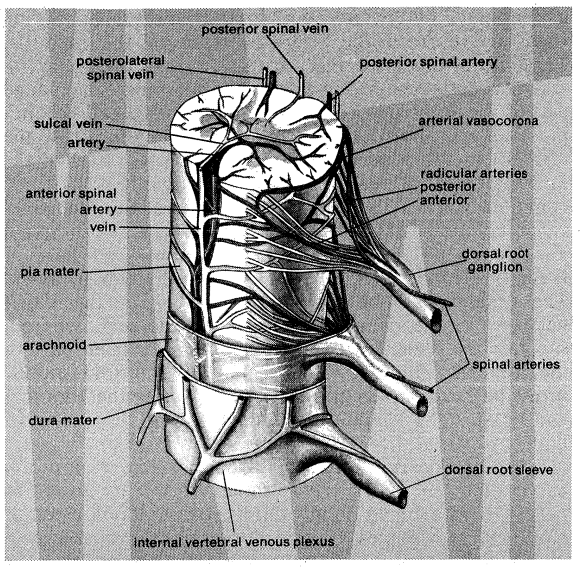

Figure 11: Portion of the spinal cord showing the nerve roots, the meninges, and the blood supply.

from the ganglia pass laterally and join the ventral root in the intervertebral foramina.

Fibres composing the ventral root are of central nervous system origin. These fibres arise from collections of large motor cells in the anterior horn of the spinal gray matter. The ventral root has no ganglion. Fibres of the ventral root emerge from the anterior and anterolateral surfaces of the spinal cord as a series of fine nerve fibres. These fibres are irregular in their arrangement and sometimes overlap. Certain spinal ventral roots contain efferent autonomic nerve fibres. Spindle-shaped cells in the lateral horns of all thoracic (chest) segments and in the first two or three lumbar (mid-lower back) spinal segments give rise to preganglionic sympathetic fibres that emerge via the corresponding ventral roots. The cells of origin of these fibres are known as the intermediolateral nucleus. Small scattered neurons located along the lateral surface of the anterior gray horn in the second, third, and fourth sacral (low-back) segments give rise to preganglionic parasympathetic fibres that exit via the ventral roots and pass to autonomic ganglia in or near the walls of pelvic viscera. Cells of these sacral autonomic nuclei appear similar to those of the intermediolateral nucleus.

The mixed spinal nerve

Dorsal and ventral roots pass laterally from their attachments to the spinal cord toward the intervertebral foramen, where they unite to form a mixed spinal nerve, or common nerve trunk. In the mixed nerve, motor and sensory fibres are blended. The first two cervical nerves pass directly laterally and somewhat upward. The roots of other spinal nerves course obliquely downward and laterally. This oblique downward course increases in caudal regions; lower lumbar, sacral, and coccygeal nerve roots pursue a vertical course downward in the vertebral canal. This progressively increasing obliquity of spinal roots is a consequence of the more rapid rate of growth of the vertebral column. During early development the spinal cord extends to the lower sacrum, but after the fourth month of fetal life the vertebral column elongates more rapidly than the spinal cord. At birth the conus medullaris (*i.e.*, terminal part of the spinal cord) lies opposite the third lumbar vertebra, and in the adult it reaches the lower border of the first lumbar vertebra. Because the spinal cord is attached to the brainstem above, there is a progressive lengthening of the spinal roots from their attachments to the spinal cord to their entrance into the intervertebral foramina. This lengthening of spinal roots is much greater in the lumbar and sacral regions than in the cervical region. The collection of spinal nerve roots below the first lumbar vertebra that surrounds the filum terminale is the cauda equina.

As spinal root filaments leave the spinal cord they become invested with pia mater, which becomes continuous with the arachnoid where the roots penetrate the dura. The two roots pierce the dura separately, and a dural investment is added. Distal to the spinal ganglion the meningeal sheaths are blended and become continuous with the connective tissue covering of the spinal nerve.

Functional components of spinal nerves. Four functional components are recognized in a typical spinal nerve. These components are: (1) general somatic afferent fibres, (2) general visceral afferent fibres, (3) general somatic efferent fibres, and (4) general visceral efferent fibres. General somatic and general visceral afferent fibres arise from cells in the spinal ganglia. General somatic afferent fibres convey impulses from skin receptors concerned with pain, thermal sense, pressure and touch, and from receptors in muscles, joints, tendons, and subcutaneous tissues. General visceral afferent fibres convey impulses from visceral structures, glands, and blood vessels. General somatic efferent fibres arise from neurons within the central nervous system and convey motor impulses to striated muscles that initiate and maintain contractions of these muscles. General visceral efferent fibres arise from cell groups in restricted regions of the spinal cord and project to autonomic ganglia which, in turn, give rise to postganglionic fibres. Sympathetic visceral efferent fibres arise from thoracic and upper lumbar spinal segments and constitute the sympathetic outflow for the entire body. Sacral segments two, three, and four provide the spinal parasympathetic outflow that passes to lower abdominal and pelvic viscera via parasympathetic ganglia.

Typical spinal nerve. As a spinal nerve emerges from an intervertebral foramen, it divides into two main branches—a dorsal and a ventral ramus. The dorsal ramus, usually smaller than the ventral ramus, divides into medial and lateral branches that innervate the skin, fascia, ligaments, and axial muscles of the back. The larger ventral ramus courses laterally and ventrally in the body wall as an intercostal (between the ribs) nerve. A lateral cutaneous branch innervates the skin on the lateral and ventral surface of the body. The principal ventral ramus continues ventrally, giving off branches that innervate intercostal muscles; the terminal part of this nerve gives rise to anterior cutaneous branches.

The dorsal and ventral rami

The ventral rami of the first thoracic to the third lumbar spinal nerves give rise to white rami communicantes that pass to sympathetic ganglia. These are preganglionic (efferent) fibres that arise from cells within the spinal cord and pass to sympathetic ganglia. The sympathetic ganglia and trunk give rise to gray rami communicantes that enter the ventral rami; these postganglionic fibres are distributed to blood vessels, glands, and piloerector muscles.

Distribution of spinal nerves. The dorsal rami of the spinal nerves innervate the skin, fascia, and muscles over dorsal parts of the head and trunk. The muscular branches of these rami are limited to the longitudinal postvertebral muscles associated with the axial skeleton. Cutaneous branches of these rami supply areas on the back of the head, the dorsum of the trunk, and in the shoulder and gluteal (buttock) regions. None of these branches supplies cutaneous areas or muscles in the extremities. The first cervical spinal nerve has a small or frequently absent dorsal root; muscular branches, mainly in the dorsal ramus, supply posterior neck muscles attached to the skull and cervical vertebrae. The second cervical nerve gives rise to small muscular branches and the greater occipital nerve, which innervates cutaneous areas over the posterior part of the scalp. The dorsal rami of the lower cervical nerves are small, and those of the seventh and eighth cervical nerves have no cutaneous branches.

The dorsal ramus of each thoracic spinal nerve divides into medial and lateral branches. In upper thoracic nerves the medial branches are cutaneous, while the lateral branches are distributed to the muscles. The reverse is found in the lower six thoracic nerves where the medial branches innervate the larger longitudinal muscle masses of the back. The dorsal rami of the first three lumbar nerves are distributed in the same fashion as the lower

thoracic nerves. Lower lumbar nerves supply only muscular branches to the longitudinal muscles of the back. The first three sacral dorsal rami give rise to medial muscle branches and lateral cutaneous branches that supply skin and fascia over the sacral and gluteal regions. The fourth and fifth sacral dorsal rami distribute only cutaneous branches to the coccygeal region.

The ventral rami of spinal nerves consist of afferent and efferent fibres and are distributed to lateral and anterior parts of the body, including the extremities. Only in the thoracic region are the ventral rami distributed in a regular manner. Other ventral rami combine to form plexuses. In these plexuses components are rearranged and distributed in a more complex manner. The principal plexuses are the cervical, brachial, lumbar, sacral, and coccygeal. Ventral rami of the cervical nerves and parts of the upper two thoracic nerves are distributed to the head, neck, and upper extremity by the cervical and brachial plexuses.

Principal plexuses of spinal nerves

Cervical plexus. The cervical plexus is formed by the ventral rami of the first four cervical nerves. From the loops of this plexus, branches are distributed to the cutaneous regions of the head, neck, and shoulder; muscles of the neck and diaphragm; and certain cranial and sympathetic nerves. Six cutaneous nerves of the plexus radiate from the posteriad border of the sternocleidomastoid muscle. Among these are the following ascending branches: the lesser occipital nerve, which innervates the upper part of the neck and the scalp behind and above the ear; the great auricular nerve, which innervates the lower part of the auricle, the scalp immediately behind the ear, and skin overlying the parotid gland and the angle of the mandible; and the transverse nerve of the neck, which supplies the skin over the anterior triangle of the neck. The supraclavicular branches radiate laterally from the neck to be distributed to skin and fascia over the inferior part of the neck, the front of the chest, and the shoulder. Lateral muscular branches of the cervical plexus supply parts of the sternocleidomastoid, the trapezius, and the levator scapulae muscles (muscles of the neck and shoulder). Medial muscular branches of the cervical plexus supply prevertebral muscles, the geniohyoid and infrahyoid muscles, and the diaphragm. The phrenic nerve, which arises from the fourth cervical nerve and to a lesser extent from the third and fifth, courses downward in the neck, passes between the subclavian artery and vein, and enters the thorax. This nerve traverses the middle mediastinum, lying between the pericardium and the pleura, and reaches the diaphragm where it separates into numerous branches.

Brachial plexus. The brachial plexus is formed from the ventral rami of the four lower cervical and the first thoracic nerves with a small contribution from the fourth cervical nerve. Considerable variations occur. If the contribution from the fourth cervical is appreciable and that from the first thoracic negligible, the plexus is called prefixed. It is called postfixed if the fourth cervical does not contribute to the plexus and the first thoracic makes a strong contribution. The ventral rami forming the plexus give rise to three primary trunks: (1) fifth and sixth cervical unite to form the upper trunk, (2) seventh cervical forms the middle trunk, and (3) eighth cervical and first thoracic unite to form the inferior trunk. Each trunk divides into an anterior and a posterior division. The three posterior divisions unite to form the posterior cord. The anterior division of the upper trunk becomes the lateral cord, while the anterior division of the lower trunk becomes the medial cord.

Prefixed and postfixed plexuses

Nerves supplying the shoulder muscles arise directly from the ventral rami or from the trunks. The dorsal scapular nerve, innervating the rhomboid muscles, arises from the dorsal surface of the fifth cervical. The long thoracic nerve, supplying the anterior serratus muscle, arises from the dorsal surfaces of the fifth, sixth, and seventh cervical. The suprascapular nerve to the supraspinatus and infraspinatus muscles arises from the upper trunk. The medial and lateral pectoral nerves, which innervate the pectoralis major and minor muscles, arise from the ventral surfaces of the upper and middle trunks and, in part, from the medial cord. The thoracodorsal and subscapular nerves arise from the posterior cord and supply, respectively, the latissimus dorsi muscle and the teres major and subscapular muscles—shoulder muscles which control movements of the upper arm.

The three largest peripheral nerves in the upper extremity (*i.e.*, radial, median, and ulnar) are formed in the following manner. The posterior cord divides into its two terminal branches: the larger radial nerve and the smaller axillary nerve. The medial and lateral cords each split into two branches. The two middle branches, one from the lateral cord and one from the medial cord, unite to form the median nerve. The outer branch of the lateral cord becomes the musculocutaneous nerve. The inner branch of the medial cord gives off two purely sensory nerves, the medial brachial cutaneous nerve and the medial antebrachial cutaneous nerve, and is continued peripherally as the ulnar nerve.

Axillary, radial, median, and ulnar innervation

The axillary nerve innervates the deltoid and teres minor muscles. The radial nerve supplies the triceps muscle and extensor muscles of the elbow, hand, and digits. Its cutaneous branches supply the posterior aspect of the arm, forearm, and part of the dorsum of the hand. The median nerve supplies most of the flexor muscles of the forearm and certain muscles in the hand. The sensory innervation of the median nerve is limited to the hand, where it includes the volar surface of the thumb, index, and middle fingers and the radial half of the fourth finger and corresponding parts of the palm. The ulnar nerve supplies flexor muscles in the forearm and certain flexor and adductor muscles in the hand. Cutaneous areas innervated by this nerve include the dorsal and volar surface of the little finger and adjacent half of the ring finger. A mild blow to the medial aspect of the elbow ("funny bone") may cause a sensation of numbness and tingling in the cutaneous distribution of the ulnar nerve.

Lumbar plexus. The lumbar plexus is formed by the ventral rami of the first four lumbar nerves, often with an additional branch from the 12th thoracic. The fourth lumbar nerve contributes to both the lumbar and sacral plexuses. Nerves arising from this plexus supply the loin region as well as part of the lower limb. The arrangement of the lumbar plexus is simpler than that of the brachial plexus in that the ventral rami do not form interlacing trunks but split into posterior and anterior divisions related primarily to primitive posterior and anterior muscle groups in the leg. Peripheral nerves to the lower extremity, lower abdomen, and genital region are formed by the union of variable numbers of either posterior or anterior divisions. Anterior divisions give rise to the following nerves: (1) iliohypogastric (anterior branch), (2) ilioinguinal, (3) genitofemoral, and (4) obturator. The posterior divisions give rise to the following nerves: (1) iliohypogastric (posterior branch), (2) femoral, and (3) lateral femoral cutaneous.

The iliohypogastric, ilioinguinal, and genitofemoral nerves supply muscular and cutaneous branches to the abdominal wall, the inguinal region, and the external genitalia. The obturator nerve supplies muscles on the medial aspect of the thigh, gives articular branches to the hip and knee joints, and sometimes distributes a cutaneous branch to the inner surface of the thigh. The large femoral nerve supplies the muscles on the anterior aspect of the thigh (*i.e.*, the extensor muscles of the thigh), gives articular branches to the hip and knee joints, and has an extensive cutaneous distribution on the medial aspect of the lower extremity to the foot. Branches of this nerve innervate the pectineus, sartorius, and quadriceps muscles. Cutaneous branches of the nerve are the anterior cutaneous nerve, distributed to anterior and anteromedial surfaces of the thigh, and the saphenous nerve, which is distributed to skin and fascia of the medial aspect of the leg and foot. The lateral femoral cutaneous nerve innervates skin and fascia over the lateral part of the front of the thigh as far down as the knee; a smaller posterior branch supplies the lateral aspect of the buttock and skin over the lateral side of the thigh.

Innervation of the legs and feet

Sacral plexus. The sacral plexus is formed by the ventral rami of the fifth lumbar and the upper three sacral

nerves with contributions from the fourth lumbar and the fourth sacral nerves. The sciatic nerve, the largest and thickest nerve in the body, is the chief continuation of all roots of the sacral plexus. This large nerve leaves the pelvis and enters the gluteal region through the greater sciatic foramen. The nerve enters the thigh at the lower border of the gluteus maximus and descends under the long head of the biceps femoris muscle. This nerve usually terminates in the popliteal fossa (*i.e.*, back of the knee) by dividing into the tibial and common peroneal nerves. The division of the nerve may occur at any higher level, as these two nerves frequently are distinct at their origin. The tibial and common peroneal nerves are bound together proximally by an investing sheath.

In addition to the sciatic nerve the sacral plexus gives rise to numerous smaller nerves. These collateral branches innervate the main external rotators of the thigh, the obturator internus, the gemelli, and the quadratus femoris muscles. The pudendal nerve arises from the second, third, and fourth sacral nerves and provides branches distributed to the anal sphincter, the scrotum (or labium majus), and the penis (or clitoris). Other branches from proximal parts of the sacral plexus are nerves to the gluteal muscles and the posterior femoral cutaneous nerve. Parasympathetic fibres from the second, third, and fourth sacral nerves join autonomic plexuses in the pelvis and are distributed to urogenital organs and the lower part of the large intestine. Nerves given off from the sciatic nerve near the lower part of the buttock innervate the hamstring muscles, the principal flexors of the knee. The common peroneal and tibial nerves are the two main trunks resulting from the division of the sciatic nerve.

The peroneal nerves

The common peroneal nerve arises from the posterior cords of the sacral plexus and is homologous with the radial nerve of the upper limb. Two cutaneous nerves arise from the common peroneal nerve in the popliteal fossa. These are the lateral cutaneous nerve on the calf, distributed over the lateral and posterior aspect of the leg, and the peroneal communicating branch, which gives branches to the lateral surface of the leg. The two terminal branches of the common peroneal nerve are the deep and superficial peroneal nerves. The division of the common peroneal nerve takes place immediately below the head of the fibula. Branches of the deep peroneal nerve innervate the tibialis anterior, extensor hallucis longus, and extensor digitorum longus muscles, which serve to dorsiflex (extend) the foot and toes. In the foot the terminal branches are: (1) the medial digital branch, supplying the skin on adjacent sides of the great and second toes; and (2) a lateral muscular branch which innervates the extensor digitorum brevis and gives rise to articular branches for tarsal, tarsometatarsal, and metatarsophalangeal joints. The superficial peroneal nerve passes downward in front of the fibula and innervates the peroneus longus and brevis muscles. Terminal branches of this nerve are cutaneous. Medial branches supply skin and fascia over the dorsum of the foot, the medial aspect of the great toe, and adjacent parts of the second and third toes. Lateral branches of the superficial peroneal nerve supply distal parts of the leg, part of the dorsum of the foot, and regions between the third and fourth, and fourth and fifth toes. Cutaneous nerves on the dorsum of the foot are subject to considerable variation, and nerves supplying the digits are smaller than plantar digital nerves.

The tibial nerve arises from the anterior divisions of the sacral plexus. This nerve is homologous with the median and ulnar nerve trunks in the upper extremity. The nerve lies deep in the posterior thigh, passes into the popliteal fossa, and distally is covered by the gastrocnemicus and soleus muscles. Branches of the nerve arising in the popliteal fossa innervate the gastrocnemicus, soleus, and posterior tibial muscles. The sural nerve, a cutaneous branch, pierces the deep fascia on the back of the leg and descends to reach the lateral surface of the foot. This nerve and its branches supply cutaneous regions on the posterior and lateral aspects of the distal third of the leg, the ankle, the heel, and the lateral border of the foot. Muscular branches of the tibial nerve in the leg innervate the tibialis posterior, the soleus, and the long flexor muscles of the foot. The terminal branches of the tibial nerve are distributed to the plantar surface of the foot by the medial and lateral plantar nerves. The medial plantar nerve is homologous with the median nerve in the hand, while the lateral plantar nerve is homologous with the ulnar nerve. The medial plantar nerve innervates the abductor hallucis and the flexor digitorum brevis muscles and gives rise to four common plantar digital nerves. The lateral plantar nerve gives branches to small muscles of the foot and cutaneous branches to the fifth toe and part of the fourth toe.

Coccygeal plexus. The coccygeal plexus is formed by the ventral ramus of the fourth sacral nerve with those of the fifth sacral and coccygeal nerves. These nerves form a plexiform cord homologous with the inferior caudal trunk of tailed animals. Some of these nerve fibres pierce the coccygeus and overlying ligaments to supply the skin and fascia near the coccyx and anus. (M.B.C.)

IV. The autonomic nervous system

By classical definition, the autonomic nervous system, sometimes called the visceral or vegetative nervous system, is that system of motor nerve fibres that supplies (carries impulses to) the cardiac (heart) muscle, smooth muscle, such as that in the blood vessels, and glands, and that consists, in its simplest form, of nerve pathways each consisting of two succeeding nerve cells. The first cell is located in the brain or spinal cord and the second in a ganglion, or collection of nerve cells, outside of the brain and spinal cord. Anatomically and functionally, however, the autonomic nervous system is much broader than the definition given above would indicate. The motor fibres comprising this system are closely associated with sensory fibres in all of their functions. An integral part of the entire nervous system, they are activated by nerve impulses arising by a reflex action, at local levels, or originating in the higher centres of the brain.

Because a modern treatment of the autonomic system can be presented only within the context of the entire nervous system, some overlap with the other sections of this article is inevitable. Such overlap, however, focusses on autonomic functions.

For the sake of clarity and to facilitate an understanding of certain functions, the autonomic nervous system will be presented as if it were a series of levels of the central and peripheral nervous systems that differ in function in that the higher the level, the more widespread and general its functions, the lower the level, the more restricted and specific its functions. The lowest level consists of the two-nerve-cell pathway mentioned above. Before the various levels are taken up in detail, a general account of the principles of organization and function is given.

GENERAL ORGANIZATION AND FUNCTION

The two-nerve-cell pathway begins with certain nerve cells located in the brainstem and spinal cord (Figure 12). The axons of these cells—that is, the fibres carrying impulses from the cells—are called preganglionic fibres (they are also known as general visceral efferent fibres). With some exceptions, taken up in later sections, the preganglionic fibres leave the brain and spinal cord and transmit impulses to nerve cells in peripheral ganglia. (A circumscribed collection of nerve cells outside of the central nervous system is usually called a ganglion; a collection of nerve cells within the central nervous system is usually called a nucleus—not to be confused with the nucleus of a single cell. If a nucleus gives rise to a cranial nerve or a spinal root, it is often referred to as a nucleus of origin.) The axons of the ganglion cells are commonly called postganglionic fibres. They terminate in cardiac (heart) muscle, smooth muscle, and certain gland cells, all of which, because they can produce actions, are often known as effectors. The most obvious effectors are skeletal muscles, which are supplied by motor (somatic efferent) fibres; these fibres go directly, without interruption, from motor cells in the brain or spinal cord to the muscle fibres.

The locations, arrangements, and connections of the

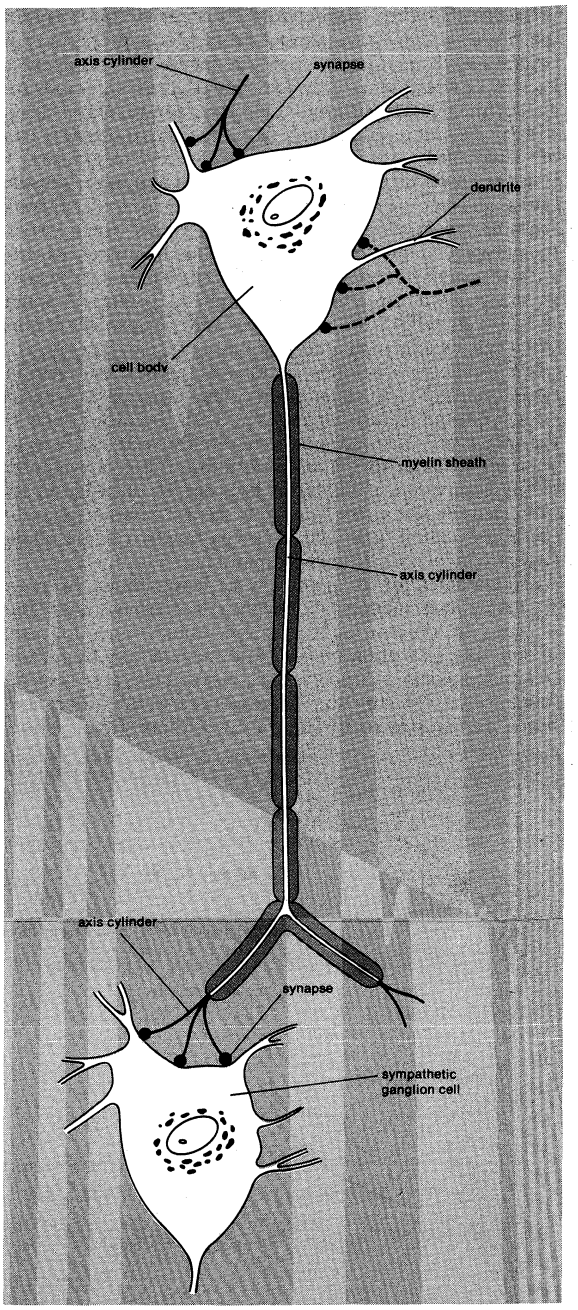

Figure 12: General features of a multipolar sympathetic nerve cell of the spinal cord (as shown by the light microscope), and of one of the many synapses between the axis cylinders axons) of this cell and nerve cells in sympathetic ganglia.

two-nerve-cell pathways of the autonomic nervous system form the basis of an anatomical classification or subdivision of the pathways into sympathetic and parasympathetic systems, or divisions. Before these two divisions are described in greater detail, it is necessary to give a brief account of the effectors they supply, namely, cardiac muscle, smooth muscle, and glands. The activation of an effector by nerve impulses takes place across a specialized nerve–effector relationship known as a neuro-effector junction or, especially in the case of skeletal muscle, a motor nerve ending.

Effectors supplied. *Cardiac muscle.* Cardiac muscle fibres comprise the bulk of the heart. The fibres are multinucleated cells that contain longitudinally disposed minute fibres—myofibrils—that have alternating light and dark segments. This structural arrangement causes the fibres to appear cross-striated when examined under the microscope. Though skeletal muscle fibres are also cross-striated, they differ from cardiac fibres in many important respects. The significant differences are in nerve supply, in the fact that cardiac fibres have an intrinsic rhythmic beat or contraction that begins in the embryo, that cardiac fibres can survive without a nerve supply, that cardiac fibres cannot be voluntarily controlled as most skeletal muscles can, and that some of the cardiac fibres are specialized for conduction rather than contraction.

The specialized fibres form the conducting system of the heart (see CARDIOVASCULAR SYSTEM, HUMAN), consisting of two definitive collections of specialized fibres called nodes (the sino-atrial and the atrioventricular node), together with bundles of fibres spreading out from the nodes to the regular cardiac fibres. Postganglionic autonomic fibres, both sympathetic and parasympathetic, form motor endings on the fibres of the nodes. From there, impulses are conducted to the ordinary cardiac muscle fibres. The two nodes, by virtue of rhythmic activity that begins in the embryo, together set the level of cardiac activity, or rate of heartbeat. The autonomic nerve supply to the heart acts by stimulating or inhibiting the ongoing nodal rhythm, thereby increasing or decreasing ongoing activity of the heart.

Smooth muscle. Many organs contain what is known as smooth muscle. The unit of a layer of smooth muscle is a small spindle-shaped cell; this contains a nucleus and myofibrils that lack alternating light and dark sections and hence are said to be smooth (uniform) rather than cross-striated. Smooth muscle cells are usually arranged in sheets or bundles, within the walls of viscera, around many glands, and in the walls of blood vessels. Contractions of smooth muscle are slower than those of striated muscle and often seem to spread from one fibre to another as a wavelike activity of the sheet or bundle. This spread may be facilitated by the low resistance contacts, or fusions, known as tight junctions, which occur between many of the fibres.

Neuro-effector junctions in smooth muscle seem to be between varicosities—bulging areas—of nerve fibres and individual smooth muscle cells. It is unlikely that every smooth muscle fibre is so supplied, and it is likely that organs differ in the density of the innervation of their smooth muscle. Also, the degree to which a single postganglionic nerve fibre may divide and supply more than one smooth muscle fibre is not known with certainty. Like cardiac muscle, smooth muscle may survive without a nerve supply and in some instances possesses intrinsic, or locally initiated, activity, the level of which may be modified by the autonomic nervous system.

Glands. Glands are composed of epithelial (covering or lining) cells adapted for the formation of materials other than those directly concerned in their intrinsic metabolism. The glands secrete such substances as hormones, enzymes, and mucus. They may be composed of one or of many cells. If the glands discharge their products onto a surface or into the channel of an organ, they are called exocrine glands, or glands of external secretion. If they discharge their contents into the blood, they are called endocrine glands, or glands of internal secretion.

Exocrine and endocrine glands

Generally, only the multicellular exocrine glands are supplied by the autonomic nervous system. The neuro-effector junctions formed by postganglionic autonomic fibres are basically similar to those of smooth muscle. Like smooth muscle, gland cells are also usually relatively unaffected by loss of nerve supply. They may continue to function normally, either by virtue of intrinsic activity or through activation by circulating hormones and other substances.

An important principle emerges from the above, namely, that the autonomic nervous system is not indispensable to the structures it supplies and that it often functions by regulating intrinsic activity. Cutting the nerve supply (denervation) is not without effect, however. Some of the consequences are discussed later (see below *Pathophysiology*).

Viscera and visceral activity. The organs containing cardiac fibres, smooth muscle, or gland cells are sometimes called viscera (hence the term visceral nervous system). The term viscera is a general one, however, and is difficult to define precisely. It is often used to refer to

Meaning of term viscera

organs and tissues that are supposedly not under voluntary control (for example, the heart), in contrast to skeletal, or striated, muscle. The distinction is more apparent than real. Many skeletal muscles, such as the diaphragm, which separates the chest and abdominal cavities, are not subject to complete voluntary control. Organs containing smooth muscle may be as much under voluntary influence or control as many so-called voluntary muscles. Moreover, certain organs, such as the pharynx, or throat, and esophagus, or gullet, contain striated muscle but are classified as viscera.

In its narrow sense, then, the term viscera refers to the heart and to the organs and tissues containing smooth muscle and glands and to a large degree under the control or regulation of the autonomic nervous system. In the broader sense, the term visceral activity is more useful. For example, skin, which is usually not classified as a viscus, contains many glands, as well as smooth muscle attached to hair follicles. Blood vessels, which often contain smooth muscle fibres, are found throughout the body. However ill defined it may be or how unaware of it one may be, visceral activity is a complex pattern involving sensory and motor nerve fibres and many parts of the central nervous system. The regulation of body temperature is an excellent example of such a complex pattern of activity, a fundamental component of which is the autonomic nervous system.

Cold-blooded vertebrates, such as fish, amphibians, and reptiles, have body temperatures that vary with the surrounding temperature. Warm-blooded animals, such as birds and mammals, keep their body temperatures constant within certain limits and are therefore to a certain extent independent of their thermal environment. Heat production and heat loss are relatively balanced. The heat that is produced by metabolic activity is lost chiefly through radiation from the blood vessels that lie near the surface of the body. A certain amount of heat is also lost with the evaporation of sweat, with the exhalation of air and water vapour from the lungs, and with the excreta. If more blood flows through the surface vessels per unit of time, and especially if more vessels are made available for blood to flow through, more heat will be lost by radiation. The autonomic nervous system can regulate the calibre of the blood vessels by, for example, activating the smooth muscle of the vessels with a resultant narrowing of the diameter of the vessels. It can also control special vessels that act as shunts—that is, when open, allow blood to bypass the surface vessels. If these vascular shunts are closed, blood is diverted to the surface vessels. This overall control of blood flow may be initiated in a number of ways. Skin exposed to the cold air, for example, becomes blanched or pale as the result of a reflex narrowing, or constriction, of the vessels in the skin, coupled with an opening of the vascular shunts. This reflex action is brought about as follows: the cold air stimulates nerve receptors that are sensitive to temperatures lower than that of the normal skin surface. The nerve impulses thus initiated reach the spinal cord or brainstem, where they activate motor cells of the autonomic nervous system. These in turn send impulses along fibres to peripheral ganglia, whose postganglionic fibres supply and activate the smooth muscle of the surface vessels, thereby constricting them and narrowing their lumen, or channel. At the same time, some fibres activate the smooth muscle of the shunts so that these vessels open. This reflex mechanism results in a decrease in heat radiation, thereby helping to maintain the internal body temperature, even though the skin may be cold, both subjectively and objectively.

In general terms, then, the autonomic nervous system is an important part of the mechanisms whereby the body keeps its internal environment (*milieu interieur*) constant. That is, it helps to maintain the temperature, fluid balance, and ionic composition of blood. The maintenance of the internal environment is called homeostasis.

In carrying out these general functions, the autonomic nervous system is concerned with a number of specific functions, such as those related to digestion, intermediate metabolism of foods, and excretion. The system is concerned with many specific regulatory functions, involving, for example, body temperature, blood pressure, and respiration. It enables the body to handle emergencies or sudden environmental changes and is thus an important part of the mechanisms by which a person reacts to stress. Finally, the autonomic nervous system is an integral part of behavioral and emotional actions and responses. It must be emphasized that, in all of these activities, sensory fibres and sensory mechanisms are often indispensable features. Most viscera have sensory fibres arising from them, some concerned with pain but many concerned with reflex mechanisms. These fibres, which are termed general visceral afferent fibres, reach the brain and spinal cord by travelling in autonomic and peripheral nerves, often side by side with autonomic fibres.

Specific functions of the autonomic nervous system

The foregoing brief description of temperature regulation illustrates how effectors may be activated as a result of nerve impulses arising reflexly, with the motor side of the reflex including autonomic nerve fibres. It has already been pointed out that these autonomic fibres characteristically comprise a pathway of two nerve cells, one in the brainstem or spinal cord and the second in a peripherally located ganglion, and that these pathways can be classified as sympathetic or parasympathetic.

The classification of pathways as sympathetic or parasympathetic is inadequate because it does not take into account the afferent (sensory) and reflex connections, the higher levels of organization, and certain functional and pharmacological characteristics. Nevertheless, it does indicate some fundamental characteristics and differences. Some are illustrated in Figure 13. Others are described

From E. Gardner, *Fundamentals of Neurology*, 5th edition (1968); W.B. Saunders Company

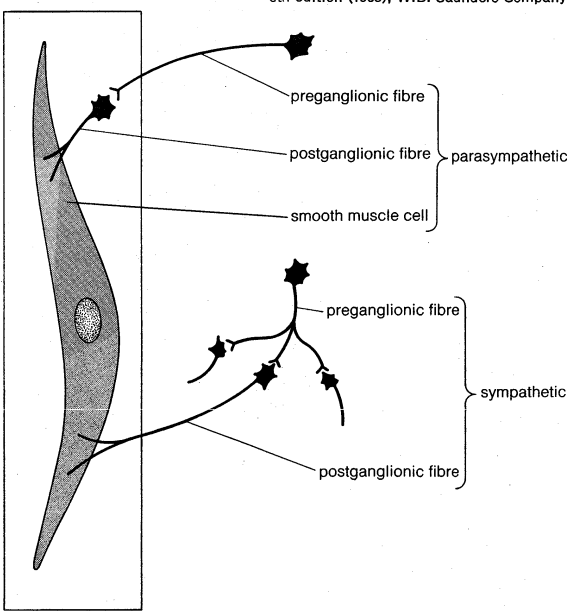

Figure 13: Differences in sympathetic and parasympathetic distribution. Sympathetic fibres synapse with many cells in ganglia of the sympathetic trunk or prevertebral plexuses, usually at some distance from the organ supplied.

later in this account (see also Table 3). Most organs are supplied by both systems, although, as indicated in Table 3, there are major exceptions. Nearly all peripheral blood vessels, for example, are supplied by the sympathetic system alone. When an organ has a double autonomic nerve supply, the two systems tend to have opposite functions. Thus, the parasympathetic system slows the heart rate, and the sympathetic increases it.

Main divisions. *Sympathetic system.* This is also called the orthosympathetic or thoracolumbar system. The nerve cells that give rise to the preganglionic fibres form a narrow column that extends throughout each side of the thoracic (chest) and upper lumbar (small of the back) parts of the spinal cord (hence the term thoracolumbar). The axons leave by way of the ventral (forward) roots of the corresponding spinal nerves. It is char-

The preganglionic fibres

acteristic of preganglionic fibres, at least in higher vertebrates, that they are small in diameter and myelinated (sheathed), whereas postganglionic fibres are still smaller in diameter and are nonmyelinated. The preganglionic fibres then reach nerve cells in nearby autonomic ganglia by way of communicating branches called rami communicantes. Most of the ganglia are contained in the sympathetic trunks, which lie one on each side of the vertebral column, extending along its whole length, from the base of the skull to the coccyx. A number of ganglia are found in the meshes of the great prevertebral plexuses, in the chest, abdomen, and pelvis, and still others comprise accessory ganglia scattered along certain spinal roots and nerves. Further details of these various arrangements are given later in this article in the sections on sympathetic and parasympathetic outflow.

Some preganglionic fibres synapse (interconnect) with nerve cells in the ganglia of the sympathetic trunks, whereas others continue through to nerve cells in prevertebral ganglia. Still others continue on to the medullae (inner substance) of the adrenal, or suprarenal, glands, where they synapse with gland cells of the medullae. Each preganglionic sympathetic fibre usually synapses with many nerve cells or medullary cells.

The postganglionic fibres that arise in the various ganglia either go directly to adjacent viscera and blood vessels or return to spinal nerves by way of rami communicantes. They usually run relatively long distances to reach the organs or tissues that they supply. Those that return to the spinal nerves are distributed by way of the peripheral nerves and supply (1) the skin with secretory fibres to sweat glands, motor fibres to smooth muscle fibres attached to hairs, (2) vasomotor fibres to the blood vessels of the limbs and trunks, and (3) motor fibres to smooth muscle and gland cells of the head and neck.

Parasympathetic system. This is also called the craniosacral system (Figure 13). The motor cells whose axons form the preganglionic fibres are found in the nuclei of origin of certain cranial nerves (listed below) and also in the sacral part of the spinal cord (hence the term craniosacral).

Cranial parasympathetic outflow

The cranial outflow is from the oculomotor, facial, glossopharyngeal, vagus, and accessory nerves (third, seventh, ninth, tenth, and 11th cranial nerves). The myelinated preganglionic fibres leave the brainstem in the corresponding cranial nerves. Those in the 11th nerve soon enter the tenth nerve and are conducted by it to parasympathetic ganglia. The fibres in the oculomotor, facial, and glossopharyngeal nerves synapse with cells in certain ganglia in the head and neck called cranial or cephalic parasympathetic ganglia. Those in the vagus nerves synapse with ganglia in the walls of the thoracic and abdominal viscera. In most instances, the postganglionic fibres are nonmyelinated; the fibres are usually rather short, and the ganglia are in or near the organ to be innervated. Moreover, each preganglionic fibre synapses with relatively few nerve cells, or just one, and the postganglionic fibres supply fewer structures than do postganglionic sympathetic fibres.

The chief parasympathetic ganglia associated with the cranial nerves are the ciliary (related to the oculomotor nerves and concerned with constriction of the pupil of the eye), the pterygopalatine and submandibular (related to the facial nerves), and the otic (related to the glossopharyngeal nerves and concerned with the secretion of the parotid salivary gland).

The motor cells comprising the preganglionic fibres issuing from the sacral part of the spinal cord form a short column of cells on each side of the middle segments of the sacral cord. The fibres leave by way of the ventral roots of the corresponding spinal nerves and reach sympathetic ganglion cells in the walls of the pelvic organs and some of the organs of the lower abdomen.

Further details of the various arrangements of the craniosacral outflow are given in the sections dealing with sympathetic and parasympathetic outflow.

LEVELS OF STRUCTURAL ORGANIZATION

As indicated before, the autonomic nervous system can be considered as if it were controlled or regulated by a series of physiological and anatomical levels that differ in function in that the higher the level, the more widespread

Table 1: Parasympathetic Ganglia Associated with Cranial Nerves

ganglion	location	parasympathetic root	sympathetic root	chief distribution
Ciliary	lateral to optic nerve	from third cranial nerve (oculomotor)	internal carotid plexus (from superior cervical ganglion)	eye and eyelid (ciliary muscle; sphincter pupillae; dilator pupillae; tarsal muscles)
Pterygopalatine	in pterygopalatine fossa	from seventh cranial nerve (facial)	internal carotid plexus (from superior cervical ganglion)	lacrimal gland and glands in oral, nasal, and palatine mucosa
Otic	below foramen ovale	from ninth cranial nerve (glossopharyngeal)	plexus on middle meningeal artery (from superior cervical ganglion)	parotid gland
Submandibular	on hyoglossus muscle	from seventh cranial nerve (facial)	plexus on facial artery (from superior cervical ganglion)	submandibular and sublingual glands

and general its functions; the lower the level, the more restricted and specific its functions. The lowest levels comprise the autonomic nervous system of classical definition.

In consideration of these levels, the general arrangement of the nervous system is notable. Certain features need to be emphasized in order to pave the way for consideration of their autonomic functions. During the course of development in the embryo, the nervous system becomes a tubular structure. This tubular arrangement is retained in the adult, though in a considerably modified form. The part of the tube in the head region develops into the brain and its various subdivisions (see Table 2), whereas the part of the neural tube that lies in the vertebral canal becomes the spinal cord. The brain and spinal cord constitute the central nervous system. The cranial and spinal nerves, their peripheral combinations, and the peripheral parts of the autonomic nervous system comprise the peripheral nervous system.

The parts of the brain

The brain, from below upward, consists of the hindbrain, the midbrain, and the forebrain, all contained within the cranial cavity. Generally speaking the Latin term *cerebrum* means "brain"; it is also used to mean specifically the forebrain and midbrain. The bulk of the brain is formed by two convoluted (or folded over) cerebral hemispheres and, lying between them, the diencephalon, or posterior part of the forebrain. The cerebral cortex, which is the thin, outer part of the hemispheres, is composed of gray matter (chiefly nerve cells, fibres, and supporting cells), in contrast to the interior of the brain, which is composed partly of white matter (consisting largely of the fibres projecting from nerve cells). The interior of the cerebral hemispheres contains not only white matter but well-demarcated masses of gray matter known collectively as basal ganglia (one of the exceptions to the general rule that collections of nerve cells in the brain and spinal cord are known as nuclei).

The diencephalon, which is composed mostly of gray matter, lies on each side of and below the third ventricle (one of several fluid-filled cavities derived from the lumen, or channel, of the embryonic neural tube; see Table 2). It forms the uppermost part of what is generally called the brainstem. This is an unpaired stalk that descends from the base of the brain and that is formed, from above downward, by the diencephalon, midbrain, pons, and medulla oblongata.

The pons and medulla oblongata, together with the cerebellum, comprise the hindbrain. The cerebellum is a large, fissured structure situated on the back of the brainstem, to which it is attached by three pairs of peduncles, or stalks. Its cortex, like that of the cerebral hemispheres, is composed of gray matter.

In their emergence from, or attachment to, the brain, the first two cranial nerves are associated with the forebrain. The third and fourth are associated with the midbrain, and the fifth to the 12th with the hindbrain.

The spinal cord

The spinal cord is a long, almost cylindrical mass of nervous tissue that occupies about the upper two-thirds of the vertebral canal. In contrast to the cerebral hemispheres, gray matter is found in the interior, somewhat in the form of the letter H, with a central canal in the bar of the H. The spinal cord has essentially the same structure throughout. Attached to the spinal cord on each side is a series of nerves, the spinal roots, named dorsal and ventral according to their position: dorsal root fibres are sensory, and ventral root fibres are motor (Figure 15). Generally, there are 31 pairs of roots on each side, which, from above downward, comprise eight cervical, 12 thoracic, five lumbar, five sacral, and one coccygeal. The part of the spinal cord to which a pair of dorsal roots and a pair of ventral roots are attached is termed a segment of the cord. Each dorsal root presents an ovoid swelling, the spinal ganglion, consisting of sensory cells conveying impulses from the periphery to the spinal cord. Distal to the ganglion (*i.e.*, beyond the ganglion in the direction away from the cord), each dorsal root combines with the corresponding ventral root to form a spinal nerve. This nerve is also connected to the adjacent sympathetic trunk by rami communicantes (Figure 15). Each spinal nerve divides into a dorsal and a ventral ramus, or branch. The dorsal rami supply the skin and muscles of the back. The ventral rami supply the limbs and the rest of the trunk. In the cervical (neck) and lumbosacral (lower back) regions, the ventral rami intermingle to form plexuses, or networks, from which peripheral nerves emerge to supply the limbs.

The various levels that control or regulate autonomic activity begin with the cerebral hemispheres, in which certain parts of the cerebral cortex and some of the basal ganglia control, regulate, or are involved in autonomic functions. These parts of the hemispheres send fibres to lower levels, especially to the hypothalamus, which is a part of the diencephalon located at the base of the brain. The hypothalamus has vascular and nervous connections

From E. Gardner, *Fundamentals of Neurology*, 5th edition (1968); W.B. Saunders Company

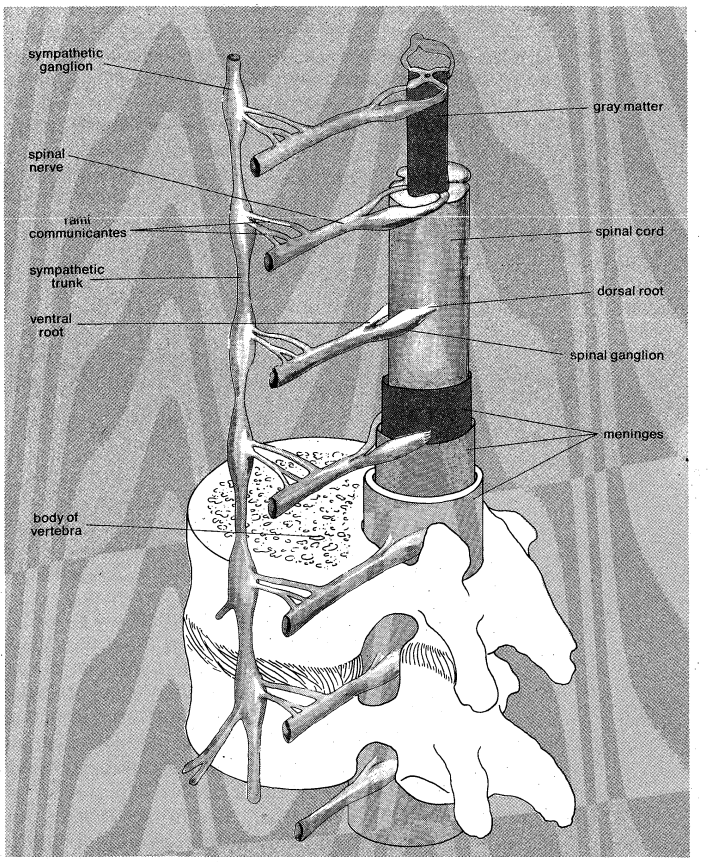

Figure 15: Diagram of the spinal cord, vertebrae, and sympathetic trunk (shown on one side only). Dorsal rami of the spinal nerves are not shown.

with the pituitary gland and also sends nerve fibres to still lower centres in the brainstem. These centres in turn send nerve fibres to the parasympathetic and sympathetic cells in the brainstem and spinal cord. The axons of these cells leave the central nervous system as preganglionic fibres to synapse at the lowest level, namely, in the sympathetic and parasympathetic ganglia. The postganglionic fibres from the cells in these ganglia are distributed to the appropriate effectors.

The purpose of the following paragraphs is to outline briefly the structural characteristics of the various levels before proceeding to a more detailed discussion of functions.

Cerebral hemispheres. As has been mentioned previously, the cerebral cortex, which is the outer part of the cerebral hemispheres, consists chiefly of nerve cells, their fibres, and supporting cells. Extensive studies have led to the conclusion that the nerve cells of the cerebral cortex are arranged in a similar pattern in all animals that have a cortex. With the exception of certain parts of the cortex that developed earlier in the evolution of the race, the nerve cells are grouped into six layers. The earliest studies of the cerebral cortex led to the naming of lobes, or subdivisions; convolutions, or gyri (ridges); fissures, or clefts; and sulci, or furrows. Subsequently, studies of cellular lamination indicated regional differences in cell density, type, and other features in the various layers. This resulted in a system of numbering (also lettering) different cortical areas, several hundred of which have been described. Some experimental and clinical studies tend to indicate specific functions for each area. While it is true that certain functional differences do exist (for example, motor areas, sensory areas, and speech areas), nevertheless, the anatomical distinctions are often not clear-cut, the connections between nerve cells are enormously complicated and not at all well understood, functional specificity is often lacking, and species differences in function are hardly understood at all.

The layers and areas of the cortex

The highest mental and behavioral activities are centred in the cerebral hemispheres, in particular the cerebral cortex. Also, the cerebral cortex controls or influences many aspects of autonomic activity, by way of connections to lower centres. There is no specific cortical region or area, however, that has as its sole function the control of autonomic activity.

The parts of the cerebral hemispheres that figure most prominently in autonomic functions include much of the cortex of the frontal lobes, certain of the basal ganglia, in particular those called the amygdaloid bodies (see below), and what is generally called the limbic lobe or limbic system.

There is as yet no general agreement as to the precise nature or extent of the so-called limbic lobe or system, sometimes referred to as limbic areas. What does seem clear is that primitive vertebrates have simple cerebral hemispheres with a single-layered cortex and that this phylogenetically old cortex—*i.e.*, this cortex that developed early in the evolutionary process—is present in higher vertebrates, including man. Together with its connections and certain phylogenetically newer structures, it comprises the limbic system (the amygdaloid bodies, each of which consists of a number of different nuclei, are often included with it). This system is found at the base of the brain, where it forms part of the frontal and temporal lobes of the hemispheres, and it borders much of the lateral ventricle (*limbus*, from the Latin, meaning "border" or "edge"). In lower vertebrates, the primitive cortex is concerned chiefly with olfaction, the sense of smell. In higher vertebrates, the structures comprising the system are still associated with this sense but in addition are involved in many other activities, including autonomic functions and certain aspects of emotion and behaviour. Indeed, the limbic system has been called the visceral brain. The term system implies a unity of structure and function that does not exist, however, and it seems likely that a more rational nomenclature will arise as connections and functions continue to be clarified.

Functions of the limbic system

The limbic system receives nerve fibres from the olfactory tracts and their connections, from the hypothalamus, and from many parts of the neocortex (the phylogenetically newer, six-layered cerebral cortex). In turn, the limbic system, especially the primitive cortex and the amygdaloid bodies, sends nerve fibres to lower centres, in particular to the hypothalamus. It is the powerful connections between the limbic system and the hypothalamus that are chiefly responsible for making possible the autonomic functions of the cerebral hemispheres.

Diencephalon. *Hypothalamus.* The hypothalamus, which is part of the diencephalon, is located at the base of the brain, where it forms the lower part of the wall of the third ventricle. Although it comprises but a small part of the brain, the hypothalamus is structurally complicated, being made up of a number of different nuclei. Some of these nuclei, particularly two that are named the supraoptic and the paraventricular, are notable for their intimate relationship to the minute blood vessels—capillaries—that form a dense network around them, for their neurosecretory functions, and for the fact that they send projections to the neurohypophysis (see below). Still other hypothalamic nuclei have projections that are closely related to the blood vessels that supply the pituitary gland (see below). These relationships between the hypothalamus and the pituitary gland comprise the mechanism by which the nervous system, especially the portions concerned with autonomic functions, can influence the production of hormones.

In spite of the fact that most of the hypothalamic nuclei have been described and named, there is not yet complete agreement on their organization, and there is strikingly little specific information about the course and destination of many of the nerve fibres leaving the nuclei. As mentioned above, some fibres go to the pituitary, and many go to the limbic system. A powerful projection is sent to the thalamus, and many fibres descend to various parts of the brainstem.

Connections with the hypothalamus

With regard to incoming fibres, nerve impulses aroused by the sense of smell reach the hypothalamus (by way of the limbic system), and it seems likely that impulses from other special senses, such as vision, also reach the hypothalamus. The neocortex is connected with the hypothalamus, chiefly indirectly by way of the limbic system, and impulses reach the hypothalamus by way of sensory pathways from all parts of the body. All of these nervous connections bring information relating to environmental changes, both external and internal. Moreover, some of the nerve cells in the hypothalamus are directly sensitive to changes in the temperature and the osmotic pressure of the blood and to levels of circulating hormones.

Pituitary gland. The pituitary gland, also known as the hypophysis, is an important endocrine organ lying mostly in the hypophysial fossa (depression) of the sphenoid bone, immediately below the brain, to which it is connected by a thin stem or stalk. The gland has a double embryological origin, developing partly from the pharyngeal (throat) region of the embryo and partly from that portion of the neural tube that gives rise to the diencephalon.

The part of the pituitary arising from the pharynx is glandular in structure and is termed the anterior lobe or adenohypophysis. This is further subdivided into so-called distal, intermediate, and infundibular parts. The anterior lobe contains different kinds of epithelial cells, all closely related to a network of blood passages called sinusoidal capillaries. These cells produce various hormones, and it is likely that a specific cell type is related to each hormone.

The anterior lobe is also characterized by a special blood supply. Briefly stated, certain arteries enter the median eminence, a ridge on the hypothalamus to which the stalk of the pituitary is attached. There they form sinusoidal capillaries. The capillaries then collect into vessels known as portal vessels, which descend into the anterior lobe and break up into a second set of sinusoidal capillaries. The latter vessels are the direct blood supply of the adjacent epithelial cells and drain into adjacent veins.

What is of major importance is the fact that nerve fibres from certain hypothalamic nuclei end in close relation-

ship to the sinusoidal capillaries in the median eminence (no hypothalamic fibres go to the adenohypophysis itself). It seems likely that the nerve cells in these hypothalamic nuclei produce substances, sometimes termed releasing hormones, that are transported down the axons to the sinusoidal capillaries and from there by the portal vessels to the anterior lobe, where they activate the epithelial cells.

The neurohypophysis

The portion of the pituitary that develops from the diencephalon is called the posterior lobe or neurohypophysis. It consists of nervous rather than glandular elements and comprises (1) the median eminence, (2) a short stalk or stem, and (3) a larger, lower part that rests in the hypophysial fossa (the median eminence is often classified as a part of the hypothalamus).

Certain hypothalamic nuclei, chiefly and perhaps entirely the supra-optic and paraventricular, send their axons down the stalk into the main part of the neurohypophysis. This part of the pituitary is considered to be a storehouse for the secretions produced by the nerve cells of the hypothalamic nuclei. These neurosecretions are transported by the axons of the cells to the neurohypophysis. Here either they are stored or they enter the bloodstream by way of adjacent capillaries. At least two hormones—vasopressin and oxytocin—reach the body by this route.

Pineal body. The pineal body or gland, also known as the epiphysis, is located at the posterior end of the third ventricle. In lower vertebrates, such as the frog, it seems to be a photoreceptor (a receptor for light stimuli, like the retina of the eye). It remains sensitive to light in higher vertebrates. In mammals, the pineal is heavily supplied by postganglionic sympathetic fibres whose varicosities are closely related to the parenchymal (functioning) cells of the pineal. In all species, the active principle of the pineal appears to be melatonin, whose function, however, may differ according to species.

Brainstem. The brainstem is formed, from above downward, by the diencephalon, the midbrain, the pons, and the medulla oblongata. It is rather similar in structure and function in all vertebrates and contains, in addition to nerve fibre tracts that descend and ascend through it, collections of nerve cells that (1) form the nuclei of origin of most cranial nerves, (2) form vital "centres" concerned with the reflex control of respiration, circulation, and other visceral activities, (3) connect with the cerebellum, and (4) are functionally associated with motor and sensory systems and mechanisms of consciousness, awareness, and sleep. A special feature is the association with pathways for some of the special senses, such as hearing, balance, and taste.

Functions of the brainstem

The diencephalic part of the brainstem has already been discussed in connection with the hypothalamus and pituitary. Those vital brainstem centres concerned with lower level, more circumscribed autonomic functions are located in the midbrain, pons, and medulla oblongata, chiefly in the last two. The centres consist of nerve cells that, in spite of the term centre, usually do not form circumscribed groups but, instead, tend to be scattered throughout the parts of the brainstem, especially the medulla oblongata. The cells receive afferent nerve impulses from higher centres (especially the hypothalamus), from the spinal cord, and from brainstem reflex paths. In turn, the constituent cells send their axons to the appropriate cells comprising the parasympathetic and sympathetic outflows. The various brainstem centres integrate and regulate a number of autonomic functions, such as blood pressure and gastrointestinal activity, and often can do so in the absence of higher control.

Cerebellum. The cerebellum is a large fissured structure that is attached to the back of the brainstem by three peduncles, or stalks, on each side. It is grossly divisible into two hemispheres and a midline connecting portion. The cerebellum is heavily supplied with input from the spinal cord, from higher centres, and from brainstem centres. In turn, it sends fibres to these regions and structures. The cerebellum has important modulating effects upon ongoing activity. While it does not of itself contain autonomic centres, most autonomic activities come under its modulating influence.

Sympathetic and parasympathetic outflow and ganglia. The sympathetic and parasympathetic cells in the brainstem and spinal cord comprise still lower and more specific levels of autonomic function. The peripheral ganglion cells to which they send axons form the lowest and most specific level of autonomic function.

As mentioned previously, the sympathetic and parasympathetic outflows are characteristically two-cell pathways. The first nerve cell is in the central nervous system, and its axon is called preganglionic. The next cell body is in a peripheral ganglion, and its axon, called postganglionic, supplies an effector. The general arrangement of this outflow, its connections with higher centres, and the structures it supplies are shown in Figure 16.

From E. Gardner, *Fundamentals of Neurology*, 5th edition (1968); W.B. Saunders Company

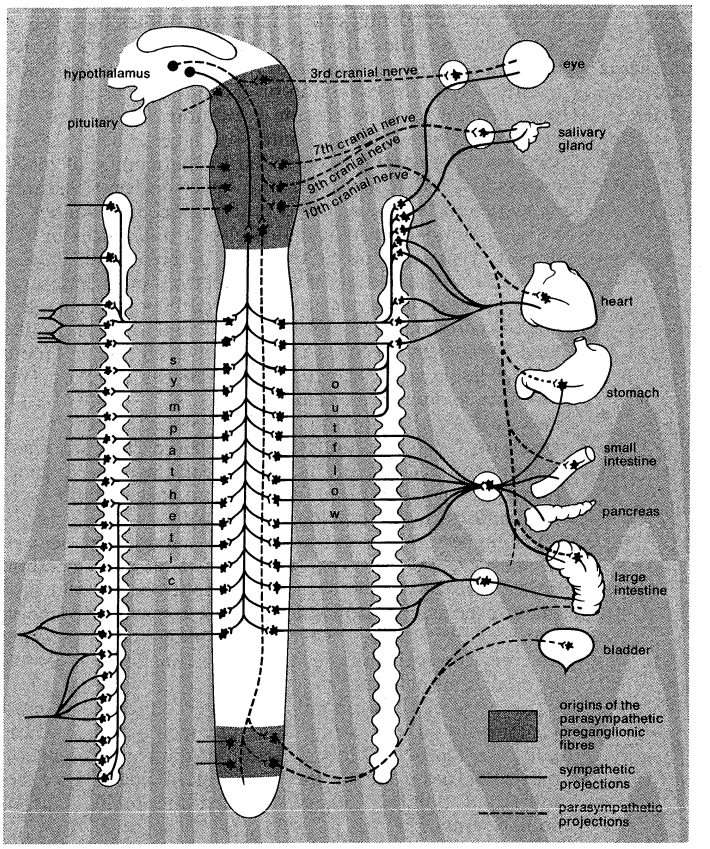

Figure 16: Schematic representation of the general arrangement of the autonomic nervous system. Autonomic fibres to the organs of the head and trunk are shown on the right side; the autonomic fibres on the left side represent the sympathetic outflow to blood vessels, sweat glands, and smooth muscle of hair follicles.

Outflow. As mentioned previously, the sympathetic outflow begins with cells that form a long column on each side of the thoracic and upper lumbar part of the spinal cord. Their axons, the sympathetic preganglionic fibres, leave by way of the corresponding ventral nerve roots, travel into the spinal nerves, and then leave the nerves by way of communicating branches, or rami communicantes. They synapse with ganglion cells in the sympathetic trunks, prevertebral plexus, or accessory ganglia or with cells of the adrenal medullae. The 12 thoracic and first two or three lumbar spinal nerves give off rami containing preganglionic fibres. All 31 spinal nerves receive rami containing postganglionic fibres from the sympathetic trunks. This means that each of the thoracic and upper lumbar spinal nerves has two or more rami communicantes. The nature of each ramus—that is, whether it is transmitting preganglionic or postganglionic fibres—is not readily ascertainable except by microscopic study. More often than not, however, the ramus that is attached to a spinal nerve more distally (further from the spinal cord) than other rami attached to the same spinal nerve

The rami communicantes

is preganglionic. This situation is of considerable practical importance to surgeons when it is necessary for them to cut the preganglionic fibres to a particular region or organ.

The columns of sympathetic cells in the spinal cord show regional differences in their distribution. For example, the cells in the first thoracic segment are the sympathetic outflow for the eye (Figure 17).

The parasympathetic outflow, as mentioned previously, has cranial and sacral parts. Both are more specifically organized than the sympathetic outflow. The parasympathetic cells of the cranial part are included in the nuclei of origin of the third, seventh, ninth, tenth, and 11th cranial nerves. The parasympathetic preganglionic fibres in the third nerve are destined for the eye; those in the seventh nerve, for the lacrimal gland, nasal glands, and salivary glands; those in the ninth nerve, for a salivary gland; and those in the tenth and 11th nerves, for viscera in the neck, thorax, and abdomen.

The preganglionic fibres in the third, seventh, and ninth cranial nerves end in certain well-defined ganglia called cranial or cephalic ganglia, from which postganglionic fibres are distributed to the various muscle cells and glands. The ganglia with which the preganglionic fibres in the tenth and 11th nerves synapse are scattered throughout the walls of the viscera. Examples of parasympathetic routes are given in Figures 17 and 18. The chief features of cranial distribution are summarized in Table 1.

Sacral portion of parasympathetic outflow

The sacral part of the parasympathetic outflow is derived from nerve cells that form a column in each half of the middle segments of the sacral part of the spinal cord (in man chiefly the third and fourth segments). The preganglionic fibres arising from these cells leave by way of the corresponding ventral roots, reach and pass through the sympathetic trunks, and emerge as the nerves known as the pelvic splanchnic nerves. These nerves enter prevertebral plexuses, chiefly the inferior hypogastric, from which fibres are distributed to the pelvic and genital organs and to the distal (most remote from the stomach) part of the large intestine (the proximal part is supplied by the vagus nerves). The ganglion cells with which the preganglionic fibres synapse are scattered in the walls of the viscera.

Ganglia. The ganglia in which the preganglionic sympathetic fibres end are complicated in structure and are incompletely understood. The nerve cells that give rise to the postganglionic fibres are multipolar and are of varying sizes and staining characteristics. A single preganglionic fibre may synapse with many ganglion cells, perhaps as many as 30. It seems unlikely that these ganglia exist solely for relaying nerve impulses, and there is evidence suggesting complicated interactions between cells. Moreover, the ganglia may contain cells of the chromaffin type (see below), whose axons also end in relation to ganglion cells. As the lowest level of autonomic function, ganglia have the most restricted or specific functions. The axons leaving the uppermost ganglion of the sympathetic chain are entirely for the supply of the face, some of the neck, and most of the cranial cavity (Figure 17).

The sympathetic trunks

The sympathetic trunks, one on each side of the vertebral column, are each a ganglionated trunk extending from the base of the skull to the coccyx. The cervical (neck) part consists of three or four ganglia connected by an intervening cord (or cords), which consists mostly of preganglionic fibres. Rami communicantes, consisting chiefly of postganglionic fibres, are connected to each of the cervical spinal nerves, and the uppermost ganglion gives off a large branch or branches (postganglionic fibres) that accompany arteries to the face and cranial cavity. The thoracic parts of the trunks commonly have 11 or 12 separate ganglia each and are connected with each thoracic spinal nerve by two or more rami communicantes. In addition, branches run to adjacent viscera; the largest of such branches are known as splanchnic nerves. The lumbar parts of the trunks are seldom symmetrical, and the lumbar ganglia are irregular in size, position, and number. Each ganglion has two or more rami communicantes and is connected to the ventral rami of two or more spinal nerves. The pelvic parts of the sympathetic trunks consist largely of preganglionic fibres; each trunk usually has three or four ganglia and ends by forming an enlargement, the ganglion impar, with the other trunk in front of the coccyx. Each pelvic ganglion tends to be connected with but one spinal nerve by rami

communicantes that consist chiefly of postganglionic fibres.

As mentioned before, many of the preganglionic fibres pass through the sympathetic trunks and are carried by branches, such as the splanchnic nerves, to the prevertebral plexuses. These plexuses lie in front of the vertebral column and are named for adjacent viscera, for example, cardiac (heart), celiac (abdominal), and mesenteric (the mesenteries are folds of membrane continuous with the membrane—peritoneum—lining the abdomen and pelvis). Sympathetic ganglion cells, with which the above-mentioned fibres synapse, occur in these plexuses. They are numerous enough so that they form ganglia, some large enough to be named. The postganglionic fibres arising from the ganglion cells go directly to adjacent viscera.

The accessory ganglia

Some of the preganglionic fibres in spinal nerves synapse in accessory (intermediate) ganglia without reaching sympathetic trunks. These ganglia are collections of sympathetic ganglion cells scattered along spinal nerves and rami communicantes, especially in the cervical, lower thoracic, and upper lumbar regions. Most of these cells send their axons into the spinal nerves with which they are associated. These ganglion cells would not be affected by usual surgical procedures (sympathectomy) designed to cut autonomic fibres and are, therefore, a source of residual autonomic function after such an operation.

The reasons for the differing locations of sympathetic ganglion cells are considered later, in the section on early development.

Finally, it must be emphasized that sensory fibres arising from viscera are contained within the various nerves. Depending upon their functions, they may reach the brainstem by way of the vagus nerves, or traverse the sympathetic trunks, reach spinal nerves by way of rami communicantes, and then the spinal cord by way of dorsal roots.

The cranial parasympathetic ganglia likewise have a complicated structure and arrangement that is incompletely understood. In general, each cranial parasympathetic ganglion has postganglionic sympathetic fibres originating in the superior cervical ganglion and passing through the ganglion, sensory fibres passing through to a cranial nerve and thus to the brain, and parasympathetic preganglionic fibres from the appropriate cranial nerve and synapsing in the ganglion. Postganglionic parasympathetic fibres are distributed to adjacent structures, as indicated in Table 1. In general, each preganglionic fibre synapses with far fewer ganglion cells than is the case with sympathetic ganglia. In general, also, no parasympathetic fibres seem to go to blood vessels, except for a few arteries to certain viscera, or to the smooth muscle and glands of the limbs and body wall. The general distribution of autonomic fibres is summarized in Table 3.

The parasympathetic ganglion cells in the walls of the thoracic, abdominal, and pelvic organs rarely form recognizable ganglia but instead are usually scattered. In the alimentary canal, however, these cells occur between the muscle layers in arrangements complicated enough to warrant the term plexuses. Moreover, there is evidence of intrinsic connections and interactions independent of the external nerve supply; these may be a factor in intrinsic activity of the organ.

Adrenal (suprarenal) glands. The sympathetic system has a special situation in that some preganglionic fibres end in relation to, or "synapse" with, certain gland cells rather than ganglion cells. The gland cells are the medullary cells of the adrenal glands and the cells of the chromaffin system.

The adrenal glands are small, paired endocrine glands; in man, they lie above the kidneys. In most animals the glands are near the kidneys but not necessarily above them.

Adrenal structure and secretions

Each gland is made up of two endocrine glands, the cortex and the medulla. The cortex, or outer substance, produces steroid hormones that are essential to life. The medulla, or inner substance, the cells of which are supplied by preganglionic sympathetic fibres and are therefore analogous to sympathetic ganglion cells, produces epinephrine and norepinephrine, also called adrenaline and noradrenaline. The effects of epinephrine are generally similar to those resulting from stimulation of the sympathetic nervous system. The sympathetic system can therefore enhance its own action, because it can stimulate the adrenal medulla and cause the release of epinephrine and norepinephrine into the circulation.

Chromaffin system. With regard to the chromaffin system, cells similar to those of the adrenal medulla are commonly found in front of the vertebrae, especially along the aorta (the major artery that conveys blood to the body from the left ventricle of the heart). These paraganglia or para-aortic bodies (which may be fairly large and constant in position), together with the adrenal medullae, constitute the chromaffin system, so named because granules in the cells stain strongly with chromium salts.

Like the cells of the adrenal medulla, most of the paraganglia secrete epinephrine or norepinephrine in response to stimulation by preganglionic sympathetic fibres. Little is known, however, of the general purpose of the chromaffin system. It is of interest that certain cells that appear to be nerve cells and that occur in sympathetic ganglia exhibit the chromaffin reaction.

EARLY DEVELOPMENT

An understanding of the early formation and development of the nervous system is essential for an understanding of the anatomy and relationships of the autonomic nervous system. The following is a brief account of such development, with emphasis on the origin of the sympathetic and parasympathetic outflow.

The entire body develops from two highly specialized cells: one, the ovum, or egg, of the female; the other, the spermatozoon, or sperm, of the male. Development begins with the penetration of an ovum by a sperm cell, thus initiating a process known as fertilization. The human embryonic period covers about the first eight weeks after fertilization. At the end of this time, during which enormous cell proliferation and differentiation occur, the embryos are in many respects like miniature adults. Differentiation is nearly completed, and subsequent changes consist chiefly of growth and maturation of structures already formed. The human fetal period, which is characterized by such growth and maturation, is normally about seven months, from the end of the embryonic period until birth.

After fertilization, the proliferation of cells soon results in a three-layered arrangement. The cells on the back, or dorsal, part of the embryo form a layer called ectoderm. The ventral layer of cells is referred to as endoderm, and the more diffuse collection of cells between the ectoderm and the endoderm is termed mesoderm. Such structures as the outer skin and the nervous system develop from the ectoderm. The skeleton, muscles, connective tissue, heart, and blood vessels are derived from mesoderm. The digestive and respiratory tracts and their glandular derivatives arise from the endoderm. This early arrangement of embryonic cells into a pattern of three germ layers is characteristic of all vertebrates.

The cells in the dorsal layer, the ectoderm, proliferate rapidly and form a neural groove and then a neural tube, which separates from the overlying ectoderm. During this separation, the junctional ectodermal cells become detached and form cells called neural crest cells. The entire adult nervous system, except for its blood vessels and certain supporting cells, is formed from the neural tube and the neural crest cells. In spite of complex changes in structure, the central nervous system remains a tube throughout the lifetime of an individual. The nerve cells that develop in the ventral part (the basal plate) of the neural tube become motor cells. The nerve cells that develop in the dorsal part (the alar plate) become associated with sensory and reflex paths. Some of the cells in the neural crest give rise to the sensory cells of the spinal ganglia. Other neural crest cells migrate, however, and, together with cells migrating from the basal plate, develop into nerve cells of the autonomic ganglia and cells of the medullae of the adrenal glands, as well as chromaffin cells. Thus, from early stages, the adrenal medullae

The neural tube and neural crest cells

are closely associated with the autonomic nervous system.

Of the migrating cells that form ganglion cells, some form accessory ganglia. Others migrate still further to the sides of the vertebra and form the sympathetic trunks. Still others proceed still more peripherally and form the ganglia of the prevertebral plexuses, the medullae of the adrenal glands, and chromaffin cells. Those cells that migrate from the brainstem and the sacral part of the neural tube form the peripheral ganglia of the parasympathetic system.

It is a matter of considerable interest and potential importance that the development and growth of the sympathetic nervous system is affected by a growth factor and perhaps depends upon it. The growth factor is a protein that can be obtained from a number of sources, including developing nervous system and mouse salivary glands. When it is injected into young chickens or mice, sympathetic and sensory ganglia enlarge, and new ones may form. An antiserum to (a serum that contains antibodies against) this nerve growth factor can virtually obliterate the sympathetic system in young mice. The factor has been studied in only a few species, and its significance in man is still uncertain, although there is preliminary evidence suggesting that it has similar effects on sympathetic ganglion cells of human fetuses.

The part of the neural tube in the head region proliferates more rapidly and forms the brain, whereas that part within the vertebral canal forms the spinal cord. That part forming the brain soon exhibits three primary enlargements, the forebrain, midbrain, and hindbrain, with the forebrain and hindbrain rapidly showing secondary enlargements. The derivatives of these various enlargements, or vesicles, are summarized in Table 2. The original cavity also persists and forms the ventricles and central canal of the adult brain.

COMPARATIVE FEATURES

Although there has been no systematic or comprehensive study of the structure and function of the autonomic nervous system on a comparative basis, involving all phyla, there is, nevertheless, a substantial amount of information about a number of features. With regard to peripheral components, for example, the study of domestic and experimental animals has led the way to what is known about synaptic transmission, both chemical and electrical, centrally and peripherally. Comparative studies have also dealt with topographic details and variations in anatomical arrangements. These details and variations are important in surgical procedures and experimental studies and in the interpretation of results. For example, in experimental studies of the nerve supply of the heart, it is essential to know the detailed anatomy. Otherwise, unrecognized species differences may result in unwarranted interpretation of results. As another example, it is notable that the relationships of the adrenal cortex and medulla show major differences according to phyla. In fish, the cortex and medulla of the adrenal are separate. In amphibians the two tissues are united but do not intermingle. In birds, and especially in mammals, the gland consists of a chromaffin medulla surrounded by a yellowish lipoidal cortex.

The purpose of these few brief paragraphs is not to provide a detailed account of comparative features but rather to emphasize the following: in spite of species differences in topography, anatomy, and local functions, the fundamental characteristics of the autonomic nervous system are similar in most vertebrates. These characteristics can be outlined as follows: cardiac muscle, smooth muscle, and glands are supplied by motor pathways each formed by two successive nerve cells, the first located in the central nervous system and the second in a peripheral ganglion. These paths have features such that the motor outflow can be divided into sympathetic and parasympathetic parts. Moreover, the motor outflow is intimately associated in all of its functions with sensory pathways and mechanisms, and itself forms the lowest of a series of levels dealing with autonomic functions, all the others being located in the central nervous system.

Fundamental characteristics of the autonomic nervous system

Most of the parts of the central nervous system concerned with autonomic functions are remarkably similar in all vertebrates, especially as regards location and general organization. The differences that do exist relate to phylogenetic and comparative levels and to differences in habitat. There is, for example, no true cerebral cortex in fish but only a single-layered cortex; this, in higher vertebrates, is found in the so-called limbic system. In following the comparative scale upward, scientists see the emergence of higher, more complex, and, at the same time, more generalized functions as related to the increasing size and complexity of the cerebral hemispheres. With regard to autonomic functions, the hypothalamus is the dominant area in the lower vertebrates and retains a major function throughout the vertebrate scale. Like the brainstem and the spinal cord, the hypothalamus in all vertebrates is similar in structural organization and anatomical details, although specific functional features obviously vary according to species. Similarly, the portal system supplying the pituitary gland, or the equivalent of a portal system, has been found in all vertebrates studied.

In general, then, the differences that occur relate chiefly to anatomical details and to specific functions. The respiratory centre in fish obviously does not function like that in mammals. The levels of sympathetic outflow differ according to species. The fine microscopic structure of ganglia and the biochemistry of synaptic transmission in ganglia may show marked differences according to phyla. Nevertheless, as mentioned above, the fundamental characteristics of the autonomic nervous system are similar in most vertebrates.

AUTONOMIC TRANSMISSION

The anatomical classification that divides the autonomic nervous system into sympathetic and parasympathetic parts is unsatisfactory in certain respects. It implies a rigid or sharp distinction between these divisions that functionally does not always exist. Also, some organs and tissues are supplied by sympathetic fibres that function like parasympathetic fibres, and others may be supplied by but one set of fibres. There is in common use another classification that is based upon the types of chemical postganglionic transmitters and upon reactions to certain drugs. In it, postganglionic fibres are called cholinergic if they release the compound acetylcholine at their terminals and adrenergic if they release noradrenaline (norepinephrine). Although this classification is also unsatisfactory in certain respects, it nevertheless is an important one. Before it is taken up in more detail, it is necessary to review briefly how nerve impulses are transmitted from one nerve cell to another or from one nerve cell to an effector. It is important to realize that much of what is known has been derived from studies of autonomic ganglia, autonomic neuro-effector junctions, and motor endings in skeletal muscle.

Cholinergic and adrenergic fibres

When a nerve impulse (a wave of transient depolarization [reversal of positive and negative poles] of the surface membrane of an axon accompanied by a transient change in membrane potential) reaches a synaptic junction or neuro-effector junction, changes occur that involve what is termed synaptic transmission or endplate (motor or neuro-effector) transmission. The precise nature of these changes depends upon the origin of the axon, the distribution and functions of its cell of origin, the existing excitability of the succeeding nerve cell or effector, and a host of other factors.

Synaptic transmission can be either electrical or chemical. Electrical synapses are more common in invertebrates than in vertebrates but in all instances seem to be less common than chemical synapses. In vertebrates, they occur in association with certain giant nerve fibres in fish, they are present in certain parasympathetic ganglia, such as the ciliary ganglia of young birds, and they may be present in the developing nervous system. Synaptic endings in electrical synapses are usually large, and the synaptic region is a tight junction. Apparently, the current flow from the nerve impulse in the axon is sufficient to depolarize the membrane of the succeeding nerve cell and cause it to fire off.

Chemical transmission

Chemical transmission occurs somewhat as follows. A specific chemical compound called a transmitter is synthesized, mostly in the nerve cell body. From there it travels down the axon, to be stored in structures called synaptic vesicles. Some synthesis may also occur in the nerve terminals themselves. When a nerve impulse arrives at the ending, it liberates the transmitter in packets termed quanta. The released transmitter then diffuses across the synaptic cleft (the very narrow space between the two cells) and combines with a substance, called a receptor, in the membrane of the succeeding nerve cell or of the effector. The term receptor in synaptic and neuroeffector transmission usually means combinations of transmitter and cell or of drug and cell that initiate a sequence of specific effects. The first is a change in the permeability of the membrane to ions (substances in solution that bear an electrical charge), resulting in a specific kind of ionic flow through the membrane, accompanied by a change in electrical potential. These changes may be excitatory; that is, they may produce a local depolarization of the membrane. This local change, either by itself or in combination with other local changes nearby, may be of sufficient magnitude and involve enough area of the membrane so that the depolarization spreads in a continuing process. In the case of a nerve cell, the change spreads outward along the axon. In the case of an effector, the result is contraction or secretion. On the other hand, the transmitter may be inhibitory; that is, it may increase the polarization of the membrane and thereby prevent discharge or stop ongoing activity. Unused transmitters may be "destroyed" by enzymatic activity, and the products of such destruction may be used in the synthesis of transmitters. Some unused transmitter may diffuse back into the axon from which it was released.

Noradrenaline and acetylcholine are excitatory transmitters in the autonomic nervous system and in certain parts of the central nervous system. Dopamine may also be a transmitter in the central nervous system. Other neurologically active substances that might be transmitters include isoprenaline, serotonin, and perhaps histamine. Much less is known about the nature of inhibitory transmitters. There is substantial evidence that one of the amino acids, gamma aminobutyric acid, is an inhibitory transmitter in the central nervous system, and it is possible that its amino-acid precursor, glutamic acid, is an excitatory transmitter.

Functions of acetylcholine

Acetylcholine. The compound acetylcholine is the chief transmitter at all autonomic ganglion cells, both parasympathetic and sympathetic, it is the transmitter at all parasympathetic postganglionic terminals and at the motor nerve endings of skeletal muscle fibres, and it is the transmitter between certain nerve cells in the brain and spinal cord. Since parasympathetic postganglionic fibres release acetylcholine at their terminals, they are classified as cholinergic fibres. Some sympathetic postganglionic fibres (to sweat glands and smooth muscle of hair follicles) also release acetylcholine and are called cholinergic.

The synthesis of acetylcholine, which requires a continuing supply of glucose and of choline (a B-complex vitamin), is dependent upon a specific enzyme, choline acetyltransferase. Once synthesized, acetylcholine travels down the axon to the axon terminals (some may be synthesized in the terminals), where it is present in several different forms, or compartments. One of these forms, called depot acetylcholine, is stored in synaptic vesicles. When acetylcholine is released from these vesicles by the arrival of nerve impulses, it diffuses across the synaptic cleft and combines with a specific receptor substance in the membrane of the succeeding nerve cell. The result of this combination is the change in membrane permeability mentioned above. Although the exact nature of the receptor substance is unknown, it seems likely that there are several forms, so that the precise action of acetylcholine depends, among other things, on the nature of the receptor substance. Moreover, there is evidence that chromaffin cells in autonomic ganglia may release noradrenaline, which then can block the action of acetylcholine or inhibit the ganglion cell.

Some acetylcholine spontaneously diffuses into the synapse cleft, and some that is released by the nerve impulse remains as excess. In both cases the acetylcholine is split into choline and acetic acid by a specific enzyme, cholinesterase, also called acetylcholinesterase. The choline becomes available for synthesis of more acetylcholine. The action of acetylcholinesterase can be prevented by a compound called eserine (also termed physostigmine), which thereby accentuates the effects of acetylcholine.

Acetylcholine is synthesized in the postganglionic neuron as in the preganglionic and is similarly stored in synaptic vesicles. When released, it diffuses across the intercellular space to the membrane of the effector, much as noradrenaline does. Here it combines with a receptor, thereby initiating the specific activity of the effector. As in the case of synaptic transmission, the complexities of the receptor are not yet fully understood.

Noradrenaline. Noradrenaline (norepinephrine), one of a group of important biogenic amines, is released at the terminals of adrenergic fibres, which comprise most postganglionic sympathetic fibres. Together with dopamine and serotonin, it is also found in high concentrations in certain parts of the brain. It seems to be present in autonomic ganglia, where its release by chromaffin cells has been postulated, but its exact role and importance here are not generally agreed upon.

Noradrenaline is synthesized in the nerve cell body and probably in the axon terminals also. It is stored in synaptic vesicles and, when released, diffuses across the intercellular space (or synaptic cleft in central nervous system synapses) to combine with a receptor in the membrane of the effector. Most of the noradrenaline released is taken up again into the nerve terminals to be stored. Some, however, is metabolized outside the cell by the enzyme catechol-O-methyltransferase, and some is metabolized inside the cell by the enzyme monoamine oxidase. The sequence of events following the release of noradrenaline may be excitatory or inhibitory, depending upon the structure or organ and its state of ongoing activity or level of hormonal activation and depending upon the species. Some of these differences may be explained by the fact that two receptors seem to be involved, one termed the alpha receptor and the other called the beta receptor. The alpha receptors have been thought, in general, to be excitatory in nature; and the beta receptors, inhibitory. There are important exceptions to this rule, however, and many aspects remain to be clarified. Noradrenaline acts chiefly on the alpha receptor; hence certain effects that it has on sympathetic activity—for example, dilatation of the coronary arteries supplying the heart—are difficult to explain. It is of considerable importance that the synthetic drug isoprenaline, which is structurally similar to noradrenaline, is the most potent mimicker of beta-receptor activity. Whether isoprenaline occurs naturally and serves as a transmitter is quite uncertain. Beta-receptor activities include dilatation of arteries supplying the heart and skeletal muscles (but not in all species), acceleration of the heart, and relaxation of bronchioles. Alpha-receptor activity is characterized by constriction of the arteries supplying the skin, abdominal organs, and heart, by dilatation of the pupil, and by relaxation of the intestine. The situation is further complicated by the fact that certain mechanisms, such as dilatation of a blood vessel, might be explained as resulting from a diminution of alpha-receptor activity as well as from an increase in beta-receptor activity. Moreover, adrenaline, which is released into the bloodstream by cells of the adrenal medulla after stimulation by the acetylcholine of preganglionic sympathetic fibres, has both alpha and beta actions. Hence, it can enhance the general actions of the sympathetic system.

Alpha and beta receptors

What emerges from the present, rather conflicting state of knowledge is that many important variables, including species differences, must be kept in mind during consideration of autonomic functions. Such functions in man, insofar as they are known, are summarized in Table 3.

As indicated by Table 3, most organs are supplied by both systems. One of the most notable exceptions has to do with blood vessels. Nearly all peripheral blood vessels

are supplied by the sympathetic system (a few vessels in the head and in the pelvis are supplied by cholinergic, vasodilator fibres, which may be parasympathetic in origin). With these few exceptions, the sympathetic system mediates both vasoconstriction and vasodilatation. One of the best examples is in connection with the coronary arteries, as mentioned previously. Similarly, the changes in blood flow associated with constriction and dilatation are important components of temperature regulation, mentioned earlier in this article. It is difficult to explain dilatation solely on the basis of a relaxation of vessel walls after a decrease in sympathetic activity. Constriction seems much more related to alpha-receptor activity, and dilatation to beta-receptor activity.

Neuropharmacology. Much of the present knowledge of the autonomic nervous system has been obtained through the experimental use of a variety of important drugs, many of which bring about profound physiological, behavioral, and emotional changes because of their effects on metabolism and synaptic transmission. A number of these drugs can be classified according to the kinds of autonomic effects they have. These effects can be considered according to whether they are chiefly parasympathetic or sympathetic in nature or can involve ganglionic transmission.

Muscarinic and nicotinic effects

A number of drugs act on the parasympathetic postganglionic terminals or the neuro-effector junction or the effector, in a manner resembling that of acetylcholine. One such drug is muscarine, which acts on the smooth muscle of viscera much as acetylcholine does; the actions of acetylcholine at postganglionic terminals are often called its muscarinic action. This action is blocked by atropine, which can be a severe poison. The drug nicotine stimulates autonomic ganglion cells when applied to the cells in low concentrations, but in high concentrations it depresses or blocks transmission. Acetylcholine acts similarly, and its properties as a ganglionic neurotransmitter are known as its nicotinic effects. Muscarine is termed a parasympathomimetic drug—that is, one that, when administered, stimulates or inhibits autonomic effectors as in parasympathetic postganglionic stimulation. In general these drugs include acetylcholine and some of its derivatives, alkaloids such as pilocarpine and muscarine, and a variety of anticholinesterases such as eserine. Many are produced synthetically, and many may have central actions also.

Sympathomimetic drugs stimulate or inhibit effectors as in sympathetic postganglionic stimulation. These drugs often have profound effects on the central nervous system also. Some of them are the biogenic amines that are also normal autonomic components, namely noradrenaline, adrenaline, isoprenaline, and dopamine. When administered, they act directly on alpha or beta receptors or on both. A number of other drugs that are also sympathomimetic, including amphetamine, cocaine, and ephedrine, act by bringing about the rapid release of stored noradrenaline in a physiologically active form. Because this release occurs in the central nervous system also, the accentuation of noradrenaline functions brings about profound behavioral and mood changes. Amphetamine is a notable example of a drug that has serious central nervous system effects brought about by the mechanism just outlined. It is of interest that another drug, reserpine, likewise brings about the release of noradrenaline, but much more slowly, so that it is deaminated (is caused to lose its amino fraction) by monoamine oxidase within the nerve cell and is released in a physiologically inactive form. The result is an induced behavioral depression and is the basis for the use of reserpine as a tranquillizer.

Monoamine oxidase inhibitors

Also sympathomimetic are the drugs that inhibit monoamine oxidase. As mentioned previously, this widely distributed enzyme is responsible for the intracellular degradation of noradrenaline. It likewise degrades adrenaline and dopamine, and by deamination it inactivates 5-hydroxytryptamine (serotonin). The inhibitors are a heterogeneous group of drugs that by blocking the actions of monoamine oxidase cause enhancement of sympathetic and serotonin activity.

Finally, there are drugs that produce synaptic and effector blockade. They may block transmission in autonomic ganglia; examples include certain quaternary ammonium compounds, as well as anesthetics such as ether, and compounds such as nicotine in high concentration. Peripherally, some drugs compete with acetylcholine at the receptor site; that is, they have an antimuscarine effect. Examples are atropine and scopolamine. Some drugs prevent the release of transmitter; an example is guanethidine, a powerful drug for combatting high blood pressure. Others block the effects of noradrenaline directly at either the alpha- or the beta-receptor sites. Examples of an alpha-receptor blocking drug are the ergot alkaloids (which have other actions also) and thymoxamine. Beta-receptor blocking agents include the compound propranolol.

GENERAL AND INTEGRATIVE FUNCTIONS OF THE AUTONOMIC NERVOUS SYSTEM LEVELS

The specific motor effects of the autonomic nervous system upon various organs are summarized in Table 3.

Table 3: Chief Functions of the Autonomic Nervous System in Man

organ	parasympathetic symptom	sympathetic symptom
Eye	stimulates ciliary muscle and sphincter pupillae—pupillary constriction to light and during accommodation	stimulates dilator pupillae and possibly radial fibres of ciliary muscle—pupillary dilatation
Lacrimal, nasal, palatine, and salivary glands	stimulates secretory cells—serous and mucous secretions	no important effect
Heart	inhibits intrinsic cardiac activity—heart rate slows	stimulates intrinsic cardiac activity—heart rate increases
Tracheobronchial tree	stimulates secretory cells and smooth muscle—serous and mucous secretions, narrowing of bronchioles	inhibits smooth muscle—relaxation of bronchioles
Alimentary canal	stimulates secretory cells and smooth muscle—digestive secretions, peristalsis, evacuation	inhibits smooth muscle—decreases peristalsis
Liver and pancreas	stimulates pancreatic cells (effect on liver unknown)	no important effect
Adrenal medulla	no effect	stimulates secretory cells—secretion of epinephrine
Urinary bladder	stimulates smooth muscle (detrusor)—emptying of bladder	no effect on emptying; may activate internal sphincter during ejaculation
Genital organs	uncertain and variable; may stimulate smooth muscle and glands; vascular dilatation	uncertain and variable; may stimulate vasoconstriction
Blood vessels	no important effect on most blood vessels	constriction and dilatation
Sweat glands	no effect	stimulation of secretory cells, mostly by cholinergic fibres—sweating
Arrectores pilorum	no effect	stimulation of smooth muscle, mostly by cholinergic fibres—erection of hair

These actions are important components of the general, more complex mechanisms of homeostasis, as well as of the outward expressions of emotions and behaviours. As mentioned previously, homeostasis is the maintenance of the internal environment; for example, body temperature, fluid balance, and ionic composition of the blood. In helping to carry out these functions, the two divisions of the motor outflow, sympathetic and parasympathetic, exhibit distinctive functional attributes. These are outlined briefly before the functions of the various levels are described.

The sympathetic system tends to respond as a whole, especially during emergencies or sudden environmental changes, and is therefore an important part of the mechanisms by which one responds to stress. Among the situations that cause stress are pain, rage, fright, exercise, cold, many drugs, and asphyxia. All of these may evoke similar patterns of response. For example, a stressing situation that results in rage or fear may also result in a rapid increase in blood pressure, pulse rate, heart output, sweating, and blood sugar; all are changes designed for "fight or flight." These acute responses to stress result

Responses to stress

from sympathetic discharge initiated by cortical and hypothalamic activity. They are generalized and widespread because of the organization of the system (for example, one preganglionic fibre synapses, or interconnects, with many ganglion cells) and also because the medullary cells of the adrenal glands are stimulated, causing epinephrine to be released into the bloodstream. Epinephrine may maintain or enhance many sympathetic activities.

In addition to the acute responses to stress, there may be more slowly developing changes in metabolic activities and defense mechanisms. These are brought about by the activation of the hypothalamic–pituitary system, leading to an increased secretion by the pituitary of adrenocorticotropic hormone. This acts on the cortex of the adrenal glands, leading to a greater output of the cortical steroid hormones, with changes in metabolic activities and cellular composition of the blood.

Characteristic functions of the parasympathetic system

The parasympathetic system is concerned with the initiation and maintenance of a number of specific functions, such as digestion, intermediate metabolism of foods, and excretion. These actions are usually initiated in response to specific stimuli; hence the necessity for specific anatomical arrangements and reflex pathways. Widespread connections such as are characteristic of the sympathetic system would interfere with, or make impossible, the specific parasympathetic functions. Widespread, generalized parasympathetic actions can occur, but they are often abnormal responses to unusual situations, such as bladder and bowel evacuation during unusual stress.

Cerebral hemispheres. The highest mental and behavioral activities characteristic of man take place in the cerebral hemispheres, particularly the cerebral cortex. Some cortical areas control muscular activity; others are concerned with sensory perception, and still others with speech mechanisms and association and integration. No region of the cortex is specifically and solely involved in autonomic activity, however. Rather, when the cortex controls, regulates, or activates a visceral function, it does so during the course of some other activity. For example, cortical activity leading to muscular contraction—a voluntary activity—also brings about an increase in blood flow in the contracting muscles—an instance of autonomic activity. Many other examples of participation in local autonomic mechanisms could be provided, all of them mediated by cortical projections to the diencephalon and brainstem. As concerns the present article, what is of particular importance is the integrated role of cortico-diencephalic mechanisms in emotional behaviour.

Emotions and behaviour. There is as yet no completely satisfactory theory or experimental formulation of emotional behaviour. It is known that the cortico-diencephalic mechanisms, including the limbic system, control or activate a wide variety of somatic and autonomic phenomena closely related to the broad range of behavioral activities customarily associated with emotional expression. Within these complex, overlapping, highly integrated mechanisms, the cortex can be viewed as the "high-level mediator," probably suppressing or inhibiting many outward expressions of behaviour (sham rage can be elicited in animals with much of the cortex removed). The diencephalon, in particular the hypothalamus, activates, controls, and integrates the peripheral mechanisms that bring about the bodily changes associated with emotional behaviour, namely, autonomic, somatic, and endocrine activities.

Effects of emotional upsets

The cortico-diencephalic mechanisms have important implications for disorders of behaviour. There is no autonomic activity that cannot be modified, or even completely disorganized, by emotional upsets. Beginning with what is usually considered relatively "normal," one can cite blushing. This is a sudden dilatation of blood vessels, usually but not always limited to those of the face, in response to an emotional situation, or the memory of one. Fright, anger, or apprehension may completely upset digestive processes and, at the same time, may cause blood pressure to rise and heart rate to increase. Students are well acquainted with such phenomena before examinations; speakers may know them as stage fright.

Dramatic behavioral changes may follow removal of various parts of the cortico-diencephalic mechanisms. Loss of cortex from certain parts of the frontal lobes of the brain may be followed by marked alterations of affective behaviour often known as "changes in personality." Temporal-lobe damage may be followed by docility and compulsive behaviour. Lesions of the amygdaloid bodies have likewise been associated with docility (taming of wild animals) and also with hypersexuality. Other symptoms include hallucinations, disordered recognition, disturbances of reality, sensory fits, and psychomotor epilepsy. In nearly all of these situations or conditions, a significant component is disordered autonomic function.

It is of interest that there seems to be a fairly constant relationship between the biogenic amines, which are also transmitters or related to transmitters, and the affective or behavioral states. Norepinephrine is found in high concentrations in certain parts of the brain, such as the hypothalamus. Drugs that depress or inactivate norepinephrine centrally cause sedation. The converse is generally associated with stimulation or excitement. For example, the amphetamines are used as psychic stimulants. They release physiologically active norepinephrine from nerve cells (and may also block its inactivation). Similarly, and as mentioned previously, reserpine interferes with the intraneuronal binding of catecholamines and serotonin, causing them to be released slowly and to be inactivated by monoamine oxidase. The result is a depression; hence the use of reserpine as a tranquillizer. It is clear, therefore, that many drugs with profound psychic and behavioral effects bring about these effects by acting upon central and peripheral autonomic structures and mechanisms, especially the transmitting systems.

Conditioned responses. The modification of behaviour on the basis of past experience is thought to be primarily a function of the cerebral cortex, although obviously requiring the participation of many other neural structures and mechanisms. It is now known that, contrary to past, indeed current, beliefs, many visceral responses can be learned. This is important for an understanding of the functions of the autonomic nervous system and normal homeostasis and for the cause and cure of abnormal psychosomatic symptoms. It also has major implications for theories of learning. How the learning of visceral responses is studied requires a brief description of conditioning.

Unconditioned and conditioned reflexes

The sight or smell of food may be as potent a stimulus for salivation as is taste. The objective response—salivation—which is an autonomic response activated by parasympathetic fibres to salivary glands, is present in newborn infants, but only later do sight and smell induce salivation. Salivation in response to taste is an unconditioned reflex, brought about by the stimulation by taste fibres of the cells of origin of the parasympathetic fibres in the third cranial nerve.

Many unconditioned reflexes may be modified by, or adapted to, new stimuli. The sound of a bell is not ordinarily followed by salivation; yet it is well-known that, if an animal is given food, or if a mild acid is placed in its mouth so that salivation occurs, and if this is accompanied or shortly preceded by another stimulus such as the sound of a bell, after repeated trials the sound alone may induce salivation (an example of the type of conditioning that is called Pavlovian). This is a conditioned response—an increase in salivary-gland activity in reaction to an auditory stimulus.

Conditioned responses generally have to be reinforced. In classical, or Pavlovian, conditioning, which is generally thought to be involuntary, the reinforcement must be by an unconditioned stimulus that already elicits the specific response to be learned. In the conditioning called operant conditioning or trial-and-error or instrumental learning, which is believed to be responsible for voluntary behaviour, the reinforcement is a reward that has no natural relationship to the response. This reward can strengthen any immediately preceding response.

Rigorously controlled studies have shown that visceral responses can be learned through both classical and operant conditioning. An example is the psychogalvanic re-

Psychogalvanic reflex

flex. This is an increase in sweating (mediated through sympathetic fibres to sweat glands) during emotional states. Where it occurs, as in the hands, resistance to the flow of an electrical current decreases, roughly in proportion to the amount of sweating. Thus, the response can be measured in a way that tends to furnish objective evidence of emotional reaction. In classical conditioning, this reflex can be tied to a stimulus that does not normally elicit it. In operant conditioning, this reflex and many other autonomic activities (including heart rate and salivation) can be learned; that is, brought about by the subject in order to obtain a reward or some desired change. It must be emphasized, however, that the mechanisms involved in conditioning, whether classical or operant, somatic or visceral, are still obscure.

Diencephalon. *Hypothalamus.* As has been mentioned previously, the hypothalamus is that part of the corticodiencephalic mechanisms that activates, controls, and integrates the peripheral autonomic mechanisms, endocrine activity, and many somatic (bodily) functions. For example, it is known to regulate water balance, body temperature, the development of secondary sex characteristics, sleep, and food intake. These functions will be illustrated by brief discussions of a major function carried out by hypothalamic projections to the brainstem and of functions mediated by hypothalamic control of the pituitary gland.

In the regulation of body temperature, described earlier in this article, changes in external temperature stimulate nerve receptors in the skin. The resulting nerve impulses reach the spinal cord and brainstem, where they initiate local reflexes. They also ascend and reach the hypothalamus, where they activate nuclei that initiate a range of activities designed to conserve heat. In addition, certain cells in the hypothalamus are directly sensitive to changes in temperature of the blood that flows through the area in which the cells are located. The overall result is that, if the external temperature drops, some hypothalamic nuclei initiate or regulate the sympathetic activities necessary to prevent heat loss. The converse occurs if the external temperature rises. Under more extreme conditions of cold, metabolic processes would be initiated to increase the production of heat (hypothalamic activation of the pituitary cells that produce the thyroid-activating hormone). The thyroid gland regulates the general metabolic level and, when rapid increase in heat production is necessary, can bring about the characteristic contractions of skeletal muscle called shivering. In other words, the hypothalamus acts as a thermostat. Under normal conditions, these various mechanisms, under the control of the hypothalamus, brainstem, and spinal cord, maintain body temperature within a degree or less of 98.6° F (37° C).

The stages of fever

The balanced maintenance of body temperature may be altered in a variety of ways, as when one has a fever, a common sign of a bacterial infection. Bacterial toxins alter the sensitivity of the hypothalamic cells so that they operate as if the thermostat were set at a higher level. For the body temperature to rise to this new level, the processes of heat retention are started. Cutaneous vessels constrict, and shunt vessels open, thus reducing the loss of heat by radiation. This may be accompanied by a subjective sense of coldness. Shivering may occur, thereby increasing heat production. The chills that may signify the onset of fever consist of shivering, plus the sensation of cold. Body temperature rises because more heat is produced than is lost. When the new level is reached, compensatory processes occur. More heat is lost, as evidenced by flushing (dilatation of cutaneous vessels). The fever does not drop, however, until the infection is over and hypothalamic cells begin to return to normal.

That the phenomena associated with fever are the result of altered hypothalamic sensitivity is shown by the fact that surgical operations in or near the hypothalamus may be followed by marked changes in body temperature, probably as a result of direct damage to hypothalamic cells. The postoperative rises or falls of temperature may be so extreme that the patient may die.

Neuroendocrinology. The hypothalamic–pituitary mechanisms comprise most of what is termed neuroendocrinology. It is through these relationships that the central nervous system can influence or regulate all endocrine activities. Among the important ones are intermediate metabolism, growth, electrolyte balance, reproduction, and the development of secondary sex characteristics. The activity of the hypothalamus in these mechanisms can be initiated by nerve impulses from many sources (for example, the special senses—sight, hearing, and so on) and by a variety of conditions in the blood, including temperature, osmotic pressure, and level of circulating hormones.

The hypothalamic nuclei that control the anterior lobe of the pituitary—the adenohypophysis—do so by synthesizing substances that enter the portal system and activate the glandular cells of the pituitary. These cells produce at least seven hormones: growth hormone, thyroid-stimulating hormone, adrenocorticotropin, prolactin, follicle-stimulating hormone, interstitial-cell-stimulating hormone, and melanocyte-stimulating hormone. These hormones, when released into the bloodstream, can activate their target organs or cells. The substances produced by the target organs, when released into the bloodstream, can, in addition to their primary actions, inhibit the pituitary. This is a feedback mechanism that provides regulating control. Moreover, some of the hypothalamic cells are also directly sensitive to, and regulated by, circulating substances from target organs, in particular, ovarian hormones.

Destruction of the hypothalamus, like destruction of the pituitary, produces profound endocrinological changes; these include changes in the skeleton, the sex glands, and metabolism.

Antidiuretic hormone and oxytocin

The two hypothalamic nuclei from which axons extend to the neurohypophysis produce the antidiuretic hormone and oxytocin, the antidiuretic chiefly from the supra-optic nuclei and oxytocin chiefly from the paraventricular.

The antidiuretic hormone is also known as vasopressin ("vessel-constricting substance"), although it produces a rise in blood pressure through activation of vascular smooth muscle only when given in high doses. The chief function of this hormone is to act on the tubules of the kidney in such a way as to decrease production of urine. It thus constitutes an important means of conserving body water. It is of interest that the cells of the supra-optic nucleus are directly sensitive to the ionic concentration and osmotic pressure of the blood. Changes in these features undoubtedly alter the activity of the nucleus. If the nucleus or its projections are destroyed, a disorder known as diabetes insipidus results. Because of the loss of antidiuretic hormone, large quantities of urine, amounting to many litres, are eliminated by the kidney each day. In order to maintain balance, large amounts of water must be drunk.

In mammals, including man, oxytocin acts chiefly on the smooth muscle of the uterus and also on certain smooth muscle cells of the mammary gland known as myo-epithelial cells. In the case of the uterus, the hormone is particularly effective during the later stages of pregnancy, and especially during parturition. It is often used as an aid in labour. In the mammary gland, it activates the special smooth muscle cells that cause the ejection of milk (the formation of milk is regulated by the hormone prolactin from the adenohypophysis). The release of oxytocin from the neurohypophysis is triggered by the act of suckling; the nerve impulses aroused in sensory endings in the nipple reach the spinal cord and ascend in the brainstem to the paraventricular nuclei of the hypothalamus.

Pineal body. Because of vast species differences, there is as yet no complete agreement on the functions of the pineal body, and many questions remain to be answered. Nevertheless, certain features have been clarified. In mammals, the gland is rich in noradrenaline, serotonin, and histamine. Activity of sympathetic postganglionic fibres, brought about by a decrease in the level of light, results in the release of melatonin. It is still uncertain whether this hormone inhibits or promotes the action of the melanin-stimulating hormone of the pituitary. Beyond this, however, melatonin seems to have an effect

upon the sex glands and, under certain conditions of overproduction may cause them to atrophy.

Autonomic functions of brainstem cells

Brainstem. The brainstem is concerned with the regulation of many specific visceral functions. For example, groups of nerve cells that are scattered throughout the pons and medulla oblongata form respiratory, vasomotor (blood-vessel-contracting or blood-vessel-dilating), and cardiac "centres." Still other groups of cells are concerned with intestinal movements, control of the pupillary diameter, swallowing, salivation, and so on. These centres are functionally restricted in the sense that the respiratory centres have no specific vasomotor or cardiac functions, although they may affect their activity. But the hypothalamus, which sends fibres to both, may control or activate them simultaneously, as when respiration and blood pressure increase during emotional states. The various centres also function on an integrated reflex level, as in the control of blood pressure (see below). Moreover, as in the case of respiration, which involves skeletal muscles, the centres are often coordinated with somatic mechanisms.

An idea of the importance of the cerebral cortex and hypothalamus as higher levels and of how the brainstem functions can be gained by studying a decerebrate animal—*i.e.*, one in which all of the brain above the level of the midbrain is destroyed or removed or isolated by a cut through the midbrain. Such an animal, even a human being, may still live. Breathing is carried on, and blood pressure is maintained reflexly at a fairly normal level. The animal, however, is unconscious, cannot eat, maintains body temperature poorly, if at all, and shows abnormal skeletal and autonomic reflexes.

Control of blood pressure. In the walls of the bifurcation (branching) of the common carotid arteries in the neck, and also in the wall of the arch of the aorta in the chest, there are nerve endings that are sensitive to changes in blood pressure. Those in the carotid arteries comprise what is termed the carotid sinus. These endings are all sensitive to the mechanical stimulation of distension caused by an increase in blood pressure. The nerve impulses resulting from such an increase ascend in visceral afferent (sensory) fibres in the vagus and glossopharyngeal nerves to the medulla oblongata and reach the cardiac and vasomotor centres. Connections of these centres to the vagus nerves cause motor impulses (parasympathetic) to descend in these nerves (via preganglionic fibres) to the heart, which they inhibit, thereby slowing its rate of contraction. At the same time, other nerve impulses from the centres descend to the spinal cord. Here they act upon cells whose preganglionic fibres in the sympathetic system control the diameter of the peripheral blood vessels, causing them to dilate. The resistance of these dilated blood vessels to the flow of blood decreases, and blood pressure drops. This may be likened to widening the nozzle of a garden hose, as a result of which the force of the stream of water decreases. With the decrease in blood pressure, fewer nerve impulses reach the brainstem centres, and the process lessens or reverses. The blood pressure then rises as peripheral vessels narrow and the heart rate increases. Under resting conditions, then, there is continually a slight shifting back and forth between rising and falling pressures. The net result is a finely balanced and integrated activity whereby blood pressure is reflexly maintained at an average level.

Slowing of the heart and dilatation of vessels

It is to be noted that, in a spinal animal (an animal in which the junction of the spinal cord and medulla oblongata is severed), neither blood pressure nor respiration can be reflexly maintained. Artificial respiration is necessary to maintain life.

Control of respiration. Respiration is also reflexly controlled. Although the muscles of respiration are skeletal in type, they are not completely under voluntary control; no one can voluntarily hold his breath to the point of asphyxiation. The control of respiration has been studied in experimental animals, but it is likely that the processes are generally similar in all mammals, including man.

Nerve cells scattered throughout the pons and medulla oblongata comprise the so-called respiratory centres. The axons of these cells project to the upper (cervical) part of the spinal cord, where they synapse with the nerve cells whose axons supply the other muscles of respiration.

Many of the above cells in the brainstem respiratory centres are intrinsically active; that is, they continuously maintain a repetitive discharge to the motor cells of the spinal cord. This intrinsic activity, however, is modified by sensory impulses and other factors so as to produce a rhythmic discharge, leading to a rhythmic pattern of breathing. The modulation is brought about as follows. When the lungs expand during inspiration, nerve endings in the lungs are stretched and stimulated. The nerve impulses that result ascend in the vagus nerves to the active cells, which they inhibit. In addition, a small mass of tissue called the carotid body, at the bifurcation of the common carotid arteries in the neck, contains nerve endings that are sensitive to changes in gaseous tensions of the blood flowing through the carotid bodies. The resulting nerve impulses ascend along sensory fibres in the glossopharyngeal nerve and reach the respiratory centres, where they have reflex connections and effects. For example, an increase in carbon dioxide tension in the blood reflexly results in an increase in the rate and depth of respiration, thereby blowing off the excess carbon dioxide. Finally, the cells in the respiratory centres themselves are directly sensitive to the concentration of carbon dioxide in the blood.

Action of the carotid body

What is of particular interest is that the reflex control of respiration is coordinated with the reflex control of blood pressure. For example, inspiration, which is characterized by an increase in chest volume and a decrease in pressure within the chest, is accompanied by an increased return of blood to the heart, necessitating an increase in cardiac output. The vascular reflexes initiated by the increased return of blood to the heart are coordinated with the respiratory reflexes to bring about the appropriate changes in the activity of the heart. This is an excellent example of the coordination of somatic, sympathetic, and parasympathetic functions to bring about an integrated reflex control of a vital function.

Control of movements of the alimentary canal. When food enters the mouth and is tasted and smelled, saliva begins to flow into the mouth. Its contained enzymes begin the digestion of certain constituents of the food. The salivation is a reflex act, the motor side of which is parasympathetic. When the food is swallowed, other reflexes are initiated. The impact of the food upon the walls of the pharynx stimulates nerve endings in the walls. The resulting nerve impulses reach the medulla oblongata over sensory fibres in the vagus and glossopharyngeal nerves. In the medulla oblongata, the impulses activate nerve cells comprising special centres, and these in turn activate the motor nuclei of the glossopharyngeal, vagus, and accessory nerves, as well as other brainstem centres. There is thus set into play a complex series of mostly involuntary actions, as follows.

The palate and the upper part of the pharynx constrict so as to prevent food from entering the nasal cavity. The upper part of the larynx, or voice box, constricts so as to prevent food from entering the passage to the lungs. The muscles just around the mass of chewed food contract, whereas those just ahead of it (below it) relax to receive it. This wave of contraction, preceded by a wave of relaxation, proceeds from the pharynx into the esophagus and thence into the stomach. The timing of this mechanism is intricate, especially in view of the fact that initially the contraction involves striated muscle fibres, but, from the middle of the esophagus on, smooth muscle is involved. Hence, the impulses descending in the vagus nerves to the smooth muscle in the esophagus now travel along parasympathetic preganglionic fibres. Also, impulses descend to the spinal cord to sympathetic fibres and thence to the esophagus, where they inhibit smooth muscle. This inhibition is evidenced as the wave of relaxation.

A wave of relaxation preceding a wave of contraction together comprise what is known as peristalsis. One of the fundamental types of movements of the alimentary canal, it propels contents, whether solid, semisolid, or liquid.

Definition of peristalsis

Additional complexities in the coordinated mechanisms

described briefly above are indicated by the fact that secretory phenomena involving digestive enzymes are usually taking place at the same time. Many of these are initiated or affected by parasympathetic activity.

Movements of the alimentary canal may be in the reverse direction, as in vomiting. The act of vomiting is brought about chiefly by the simultaneous contraction of the external abdominal muscles and the diaphragm, thereby increasing the intra-abdominal pressure and forcing movement of intestinal contents in the direction of the mouth. It is not known whether a special brainstem centre controls vomiting. Vomiting may be reflexly induced, however, by nerve impulses that result from irritation of the mucous membrane of the stomach, by putrid odours, and so forth. Also, there is a drug, apomorphine, that, when given, apparently acts directly on brainstem cells and induces vomiting. Finally, brainstem damage, for example, from an increase in intracranial pressure, may cause vomiting.

Cerebellum. Little can be added to what was said previously about the cerebellum. This important organ regulates and coordinates all muscular activity, and its influence extends to virtually all autonomic functions. Presumably, the modulation is carried out by way of cerebellar nerve fibres that extend to the diencephalon, brainstem, and spinal cord.

Sympathetic and parasympathetic outflow. The organization, arrangement, and connections of this autonomic outflow have already been described, and some of the specific functions are listed in Table 3. What remains is to illustrate how local and restricted functions can occur, as exemplified by certain reflexes and by a consideration of the autonomic functions of an isolated spinal cord. A common brainstem reflex is parasympathetic-mediated salivation in response to the taste or smell of food. Another example relates to alteration of the diameter of the pupil. If a light is flashed in the eye, the pupils of both eyes narrow, thereby restricting the amount of light that can enter. The nerve impulses that are initiated in the retina by the light travel along fibres of the optic nerve. Some of these fibres enter the brainstem; there, after several synaptic connections, impulses reach the cells from which parasympathetic preganglionic fibres in the third cranial (oculomotor) nerves originate. Impulses over these fibres then reach and activate the constrictor muscle of the iris (the second, or postganglionic, neuron is in the ciliary ganglion). The converse, a widening of the pupils, may result from inhibition of this parasympathetic pathway but may also be due to an activation of the dilator muscle of the iris by the sympathetic system. The cells from which the preganglionic sympathetic fibres originate are in the upper part of the thoracic cord; the postganglionic fibres originate in the superior cervical sympathetic ganglion and ascend along the carotid arteries and their branches to the eye.

Response of pupils to light

Local autonomic reflexes in the spinal cord are clearly demonstrable when the spinal cord is severed (the transection must be at the lower cervical segments, or lower, if respiration is to continue and life be maintained). A study of such injuries in man as well as in lower animals has given some insight into the autonomic functions of the spinal cord. As has been mentioned before, they are characterized by their restricted nature.

Transection of the spinal cord is immediately followed by spinal shock during which all functions, including the autonomic, are depressed. As the spinal shock begins to disappear, evidences of sympathetic activity begin to reappear. Cutaneous blood vessels begin to show reflex reactions, and sweating may be reflexly induced. After full recovery from spinal shock, stimulation of the skin may be followed by mass reflexes accompanied by widespread reflex sweating. Blood pressure is unstable and is poorly controlled reflexly, and body temperature in the affected parts is also poorly maintained.

Of particular importance are autonomic activities related to the bowels and the urinary bladder. The rectum and large intestine may gradually develop reflex emptying mechanisms that, in part, involve parasympathetic fibres from the sacral portion of the spinal cord. The sensory stimulus for evacuation seems to be distension of the rectum. The resulting nerve impulses reach motor cells and parasympathetic cells in the sacral portion of the spinal cord. The result is a contraction of the sigmoid colon and the rectum and relaxation of the sphincters of the anal canal.

The urinary bladder

The urinary bladder may function almost automatically and become what is called a "cord bladder." It tends to fill and empty spontaneously. An increase in pressure in the bladder as urine flows into it from the kidneys stimulates nerve endings in the bladder wall. The resulting nerve impulses reach parasympathetic cells in the sacral portion of the spinal cord. The nerve impulses leave over preganglionic fibres and reach the bladder wall, where the ganglion cells are located. The postganglionic fibres activate the smooth muscle of the bladder. At the same time the urethras contract, as do the external abdominal muscles; these increase the intra-abdominal pressure, resulting in emptying of the bladder.

In a man whose spinal cord has been severed at its junction with the medulla oblongata, sexual functions are also interfered with. Psychic stimuli are unable to influence sexual activity. There appear to be mechanisms in the lumbosacral part of the cord, however, that, especially in males, can produce integrated sexual activity, not only after direct stimulation of the external genitalia but frequently after any type of cutaneous stimulation.

The peripherally located autonomic ganglia are still more restricted in outflow and function. Moreover, so far as is known, no reflex connections of any physiological significance are established within them, although their complex structure certainly indicates that they have more than a simple relay function (see previous discussion), both in terms of preganglionic–postganglionic ratios and distribution and in terms of transmitter mechanisms.

If the preganglionic fibres to a specific ganglion are cut, the structures supplied by that ganglion are effectively denervated. However, these structures may not show any altered sensitivity. If a ganglion is removed, or its rami (branches) to peripheral nerves cut, the denervation is likewise complete (postganglionic sympathectomy). In this instance, however, the structures supplied may show altered sensitivity to circulating substances.

If a peripheral nerve is cut, postganglionic fibres in it are severed, just as in the case of removal of a ganglion or its rami. Depending upon the type of nerve, there will be sensory deficits, paralyses or weaknesses, and autonomic losses. The effects of loss of autonomic function include vasodilatation (evidenced by a warm skin) and loss of sweating (evidenced by a dry skin) in the area of distribution of the peripheral nerve.

Finally, it must be emphasized that, with an isolated spinal cord, the sympathetic supply to the adrenal glands is intact and that widespread reflex autonomic responses may in part bring about the release of adrenaline and in part be accentuated by such release.

PATHOPHYSIOLOGY

These few paragraphs are intended merely to provide a few examples of some pathological changes, autonomic disorders, and clinical applications. It has already been pointed out that the autonomic nervous system is involved in many complex, integrated physiological and behavioral activities. Consequently, its malfunctioning is a factor in many psychosomatic diseases and disorders. Of particular importance are those involving the hypothalamus, pituitary, and cerebral cortex. Some of the major implications have already been discussed.

The autonomic nervous system is frequently involved in surgical procedures. With the exception of vagotomy (involving severing of parasympathetic fibres) in the treatment of gastric ulcer, most surgery of the autonomic nervous system involves the sympathetic outflow. Modern surgical procedures include those aimed at sympathetic denervation of a limb with a vascular disease, in order to improve the circulation of that limb. They include procedures for treating certain kinds of hypertensions by denervating abdominal viscera, especially the

Surgery to improve circulation

kidney. Other procedures include denervation of the carotid sinus for the relief of fainting and other symptoms of a suddenly falling blood pressure due to a sensitive sinus. Finally, there are many procedures aimed at relieving pain; for example, sympathetic denervation of a limb for phantom limb pain and other painful disorders, sympathectomy for the relief of heart pain, splanchnic-nerve section for the relief of the pain of acute pancreatitis, and section of sympathetic plexuses for the relief of dysmenorrhea (painful menstruation). The rationale of treating pain by surgery on the autonomic nervous system is often not clear, nor are the procedures always successful. When they are, the relief may be temporary. Sometimes a procedure for relieving pain is effective because it cuts sensory fibres that happen to be travelling in or through an autonomic nerve or ganglion. This does not explain the good results sometimes obtained where sensory fibres may not be involved, however. For example, sympathetic block or denervation may relieve phantom limb pain. Patients who have had a limb amputated usually feel subsequently as if that limb were still present. Apparently, the cut ends of the nerves in the stump continue to be stimulated. The resulting nerve impulses arrive at the brain, where they are interpreted as if they were coming from the limb that the nerves previously supplied. Sometimes these sensations are painful. In such instances, the nerve impulses may reflexly activate sympathetic cells in the spinal cord. The autonomic impulses arriving at the vessels in the stump may produce vascular changes that further activate the cut ends of the nerves, or these autonomic impulses may directly stimulate sensory fibres adjacent to them in the stump. Whatever the explanation (and similar explanations have been offered for other painful conditions), stopping the autonomic impulses by sympathetic denervation may relieve or eliminate the pain.

Degeneration and regeneration of nerve fibres

When peripheral autonomic fibres, whether preganglionic or postganglionic, are cut, they degenerate. Provided that their cells of origin remain intact, regrowth—that is, regeneration—usually takes place, beginning at the cut ends. As a result, function may be restored, often completely in the case of postganglionic-fibre section. Moreover, it is difficult to remove all of the postganglionic fibres to an organ or a region, and, in addition, extraordinary precautions may have to be taken to prevent regeneration of postganglionic fibres. In attempting to sever sympathetic nerves to a region, such as a limb, surgeons generally use a combination of preganglionic-fibre section (cutting) and ganglionectomy—that is, removal of appropriate autonomic ganglia. Even then, denervation may not be complete because impulses may still reach the region through accessory ganglia unaffected by the surgical procedure.

One of the significant effects of denervation exhibited by certain effectors, especially vascular smooth muscle, is denervation sensitivity: the effector becomes sensitive to circulating or directly applied transmitters and drugs. For example, certain vascular disorders in which vasoconstriction causes pale, cold, aching fingers and hands may be temporarily relieved by sympathectomy. Unfortunately, these vessels may become so sensitive to circulating adrenaline that they again constrict, sometimes to a greater degree than before.

It is of interest that transplanted hearts are completely denervated. The conducting system of the transplanted heart, however, maintains relatively normal rhythmic activity. This points up what has been mentioned before, that many organs possess intrinsic activity that can carry on without an autonomic supply. There is some evidence that, in experimental animals, transplanted hearts may be re-innervated, but as yet there is not good evidence that this occurs in man.

In general, it may be said that the autonomic system is involved in a wide variety of disorders, including those of emotion and behaviour, and that understanding of its role, limited as that may be, depends upon understanding of the normal structure and function of the autonomic nervous system, an understanding whose enhancement depends upon research at all levels. (E.D.G.)

Nervous System Diseases

Diseases of the human nervous system underlie a remarkably broad array of symptoms of disorders, ranging from the subtlest disturbances of personality through such major signs as gross crippling, blindness, and violent and suspicious behaviour; all too often the result is the premature death of the sufferer (*e.g.*, through heart failure of neural origin). The discussion to follow assumes some understanding of the basic arrangement and function of such structures as the brain and spinal cord as given in NERVOUS SYSTEM, HUMAN; see also NERVES AND NERVOUS SYSTEM. In medical practice the diagnosis and treatment of nervous system diseases hinge on a carefully conducted, systematic neurological examination, which itself rests on a thorough and detailed study of the individual's medical history.

This article is divided into the following sections:

The neurological examination
- Tests of the cranial nerves
- Muscle examination
- Testing reflexes
- Other sensory tests
- Laboratory and other special tests

Neurological manifestations secondary to other diseases
- Endocrine glands
- Other organ systems

Neurochemical disorders
- Proteins
- Fats and other lipids
- Carbohydrates

Developmental defects
Diseases of peripheral nerves
- Radiculitis
- Neuritis
- Neuralgia

Diseases of the spinal cord
- Vascular lesions
- Tumours
- Syringomyelia

Diseases of the autonomic nervous system
Diseases of the brainstem and cranial nerves
- Brainstem
- Cranial nerves

Motor system disorders
- Chorea
- Paralysis agitans (Parkinson's syndrome)
- Dystonia musculorum deformans
- Spasmodic torticollis (wryneck)

Diseases of the cerebellum
Intracranial tumours
Diseases of the cerebrum
- Cerebral vascular accident
- Intracranial aneurysms and primary subarachnoid hemorrhage
- Presenile dementia (Alzheimer's and Pick's diseases)
- Degenerative diseases
- Down's syndrome (mongolian idiocy)
- Cerebral palsy (Little's disease)

Infections
- Bacterial infections
- Virus infections
- Other infections

Demyelinating disorders
- Myelinoclastic (sheath-destructive) diseases
- Dysmyelination disease

Craniocerebral trauma
- Complications of head injuries
- Sequelae (residual symptoms) of head injuries

Epilepsy (recurrent convulsive seizures)
Toxins
- Bacterial toxins
- Metallic poisoning

Neuromuscular disorders
- Amyotrophic lateral sclerosis
- Progressive muscular dystrophy
- Myotonia congenita
- Myotonic muscular dystrophy
- Myasthenia gravis
- Familial periodic paralysis

THE NEUROLOGICAL EXAMINATION

Examination of the nervous system is routinely preceded by a thoroughgoing general physical examination that includes measures of vital signs (*e.g.*, temperature, pulse rate, and blood pressure) and study of the heart, lungs, abdomen, skeletal structure, skin, and other organs. During the course of history taking and general physical examination, valuable information will be elicited with regard to sensory and muscular function and psychiatric condition. The status of the muscular system, for example, may be observed as the person walks into the physician's office or by noting spontaneous movements of his face, trunk, and extremities as he lies in bed.

The general appearance and cooperation of the individual (*e.g.*, neatness of clothing, evidence of personal hygiene, facial expressions, tone of voice, posture, presence of tics or other abnormal movements) provide evidence of contact with the environment and of possible neural disease. Signs of irritability, suspiciousness, hostility, suicidal depression, inattentiveness, or indifference are especially significant. Poverty of speech may signal depression; a continuous flow of words with punning or flight of ideas can mean manic excitement; senility is associated with repetitive and garrulous conversation, while speech is incoherent and rambling in delirium; strange new words (neologisms) or high-sounding, apparently meaningless sentences often are observable in schizophrenia. There also may be gross evidence of such psychiatric symptoms as hallucinations, delusions, obsessive ideas, and compulsions (see PSYCHONEUROSES; PSYCHOSES).

Psychiatric symptoms

Remote memory is readily assessed by the person's ability to give an account of his life (as known from other sources, such as relatives) and of his recorded illnesses. Recent memory is tested by asking him about events of the last few days, and immediate recall is gauged by reading a short sentence and asking him to repeat it. Somewhat longer retention is indicated if he can successfully recall after five minutes a list of a few common objects, such as chair or knife, and a fictitious address (see also MEMORY, ABNORMALITIES OF).

Difficulties in speech and other language skills often can signal disease of the nervous system. Dysarthria (dysphonia), for example, in which there is impaired control of the muscles of phonation, can arise from damage (lesions) in several parts of the brain and associated nerves (see SPEECH, PHYSIOLOGY OF). Questions and commands designed to assess the person's ability to understand spoken words should be fairly complicated, because even a person with extensive brain lesions may still be able to respond well to simple commands. People who are unable to understand spoken words (auditory agnosia) yet still have the capacity to talk may be quite voluble but unable to monitor what they are saying. They are likely to become angry when they cannot make themselves understood. Lesions involving a very limited portion of the brain cortex (Wernicke's area) are associated with trouble in understanding spoken words, while in other parts of the cortex (angular gyrus of the inferior parietal lobe) the lesions may cause disturbances in understanding written words.

Aphasia and apraxia

In what is called motor aphasia, the patient is hard put to express himself and may respond to questions only by repetition of a few of the words he hears. This is usually accompanied by loss of ability to read (alexia) and is associated with cortical lesions in the inferior frontal gyrus of the dominant cerebral hemisphere (in more than 95 percent of people, on the left half of the brain). A less severe disturbance in motor speech is anomia, difficulty in recalling nouns, particularly the names of objects. Anomia characterizes the disorder called amnesic aphasia and arises from lesions in the temporal lobe (on the side of the head) in the dominant hemisphere. Amnesic aphasia should be differentiated from agnosia; in visual agnosia, for example, the person cannot recognize familiar objects or words that he sees. The latter disturbance may accompany lesions of the occipital lobe at the back of the brain.

Apraxia describes the inability to perform voluntary, purposeful movement of parts of the body that are not paralyzed; automatic or associated movements may still be observed. Apraxia of the tongue, for example, may be manifested by an inability to protrude it on command. The sufferer may, however, freely lick fluids or food placed on the lips. Apraxia is usually associated with le-

sions of a limited portion (the supramarginal gyrus) of the parietal lobe (toward the top of the head) in the dominant hemisphere and is not infrequently accompanied by aphasia.

Inspection of the head

The head should be inspected carefully for any skin lesions and palpated for tender spots, swellings, or local overgrowth of bones. Infants with increased fluid pressure within the brain (hydrocephaly) may show bulging soft spots (fontanels) and enlargement of the skull. The blood vessels in the neck are felt and a stethoscope applied to listen for unusual noises there and in other parts of the head. Voluntary and examiner-manipulated (passive) movements of the neck in several directions are made to reveal any weakness or limitation of motion.

Tests of the cranial nerves. The cranial nerves are the 12 pairs of nerves connected directly with the brainstem; most nerves enter and leave by the spinal cord.

Olfactory. In examining olfactory (smell) function, the person is asked to sniff strongly alternately through each nostril, since there are two separate olfactory nerves. He is asked to identify by smell such things as cigarettes, coffee, vanilla, peppermint, and menthol.

Optic. Clues to optic nerve function derive from examination of the eye, including determination of the pressure in the eyeballs, testing of visual acuity and visual fields, and inspection of the retina of the eye by a device called an ophthalmoscope. Of special neurological interest are drooping lids, protrusion of either eyeball (exophthalmos), and inequalities in the size and shape of the pupils (see EYE AND VISION, HUMAN).

Oculomotor, trochlear, and abducens. These three cranial nerves work together in the control of eye movements. The individual is asked to follow the movement of a small light or the examiner's finger upward, downward,

Eyeball movements

and to either side and to report any experience of double vision (diplopia). The position of the eyeballs at rest, any defect in movement, and their position when diplopia occurs can indicate which of these nerves may be injured.

Trigeminal. The functions of the trigeminal nerve are tested by stimulation (*e.g.*, with a pin) on the upper and lower jaw and around the eye. Normal trigeminal function serves the corneal reflex; *i.e.*, contraction of the lids elicited by touching the front of the eyeball (*e.g.*, with a wisp of cotton) as the person looks upward. The state of the chewing muscles is tested by palpation and by observing jaw movements.

Facial. Both taste and muscle function are served by the facial nerve. Asymmetry or lack of mobility of facial expression are signs of disorder. Voluntary movements of the muscles of the face are tested by asking the person to wrinkle his forehead and to forcibly close his eyes and by having him show his teeth, pucker his lips, whistle, or smile. Taste (gustatory) function is tested usually with sweet, sour, and salty solutions to selected parts of the tongue. Lesions of the facial nerve are accompanied by impairment of taste on the front two-thirds of the tongue and lesions of the glossopharyngeal nerve (see below *Glossopharyngeal*) by impairment on the posterior one-third.

Vestibulocochlear. This cranial nerve serves both hearing and equilibrium. Hearing is tested with normal and whispered voice or with a ticking watch held close to one ear while the other is blocked. Further testing can be made with a special device (audiometer). Neural disorder is indicated if the person has trouble hearing even when such structures as the eardrum are bypassed (*e.g.*, by placing the stem of a vibrating tuning fork on the mastoid bone behind the ear).

Unilateral (one-sided) disturbance of the vestibular branch of the nerve is manifested by such signs as dizziness, falling to one side, or even complete inability to walk. Less severe vestibular disturbances are indicated by such behaviour as difficulty in attempting to raise one arm overhead and accurately return it to the same spot on a horizontal rod. Oscillatory eye movements (nystagmus) are observed in vestibular disturbances because of an intimate connection with parts of the brainstem concerned with eye movements. The vestibular nerve can be further tested by syringing the ears with hot and cold water or air (caloric test) or by spinning the person in a rotating chair with his head held in various positions to selectively stimulate different semicircular canals in the inner ear (Bárány test; see also EAR AND HEARING, HUMAN).

Glossopharyngeal. Functions of the glossopharyngeal nerve are tested by observing the movement and sensibility of the pharynx during examination of the mouth and throat. The taste function of the nerve is assessed during the examination for the facial nerve (see above *Facial*).

Vagus. Some impairments of the vagus nerve are evidenced by difficulties in talking and swallowing. Paralysis on one side is indicated by movement of the palate to the opposite side. Abnormal movements of the vocal cords, also signs of vagus difficulties, are observed with a special laryngeal mirror.

Spinal accessory. The function of the spinal-accessory nerve is tested by noting the state of nutrition of specific neck muscles (sternomastoid and trapezius muscles) and by testing their strength in rotation of the head and in shrugging the shoulders.

Hypoglossal. The hypoglossal nerve is tested by noting the state of the muscles of the tongue, especially being alert for trembling (fibrillations) or other unusual movements. A tendency to protrude the tongue to one side indicates weakness of muscles in that half of the tongue.

Muscle examination. Careful observation of the person as he walks may reveal abnormalities of posture and gait that reflect nervous system disease.

Muscular atrophy (shrinking) and hypertrophy (overdevelopment) may be determined by simple palpation and by measurement. The circumferences of the same portions of the limbs on opposite sides of the body are compared. The presence or absence of fibrillary twitchings are sought, especially when there is generalized or localized muscular atrophy. Limbs are flexed and extended at the joints by the examiner to see if the degree of resting muscular contraction is abnormally reduced (hypotonus) or increased (spasticity or rigidity).

Coordination is tested by asking the person to extend his arms to the side and then to bring the tips of the index fingers together or to place them one at a time on the nose, to repeatedly flex and extend the fingers, or to rotate the forearm. He may be instructed to touch the examiner's finger with a big toe or to place one heel on the opposite knee and run the heel down the leg (heel–shin test).

Finger-to-nose test

Testing reflexes. A number of reflexes have been found to be of value in determining the site of lesions in the nervous system. Tendon reflexes in the extremities are elicited by placing a finger on the tendon of the muscle (*e.g.*, just below the kneecap) and tapping the tendon briskly with a soft hammer. When reflexes are exaggerated, a single stimulus may set off a continuous repetition (clonus) of the reflex. Clonus is most common in muscles of the wrist, knee, and ankle.

Abdominal reflexes are cutaneous (elicited by stimulating the skin). The person lies flat on the back with muscles relaxed; a brisk stroke with a pencil or dulled pin is made in each quadrant of the abdomen, starting from the edge and directing the stroke toward the umbilicus. The normal response is contraction of the abdominal muscles and a movement of the umbilicus toward the stroking instrument. The sole (plantar part) of the foot is also stroked, starting from the heel and across to the base of the big toe. The normal response consists of flexion of all of the toes, accompanied by a slight flexion and inversion of the tip of the foot. In all but the youngest infants, an extensor plantar response (Babinski reflex) is abnormal; it consists of extension of the big toe accompanied by flexion and fanning out of the other toes.

Other sensory tests. Sensitivity to light touch is usually tested by the stroke of a fine, soft brush or a wisp of cotton. All areas of the skin of the trunk, extremities, and face are tested, and comparison is made of the intensity of the stimuli needed to elicit a response in various areas.

Pain sensitivity of the skin is tested by light pricks of a needle or pin. All areas of skin are tested, and comparisons of areas are made as with light touch. Ability to

localize the point stimulated is determined by asking the person to indicate (without having looked) the exact place just pricked.

Temperature sensation may be tested by the application of test tubes containing hot and cold water. Comparison of the ability to recognize the difference between the hot and cold stimuli is made in all parts of the body.

Two-point cutaneous discrimination is tested by determining the shortest distance between the two points of an artist's compass at which the points can definitely be distinguished as separate by touch alone.

Proprioception, the sensing of changes in the muscles and tendons, is evinced by ability to recognize passive movements of the joints and to detect vibrations produced by a tuning fork placed on the bony prominences and on the skin.

Laboratory and other special tests. Major portions of the nervous system can be observed or assessed only by the use of such methods as chemical analysis, X-ray examination, and electroencephalography. Chemical examination of the blood, for example, to seek the presence of such drugs as bromides, barbiturates, and alcohol, is made in undiagnosed cases of coma. Similar studies are made of the urine and other body fluids, including cerebrospinal fluid (ordinarily tapped from the spine with a long hypodermic needle). Thus, the cerebrospinal fluid may reveal bacteria that produce brain inflammation (meningitis or encephalitis).

Roentgenography (X-ray examination). Ordinary X-ray films of the skull and spine are of value in revealing abnormal conditions such as tumours. To enhance the contrast in the films it is often helpful to introduce some foreign material (a contrast medium) into the tissues before they are X-rayed. Thus, the cavities (ventricles) of the brain are easier to visualize in roentgenograms after the injection of air as a contrast medium. The introduction of air into the head, however, is accompanied by definite risk to life. X-ray visualization of blood vessels (angiography) by the injection of dyes as contrast media (*e.g.*, into the carotid artery in the neck, which delivers blood to the brain) has the advantage over air injection in that it is a less dangerous procedure with a low mortality rate, but transient untoward symptoms occur in about 10 percent of the cases. Angiography is of great value in the localization of tumours of the brain and in revealing abnormalities of the blood vessels. Similarly, the introduction of contrast media (oils or air) is of value in localizing lesions (*e.g.*, ruptured disks) that compress the spinal cord or nerve roots.

Injection of air into the brain

Echoencephalography. In echoencephalography, high-frequency vibrations (ultrasound) are passed through the head, the returning echoes being recorded. Echoencephalography is an easy, rapid, and harmless procedure with high accuracy in the diagnosis of a brain tumour, blood clot, or other space-occupying lesion in the skull.

Radioactive scanning. Localization of lesions in the brain by means of their differential tendencies to incorporate radioactive substances is a valuable diagnostic aid. Radioactive arsenic, mercury, iodine, or other substances are injected intravenously, and scanning of the skull is accomplished with devices related to Geiger counters. The nature of any brain lesion present can be inferred from the rapidity of appearance and disappearance of abnormal concentrations of radioactivity. This relatively harmless procedure commonly can be used in lieu of the more troublesome angiography or air studies.

Rheoencephalography. Rheoencephalography is the study of variations in the electrical conductivity of cranial tissues to high-frequency alternating currents. Such electrical changes are found extremely useful in the detection of disturbances in the circulation of blood within the skull.

Electroencephalography. Recording of the electrical activity of the brain can be performed with safety and comfort. The electroencephalogram (EEG) is of special diagnostic value in cases of head injury, brain tumours, cerebral infections, cerebral-blood-vessel lesions, degenerative diseases of the nervous system, and convulsive disorders (*e.g.*, epilepsy). Latent brain-wave abnormalities can be activated by deep breathing (hyperventilation), stimulation with flickering light, or with small doses of stimulant drugs.

Neuromuscular electrodiagnosis. Nerve-conduction velocity is indicated by how long it takes between stimulation of a nerve and the appearance of action potentials (electrical activity) in the muscles supplied by the nerve. Slowing of the conduction velocity below normal indicates damage to the nerve and suggests that the spinal cord is not responsible for any muscular paralysis present. Comparison of the conduction velocity of the nerve at various points may indicate the exact site of a lesion.

The electrical activity of muscles can be determined by the insertion of needle electrodes. There are characteristic changes in the activity when the nerves or muscles are damaged. With complete interruption of a nerve, there is no action potential from the paralyzed muscle. Subsequent return of activity indicates regeneration of the injured nerve. When the spinal cord is damaged (as in some forms of poliomyelitis), increased muscle activity is seen on insertion of the needle, and there are distinctive electrical discharges when the muscles are at rest.

Electrical activity of muscles

Biopsy. Removal of living tissue (biopsy) from nerves is of value in determining the presence and nature of neural lesions. Degeneration of the nerve's insulating material (myelin sheath) is found in most of the common varieties of nerve inflammation (polyneuritis). Inflammatory reaction around the nerves is seen in a number of disorders, including Hansen's disease (leprosy). For ethical reasons, biopsy of brain tissues is rarely made, except for tumours of the brain, in which case it is valuable in determining whether an attempt should be made to remove a tumour or to treat with radiation.

NEUROLOGICAL MANIFESTATIONS SECONDARY TO OTHER DISEASES

The nervous system is involved secondarily in diseases of other organ systems, particularly those of the endocrine glands, blood, liver, the connective tissues, and bone.

Endocrine glands. The functioning of the nervous system is affected to some degree by all of the endocrine (ductless) glands. Disturbances of consciousness and thinking as well as various sensory and motor symptoms may occur when these glands are overactive (hyperfunction) or underactive (hypofunction). As an example, diabetes insipidus (characterized by excessive amounts of urine and insatiable thirst) usually arises from an injury to the fibre tracts connecting the base of the brain (the hypothalmus) with the pituitary gland. A disorder called Cushing's syndrome is associated with oversecretion of a special portion (the basophilic cells) of the pituitary. The fully developed syndrome, most common in females, includes swollen face, obesity, overgrowth of facial and body hair, purple abdominal streaks (striae), high blood pressure, increase in the number of red cells in the blood, absence of menstruation, elevated blood sugar, muscular weakness and wasting, and softening of the bones of the skeleton. Mental symptoms are common. Most of the features of Cushing's syndrome also can be produced by the administration of pituitary or adrenal hormones.

Pituitary gland

Oversecretion of the portion of the pituitary that secretes the growth hormone (acidophilia cells) causes gigantism if the activity starts before puberty, and acromegaly when it occurs after this age.

Deficiency of the secretion of the thyroid gland (hypothyroidism) in infancy produces cretinism, in which there is retardation of physical and mental development, both of which may be severe. Hypothyroidism developing in late childhood or in adult life results in myxedema, characterized by lethargy, weakness, slowness of speech, swelling (edema) of the tissues, coarse, pale skin, dry, brittle hair, and excessive sensitivity to cold. Neurological complications include headache, cranial-nerve palsies (*e.g.*, bodily tremors), peripheral neuritis, psychotic episodes, and convulsions. Excessive secretion of the thyroid (hyperthyroidism) is associated with such neurological symptoms as tremor of the extended hand, infrequency of blinking, weakness of muscles, emotional instability, and even psychotic episodes.

Deficiency in the secretion of the calcium-regulating parathyroid hormone produces parathyroid tetany, characterized by numbness and cramps in the extremities, spasm of the fingers or toes, convulsive seizures, and psychotic episodes. Increased intracranial pressure with associated visual effects is one of the rarer neurological manifestations of the disease. The abnormal laboratory findings include decrease in blood and urinary calcium and various abnormalities (*e.g.*, slow waves) in the electroencephalogram. When there is an excess of the parathyroid hormone, thinning of the bones, formation of stones in the kidneys, and muscular weakness may occur.

Insulin, the hormone secreted by the pancreas, regulates sugar (glucose) metabolism. The nervous system depends on glucose for its energy, and loss of consciousness develops rapidly when the amount of that sugar in the blood falls below critical levels (hypoglycemia). An excess of glucose in the blood associated with a deficiency in the secretion of insulin (diabetes mellitus) may cause a variety of disturbances of the nervous system. Excessively high levels of blood glucose (hyperglycemia) usually are accompanied by confusion and coma. Involvement of the cerebral blood vessels may be followed by blood clots (thrombosis) with paralysis (*e.g.*, hemiplegia) or other signs appropriate to the location of the clot within the brain. Neuritis with or without involvement of the cranial nerves may also occur, probably related to a generalized diabetic disturbance of the nerves of as yet unknown nature.

Oversecretion of insulin (hyperinsulinism) is rare, although hypoglycemia may occur after an injection of too much insulin. Occasionally, it is found in people with tumours of the pancreas. The symptoms of severe hyperinsulinism are paroxysmal (*e.g.*, convulsions) and tend to occur at times when the blood sugar is expected to be low; *i.e.*, early in the morning or after fasting or exercise. Other symptoms attributable to hypoglycemic disturbance of the nervous system include lightheadedness, tremors, sweating, pallor, palpitations, headache, abdominal pain, nausea, vomiting, or ravenous hunger. There also may be tingling in the extremities, diplopia, or blurred vision, generalized weakness, transient hemiplegia, aphasia, confusion, abnormal behaviour, and coma (the latter usually preceded by convulsions).

Low blood sugar

The adrenal gland is composed of two portions, an outer cortex and an inner medulla: both elaborate a number of specific hormones that can affect the nervous system. Hypofunction of the adrenal cortex (Addison's disease) may be associated with such symptoms as weakness, fatigue, low blood pressure, low blood sugar, irritability, and anxiety. Hyperfunction of the adrenal cortex can produce Cushing's syndrome (see above) and, depending on which hormones are oversecreted, can lead to such sexual disturbances as premature puberty, enlargement of the genitals or feminization in the male, and virilism (*e.g.*, hairiness) in females. Oversecretion of the adrenal medulla can produce high blood pressure.

Neurological complications of the administration of contraceptive hormones that affect the ovaries are uncommon considering the number of women taking them. Symptoms of involvement of the nervous system are headaches of the migraine type, increased intracranial pressure, optic neuritis, diplopia, and cerebral vascular lesions; in most cases the symptoms subside with discontinuance of the use of the hormones.

Other organ systems. *Bones.* Osteitis deformans (Paget's disease) is characterized by bowing and irregular flattening of the bones. The skull and spine may show signs of overgrowth and softening, and involvement of the nervous system arises from compression of nervous tissue. Headaches, convulsions, and compression of cranial nerves are the most common symptoms. Paralysis (paraplegia) may occur as a result of compression of the spinal cord. Degenerative and arthritic changes (*e.g.*, cervical spondylosis) are common in the spine in middle-aged or elderly people. Symptoms that result from compression of the spinal nerves of the cord itself include pains and paresthesias (*e.g.*, pricking and tingling) in the neck and back extending to the extremities, stiffness of the spine, weakness of muscles, impairment of sensation, and loss of the reflexes innervated by the affected nerves.

Liver and blood. Incoordinated gait, tremor, dementia, paraplegia, and coma may occur with disease of the liver, and the ammonia content of the blood tends to be increased.

Indeed, damage to the nervous system may be a feature of various diseases affecting the blood. Among these are degeneration of the spinal cord associated with anemia and other neurological symptoms arising from thrombosis, as when the number of red cells is grossly elevated (*e.g.*, polycythemia vera). The nervous system may be the site of collections of tumour cells in leukemia, with resulting cranial nerve palsies, polyneuritis, hemiplegia, and other localized neurological symptoms. Degeneration of the spinal cord associated with primary anemia was formerly common but became quite rare after discovery of an effective treatment (which includes vitamin B_{12}) for the anemia.

Cancer of other organs. The nervous system may be affected by malignant tumours in the lungs or other organs without direct involvement of the nervous tissue. In addition, infection of the brain membranes (meningitis) and abscess of the brain with yeast and other fungi is likely to occur in cancer sufferers whose immune reactions are suppressed by the administration of anticancer drugs. Indirect effects of malignant tumours in the nervous system include damage in the brain and spinal cord (multifocal leukoencephalopathy), probably from invasion by viruses. Polyneuritis may occur as a result of the spreading of cancers (metastatic invasion) to the nerves or by an unknown toxic process.

NEUROCHEMICAL DISORDERS

A number of degenerative diseases of the nervous system have been shown to result from inborn metabolic defects. Many of these hereditary diseases are associated with inborn defects in the metabolism of proteins, fats, and other substances.

Proteins. A number of diseases are recognized in which there is a deficiency of a specific enzyme concerned with the metabolism of one or more amino acids (protein constituents). Injury to the nervous system results from the accumulation of abnormal metabolic products in the blood. In general, it can be said that these diseases are rare, the most common being phenylketonuria (see the Table), for which the estimated incidence in the U.S. is one in every 20,000 births. Onset of symptoms is usually in infancy, and fatalities or serious disabling symptoms are usually related to involvement of the nervous system. Mental retardation and convulsive seizures are the most common symptoms. Many of the affected individuals die in infancy, although this may be preventable through early treatment by feeding a diet low in the specific amino acid for which metabolism is defective.

Some Defects of Protein Metabolism

metabolic disease	amino acids involved	typical neurological symptoms
Phenylketonuria	phenylalanine	convulsions; mental retardation
Maple-syrup urine disease	valine; leucine; isoleucine	convulsions; muscular rigidity; rapidly fatal
Homocystinuria	methionine	mental retardation; convulsions; cerebral thromboses
Hartnup's disease	many excreted in excess in urine	periods of ataxia; psychotic episodes; mental deterioration
Oculo-cerebral-renal syndrome of Lowe	many excreted in excess in urine	convulsions; mental retardation; loss of reflexes; visual defects

Fats and other lipids. There are a number of diseases in which there is a disturbance of the metabolism of fatlike substances (lipids). In some, the nervous system is the primary or chief site of the disturbance (*e.g.*, Tay-Sach's disease), and in others it is affected as part of a general involvement of other organs; *e.g.*, the abdominal viscera (Gaucher's disease and Niemann-Pick disease) or the bones (Hand–Schüller–Christian disease).

Cerebromacular degeneration (Tay-Sachs disease). Also called amaurotic familial idiocy, this is a relatively

rare hereditary disorder characterized by loss of vision, convulsive seizures, paralysis, and dementia. There is degeneration of the nerve cells (neurons) in the central nervous system (brain and spinal cord) and in the retina, with deposition of lipoid (fatlike) pigments in the degenerated cells. The onset of symptoms is common in the first few months of life (infantile form), but it may be delayed to the third to fifth year of life (late infantile type) or to early or late childhood (juvenile form). Symptoms are similar in all three forms, but there is considerable variation in their severity. The infantile form is characterized by its occurrence in Jewish children, the presence of a cherry-red spot at the point of direct vision (the macula) in the retina and a rapidly downhill course. The late infantile and juvenile forms usually occur in non-Jewish families; there is pigmentary degeneration of the retina rather than a cherry-red spot in the macula. Severity is related to the age of onset; when symptoms first appear after the age of eight years, the degree of cerebral degeneration is less, and the length of life is greater. Nervous system symptoms similar to those of cerebromacular degeneration may occur in Niemann–Pick or Gaucher's disease.

Cranial xanthomatosis (Hand–Schüller–Christian disease). This arises from a disturbance of metabolism of a fatlike substance (cholesterol) with deposition of lipoid-containing cells in membranous bones, particularly the skull. The characteristic symptoms include defects in the bones (easily demonstrated by roentgenography), diabetes insipidus, and bulging eyes (exophthalmos). Rubbery masses of lipoid-containing cells in the dura (one of the membranes) under the frontal lobes and in the hypothalamic regions of the brain are responsible for the exophthalmos and the diabetes insipidus, as well as the retardation of growth that is present in about one-third of the cases. The disease is rare; males are affected twice as often as females. The onset of symptoms is usually in the first two decades of life, and the course, if unsuccessfully treated, is slow, progressive deterioration.

Related disorders include hereditary ataxic polyneuritis (Refsum's disease), a rare form of polyneuritis resulting from an inborn error of lipid metabolism. It is also characterized neurologically by pigmented, degenerated retina and by deafness. These and other symptoms have their onset in the first or second decades of life with slow progression and death before the age of 50 years, although special dietary restrictions (of foods containing phytol and phytanic acid) may have a beneficial effect.

Another example is the Bassen–Kornzweig syndrome, a rare lipid disease affecting chiefly the cerebellum of the brain; the inherited metabolic defect is associated with ataxia (incoordinated gait). Such neurological symptoms start in childhood and progress slowly to adult life, when they tend to become static.

Carbohydrates. *Galactosemia.* A rare inherited defect in the metabolism of the sugar galactose (related to lactose, or milk sugar) results in an intolerance to milk. The symptoms usually appear in the first week of life and include vomiting, diarrhea, jaundice, enlargement of the liver and spleen, accumulation of fluids (ascites) in the body cavities, and cataracts. When treatment is not instituted because of failure in recognizing the disease, there is psychomotor and mental retardation. There is an increase in the excretion of galactose, protein, and amino acids in the urine. All of these are reversible if milk and other sources of lactose and galactose are rigidly excluded from the diet; mental development then will be normal unless, of course, the brain already has been too seriously damaged.

Gargoylism (Hurler's disease). This is a rare metabolic disease in which there is a peculiar malformation of bones associated with mental deficiency. The symptoms are caused by deposition of carbohydrates called mucopolysaccharides (*e.g.*, chondroitin sulfate and heparitin sulfate) in the central nervous system, the retina, and other organs. The disease is manifest in the early months of life, with the child taking the appearance of a short-limbed dwarf with coarse facial features. While mental and physical development are retarded, the degree of mental deficiency is variable, and the disease is not incompatible with many years of life. Other disorders of mucopolysaccharide metabolism with variations of the clinical picture of gargoylism have been described.

Glycogen-storage disorders. Carbohydrate is normally stored in the liver in the form of a chemical called glycogen. Abnormal deposition of glycogen may occur in a number of congenital disorders, each probably representing a specific enzyme deficiency. The most common is von Gierke's disease (hepatorenal glycogenosis), in which the liver and kidneys are chiefly involved secondary to a deficiency of the enzyme glucose 6-phosphatase. In generalized glycogenosis (glycogen heart disease, or Pompe's disease), glycogen deposition is most marked in the heart and skeletal muscles. Nerve cells in the brain and autonomic nervous system may also be involved. Onset is in early infancy, and symptoms of skeletal muscle weakness and hypotonia (flabbiness) may suggest other muscle diseases. Death from heart failure usually occurs within the first two years.

DEVELOPMENTAL DEFECTS

Many defects of the nervous system may be congenital (present at birth). The damage may be limited to the brain and spinal cord, or the skull and spinal bones may be affected. Congenital defects in other organs may also be present (see BIRTH DEFECTS AND CONGENITAL DISORDERS).

Defects in the development of nervous tissue may be extensive, as in absence of the cerebral hemispheres (anencephaly), or may be limited to defects in the development of one or more brain structures, including the cerebellum, brainstem, and the spinal cord. Other defects include microcephaly ("pinhead"), porencephaly (abnormal cysts or cavities in the brain), and hydrocephalus ("water on the brain"). Defects in the development of the bony structures may occur with or without concomitant damage to nervous tissue.

Common forms of developmental defects of the central nervous system and its bony covering include spina bifida, in which there is failure of closure of the bony spine, and cranium bifidum, in which there is failure of closure of the skull. The Arnold–Chiari malformation is characterized by downward elongation of the brainstem and cerebellum into the spinal canal of the neck. Ocular hypertelorism, characterized by a facial defect in which there is an excessive distance between the eyes, is associated with mental retardation.

Causes of developmental defects

Not all of the causes of these and other related malformations are known. Genetic factors play a role; many of these developmental defects are associated with chromosomal abnormalities and have a tendency to run in families, but other factors are probably of greater importance. The nervous system of the developing fetus is especially vulnerable to lack of oxygen (anoxia), radiation, infectious and metabolic diseases in the mother, and her ingestion of drugs during critical stages of development of her unborn child. Serious defects in the development of the nervous system usually result in death within the uterus or shortly after birth. Minor defects (*e.g.*, in some lesser forms of spina bifida) may not be accompanied by any neurological symptoms, and moderately severe defects tend to produce a degree of disability related to the extent and site of the damage.

DISEASES OF PERIPHERAL NERVES

Peripheral nerves are those that extend beyond the central nervous system (*i.e.*, beyond the brain and spinal cord).

Radiculitis. This inflammation of the roots of the spinal nerves (*i.e.*, at their point of entry into the spinal cord) causes paralysis of the muscles and loss of sensation in the skin innervated by the root involved. Severe burning pains are present when injury is due to either compression or inflammation.

The nerve roots and plexuses (mingled fibres of two or more nerves) may be damaged at birth or by trauma (injury) after birth. Individual nerve roots may be injured by tumours, ruptured intervertebral discs, and ar-

thritic changes in the vertebrae. The posterior root and its relay centre (ganglion) are inflamed (herpes zoster) in specific virus infections.

Neuritis. Neuritis is the term generally used to denote inflammation of nerves from any cause. In the majority of the cases this is not caused by an infectious process, and the term neuropathy is preferred by some authors. Injury (trauma) is the most common cause of localized inflammation of a single nerve (mononeuritis), whereas toxic agents and metabolic disturbances usually cause diffuse involvement of many nerves (polyneuritis).

The symptoms that result from injury to a single nerve are related to the nature of the nerve affected. Involvement of motor nerves (those that carry impulses away from the central nervous system) causes paralysis, atrophy, and loss of reflexes in the muscles supplied by the given nerve. Loss of sensation in an area of tissue slightly less than that of the anatomical distribution of the nerve occurs with lesions of sensory nerves. Vasomotor disturbances (*e.g.*, circulatory difficulties) are common when a sensory or mixed (sensory and motor) type of nerve is damaged. Peripheral nerve injuries are common in war from gunshot and shrapnel wounds, and trauma (as in athletics and vehicular collisions) is also the most common cause of nerve injuries in civil life. Other causes include compression by tumour and trauma associated with the injection of drugs.

When the injury to a peripheral nerve is of minor nature, recovery usually takes place in the course of a few days or weeks. If the injury is severe or if there has been degeneration of the fibres (axons) of the nerve cells, recovery is delayed. Severed nerve ends can be brought together (anastomosed) by surgical suturing.

Polyneuritis

Polyneuritis (multiple peripheral neuritis) can be caused by a great number of toxic and metabolic disturbances, including vitamin deficiency, lead poisoning, leprosy, thyroid-gland disorders, and cancers. The actual cause of the degenerative changes in the peripheral nerves is unknown, but it is probable that both toxic and metabolic disturbances may interfere with the enzymes concerned with the nutrition of the nerves. The clinical symptoms are similar regardless of the cause of the polyneuritis, but there are variations in the distribution of paralysis and in the degree of the motor and sensory defect. Sufferers of mild polyneuritis complain of pains and paresthesias, but no weakness, sensory loss, or reflex disturbances occur; the disorder is termed moderate when the pains and paresthesias are accompanied by slight weakness of the upper or lower extremities and loss of deep reflexes; it is severe when there are complete paralysis and loss of sensation in the distal parts (ends) of all extremities and loss of all deep reflexes. The weakness usually is confined to the extremities, but, in severe cases, it may extend to involve the muscles of the trunk and the muscles supplied by the cranial nerves.

Paralysis of the facial muscles and of the pharyngeal muscles is common in infectious and diphtheritic polyneuritis. Sensory loss, when it occurs, usually is confined to a drop in or loss of sensitivity (anesthesia) of the distal parts of the extremities over the areas of skin commonly covered by a glove or stocking. Proprioceptive (muscle and joint) sensibility usually is more impaired than is cutaneous (skin) sensibility. Confusion, disorientation, amnesia, and other memory defects are occasionally seen in any form of polyneuritis but are most common in the alcoholic-vitamin-deficiency form (Korsakoff's psychosis) or that associated with pregnancy.

Complete recovery is the rule in most of the cases of polyneuritis, but it is slow when damage to the nerves is extensive, and there may be residual symptoms in the form of muscular wasting and sensory loss. Treatment of polyneuritis is accomplished by the removal of any toxic agent and the alleviation of any metabolic or deficiency state. Physiotherapy is most helpful in the convalescent stage.

Neuralgia. Pain of neural origin (neuralgia) is a common symptom in patients with neuritis and severe neuralgic symptoms in the form of lightning-like pains and burning paresthesias are likely to occur with injury to certain nerves. Burning pains (causalgia) often accompanied by trophic (nutritional) changes in the skin may occur with incomplete lesions of sensory or mixed nerves.

Nerve compression

Certain nerves are especially subject to compression by fibrous tissues (fascial bands), resulting in pains, paresthesias, and weakness in the distribution of the affected nerves (entrapment syndrome). The median nerve, for example, may be compressed by the transverse carpal ligament at the wrist (carpal tunnel syndrome); the lateral femoral cutaneous nerve of the thigh often may be compressed by tight belts or corsets, with resulting pains and paresthesia in the lateral surface of the thigh (meralgia paresthetica); the posterior tibial nerve may be compressed at the anklebone (medial malleolus), with pains and paresthesias in the feet similar to those in the hand resulting from compression of the median nerve; and the genitofemoral nerve under compression of the fibres in the abdominal wall produces painful hyperesthesia (enhanced sensitivity) of the root of the thigh and scrotum. The treatment of neuralgic disturbances associated with entrapment is relief of the constriction by section (cutting) of the fascial band or by surgical relocation of the nerve.

The fifth (trigeminal) and ninth (glossopharyngeal) cranial nerves are subject to neuralgic disturbance of unknown origin; for example, there are no significant lesions observable in the nerves. Trigeminal neuralgia is the most common form of neuralgia and is characterized by the paroxysmal occurrence of attacks of burning, stabbing pains in the face along the course of one or more branches of the nerve. Attacks are usually brief, but they may occur quite frequently and are often precipitated by a touch on a so-called trigger point on the face or by movements of the facial muscles. The disease commonly has its onset in middle or later life, the second and third division (branch) of the nerve being most frequently affected. There may be periods of remission (freedom from symptoms) lasting several months or years, but recurrence is the rule. Treatment is by the administration of drugs (carbamazepine alone or in combination with diphenyl hydantoin). Surgical section of the nerve root is indicated for the cases in which these drugs are not effective.

The pains in glossopharyngeal neuralgia are similar to those of trigeminal neuralgia except that they are localized in the region of the tonsils, posterior pharynx, back of the tongue, and the middle ear. They may occur spontaneously but are often precipitated by stimulation of these areas by the swallowing of the food. The pains may be relieved by anesthetizing the sensitive areas, and the paroxysms may be prevented by section of the ninth nerve. The medical treatment is the same as that for trigeminal neuralgia.

Other neuralgias signalled by sharp shooting pains in various portions of the body may occur as a sign of herpes zoster (virus infection) and are not uncommon in tabes dorsalis (a form of syphilis). In addition, there are a number of patients with persistent or unremitting pains in the face, head, and neck that are not confined to the distribution of the trigeminal or glossopharyngeal nerve (atypical facial pain). The pains are not relieved by the accepted treatment for trigeminal neuralgia. Relief of symptoms may occur, but by no means commonly, after operations on the nerve supply for the head and neck. It is possible that the pain in some of the sufferers is a neurotic manifestation (conversion hysteria).

Pains in the face, head, and neck

DISEASES OF THE SPINAL CORD

The spinal cord may be involved directly by infections, tumours, trauma, developmental defects, vascular lesions, degeneration, and demyelinization (loss of myelin, which insulates neurons) and secondarily by metabolic diseases and blood disorders. The lesions may be localized in the motor or sensory cells, in the horn-shaped gray matter within the spinal cord, or in the fibres (white matter) of the tracts that carry nerve impulses along the cord.

Destruction of the motor cells in the anterior horn produces a flaccid (flabby) paralysis and atrophy (shrivel-

ling) of the muscles innervated by the segments of the spinal cord involved. The classical examples of these are acute anterior poliomyelitis (infantile paralysis) and chronic anterior poliomyelitis (progressive muscular atrophy or amyotrophic lateral sclerosis). Damage, usually from the virus of herpes zoster, to the sensory cells in the posterior root ganglion (posterior poliomyelitis) causes pain and an eruption in those parts of the skin served by the affected segments.

Damage to the descending, or motor, tracts (particularly the corticospinal) produces a spastic paresis (stiff paralysis) of the muscles below the point of the lesion in the cord, with an increase in the tendon reflexes and an extensor plantar reflex response of the foot (Babinski sign).

Injury to ascending, or sensory, tracts in the spinal cord produces a loss of sensation below the level of the lesion, the loss usually being most pronounced for pain, temperature, and proprioceptive sensation. Severe damage to the fibres of some of the principle divisions of white matter (posterior funiculi) at the appropriate level may result in loss of the tendon reflexes.

Spinal cord transection

The spinal cord may be structurally (anatomically) or functionally (physiologically) transected (transverse myelitis) by trauma, tumours, and infectious or demyelinating processes. Below the level of the lesions there is complete paralysis of the muscles, loss of all forms of sensation, and paralysis of the muscles that control the bladder and rectum. The reflexes are lost in the acute stages of severe lesions (spinal shock), but with partial recovery the reflexes return and may become hyperactive. There is also some degree of return of bladder and rectum control. The isolated segment of the spinal cord may become hyperirritable to produce flexor or extensor spasms of the legs when the skin there is stimulated.

Section of only one half side of the spinal cord results in the Brown–Sequard syndrome, characterized by symptoms below the level of lesions. On the same side as the lesion there is paralysis of muscles, an increase in tendon reflexes, a Babinski response, and impairment of proprioceptive sensation. On the side opposite, impairment of pain and temperature sensibility may be observed. The Brown–Sequard syndrome may be caused by tumours, trauma, and by vascular and demyelinating diseases.

Vascular lesions. Hemorrhage into the substance of the cord (hematomyelia) is usually the result of trauma, occurring only rarely in diseases of the spinal blood vessels. Thromboses (clots) of the arteries of the spinal cord are uncommon in comparison to the number of those in the brain. Clots may occur in association with inflamed arteries (arteritis) in syphilis or in other infections of the membranes (meninges), but they are uncommon in sufferers of hardening of the arteries (arteriosclerosis). Acute softening of the spinal cord may follow compression of the arteries or veins by tumours, as in Hodgkin's disease, in which there are abnormal growths of tissue (granulomas). In these cases, the signs of cord involvement are usually of sudden onset and take the form of a transverse myelitis (see above).

Tumours. Spinal-cord tumours are relatively common. They may be located outside of the dural membrane that envelopes the cord (extradural), between the dura and the cord (intradural), or intramedullary (within the substance of the cord). In contrast to tumours of the brain, the extramedullary tumours are more common than those within the substance of the spinal cord; there is also a higher percentage of relatively benign tumours.

Extramedullary tumours are accompanied by nerve-root pains and signs of compression of the cord in the nature of complete or incomplete transverse myelitis or hemisection of the cord (Brown–Sequard syndrome). Intramedullary tumours are accompanied by pains and signs similar to those of the extramedullary type.

Spinal-cord tumours are localized by roentgenograms of the spine and contrast-injected cord (myelography). Treatment is by surgical removal of the extramedullary tumour and radiation therapy of the intramedullary growths. The prognosis (probable outcome) is good in the cases of extramedullary tumours in which the development of symptoms has been slow.

Syringomyelia. Syringomyelia is a disease characterized by growths of special cells called neuroglia (gliosis) and the formation of cavities in the spinal cord and lower brain (medulla oblongata) and by the presence of muscular weakness and wasting. There are various types of sensory disturbances, often of a segmental nature, involving mainly pain and temperature, with signs of injury to the long motor and sensory tracts and the development of disturbances in the skin and bones. Cavitation of the medulla oblongata (syringobulbia) is manifested by difficulty in talking and swallowing, weakness of the muscles of the neck, loss of pain and temperature sensitivity in the face, and drooping eyelids (as in Horner's syndrome). Onset of symptoms is most common in the third or fourth decades of life, but it may occur at any time. Deterioration in syringomyelia is slowly progressive, and the course may extend over many years before the sufferer is incapacitated. There is no known treatment, although radiation therapy is of value in cases with an associated tumour of the spinal cord.

DISEASES OF THE AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system is concerned with the regulation of activities of parts of the body that are not ordinarily subject to voluntary control: the heart, lungs, intestines, genitourinary tract, the pupils of the eyes, blood vessels, salivary glands, lachrymal (tear) glands, and the glands of the skin. It is also concerned with the regulation of the activity of the endocrines and in turn is greatly affected by the secretions of the glands, particularly those of the thyroid, adrenal, and pancreas.

Customarily divided into two portions (sympathetic and parasympathetic), the autonomic nervous system is composed only of peripheral neural structures (*i.e.*, those outside the brain and spinal cord). Nevertheless, it is subject to regulation by centres in the brain's cortex (limbic lobes), hypothalamus, brainstem, and spinal cord.

There are only a few diseases in which the autonomic nervous system is primarily affected. Among them are Raynaud's disease, with such symptoms as pain and cyanosis (blueness) of the fingers and toes resulting from constriction of the blood vessels. In another there is a heightened tendency toward a feeling of giddiness or actual fainting on changes of posture from sitting or supine posture to the erect position; this orthostatic hypotension arises from failure of compensatory constriction by blood vessels in the extremities and torso.

Disturbances in the hypothalamus, the main regulator of the autonomic system in the brainstem, are accompanied by a variety of symptoms, among which are diabetes insipidus (see above), abnormal body temperature, excessive sleep (hypersomnia), obesity, emaciation, stomach ulcerations, and psychiatric disturbances.

Dysautonomia

A rare disease known as dysautonomia (Riley–Day syndrome) is accompanied by widespread disturbance of the autonomic nervous system. In this disorder, which occurs predominantly in Jewish children, there is emotional instability, decreased secretion of tears, increased sweating, transient blotching of the skin, attacks of high blood pressure, episodes of fever and vomiting, convulsive seizures, difficulty in swallowing, absent tendon reflexes, relative insensitivity to pain, impairment of taste discrimination, and absence of the fungiform and circumvallate papillae of the tongue. Degenerative changes have been found in the peripheral sympathetic ganglia and in the lateral columns and various tracts of the spinal cord. In some cases with symptoms of dysautonomia, no pathological changes of this sort have been observed. It is probable that the symptoms are then secondary to a defect in metabolism because a chemical called homovanillic acid is excreted in excessive amounts in the urine. There is no known effective treatment for the Riley–Day syndrome, and it is usually progressive, with death before the age of 20 years.

DISEASES OF THE BRAINSTEM AND CRANIAL NERVES

Brainstem. The brainstem functions in a manner similar to that of the spinal cord in the control of movements of the muscles of the eyes, face, jaw, palate, and pharynx and in receiving touch, pain, and proprioceptive impulses

from these parts. It has special groups of cells (motor nuclei) that serve in regulating the action of the viscera, in controlling the sphincter muscles of the iris of the eye, and the activity of the lachrymal (tear) and salivary glands. There are also sensory nuclei that receive impulses for hearing and equilibrium (vestibular) from the ear and for taste from the tongue. The brainstem serves as a conduit through which impulses are transmitted up to the brain's thalamus and down to the spinal cord. It also has a number of special nuclei that serve to coordinate the activity of other parts of the brain (*e.g.*, the cerebellum and cerebral cortex).

The brainstem is involved in many of the same diseases of infectious, demyelinating, or degenerative nature that affect other portions of the nervous system. This section thus deals mainly with brainstem difficulties produced by vascular (blood-vessel) lesions and tumours.

Vascular lesions. The brainstem is supplied by arteries that are not infrequently the site of sclerosis (hardening). In general, structures near the midline (paramedian area) of the brainstem are supplied by short blood vessels that enter the backside (dorsal) surface. Structures in the lateral portion are nourished by long circumferential vessels that enter the lateral surface and also send branches back to supply portions of the brain's cerebellum. Occlusions (*e.g.*, thromboses) of these arteries or their major branches produce characteristic syndromes (groups of symptoms).

Occlusion of the short vessels to the paramedian area usually involves one or more of the motor nuclei and the corticospinal tract to produce such symptoms as paralysis of eye muscles or of the tongue in one side of the body and the arm and leg on the opposite side (alternating hemiplegia). Lesions of the vessels supplying the lateral area of the brainstem are characterized by impairment of the pain sense in the face on the side of the lesion and in the trunk and extremities on the opposite side (alternating hemianesthesia). In addition, there can be evidence of injury to such structures as the visceral motor nuclei and their tracts.

Tumours. Intramedullary tumours of the brainstem produce symptoms by invading and destroying nuclei and fibre tracts. Both sides are usually involved, and there is enlargement of the brainstem in the region affected. The signs and symptoms are appropriate to those of the nuclei and tracts affected. Signs of increased intracranial pressure are usually absent. Destruction of both abducens nuclei, which serve the sixth (abducens) pair of cranial nerves, commonly leads to paralysis of the muscles that permit one to gaze to either side.

Vestibulocochlear neuromas

Neuromas (nerve tumours) arise in the vestibular portion of the vestibulocochlear nerve and produce symptoms by compression of neighbouring cranial nerves, brainstem, and cerebellum. Ringing in the ear, loss of hearing, jerky eye movements (nystagmus), facial palsy (paralysis), impairment of sensation in the face, and ataxia are common symptoms. The treatment of vestibulocochlear neuroma is by surgical removal.

Cranial nerves. *Olfactory (first cranial nerve).* The sense of smell can be impaired on one or both sides in cases of common cold or of atrophy of the mucous membrane of the nose. The sense of smell may be lost when the nerve filaments of the nose have been torn in trauma to the head or when the nerve has been damaged by tumours in the skull. Hallucination of smell, accompanied by the déjà vu sensation of strange familiarity, transient confusion, or convulsions (hippocampal fits), may occur in association with tumours or other lesions in the olfactory centres of the temporal (side) lobe of the brain.

Optic (second). The fibres of the optic nerve partially cross over (decussate) where they enter the base of the brain (at the optic chiasm). The fibres from the temporal (side) fields of vision cross in the central (medial) portions of the chiasm, while those visual fields closest to the nose stay on the same side of the brain. Lesions in the optic nerve produce blindness in the eye on the same side. Lesions in the medial portion of the optic chiasm cause a loss of vision in both temporal fields (bitemporal hemianopia). Damage on one side of the brain between the chiasm and the visual area of the occipital cortex at the back of the brain produces blindness in the opposite temporal field of vision and in the nasal field on the same side (homonymous hemianopia).

Inequalities in the size of the pupils may be related to disease of the iris or of the optic or oculomotor nerves. As a rule, the pupil of a blind eye is larger than that of a normal opposite eye. Inequalities in the size of the pupils and impairment of their reaction to light may be present with damage to reflex centres in the brainstem by tumours or other diseases. Almost distinctive of syphilis of the nervous system is the Argyll–Robertson pupil, a small pupil that does not react to light or to noxious stimuli (pinching the skin of the neck) but that reacts promptly to voluntary changes in near and far vision (accommodation). A pupillary disturbance sometimes confused with the Argyll–Robertson pupil is seen in Adie's syndrome; in this benign condition the pupils may react so slowly to light that they appear on superficial examination to be nonreactive. The accommodation reflex may also be similarly affected, and the tendon reflexes in the legs are absent.

Oculomotor (third), trochlear (fourth), and abducens (sixth). Injury to these nerves produces a paralysis of the muscles they innervate. Their brainstem nuclei, which affect the movements of the eyes, also may be damaged by tumours, vascular lesions, and demyelinating and inflammatory processes. The nerves may be compressed by extramedullary tumours of aneurysms (abnormal saclike bulges or "blowouts" in blood vessels). The third nerve may be compressed by herniation (rupture) of the brain with sudden increase in intracranial pressure. The sixth cranial nerve, because of its long course at the base of the brain, may be damaged in persons with excessive intracranial pressure. In such cases, however, the paralysis is not specifically useful in localizing the lesion. Paralyses of the ocular muscles are common in a generalized muscular disorder called myasthenia gravis and occasionally in exophthalmos (bulging eyes) associated with hyperthyroidism (oversecretion of the thyroid gland).

Muscular paralysis

Trigeminal (fifth). This is a mixed (sensory and motor) nerve, transmitting sensory impulses from the face and controlling the muscles of chewing.

Lesions in the pons (a bulge of white matter in the brainstem) usually involve the motor and main sensory functions, while lesions in the medulla oblongata affect only the motor portion of the fifth nerve.

The fifth nerve itself may be injured by trauma, tumours, aneurysms, or infections. Occasionally, it may be involved in poliomyelitis and generalized polyneuritis. The sensory and motor brainstem nuclei in the pons and medulla may be destroyed by intramedullary tumours or vascular lesions. In addition, the motor function is frequently impaired in syringomyelia and multiple sclerosis (patches of hardening in the central nervous system). The fifth nerve is also the site of a neuralgic disturbance, trigeminal neuralgia (see above).

Facial (seventh). Injuries to the facial nerve produce a paralysis of the facial muscles with or without loss of taste sensation on the anterior (front) two-thirds of the tongue and a disturbance in the secretion of the lachrymal and salivary glands, depending upon the portion of the nerve that is involved.

Lesions of the facial nerve's nucleus in the brainstem cause a paralysis of the muscles that change the expression of the face. Lesions of the facial-area motor cortex of the brain or in the connections between the cortex and the facial nucleus are accompanied by a partial paralysis of the muscles, which is usually most severe in the muscles of the lower half of the face (supranuclear palsy). The motor nucleus of the seventh nerve in the medulla oblongata may be damaged by tumours, inflammatory lesions, vascular lesions, demyelinizing processes, and sclerosis.

The facial nerve itself may be damaged by extramedullary tumours that are usually vestibulocochlear neuromas (see above). The peripheral portion of the nerve may be damaged by trauma and in such disorders as the polyneuritis associated with leprosy. Not infrequently, there is a

poorly understood paralysis of muscles served by the seventh nerve (Bell's palsy) that often follows exposure to cold (as in riding in an open car). Bell's palsy may occur at any age but is somewhat more common from the 30s to the 50s.

Vestibulocochlear (eighth). Symptoms of involvement of the cochlear (acoustic) branch of the nerve are impairment of hearing and ringing in the ear; those involving the vestibular portion include dizziness, disturbance of postural equilibrium, and nystagmus (involuntary oscillation of the eyeballs).

The nuclei of the eighth nerve may be affected by inflammation, tumours, vascular lesions, and demyelinization. Lesions of the pathways from the nerve's nuclei into the brain on one side of the body generally produce vestibular symptoms only; *e.g.*, nystagmus.

The peripheral portion of the nerve may be damaged by inflammatory processes, especially meningitis. The total and permanent hearing loss in many such cases suggests that the nerve is impaired through thrombosis of the internal auditory artery. The eighth nerve may be compressed by tumours, affected by inflammatory, degenerative, or toxic processes in the middle or inner ear, and by drugs (quinine, streptomycin). A disturbance in the function of the eighth nerve, characterized by ringing in the ear (tinnitus), impairment of hearing, and paroxysmal sensations of the environment revolving (vertigo), is known as Menière's syndrome.

Menière's syndrome

Glossopharyngeal (ninth). The ninth cranial nerve has motor fibres that serve the constrictions of the pharynx and has other fibres that transmit general sensory impulses from the upper part of the pharynx and from the taste receptors in the posterior third of the tongue. Isolated lesions of the ninth nerve are rare, but the nerve may be affected by any of the processes that involve the brainstem. The glossopharyngeal nerve is occasionally the site of a neuralgic disturbance, glossopharyngeal neuralgia (see above).

Vagus (tenth). Lesions of one of the vagal nuclei (the nucleus ambiguus in the medulla) cause difficulty according to their site. Lesions confined to the lower portion of that nucleus impair swallowing, while lesions of its upper portion produce difficulty in talking. Damage to only one side of another (the dorsal motor) nucleus produces no symptoms of autonomic disturbance, but damage to both sides is fatal. Lesions of the nuclei of the vagus nerve may result from inflammatory disorder (particularly anterior poliomyelitis), syringomyelia, intramedullary tumours, vascular damage, demyelinizing disorders, and degenerative diseases.

The peripheral portion of the tenth nerve or its branches may be involved in polyneuritis or can be compressed by tumours or aneurysms. Injury to the pharyngeal branches results in difficulty in swallowing. Lesions of the superior laryngeal nerve produce anesthesia of the upper part of the larynx and paralysis of the cricothyroid muscle in the Adam's apple. Impairment of the recurrent laryngeal nerve, frequent in aneurysms of the aorta (the great artery of the heart), causes hoarseness and difficulty in speaking (dysphonia) as a result of unilateral paralysis of the abductor muscle of the vocal cord. Bilateral abductor paralysis, which may occur rarely as a result of pressure on both recurrent laryngeal nerves (or when both nuclei ambiguus are involved by tumours or syringobulbia), causes breathing difficulty without any direct impairment of voice production (phonation).

Spinal accessory (11th). The nucleus of the 11th nerve may be destroyed by tumours and inflammatory, degenerative (syringobulbia, progressive muscular atrophy), and demyelinizing processes in the medulla. The extramedullary and peripheral portions of the nerve may be injured in meningitis, tumours, and destructive processes in the occipital bone at the back of the skull.

Hypoglossal (12th). Injury to the 12th nucleus or to the nerve itself causes atrophy of the muscles of the tongue. In bilateral damage, the tongue cannot be moved from the floor of the mouth. In unilateral lesions, half of the tongue is atrophied and deviates to the side of the lesion on protrusion. Movements toward the opposite side are impaired. The 12th nucleus may be involved in acute anterior poliomyelitis, syringobulbia, intramedullary tumours, progressive bulbar palsy (in which cases the atrophy will be accompanied by fibrillation of the tongue), or by vascular lesions. Lesions of the peripheral portion of the nerve are rare.

MOTOR SYSTEM DISORDERS

Movements of muscles are under the direct control of motor neurons (cells) in the brainstem and spinal cord. Voluntary contraction also depends on the motor cortex of the brain. The motor cells in the spinal cord and brainstem are affected by impulses from many sources, including the muscles; there is also considerable interaction (feedback) with other parts of the nervous system.

Control of muscle movements

Since diseases of the spinal cord, brainstem, cerebellum, and cerebral cortex are considered elsewhere in this article, this section deals with injuries to the basal ganglia, a collection of nuclei at the base of the brain. Specialized structures included among the basal ganglia are called the red nucleus, substantia nigra, subthalamic nucleus, the globus pallidus, the putamen, and the caudate nucleus. All of these nuclei receive incoming (afferent) impulses and send fibres to the brain's thalamus, which relays them to the motor cortex and other areas of the brain's cerebrum. There are feedback mechanisms from the cortex to the basal ganglia, as well as to the cerebellum and the brainstem.

In general, disease of the basal ganglia results in disturbance in the tone of the muscles (so-called cogwheel rigidity) and produces tremor and other involuntary movements (described by such terms as chorea, athetosis, dystonia, and hemiballism). These disorders are often accompanied by symptoms of autonomic dysfunction, because neighbouring hypothalamic nuclei also may be injured. The tremor and other involuntary movements are influenced by the emotional state of the sufferer, increasing when he is excited or tense and disappearing when he is asleep.

The basal nuclei may be individually injured by the usual infections, trauma, and tumours, but classical symptoms of basal ganglia disease involve the cells of these nuclei in a diffuse manner. The symptoms (*e.g.*, rigidity and tremor) are absent when specific motor tracts in the internal capsule (higher in the brain) are also injured, and they also tend to yield to symptoms of paralysis (hemiplegia) from a cerebral vascular lesion.

Chorea. *Sydenham's chorea.* The basal ganglia may be involved in rheumatic fever, with the occurrence of choreic (jerky) movements of the extremities, face, and trunk. Also called St. Vitus' dance, Sydenham's (or minor) chorea is most common in children but may occur in young pregnant women (chorea of pregnancy). The chorea usually abates by itself in a few weeks; it is managed with rest in bed in a quiet room and by the administration of sedatives or tranquillizers.

St. Vitus' dance

Chronic progressive chorea (Huntington's chorea). This hereditary disorder of the basal ganglia also involves shrinkage of other brain parts, such as the cerebral cortex. It is characterized by choreic movements of the trunk and extremities, psychotic behaviour, and gradually worsening dementia. It is relatively rare except in communities where a number of families with the genetic tendency are located. The symptoms may become manifest at any age but commonly appear between the ages of 30 and 50. The choreic symptoms may precede or follow the development of psychotic symptoms or mental deterioration. This adult chorea is chronically progressive, requiring institutional care and leading to death about 15 years after its onset. There is no treatment known, although the violence of the choreic movements is influenced to some extent by tranquillizers.

Paralysis agitans (Parkinson's syndrome). The symptoms of Parkinsonism have been traced to widespread, diffuse lesions (usually of unknown origin) in the basal ganglia. Chief among the signs are a masklike face, speech difficulties (dysarthria), alternating tremor, stooped posture, abnormalities of gait, slowness and poverty of movement (akinesia), loss of associated move-

ments, and symptoms of dysfunction of the autonomic motor system.

Symptoms resembling those of Parkinsonism may result from carbon monoxide or manganese poisoning. The syndrome was a common sequel of a worldwide epidemic of encephalitis lethargica (sleeping sickness) that abated in the mid-1920s. Patients taking certain drugs (*e.g.*, reserpine or phenothiazines) may develop the typical symptoms of Parkinsonism, but these disappear when the medications are withdrawn.

Although the degenerative changes are widespread, the basal nucleus called the substantia nigra is severely affected with almost complete loss of its melanin- (pigment-) containing cells. A decrease in the concentration of a substance called dopamine in the substantia nigra and in other basal ganglia is found. It is thought that the disturbance in the function of these cells and their eventual destruction result from the deficiency. Dopamine is essential to the transmission of nerve impulses in the basal ganglia.

Typically a disorder of old age, paralysis agitans is one of the most common diseases of the nervous system. It has been estimated that one out of every 40 individuals develops the disease. The onset of the symptom is insidious, usually in the sixth to eighth decades of life. In spite of its somewhat dramatic nature, the tremor itself is less disabling to the patient than are the accompanying rigidity and akinesia.

Other symptoms that almost inevitably develop are impairment of handwriting (micrographia), increased sweating, undue sensitivity to heat, excessive salivation, nocturnal incontinence (*e.g.*, bedwetting), and mental symptoms. The latter are often related to medication (particularly with such drugs as atropine). The course of the disease is usually chronically progressive, extending over one or more decades. Death is usually the result of factors (*e.g.*, infections) other than the disease itself.

Levodopa

Treatment includes the administration of a substance called levodopa, a precursor of dopamine. A bioamine (related to the amino acids of proteins), levodopa has a remarkable beneficial effect in relieving the rigidity and akinesia but is less effective for the tremor. It remains to be shown whether levodopa will halt the progress of the disease; other drugs with atropine-like action are also of value.

Surgical destruction of various portions of the basal ganglia has been used in the treatment of Parkinson's syndrome. The most effective method is destruction by freezing (cryotherapy) of part of the thalamus (the ventrolateral nucleus). This usually results in relief of tremor and rigidity, but the akinesia and the progress of the disease are not as significantly affected.

Dystonia musculorum deformans. Of unknown cause, this rare disease of the basal ganglia is characterized by the development of slow, forceful, and sustained twisting and writhing movements of the muscles of the trunk or extremities. Perhaps there is a hereditary predisposition, since it is most common in families of Russian-Jewish extraction. The onset is commonly between the ages of five and 15, often showing as an abnormality of the gait with bizarre stepping or bowing movements. The disease tends to be progressively incapacitating, although mental faculties are preserved. In some cases, the disease ceases to progress, and the sufferers are able to carry on useful lives compatible with their muscular disability. Good results have been reported from surgical destruction of the same portion of the thalamus as in paralysis agitans, and a limited percentage of cases have been treated with levodopa with beneficial results.

Spasmodic torticollis (wryneck). This typically intermittent disorder may be a feature of postencephalitic Parkinsonism or of Wilson's disease (a hereditary defect in copper metabolism). Wryneck may also occur without any known cause, although such influences as psychoneurosis (hysteria) have been suggested. The symptoms are usually limited to twisting movement of the head caused by intermittent or sustained contraction of the muscles of the neck. The course is usually characterized by an increase in the severity of the movements, but partial or complete remissions (improvements) may occur. The symptoms have been relieved in some patients with thalamic surgery.

DISEASES OF THE CEREBELLUM

A two-lobed, wrinkled structure at the rear underside of the brain, the cerebellum may be damaged by tumours, trauma, vascular lesions, infections, intoxications, and metabolic diseases. In addition, the cerebellum is involved in a number of hereditary degenerative diseases, the most common of which is Friedreich's ataxia.

This disorder is characterized by the development of ataxia of the trunk and extremities, absence of deep reflexes, loss of proprioceptive sensations in the extremities, extensor plantar (Babinski) responses, clubfeet, and curvature of the spine (scoliosis) in the first or second decade of life. Dysarthria, muscle atrophies, degeneration of the optic nerve, and involvement of the heart muscles may occur in the late stages. The disease may occur in abortive forms (*formes frustes*) that may be compatible with a relatively normal life-span, but in the usual case the course is slowly progressive, with complete incapacity by the age of 20. Death is usually caused by intercurrent infections or involvement of the heart muscles.

Hereditary ataxia

Other heredodegenerative diseases of the cerebellum that have been considered to be variations of Friedreich's ataxia are (1) hereditary ataxia with muscular atrophy (Lévy–Roussy syndrome), which differs from Friedreich's ataxia in that there is more severe wasting of the muscles of the legs, a lesser degree of ataxia, and a less severe course; (2) hereditary cerebellar ataxia with spasticity (Marie's or Sanger-Brown's ataxia), which differs from Friedreich's ataxia in showing late onset of symptoms, increased response of the tendon reflexes, and frequent occurrence of optic atrophy and oculomotor palsies; and (3) olivocerebellar and olivopontocerebellar atrophy, a rare syndrome characterized pathologically by degenerative changes in the cerebellum, olivary nuclei in the medulla oblongata, and pons. Symptoms include the development in middle life of ataxia of trunk and extremities and scanning speech (regularly occurring pauses in speaking); there are signs of involvement of the basal ganglia in a small percentage of cases.

INTRACRANIAL TUMOURS

Tumours are found in approximately 2 percent of all human skulls opened after death. They may arise from the skull itself, in the meninges, or in any of the elements of the nervous system, or they may be metastases that spread from tumors in other organs. Cancers (gliomas) of specialized cells (called glia or neuroglia and with which the neurons are closely associated) lead the list of intracranial tumors, accounting for about 45 percent.

The general symptoms include headache, nausea and vomiting, diplopia, lethargy, somnolence, mental changes, and convulsive seizures. They are related to such factors as increased intracranial pressure and edema (swelling) of the brain. Localized (focal) bodily symptoms of brain tumour that are the result of destruction of brain tissue reflect the specific part of the brain that is involved.

The onset of symptoms is insidious, and the progress extends over many months, except in cases of rapidly growing glial tumours (glioblastomas) and of metastatic tumours, with which death may ensue in a few months.

An intracranial tumour is suspected when severe headaches develop in a person previously free of them, when convulsive seizures have their onset in adult life, or when there is behavioral or clinical evidence of slowly progressive damage to one portion of the brain. The findings on neurological examination serve to localize the areas of the brain damage in most of the sufferers. In others, special diagnostic tests may be required. The examinations that are of value in establishing the diagnosis of a brain tumour and in determining its location and type include plain X-rays of the skull, echoencephalography, electroencephalography, examination of the cerebrospinal fluid, ventriculography, angiography, and radioactive scanning (see above *The neurological examination*).

The clinical course of the sufferer is related to the type

of brain tumour and to its location. In general, the signs and symptoms are of slow onset and progressive in most instances until they cause death; remissions are rare.

Meningiomas (tumours of the membranes around the brain) and acoustic (eighth-cranial-nerve) neuromas are usually slow-growing, well-encapsulated hard tumours located on the outer surface of the brain. This makes them relatively accessible to the neurosurgeon, and usually they can be removed partially or *in toto*. Metastases and soft glial tumours (particularly the glioblastomas that infiltrate or invade both cerebral hemispheres or brainstem) typically have such a rapid course that they are not amenable to surgical therapy. The treatment of brain tumours by surgical removal or by radiation therapy is supported by the use of anticancer drugs. Chemotherapy of malignant brain tumours, however, is still in its experimental stages.

The choice between surgery and radiation therapy is often difficult. Surgery is most often used for such growths as meningiomas, cystic (saclike) tumours of the brain's third or fourth ventricle, and most tumours growing from congenital rests (fragments of embryonic tissue trapped inside the body). Radiation therapy (alone or combined with partial surgical removal) is favoured for malignant gliomas and metastatic tumours. Tumours of the pituitary gland are likely to be treated by radiation therapy unless surgery becomes urgent because of rapid failure of vision or when it is suspected that there has been cyst formation in the tumour.

DISEASES OF THE CEREBRUM

The cerebrum, which comprises the upper bulk of the brain, may be involved in malformations and has the typical susceptibility of neural tissue to trauma, tumours, bacterial and other infections (encephalitis and abscess formation), demyelinating diseases, neurochemical disorders, and toxins. This section, however, focusses on injury to the cerebrum by vascular and degenerative diseases.

Cerebral vascular accident. Sudden cerebral damage (accident) is a leading cause of death throughout the world. In addition, large or small vascular lesions are discovered in about 25 percent of routine autopsies. Cerebral arteriosclerosis, usually a specific feature of generalized hardening of the arteries, is the most common cause of cerebral vascular disease.

Strokes

Perhaps two-thirds of all cerebral vascular accidents (sometimes called strokes) are the result of thrombosis: blood clots that plug (occlude) the vessels of the brain. Cerebral hemorrhage, although less common (about 20 percent) than cerebral thrombosis, is the most serious form of cerebral vascular accident. The hemorrhage is usually from a vessel at the base of the brain. Blood is discharged (extravasated) into the brain substance itself, often resulting in apoplexy (coma and paralysis). Death is almost inevitable if the hemorrhage is large.

Occlusion of one of the branches of the main arteries in the brain by arteriosclerosis or embolism (any obstruction, including air bubbles, fat globules, as well as clots) usually results in the death of tissues (infarct formation) served by the vessel. Occlusion of the large vessels in the neck may be accompanied only by transient symptoms (cerebral vascular insufficiency) or by none of consequence. If, however, collateral circulation (through smaller, unaffected vessels) is inadequate, infarction still may ensue.

Obstruction of the anterior cerebral artery on one side of the brain usually causes paralysis and sensory loss in the leg on the opposite side. If the artery of the dominant (almost always left) hemisphere is affected, mental confusion and aphasia (*i.e.*, speech impairment) may also occur.

Plugging of the main branch of the middle cerebral artery on one side produces paralysis and sensory loss on the opposite side, mainly affecting the face and the arm. Aphasia is also present when the lesion is in the dominant hemisphere. Occlusion of smaller vessels of the middle cerebral artery produces hemiplegia, hemianopia (one-sided blindness), inability to read (alexia) or recognize sensory stimuli (agnosia), or to perform skilled movements (apraxia) in combinations or as isolated symptoms.

Occlusion of the main trunk of the posterior cerebral artery on one side causes damage to the thalamus and the visual (occipital) cortex, with hemianopia, fleeting hemiparesis (muscular weakness), and sensory loss accompanied by burning pains, choreiform movements, and ataxia (thalamic syndrome of Déjerine–Roussy).

Blocking of the basilar artery on the underside of the brain is serious, often resulting in paralysis and sensory loss in all extremities and in the muscles supplied by the brainstem nuclei. Occlusion of the vertebral artery that runs down toward the spinal cord or of minor branches of the basilar artery is usually not fatal, although the symptoms can be disabling.

Chances of survival are poor for the victim of a cerebral hemorrhage of any considerable size. The majority of those with a cerebral thrombosis are likely to recover from the initial damage, although a number of them die in the first few weeks after the cerebral accident from pneumonia or from heart or kidney complications. Survivors tend to show gradual improvement in the neurological difficulties over the ensuing months.

General care in the initial stages is the chief form of therapy for cerebrovascular accidents. Physiotherapy (*e.g.*, special exercise) and speech therapy are important in the convalescent stages of people with hemiplegia or aphasia. Attempts have been made to remove surgically the vessels and debris of intracranial hemorrhage, but the poor condition of the sufferer militates against success. Long-continued administration of drugs to prevent clotting (anticoagulants) has been recommended for persons with intermittent symptoms of cerebral thrombosis (or any embolus). Reconstructive surgery (*e.g.*, reaming out) of the vessels in the neck for patients with arteriosclerotic narrowing of those vessels has been tried as a preventive (prophylactic) measure with a moderate degree of success.

Intracranial aneurysms and primary subarachnoid hemorrhage. Intracranial aneurysm usually arises from congenital weaknesses in the walls of affected vessels, which bulge locally in a manner resembling that of a defective inner tube in a pneumatic tire. Found in approximately 2 percent of routine autopsies, these aneurysms may rupture, being responsible for about 10 percent of all cerebral vascular lesions. About 85 to 90 percent of intracranial lesions are found in five arteries: the middle cerebral, internal carotid, basilar (and its branches), anterior communicating, and anterior cerebral. Rupture may occur at any age but is most common in middle life. In addition, the presence of an intracranial aneurysm may not even be suspected until it ruptures. Occasionally, it may be so located that it compresses one or more of the cranial nerves, thus alerting the physician to the peril of future hemorrhage.

Blood-vessel rupture

Symptoms associated with the rupture of an intracranial aneurysm are usually those resulting from the presence of blood in the subarachnoid spaces between the brain and its membranes. Headache and stiffness of the neck are common, and coma may occur if the aneurysm ruptures in the cerebrum as well as into the subarachnoid space. After such hemorrhages the cerebrospinal fluid becomes grossly bloody, and intracranial pressure increases. About 35 percent of sufferers of aneurysm rupture die as a result; those that survive are in constant danger of subsequent intracranial bleeding. The presence and location of an aneurysm that caused a subarachnoid hemorrhage can be established by angiography.

There is controversy as to the best method of treatment. Some advocate conservative treatment in the form of bed rest and therapy that avoids radical intervention in the lesion. Other physicians, because of the ever-present risk of rupture, advise surgical treatment of the aneurysm by tying off (ligating) its neck or by ligation of the common or internal carotid artery in the neck.

Presenile dementia (Alzheimer's and Pick's diseases). Generalized sclerosis (hardening) of the intracranial arteries may result in occlusion of small cortical vessels with

gradual decrease in mental faculties (arteriosclerotic dementia). In addition, the cerebral cortex is subject to degenerative changes associated with diseases other than arteriosclerosis, the most common of these being Alzheimer's and Pick's diseases. The cardinal symptoms of these two diseases have their onset between ages 40 and 65 and include progressive dementia and disturbances in speech (aphasia or dysphasia). The degenerative changes involve the nerve cells in parts (association areas) of the frontal and temporal lobes of the brain. Although there are differences in the nature of lesions found in Alzheimer's and Pick's forms of the disease, the clinical symptoms are so similar that differentiation between them is rarely feasible while the victim is alive. The course is progressive, terminating in incapacity and death within four to ten years. Paralysis is not a feature of the disease until the terminal stages.

Degenerative diseases. *Primary degeneration of the corpus callosum (Marchiafava–Bignami disease).* This rare degenerative disease involves the tracts of white matter (the corpus callosum, the anterior commissure, and the middle cerebellar peduncles) that connect the two halves of the brain. The disorder usually but not exclusively affects Italian males who are addicted to the use of red wine. The onset is insidious, with psychotic episodes and dementia, the progressive course leading to death in from three to six years.

Central pontine myelinosis. This rare disease is characterized by degeneration of the central portion of the pons (which bridges the medulla with the cerebellum). Occurring in young or middle-aged adults, central pontine myelinosis is commonly associated with chronic alcoholism or other conditions associated with chronic malnutrition. Confusion and other mental symptoms, quadriplegia (paralysis of all four limbs), pseudobulbar palsy, and cutaneous sensory loss are common symptoms. Death usually occurs within a few weeks or months after the onset of symptoms.

Alcoholism and malnutrition

Down's syndrome (mongolian idiocy). In this congenital disorder associated with chromosomal abnormality, the mentally defective sufferers exhibit facial and bodily features that have a superficial resemblance to those normally present among such Asians as the peoples of Mongolia (see GENETICS, HUMAN; BIRTH DEFECTS AND CONGENITAL DISORDERS).

Physical features of the disease include shortening of the skull, flattening of the face, narrowing and slanting of the gap between the eyelids, shortening of the nose, broadening of the tongue, shortness of stature, widening of the hand with simian (apelike) crease on the palm, spina bifida, webbing of fingers or toes (syndactylism), and maldevelopment of internal organs, particularly the heart.

Many of the affected individuals die in infancy, but a number reach adulthood. The chief causes of death are the associated congenital heart disease and infections.

Cerebral palsy (Little's disease). Cerebral palsy describes a heterogeneous group of symptoms that arise from damage to the nervous system before birth, at birth, or early in life. The syndrome that results is related to the portion of the nervous system affected. The groups of symptoms can be roughly identified as spastic, athetotic, or ataxic, depending upon whether the cerebral cortex, basal ganglia, or the cerebellum is the most severely affected (see above).

Cerebral palsies can derive from chromosome abnormalities, inherited metabolic defects, prenatal injury to the fetus and factors that lead to premature birth, damage to the infant because of oxygen deficiency or mechanical injury at the time of delivery, and jaundice, hypoglycemia, or infections of the nervous system in the first few months after birth. Cerebral palsy is observed slightly less often than once in every 1,000 births in the U. S.

Severe damage to the nervous system may be evident at the time of birth, but it is more usual for the symptoms to be manifested during the second to fourth year of life through failure of the child to attain normal physical and mental development.

The course in cerebral palsy is quite variable; if damage to the nervous system is severe, the infant may die in the first few months of life. Children with a lesser degree of damage may develop to normal adult life with only mild spasticity, athetosis, or ataxia. In most cases, however, there are serious handicaps requiring special care throughout life (*e.g.*, physiotherapy and special education).

INFECTIONS

The nervous system may be invaded by a wide variety of disease-producing agents (*e.g.*, bacteria, viruses). The symptoms that result are related to the site of the infection and the type of invading agent. These infections can be roughly divided into large groups (meningitis and encephalitis), depending on whether the coverings (*e.g.*, meninges) or the functioning elements (parenchyma), such as the neurons of the brain, are mainly affected.

Bacterial infections. Infections of leptomeninges (the arachnoid and pial membranes) are divided into two groups, acute (brief and severe) and subacute (more prolonged and milder), according to the nature of the disease process and the mode of onset of symptoms. They can be further subdivided as purulent (associated with pus formation) and nonpurulent, the former representing the greater degree of inflammatory reaction.

Acute purulent meningitis. This syndrome is usually the result of infection with disease-producing (pathogenic) bacteria, commonly meningococcus, *Hemophilus influenzae,* pneumococcus, streptococcus, or staphylococcus. With the exception of infections with meningococcus, which tend to appear in epidemics, the occurrence of the disease is sporadic. People of any age may be affected, but the incidence is high in infancy and early childhood.

Early symptoms include fever, headache, nausea and vomiting, stiffness of the neck, pains in the back and clouding of consciousness. Convulsions may occur in infants and children. The diagnosis is made from the fluid tapped from the spine (lumbar puncture). The fluid is under increased pressure and is purulent, containing several thousand pus (white-blood) cells per cubic millimetre, and the glucose content is low. The causative organism can be cultured (grown from the spinal fluid).

While the mortality rate was once quite high, most victims of acute purulent meningitis can be cured with drugs (*e.g.*, penicillin). The choice of the drug to be used is determined by testing the sensitivity of the cultured organisms. Occasionally, especially in sufferers who have already received antibiotics, organisms fail to be cultured from the cerebrospinal fluid. Under these circumstances, treatment with a combination of drugs (*e.g.*, penicillin, sulfadiazine, and chloromycetin) is commonly undertaken in the expectation that at least one of them will be effective.

Drug treatment

Subacute meningitis. This form of meningitis is usually the result of infection with tubercle bacilli or mycotic organisms (fungus). The syndrome shows a less acute onset than does acute purulent meningitis; the inflammatory reaction also is more chronic, the course is more prolonged, and relapses are likely to occur. The cerebrospinal findings also differ in that the fluid is usually cloudy ("ground-glass") in appearance rather than purulent. The number of pus cells is lower, falling in the range of 50 to several hundred per cubic millimetre, and the glucose content is not so sharply reduced.

Tuberculous meningitis. The occurrence of tuberculous meningitis greatly decreased after the introduction of effective therapy for tuberculosis of the lungs and other organs; nevertheless, it remains the most common cause of death from tuberculosis in children. The mortality rate in tuberculous meningitis has been reduced from almost 100 percent to less than 20 percent by combining such drugs as streptomycin, isoniazid, and para-aminosalicylic acid administered over a period of eight to 12 months.

Fungal meningitis. A great increase in the number of cases of meningitis arising from infections with fungi (most commonly cryptococcus) followed the general use of drugs that kill bacteria normally present in the body. Apparently, such bacteria prevent the growth of fungi; in addition, some drugs (*e.g.*, corticosteroids) suppress nor-

mal immune reactions to increase susceptibility to invasion by fungi. Low-grade symptoms similar to those of tuberculous meningitis are the most common manifestation of mycotic (fungal) infections of the membranes, but such problems as abscesses may also arise.

Infections with the fungi are usually fatal after an acute or prolonged course. Treatment remains unsatisfactory, although sulfonamides, tetracycline, or penicillin may be helpful in some forms. Prolongation of course and presumptive cures in some cases have been reported with the use of other drugs (*e.g.*, hydroxystilbamidine and amphotericin B).

Cerebral epidural and subdural meningitis. The cerebral spaces on either side of the outermost of the meninges (the dura) may be invaded by pathogenic bacteria by extension of infections from the scalp, bones of the skull, ear or nasal sinuses. The symptoms, associated with epidural or subdural pus, superficially resemble those of subacute meningitis, but convulsions, hemiplegia, aphasia, or other focal signs may occur when there is thrombosis of the vessels in the meninges. The cerebrospinal-fluid findings are those that occur with infections near the meninges that are not accompanied by a bacterial invasion of the pia and arachnoid (the leptomeninges). There is a moderate increase in the number of cells in the fluid, but the glucose content is normal, and no organisms can be cultured from the fluid. Treatment is by surgical evacuation of the pus and the administration of drugs to combat the infection.

Spinal epidural abscess. The fatty tissue in the spinal epidural space may be invaded by micro-organisms that first infect the bones of the spine or from purulent infections of the skin. The symptoms of this spinal form of meningitis are pain in the back and stiffness of the neck. As the abscess grows, the spinal cord may become compressed. Thrombosis of the spinal vessels as a result of the infection produces an acute softening of the cord with signs of transverse myelitis (see above). Surgical evacuation of the pus and the administration of antimicrobial agents comprise the treatment. Complete recovery is the rule if the operation is performed before the onset of paralysis.

Brain abscess. Invasion of the brain itself by pathogenic organisms results in the formation of pus that eventually becomes encapsulated (walled in). Brain abscess usually follows infections of the mastoid bone (behind the ear), of the nasal sinuses, or of gaping (compound) fractures of the skull, but it may also be the result of the spreading of micro-organisms that initially attacked the lungs or heart. The incidence of brain abscess greatly decreased after improvement in methods for treating infections of the mastoid bone and nasal sinus.

The symptoms and signs of brain abscess are similar to those of brain tumours or other expanding intracranial lesions. An abscess may be suspected when signs of an expanding intracranial lesion develop in someone known to have an infection in the skull or elsewhere in the body. This can be confirmed, and the site of the abscess may be located with angiography or pneumoencephalography (see above). Treatment calls for the surgical evacuation of the pus or removal of the whole encapsulated abscess followed by the administration of antimicrobial agents.

Virus infections. The central nervous system of man may also become infected with viruses (see VIRUS), including those that produce mumps, so-called cold sores (herpes), and rabies. Such virus infections in man usually occur in epidemics, but sporadic cases are not uncommon. Many mammals serve as reservoirs of viruses (*e.g.*, horses in equine encephalomyelitis), and a number of arthropods (*e.g.*, ticks and lice) have been identified as transmitting viral infection. The virus of infantile paralysis can produce disabling motor symptoms, and that of herpes zoster (shingles) may lead to severe sensory disturbance (*e.g.*, excruciating pain), but in most viral disorders the symptoms are those of acute meningitis or encephalitis of mild or moderate degree. In the latter cases, the disease is usually self-limited, recovery even without treatment ensuing with few or no aftereffects (sequelae). Fatalities or severe sequelae are uncommon except in rabies, equine encephalitis, herpes invasion of the brain, and acute anterior poliomyelitis (see below). In such viral infections, severe destruction of the brain or spinal cord may result in extensive paralyses and impairment of mental function.

Cold sores, rabies, and shingles

Diagnosis is established by the recovery of the virus from such sources as the blood, cerebrospinal fluid, saliva, nasal washings, and brain tissues (usually at autopsy) and from special serological (blood) tests similar to those for some venereal diseases (*e.g.*, syphilis). No adequate treatments for the majority of virus infections of man are known. Immunization procedures are available for some of them (*e.g.*, rabies, acute anterior poliomyelitis).

Acute anterior poliomyelitis. Although the introduction of effective immunization (Salk and Sabin vaccines) almost completely eradicated it in most places, this disease (known also as infantile paralysis and Heine-Medin disease) was a scourge of children before the late 1950s. The widespread distribution of the disease, its devastating symptoms, and difficulties in treating the acute and convalescent stages all highlight the dramatic benefits obtained by vaccination. The disease was at one time worldwide in distribution, affecting millions of victims, commonly children between the ages of one and ten. Particularly severe epidemics occurred in the early 1950s in Belgium, Denmark, Germany, and the U.S. Inadequate immunization programs apparently led to outbreaks in the late 1960s in Spain, Turkey, Africa, and Latin America. The symptoms at the onset are those of any acute infection (*e.g.*, fever), followed in a few days by headache, stiffness of the neck, and flaccid paralysis of muscles.

The extent of the paralysis varies from weakness of a few muscles in one extremity to complete paralysis of all the muscles of the trunk and extremities. When death occurs, it is usually from paralysis of the respiratory muscles. Partial paralysis of the affected muscles is a common residual symptom, and many survivors of infantile paralysis live into old age with atrophy and weakness of one or more extremities.

Other infections. *Rickettsial diseases.* A mild or moderately severe degree of encephalitis may accompany infections with micro-organisms known as rickettsiae, which are intermediate in structural complexity between bacteria and viruses. Rickettsial infections are transmitted to man by such animals as the flea, louse, or tick. These human diseases include typhus, spotted fever, and scrub typhus (tsutsugamushi disease), all of which can impair the blood vessels of the brain. The diagnosis is made by recovery of the organism from laboratory animals injected with blood from infected persons and through serological tests (Weil–Felix reaction). Treatment is with such drugs as aureomycin, chloramphenicol, or terramycin.

Typhus and scrub typhus

Neurosyphilis. Syphilis of the nervous system became less common after the introduction of penicillin and other drugs for treating early manifestations of syphilis (see REPRODUCTIVE SYSTEM DISEASES). The nervous system seems affected in approximately one-third of all cases of syphilis that remain long untreated. Although evidence of mild subacute meningitis has occurred occasionally in the primary or secondary stages of the disease, symptoms of involvement of the nervous system are usually delayed for some time (15 to 25 years) after the initial infection. Any part of the nervous system can be affected, but the most likely involvements are of the spinal cord (tabes dorsalis) or of the brain (dementia paralytica).

Tabes dorsalis is characterized by degenerative changes in the sensory (posterior) roots of spinal nerves and in the spinal cord itself and by sharp, cutting pains, progressive ataxia of the limbs, loss of reflexes, varying degrees of sensory loss, and disorders of the functions of the bladder, rectum, and sexual organs.

Dementia paralytica (general paresis of the insane) results from a chronic syphilitic meningoencephalitis that destroys the cerebral cortex, leading to general dissolution and death within three to ten years. The disease at one time accounted for 10 percent of all admissions to mental hospitals.

Syphilitic invasion of the nervous system can be pre-

vented by drug treatment in the earlier (primary or secondary) stages of syphilis, and once in the nervous system it can be cured or arrested the same way.

DEMYELINATING DISORDERS

Loss of myelin, the fatlike sheath around many nerve fibres, may be a feature of vascular lesions, infectious processes, nutritional deficiencies, and other diseases. Demyelinization in these cases is only one feature of the pathological process; there are other destructive neuronal changes as well. The term demyelinating diseases, however, is used specifically for significant myelin loss of unknown cause. When there is destruction of previously normal myelin, the disease is called myelinoclastic. By contrast, in what are termed leukodystrophies, there is a defective development (dysmyelination) rather than destruction of the myelin sheath. Dysmyelination is often accompanied by the deposition of pigment in the degenerated parts and occasionally also in the peripheral nerves and other organs.

Myelinoclastic (sheath-destructive) diseases. *Multiple sclerosis.* Multiple sclerosis is a chronic disease characterized by the presence of many separate patches of demyelination (lesions) in the brain and spinal cord and by a wide variety of neurological signs and symptoms that at first have a tendency to come and go. While there is variation in the number of symptoms from time to time, evidence of multiple lesions is usually present at any one time. The cause of this myelinoclastic disorder is poorly understood; some theorize that it is attributable to an autoimmune reaction (*i.e.*, immunity against one's own cells) or to infection by slow-acting viral invaders.

Symptoms of multiple sclerosis

Onset of symptoms may be at any age but is most commonly observed in the late teens or in the third or fourth decade of life. Any part of the nervous system may be affected, but common early symptoms are those of involvement of the optic nerve (optic neuritis) or of the spinal cord with paresthesias (*e.g.*, prickling or burning) in one or more extremities and weakness or ataxia in the arms or legs. The initial symptoms usually disappear almost completely, but, in the course of a few months or years, new symptoms are most likely to appear. The course of the disease is quite variable; some victims may live for many years without suffering severe disability, but more often each new attack is followed by more severe sequelae. The disease is seldom rapidly fatal, and the average duration of life after onset is about 25 years, or about five years after relatively complete incapacitation. In the terminal stages, practically every portion of the nervous system is affected. There are variations from the typical form of multiple sclerosis: neuromyelitis optica, in which the optic nerves and the spinal cord (transverse myelitis) are mainly affected; and acute encephalomyelitis, in which there is an acute onset of widespread evidence of damage to the nervous system. Many of these atypical cases follow a course similar to that of multiple sclerosis. No treatment is known to favourably influence the symptoms of multiple sclerosis at any stage of the disorder.

Schilder's disease (encephalitis periaxialis diffusa). This is a rapidly progressive sheath-destructive disease in which there is widespread demyelination of the neurons in the cerebral hemispheres. Children are more commonly affected than adults, the disease rapidly progressing to death within a few years of onset. The common symptoms are convulsive seizures, repeated myoclonic jerks (as in the occasional sudden, jerky awakening experienced when one is drifting into sleep), optic atrophy, hemianopia, hemiplegia, blindness from cortical damage, aphasia, and mental symptoms (*e.g.*, dementia).

Dysmyelination disease. The classic example of this form of myelin disease, metachromatic leukodystrophy (sulfatide lipoidosis), exhibits diffuse impairment in the development of myelin in the brain associated with a firm toughness of the white matter of the cerebrum and cerebellum. The disorder shows a predilection for the fibre tracts that normally should myelinate after birth and tends to spare the arching (arcuate) fibres in the cerebral cortex. The affected tissues contain granular material that stains (with toluene blue) various shades of red in the early lesions and golden brown in the older lesions. Accumulation of this pigmented material results from a defect in the metabolism of fatty substances called sulfatides, appearing in the nerves, pituitary gland, liver, testes, and kidneys and excreted in the urine. Signs of involvement of the nervous system may be manifest in infancy, childhood, or early adult life in the form of convulsive seizures, optic atrophy, paralyses, and such mental symptoms as dementia and emotional abnormalities. The disease rapidly progresses to death within a few years of onset. Satisfactory treatment remains to be developed.

CRANIOCEREBRAL TRAUMA

Injury to the head is one of the common causes of death in young adults. Severity of symptoms depends on the extent of the damage to the brain rather than on the presence or absence of bone fracture. Survivors of head injury may show convulsive seizures, psychosis or other mental disturbances, and a constellation of other symptoms (posttraumatic syndrome).

The diagnosis of a head injury is not difficult except when the victim is found in unexplained coma. The head is carefully examined for lacerations (torn wounds) or contusions (bruises); the ears and nose are inspected for bleeding. X-rays are taken to reveal possible fractures, and an echoencephalogram may be employed to show any displacement of structures within the skull. Electroencephalograms are taken routinely at many hospitals in cases of coma. Lumbar puncture is also of value in assessing the severity of any injury; *e.g.*, through examination of the spinal fluid for the presence of blood. Pneumoencephalography or angiography may be needed to establish the diagnosis of extradural, subdural, or large intracerebral hemorrhages.

Concussion

The mortality rate is almost nil in sufferers of simple concussion (blows to the head) and less than 2 percent if the injury produces only a minor degree of cerebral edema or congestion. The mortality rate rises when the brain cortex itself is contused (5 percent) and increases sharply when the brain is lacerated (40 percent). Death may occur in the period immediately after the injury, or it may be delayed for several weeks.

The course of progress in victims of head injury is related to the severity of damage to the brain and to the presence of complications. In general, there is a rapid return of consciousness in those who have incurred minor injury (simple concussion). Usually there is impairment of memory for the immediate period prior to the injury (pretraumatic amnesia) and the period directly following recovery of consciousness (posttraumatic amnesia). Headaches, dizziness, or vertigo are usually present after consciousness is regained. These symptoms usually disappear in a few weeks, but not infrequently they may endure as long as several months.

With severe injuries the period of coma may be prolonged, and there is a period of confusion and mental clouding before full consciousness is restored; and there may be signs of focal damage to the brain or of cranial-nerve palsies. With the passage of time, considerable improvement in symptoms is the rule, although enduring sequelae (*e.g.*, convulsive seizures, paralysis, and mental impairment) are not uncommon.

Treatment of craniocerebral injuries includes superficial cleaning and closing of wounds, removal of fragments of bone and dead tissue, and elevation of caved-in parts of the skull from underlying soft tissues. Nonsurgical treatment chiefly involves general care and control of increased intracranial pressure (*e.g.*, with such medications as corticosteroids).

Complications of head injuries. *Extradural hemorrhage.* Leaking of blood into the extradural space occurs in less than 1 percent of cases as a result of torn meningeal arteries (usually the middle meningeal). The mass of blood (hematoma) is often quite large, commonly extending over part of one hemisphere in the middle fossa (hollow) of the skull. The typical sequence is loss of consciousness at injury, a lucid interval of several hours, followed by relapse into coma and hemiplegia. In the ab-

sence of this sequence of events, angiography may be required to detect the hematoma. Death almost invariably ensues unless the clot is removed surgically.

Subdural hemorrhage. Bleeding into the subdural space comes from rupture of arachnoid vessels or of small vessels extending between the arachnoid and dural membranes (meninges). It occurs in about 2 percent of people who incur trauma to the head. The frequency of subdural hemorrhage is related to the severity of the injury, although it may occur in apparently mild injuries. Subdural hemorrhage is suspected when there are daily fluctuations in consciousness or when recovery fails to occur as expected. Echoencephalography, repeated electroencephalograms, and angiography can help in diagnosis; treatment consists of surgical removal of the clot.

Subarachnoid hemorrhage. Hemorrhage into the subarachnoid space is present in practically all cases of head injury of moderate or severe degree. Usually of no great consequence, the clot is generally absorbed spontaneously.

Intracerebral hemorrhage. Pinpoint hemorrhages, or small leaks of blood into the substance of the brain, are common in persons with severe injuries and do not require surgical therapy. The debris of large hemorrhages typically is removed surgically.

Infections. Infections of the bone, leptomeninges (purulent meninges), or intracerebral abscess are rare complications of head injury. Their diagnosis and treatment are the same as for other similar infections.

Cranial-nerve palsies. Damage to the cranial nerves occurs in about 5 percent of head injuries. The olfactory, facial, and acoustic nerves are most commonly affected (see above). Complete or partial recovery is the rule except for lesions of the olfactory nerve.

Focal cerebral lesions. Hemiplegia, aphasia, or other signs of localized (focal) damage to the brain may occur in sufferers of severe head injuries. The symptoms are usually related to contusion and laceration of the brain or to small hemorrhages into the substance of that organ.

Sequelae (residual symptoms) of head injuries. *Epilepsy.* Convulsive seizures occur in approximately 2 percent of those who suffer head injury. The incidence is much greater (more than 40 percent) when the brain itself is injured (*e.g.,* by penetrating objects such as shrapnel) or when the dura and arachnoid membranes are torn by compound fractures of the skull. Convulsions may occur immediately following injury but more commonly appear months or years afterward. They are similar to epilepsies arising from other causes except that focal seizures (*e.g.,* involuntary leg or arm twitching) are more common than are generalized convulsions. The treatment is the same as that for seizures from other causes and may include the use of sedatives and other drugs.

Major psychiatric disturbances. Transient psychotic episodes and some impairment of mental faculties are not uncommon after severe trauma to the brain, but long-continued psychotic episodes are rare. They account for less than 1 percent of admissions to psychiatric hospitals.

Posttraumatic syndromes. Headaches, dizziness, irritability, restlessness, inability to concentrate, increased sweating, depression, and other personality changes occur in more than one-third of victims of head injury. These symptoms do not seem to be related to the severity of injury to the brain, being attributed to minor derangement of cerebral function or to psychological reactions. Typically appearing shortly after the patient is allowed out of bed, the symptoms tend to decrease in severity and to disappear after three to six months.

Personality changes

Reassurance of the sufferer that the symptoms are not due to serious injury to his brain and that they will ultimately disappear is most beneficial. He is encouraged to participate in social and recreational activities and to return to appropriate work as soon as his symptoms permit. Mild sedatives and analgesics (*e.g.,* aspirin) are often of value in posttraumatic syndromes.

EPILEPSY (RECURRENT CONVULSIVE SEIZURES)

Epilepsy is a paroxysmal disorder of the nervous system recognized by recurring attacks of loss or impairment of consciousness with or without convulsive movements.

Classification. One way to classify sufferers of convulsive seizures is to consider those with demonstrable neural damage (symptomatic epilepsy) as essentially different from the rest (idiopathic epilepsy). This controversial view presumes no physical lesion as a basis for idiopathic epilepsy, almost as if the inherited tendency found for the disorder had no physiological repercussions in the nervous system.

More objective systems classify epilepsies according to the manifestations observed during seizures. This method serves to indicate the location of abnormal tissues (the neural focus of symptoms) and to show how their influence spreads in the nervous system. Distinctions of this sort are indeed of value in selecting treatment methods for each individual case.

Causes of convulsions. Convulsions may result from acute lack of blood sugar or oxygen for any reason, from disturbances of calcium and phosphorus metabolism and other metabolic disturbances, and from drugs and poisons. The common occurrence of seizures in patients with brain disease indicates that damage to cerebral tissue is the most common cause of what is called epilepsy.

The extensive list of diseases frequently accompanied by seizures includes developmental and congenital defects, birth injuries, infectious diseases of childhood, meningitis, encephalitis, cerebral trauma, tumours, abscesses, and degenerative diseases of the nervous system. Attacks may not appear for several or many years after initial damage to the brain.

Occurrence. Approximately 0.5 percent of people are subject to recurrent convulsive attacks. Males tend to be affected more frequently, and so-called idiopathic attacks commonly first appear before age two or at about the time of puberty. These peaks are related to congenital defects, birth injury, and diseases of childhood. In cases with onset in adult life, head trauma, brain tumours, and degenerative diseases contribute to the symptoms.

Symptoms. The characteristics of convulsive seizures are related to the site of the abnormal focus in the brain and to the rapidity of its neural discharge. They may be classified as grand mal (generalized) seizures, focal seizures (*e.g.,* Jacksonian epilepsy), generalized convulsions growing out of focal onset, petit mal (minor) attacks, psychomotor (partial) attacks usually related to damage to the temporal lobe of the brain, and epileptic equivalent (*e.g.,* outbursts of rage without convulsion). Grand mal or grand mal seizures with focal onset are the most common types of attack. Petit mal seizures are almost exclusively found in children; alternations in types of seizures displayed by the same person are common.

Characteristics of convulsive seizures

Diagnosis. Sufferers of convulsive seizures are routinely examined by roentgenograms of the skull, electroencephalography, brain scans, and studies of the cerebrospinal fluid. Pneumoencephalography or angiograms ordinarily are avoided unless brain tumour appears to be the cause of the convulsions. The electroencephalogram is especially valuable in classifying the type of seizure through its brain-wave patterns, in localizing focal abnormalities, and in following the course of the disorder (*e.g.,* in evaluating the effects of treatment).

Treatment. Epileptic seizures are treated by removing known precipitating factors, by methods of physical and mental hygiene, and by using anticonvulsant drugs. Removable causative factors (*e.g.,* operable brain lesions) are found in only a small percentage of cases, and treatment rests heavily on medication. Considerable care is taken in each individual case to find the best drug or combination of drugs and the proper dosage of each and to enlist the sufferer's cooperation in taking them and in avoiding such precipitating factors as alcohol and emotional stress. In grand mal, focal, or psychomotor seizures, such anticonvulsants as sodium diphenylhydantoin and sedatives (*e.g.,* phenobarbital), alone or in combination, are usually most effective; other specific drugs (*e.g.,* ethosuximide) are preferred in petit mal epilepsy.

Anticonvulsants and sedatives

TOXINS

Many poisons (toxins) affect the nervous system, including those produced by infectious micro-organisms and

viruses, compounds of many metals (*e.g.*, arsenic, lead, manganese, mercury, and thallium) and other substances used in industry, and many drugs (see also POISON AND POISONING; POISONOUS ANIMALS AND PLANTS; DRUG AND DRUG ACTION).

Bacterial toxins. *Diphtheria.* The bacterium that causes diphtheria produces a toxin that spreads from the site of infection in the throat or skin and affects the nerves that serve the muscles of the palate, larynx, and eyeball, also producing generalized polyneuritis. Widespread immunization and early use of effective treatment when infection occurs have made the neural complications of diphtheria rare in many countries.

Tetanus (lockjaw). The toxin produced by lockjaw bacteria leads to localized and generalized spasms of the muscles and convulsive seizures. The symptoms commonly appear about five to ten days after a wound has been contaminated by the organisms that cause tetanus. Widespread immunization of children, military personnel, and farmers and prophylactic (preventive) treatment (with tetanus toxoid or antitetanic serum) of any wounded person have reduced the number of cases. Narcotic addicts are particularly likely to develop lockjaw when they use contaminated hypodermic needles or other objects that break the skin.

Treatment of full-blown cases of tetanus is difficult and not reliably successful. Intravenous injection of antitetanus serum, administration of tranquillizers, general supportive measures, regulation of salt and water intake, and the use of such drugs as penicillin have lessened the mortality rate of the disease.

Botulism. The botulism bacterium makes a toxin that causes weakness of the muscles throughout the body. The toxin is readily destroyed by heat, and poisoning usually results from eating poorly cooked or canned foods (*e.g.*, string beans) contaminated with the bacteria. Symptoms appear within 12 to 24 hours after eating the tainted food and may be preceded by nausea, vomiting, or diarrhea. Difficulty in fixing (converging) the eyes on objects is usually the first symptom, followed by drooping of the eyelids, dilation of the pupils, paralysis of the eyeball muscles, difficulty in swallowing, and weakness of the muscles of the trunk and extremities. The mental faculties are preserved, but convulsions and coma may develop toward the end in fatal cases. Complete recovery is the rule, however, when small amounts of the toxin are eaten. In severe botulism, death typically occurs in four to eight days as a result of respiratory and circulatory failure. Botulism can be prevented by taking proper precautions in the preparation of canned foods and by discarding (without sampling) foods with a rancid odour in which gas has formed. Treatment consists of pumping out the stomach and giving a specific antitoxin.

Metallic poisoning. When metallic poisons are taken, neurological symptoms may or may not be preceded by digestive upsets.

Arsenic. Chronic ingestion of small doses of arsenic in any form causes a generalized polyneuritis that is usually not fatal; ingestion of large amounts or the injection of arsenical drugs may result in fatal hemorrhagic encephalitis. The specific treatment of arsenic poisoning involves the injection of a substance called British anti-lewisite (BAL).

Lead. Lead poisoning usually results from industrial exposure to the metal or by eating lead compounds (as in some house paints). The neurological complications of lead poisoning include polyneuritis with weakness of the forearm muscles (wrist drop) and what is called lead encephalopathy. The latter most commonly occurs among children who eat lead paint from walls or furniture and is characterized by lethargy, convulsions, coma, and increased intracranial pressure; lead encephalopathy has a mortality rate of about 20 percent. Mental retardation or recurrent convulsive seizures may be present in children who recover. Treatment includes measures to control seizures, efforts to reduce intracranial pressure, and the use of drugs (*e.g.*, edathamil disodium calcium).

Lead encephalopathy

Manganese. Chronic poisoning with manganese occurs most often in miners. The basal ganglia are mainly affected, producing a syndrome similar to that of Parkinson's disease. Indeed, as in Parkinsonism, the symptoms respond to levodopa (see above).

Thallium. Accidental ingestion of any form of this metal in rat poisons or by its absorption through the skin in some treatments for ringworm or from certain hair removers (depilatories) can produce thallium poisoning. Optic neuritis and generalized polyneuritis are the most common neurologic symptoms. Death usually occurs when large amounts of the metal enter the body, although the chances of survival are good in chronic poisoning. The polyneuritis usually clears up entirely, the most common of the sequelae being some reduction in visual acuity.

NEUROMUSCULAR DISORDERS

Weakness and atrophy of muscles frequently reflect diseases associated with lesions in the spinal cord, peripheral nerves, or the muscles themselves.

Amyotrophic lateral sclerosis. Of unknown origin, amyotrophic lateral sclerosis is characterized by muscular atrophy and fibrillation (trembling) associated with degeneration of the motor neurons in the spinal cord and medulla oblongata. Relatively common (five persons per 100,000), the disease affects men about twice as frequently as women; onset of symptoms usually is between the ages of 40 and 60.

A number of symptom combinations may develop. If the motor (ventral horn) cells in the spinal cord are most severely affected, the symptoms are those of progressive spinal muscular palsy; when the medulla oblongata bears the brunt, the syndrome of progressive bulbar palsy develops; if the upper motor neurons in the brain cortex are affected early, the syndrome may be described as primary lateral sclerosis.

In most cases there is weakness and atrophy of muscles, with hyperactive tendon reflexes and muscular irritability. In later stages (with severe atrophy of the muscles), normal reflexes are lost, the only evidence of corticospinal disease being extensor plantar (Babinski) response. Even the Babinski reflex fails to appear if the muscles of the toes are too atrophied to respond.

The course of amyotrophic lateral sclerosis is chronically progressive, showing paralysis of the muscles of speech and swallowing in its late stages. Death is usually from paralysis of the muscles of breathing or associated pneumonia. The average duration of the disease is about three years; when the site of initial lesion is the spinal cord, survival of ten or more years is observed in occasional cases. The course is rapid when the nuclei in the medulla oblongata are involved at the onset.

Progressive muscular dystrophy. Of hereditary origin, this disease is characterized by diffuse weakness and wasting of the muscles during early childhood. It has a frequency of occurrence of four cases per 100,000 people. Structural changes include degeneration of the muscles and replacement of muscle substance by connective tissue and fat. The child becomes clumsy in walking and has difficulty in climbing up and down stairs and in lifting heavy objects. Enlargement of weak muscles (pseudohypertrophy), when present, is most common in the calf muscles. Tendon reflexes usually disappear, while sensory and mental development remain normal.

There is a decrease in the excretion of creatinine (a substance deriving from muscle tissue) proportional to the loss of muscular mass and a drop in the ability of the body to store a related substance called creatine (*e.g.*, from meats).

As a rule, there is a gradual progression of the weakness, especially in the Duchenne form of muscular dystrophy, in which the child is usually incapacitated within five to 15 years. Death stems from associated infections or from involvement of the respiratory or heart muscles. In the other forms of muscular dystrophy, progress is slower, and survival into adult life (even to middle age) is not uncommon. No treatment is known to affect the progress of the disease.

Duchenne form of dystrophy

Myotonia congenita. "Myotonia" describes muscles characterized by prolonged contraction and slowness to

relax, particularly noticeable during efforts to make quick or forceful movements; *e.g.*, asking the person to forcefully grasp the examiner's fingers. Myotonia can also be observed by noting the mound of muscles at the base of the thumb when that place is tapped with a rubber hammer. Congenital myotonia is usually localized in a few muscles of the body, but many may be involved in some cases. A possible clue to the physiological basis of myotonia is that it tends to diminish in response to the administration of quinine and to increase when a drug called neostigmine is taken.

Myotonic muscular dystrophy. This hereditary disorder is characterized by myotonia and atrophy of the muscles (especially those of the face and neck) and by cataracts, early baldness, and atrophy of the gonads.

The disease is less common (by about 25 percent) than is progressive muscular dystrophy and tends to appear more often in males. Transmission of the hereditary tendency to show the full-blown disease is rare, because early gonadal atrophy prevents many sufferers from having children. Symptoms in the parents of most sufferers are usually confined to early development of cataracts (opaque lenses in the eyes). Weak facial muscles produce a characteristic hatchet face; the voice may be nasal; and there may be some slight difficulty in swallowing. The myotonia usually makes it difficult for the afflicted person to relax the hand muscles when an object is grasped. When the trunk muscles are involved, the sufferer may fall when making sudden movements and have trouble getting up. Mental retardation is a frequent concomitant, a number of victims being found in institutions for defectives.

Sufferers of myotonic muscular dystrophy rarely become badly incapacitated. The myotonia tends to lessen with the years, possibly as the victim learns to compensate by being careful to move more slowly and less emphatically. There is no known treatment for the muscular weakness or atrophy, although the myotonia responds to such drugs as quinine, diphenyhydantoin (also used in epilepsy), and procaine amide.

Myasthenia gravis. Characterized by weakness and abnormal fatigability of the striated muscles, myasthenia gravis is probably the result of a defect in the utilization of a chemical (acetylcholine) at the junctions between muscles and nerves. The thymus gland in the chest is enlarged or is the site of a tumour in half of the cases, and some abnormality (lymphoid hyperplasia) of the thymus is almost always present.

Occurring in about two persons of every 100,000, the onset of symptoms of myasthenia gravis may be at any age but is most common in the second or fourth decades. When symptoms begin before age 40, females are much more frequently affected, after which there is a slight preponderance of male sufferers.

Symptoms of myasthenia gravis

There is a characteristically progressive weakening of the muscles with each succeeding contraction, with strength returning after rest. Usually all of the muscles are affected equally: weakness may be confined to the trunk and extremities and rarely only to the eye muscles. The course may be punctuated by temporary improvement and worsening; more commonly death results in a few years unless treatment includes compounds such as neostigmine that enhance the effects of acetylcholine. Beneficial effects have followed the use of corticosteroids and removal of the thymus (particularly in young females).

Familial periodic paralysis. A rare and poorly understood disease, this disorder is characterized by recurrent attacks of weakness or paralysis of the voluntary muscles and loss of deep reflexes; affected muscles fail to respond even to direct electrical stimulation. Men are affected more than twice as often as women. In the hyperkalemic form, attacks are related to a fall in the potassium level of the blood. The first attack usually occurs about the time of puberty but may appear years before or after.

Attacks commonly begin after a period of rest, varying from a slight weakness to complete paralysis, usually of the muscles of the trunk and extremities, that lasts from a few minutes to a full day. The interval between attacks may be as long as a year, or several brief episodes may occur daily, potassium level returning to normal when symptoms stop. The short duration of many attacks makes it difficult to evaluate any therapy, but potassium salts are commonly given. Prophylactic treatment includes restriction of carbohydrate intake and the administration of potassium chloride by mouth.

Another (hyperkalemic) form of the disease has an early age of onset, tends to show milder and shorter attacks, and is associated with increased blood-potassium levels. Calcium gluconate and insulin are used in the treatment of an attack, while daily doses of dextroamphetamine are recommended as prophylaxis.

Myotonia (particularly of the upper eyelids) in association with familial periodic paralysis has been called paramyotonia congenita. In such cases the myotonia and the paralysis can be precipitated by immersing an affected limb in cold water or by the application of cold compresses to the eye.

This disorder and those already mentioned throughout this article represent only the better known fraction of nervous system diseases. Others are considered in such articles as HEADACHE; PAIN, THEORIES OF; and PSYCHIATRIC TREATMENT, CONCEPTS OF.

(1967); WALTER RUSSELL BRAIN, *Diseases of the Nervous System*, 7th ed. (1969); and W.R. GOWERS, *A Manual of Diseases of the Nervous System*, 2nd ed. rev., 2 vol. (1970, reprint of the 1893 edition).

(H.H.M.)

Nestorius

Nestorius was an early bishop of Constantinople whose views about the nature and Person of Christ led to a fierce controversy, resulting in the calling of the third ecumenical council to Ephesus in AD 431. The ensuing debate produced greater doctrinal clarification, on the one hand, and the creation of separate Nestorian churches, which still exist, on the other.

Birth and early career

Nestorius was born of Persian parents in the last quarter of the 4th century AD at Germanicia in Syria Euphratensis. Trained at Antioch, where he was ordained presbyter, he may have been a pupil of Theodore, bishop of Mopsuestia. He entered the nearby monastery of St. Euprepius and gained a wide reputation as a preacher. It is recorded that he had an excellent voice, was fluent of speech, and possessed fine eyes and red hair.

In 428, when the emperor Theodosius II invited him to become bishop of Constantinople, the situation in the capital was disturbed. An interregnum had followed the death of the previous bishop, Sissinius, and an unresolved rivalry between two candidates, Philip of Side, a church historian, and Proclus, who was himself to become bishop of Constantinople in 434. There was a large number of heretical groups whose existence affronted the orthodox. Preaching at his consecration on April 10, Nestorius declared: "Give me, O emperor, the earth purged from heretics, and I will repay you with heaven." On May 30 Theodosius issued an edict against heretics, and Nestorius was zealous in their suppression.

Nestorius had brought with him as his domestic chaplain a man named Anastasius, and on November 22 this man preached a sermon in which he objected to the title Theotokos (Mother of God) as applied to Mary. Many were scandalized, for the term had long been in use. Nestorius supported Anastasius and, on Christmas Day, began a series of addresses arguing that Mary was not Theotokos. He believed, incorrectly, that the title represented a recrudescence of Arianism—a belief, first propounded early in the 4th century by Arius, that Jesus was a creature and only semidivine.

To many people it seemed that Nestorius himself was denying the divinity of Christ and regarding him as a mere man who had been adopted by God as his son. He was charged with reviving the heresy of Paul of Samosata, bishop of Antioch *c.* 260–270. It was at this juncture that Cyril, bishop of Alexandria 412–444, chose to intervene and to set in motion the series of events that finally resulted in Nestorius' downfall.

Copies of Nestorius' sermons were circulating abroad and had given rise in Egypt to some dissension in the monasteries. Cyril, therefore, issued a circular letter, shortly after Easter 429, in which he attacked Nestorius' views. Cyril's motive was twofold. He sincerely believed that Nestorius was undermining the purity of the faith; Nestorius' refusal to style Mary as Mother of God seemed to Cyril to deny the unity of the God-man. Further, as bishop of Alexandria, Cyril was eager to belittle the rival see of Constantinople, as his immediate predecessor, Theophilus, had done in the case of John Chrysostom. Theological and political considerations were thus combined.

Toward the end of the summer, Cyril wrote to Nestorius, calling on him to admit his errors. Upon receiving only a curt acknowledgment and learning that Nestorius was supporting certain of his own clergy whom he had disciplined and who had fled to the capital, he sought the assistance of the imperial family, having previously approached Celestine, bishop of Rome (422–432). Celestine himself was not ignorant of the situation nor well disposed toward Nestorius, who had also received some of the followers of Pelagius—the denier of the doctrine of original sin—previously condemned in Rome. Celestine sent copies of Nestorius' writings to John Cassian, a leading theologian and one of the prime organizers of Western monasticism, asking him to submit a report. He then held a council in August 430 that condemned Nestorius.

Condemnation of Nestorius

In November Cyril summoned his bishops to Alexandria and wrote to Nestorius requiring him to anathematize 12 propositions on pain of excommunication. When his envoys reached Constantinople, they found that they had been forestalled. The Emperor had summoned a council to meet at Ephesus by Pentecost 431. It was Nestorius' hope that the result would be the condemnation of Cyril on the charges made against him by the Egyptian refugees.

Although the council was to begin on June 7, there was delay because of the late arrival of certain delegates—in particular, John, bishop of Antioch (428–441), who supported Nestorius. Cyril, having the ear of the local bishop, Memnon, decided to press on, as he feared John's influence, and so the first session opened on June 22. Nestorius refused to attend and was condemned in his absence. Four days later John reached Ephesus and proceeded to hold a countersession that itself deposed both Cyril and Memnon. On July 10 the three Roman legates representing Celestine arrived; Cyril again seized the initiative, and the condemnation of Nestorius was renewed. Both sides appealed to the Emperor. Intrigue followed upon intrigue, until Theodosius, influenced by his sister Pulcheria (whom Nestorius had offended), relegated him to his former monastery near Antioch, and the council was dissolved.

Nestorius remained in the monastery for four years (431–435) and spent his time writing about his case in a work entitled *Tragedy*, of which only fragments survive. He was not in a position to have much influence. Controversy continued, but gradually, in the interests of church unity, the "Orientals" (*i.e.*, the supporters of John of Antioch) and the Cyrillian party came to an understanding, the doctrinal issue being separated from the personal question of Nestorius' own fate. His continued presence near Antioch became an embarrassment, and John eventually recommended to the Emperor that he should be exiled. An imperial order was issued sending him to Petra in Arabia. Soon this was considered too lenient and he was transferred to the Great Oasis (now the Oasis of Khārijah) in the Libyan Desert (*c.* 436–437). Later still, marauders carried him off to Panopolis (Akhmīm), whence he was removed to Elephantine opposite to Syene (Aswān) and then back to Panopolis.

During his exile, Nestorius was not completely isolated. He received visitors and correspondence. He followed the course of the Eutychian controversy, a reaction to his own teaching, which involved the assertion that the humanity of Christ was swallowed up by his divinity and so ceased to exist. He wrote to the citizens of Constantinople in support of their bishop, Flavian (446–449), and of Leo, bishop of Rome (440–461), and saw in the treatment of Flavian by Cyril's successor, Dioscurus, a repetition of what he had suffered. He devoted time to a work that was to be a defense of his teaching and a history of his life. He entitled it the *Book of Heraclides of Damascus*, using a pseudonym to have it published. The sole treatise from his pen to have survived, it was discovered in 1895 in a Syriac translation.

Nestorius survived the death of Theodosius on July 28, 450, and it seems likely that the emperor Marcian had decided to allow him to return to civilization, but the news arrived after his death. Whether his death occurred just before, or shortly after, the opening of the Council of Chalcedon in 451 is not known.

Doctrines and significance

Nestorianism, as it was understood at the time, so insisted upon the full humanity of Christ's human nature that it was believed to divide him into two Persons, one human and the other divine. Nestorius repudiated such a view, and Cyril's interpretation was based on a misunderstanding.

What he actually taught was a prosopic union. The Greek term *prosōpon* means the self-manifestation of an individual that can be extended by means of other things —*e.g.*, a painter includes his brush within his own *prosōpon*. So the Son of God used manhood for his self-manifestation, and manhood was, therefore, included in his *prosōpon*, so that he was a single object of presentation.

While Nestorianism was crushed within the Roman Empire, it survived outside its frontiers. The Persian Church adopted it, largely to obtain the protection of their rulers by assuring them that their religion was not that of their enemies the Romans. It has continued until the present day, although its adherents are few in number, with groups being found in Iraq, the U.S.S.R., India, Iran, Syria, and North and South America.

BIBLIOGRAPHY. B.J. KIDD, *A History of the Christian Church to A.D. 461*, 3 vol. (1922), draws together the many known details into a comprehensive narrative. F. LOOFS, *Nestoriana* (1905), contains the majority of the surviving fragments of Nestorius' works. G.R. DRIVER and L. HODGSON (eds.), *Nestorius, The Bazaar of Heracleides: Newly Translated from the Syriac* (1925); and F. NAU, *Nestorius: Le livre d'Héraclide de Damas* (1910), both give translations of Nestorius' major extant work and provide full introductions and notes. A.R. VINE, *An Approach to Christology* (1948), discusses Nestorius' Christology. J. QUASTEN, *Patrology*, vol. 3, pp. 514–519 (1963), provides a comprehensive bibliography.

(J.G.D.)

Netherlands, The

One of the smaller countries of Europe, the Kingdom of The Netherlands is a parliamentary democracy under a constitutional monarch. The Netherlands has often been known in English as Holland (literally Hollow Land). This name, which was originally given to the medieval core of what later became the state and which is still used for two of its 11 provinces (Noord-Holland and Zuid-Holland), accurately reflects the country's character. The irregular outline of The Netherlands, not unlike a piece of a jigsaw puzzle, encloses some 15,892 square miles (41,160 square kilometres) of extraordinarily flat land lying between the North Sea on the north and west, the Federal Republic of Germany on the east, and Belgium to the south. The kingdom incorporates the former colonies of Surinam and The Netherlands Antilles as well.

Some 3,000 square miles of this land have been wrested from the sea by a process of careful water management, drainage, and reclamation that dates back to the 12th century, although the really large schemes were initiated in the 20th century. Much of the Zuiderzee, the great arm of the sea that formerly tongued into the country from the north, has been turned into *polderland*, land surrounded by dikes and artificially drained. The Waddenzee, the northern seaward sector, is now separated from the larger southern portion, known as IJsselmeer (Lake IJssel), by a huge barrier dam almost 20 miles long. Plans for reclaiming the Waddenzee itself are maturing, as is an equally ambitious project to cordon off the sea

The struggle against the sea

from the islands and deltas of the southwestern province of Zeeland.

The Netherlands was the home of more than 13,000,000 people in the early 1970s. Despite a government-encouraged emigration after World War II, which sent some 500,000 persons out of the country (mostly to the English-speaking countries of North America and the traditionally white nations of the then British Empire and Commonwealth), the country is today one of the most densely populated nations in the world. Partly as a result of the earlier emigration, about one-tenth of the citizens are now over 65 years old, but this fact has not prevented the capital, Amsterdam, from becoming one of the liveliest centres of the international counter-culture of Western youth. This independence of outlook, if it can be thus interpreted, has very strong roots in The Netherlands. Citizens of the 16th and 17th centuries rose time and again against foreign domination to found and secure their own republic. Dutch merchant ships sailed the world and helped to lay the foundations of a great trading nation characterized by a vigorous spirit of enterprise. The Netherlands contains the estuaries of the rivers Rhine, Maas, and Scheldt, and through their seaports the Dutch control a large share of the world's waterborne traffic. All this is a far cry from the phlegmatic composure that other Europeans have sometimes ascribed to the Dutch, though something of the traditional image of the country may be preserved in the neat, brick-built little towns, the countless windmills, and the magnificent colours of the spring tulip fields, even if the famous peasant dress—wooden clogs, the full-bottomed trousers of the men, and the white caps and wide skirts of the women—is not so widespread today.

With Belgium and Luxembourg, The Netherlands is a member of the economic union known as Benelux, in which foods, goods, and people can freely circulate; this union, in fact, served as a model for the larger European Economic Community (EEC), of which the Benelux nations are members. Since the formation of Benelux, production in The Netherlands has risen in quality and technical refinement. The country is also a member of the North Atlantic Treaty Organization (NATO) and the Organization for Economic Co-operation and Development (OECD). Of the former Dutch colonies, the Dutch East Indies became independent as Indonesia in 1949, while Surinam and the Netherlands Antilles were united with the European Netherlands in 1953, under the Statute of the Kingdom of The Netherlands. (For related information, see AMSTERDAM; HAGUE, THE; LOW COUNTRIES, HISTORY OF; and ROTTERDAM.)

THE NATURAL AND HUMAN LANDSCAPE

The natural environment. *Relief features.* The landscape of The Netherlands is almost entirely flat. It is characterized by dunes and dikes protecting the most densely populated part of the country, which would otherwise be inundated. Indeed, 38 percent of the country would be swallowed by the sea if there were no man-made dikes. Villages and estates are surrounded by dikes and a system of drainage canals, while about half of the land area consists of polders, which intensify the flat appearance of the land.

There are several hundred polders, some made possible by the operation of windmills, which, despite their limited power, carried out the drainage in earlier times. But the larger polder areas, such as those of IJsselmeer, have been created by steam, diesel, and electric pumps. Fen, river, and sea polders lie on peat land along the rivers, but some polders above sea level, created by silting, are drained of excess water by sluice gates at ebb tide. The western part of The Netherlands lies below sea level, sometimes as much as 22 feet (6.7 metres) below. On such land, building is only possible after driving piles down to the sand layer.

Limburg, in the border zone of the Ardennes, is the only area that is not part of the lowland. Indeed, in the entire country the only relief contrasts are provided by the Torenberg, in the Veluwe region (340 feet [104 metres] high); a 315-foot (96-metre) elevation around Nijmegen; and the highest point in The Netherlands, the Vaalserberg, rising 1,050 feet (321 metres) in the south of Limburg.

The Zuiderzee

The Zuiderzee was originally an estuary of the Rhine. It then became a shallow inland sea, biting deep into the land, and eventually was hollowed into an almost circular shape by the action of winds and tides. Only in 1932 did the barrier dam, running northeastward to connect the province of Noord-Holland with that of Friesland, finally tame and divide the sea into the outer Waddenzee and the inland IJsselmeer. In the latter, four giant polders were constructed around a freshwater basin fed by the IJssel River and linked with the sea by sluices. Ninety percent of the land thus reclaimed is arable, and it is parcelled out in large plots that are rented to farmers. After World War II, additional development made the polders available for industrial, residential, and recreational purposes as well as for agriculture.

Further south, the disastrous spring tide of February 1, 1953, which flooded 400,000 acres of land and killed 1,800 people, called into existence the Delta Plan, which aims to close the sea inlets of the southwestern province of Zeeland. These huge delta works will shorten the coastline by 450 miles, combat the salination of the soil, and allow the development of the islands of Zeeland. The Oosterschelde (Eastern Scheldt) is already dammed; large sluices dominate the Haringvliet (river), and the embankment dikes along the Westerschelde (Western Scheldt) have been strengthened. Though future spring tide catastrophes may be avoided, the enterprise will doom the oyster culture and the shrimp and mussel fishing.

Glacial, riverine, and marine deposits

Soil. After the Ice Age (about 10,000 years ago), a large area in the north of what is now The Netherlands was covered by moraine (the glacial accumulation of earth and stones). In the centre and south, the Rhine and Maas unloaded thick layers of sand and gravel from the European mountain chains. Behind the coastal dunes, sea clay was deposited in the sheltered lagoons, and peat soil often subsequently developed in these areas. If the peat soil was washed away, sea clay was deposited again, and the alluvial layer had to stabilize through drainage and settlement.

Climate. The climate is temperate, with gentle winters, cool summers, and rainfall in every season. Southerly and westerly winds predominate, and the sea moderates the climate through onshore winds and the effect of the Gulf Stream.

The position of The Netherlands—between the area of high-pressure air masses centred on the Azores and the low-pressure region centred on Iceland—makes the country an area of collision between warm and polar air masses in summer, thus creating unsettled weather. In springtime, on the other hand, northern winds often cause night frosts. Winds meet with little resistance over the flat country, though the hills in the south diminish by more than half the 13-mile-per-hour wind velocity that prevails along the coast. Frost averages 60 days per year. July temperatures average about 63° F (17° C), and those of January average 35° F (2° C). The rainfall averages 31 inches (790 millimetres), with only about 25 clear days per year. The average rainfall is highest in summer (August) and autumn and lowest in springtime. The country is known—not least through the magnificent landscapes of Dutch painters—for its heavy clouds, and on an average day three-fifths of the sky is clouded.

Vegetation and animal life. The fauna of The Netherlands has been greatly affected by the activities of man; thus, the badger, hawk, river lobster, and marsh turtle have disappeared, while various fish species and the boar have been introduced, and the red-grouse population has been nurtured.

The Netherlands possesses the characteristic flora of the Atlantic district of the Euro-Siberian vegetation province to which it belongs. The flora is dominated by plants of the dunes (salt plants and water plants) and by plants of the woods, of cultivated land, and of meadows. In addition, the cultivation of ornamental plants, flowers, and bulbs has become a major industry.

The growth of urban centres

Urban and rural settlement. Urbanization in The Netherlands has taken place mainly in the 20th century. In 1900, over half the population was still living in villages or towns of fewer than 10,000 inhabitants. In 1972 this figure was only a little less than 20 percent. The population of the cities and towns is growing much faster than the population of the rural areas, for migration to the towns more than exceeds the rural areas' higher birthrate. The 1960s nevertheless saw a decrease in the downtown population of the large cities. These inner-city regions are now becoming economic and cultural centres, their populations having spread outward in search of newer housing and greater living space in the suburbs. Urbanization is concentrated in areas of industrial growth, especially around the harbours of the Nieuwe Waterweg (New Waterway) centred on Rotterdam or the Noordzeekanaal (North Sea Canal) centred on Amsterdam.

The bulk of the Dutch population is concentrated in the urban circle (known as the Randstad) comprising Rotterdam, The Hague, Leiden, Haarlem, Amsterdam, Hilversum, and Utrecht; in Noord-Brabant (in the three main cities of Breda, Tilburg, and Eindhoven); and in the Twente District around the city of Enschede. It is established policy to keep traditional towns and cities separated by strips of agricultural or recreational land. Even in the Randstad, public authorities try to maintain a "green heart."

THE PEOPLE

Ethnic and religious makeup. In origin, the Dutch people are a mixture of Frisians, Saxons, and Franks.

Under the Romans, a German infiltration started that continued for centuries. The result was a predominantly Anglo-Saxon Frisia in the northeast, while the original Holland, further south, developed under Frankish influence.

Also of significance has been the attraction of countless refugees to the tolerant Dutch cities. Over the centuries, these have included southern Lowlanders, French Huguenots, Salzburgers, Swiss, and Portuguese Jews who left their respective homelands as a result of religious or political pressures. In addition, many Germans and non-Iberian Jews have also tended to immigrate to The Netherlands for more purely economic reasons. In the 20th century, Dutch-Indonesians and non-white peoples from Ambon, in the East Indies, and Surinam, on the northeast coast of South America, have added to the influx.

The heritage of Dutch Humanism

The Netherlands, a small state among big ones, has consistently preached freedom of thought. Dutch Humanism has always been a judicious mixture of piety and knowledge, epitomized in the development during the 14th and 15th centuries of a bourgeois civilization with a military and commercial spirit. These traditions, together with rigid Calvinism and a more tolerant Protestantism and Roman Catholicism, continue to characterize much of Dutch life. Even today, political, educational, and territorial divisions are along religious lines. Not even World War II and the unity forged under German occupation were able to break up the pattern, and only now are signs of change appearing.

Finally, even though in such a small country, individual regions have acquired their own distinctive personalities. The Zeelanders of the north are often thought of as possessing a certain asceticism in their life-style developed through centuries of struggle against the sea—in contrast to the more easygoing, almost Burgundian French, way of life in the south.

Demographic trends. In 1970 the population of The Netherlands passed the 13,000,000 mark, an increase of nearly 4,000,000 since World War II.

Live births, although increasing in absolute terms, have been declining relatively from 24 per 1,000 persons during the period 1945–54 to about 18 per 1,000 more recently. The mortality rate, moreover, down to 7.7 per 1,000 during the period 1955–64, had risen slightly by the early 1970s, when the life expectancy at birth was just under 71 years for males and over 76 years for females.

The average age of the Dutch is now almost 33, reflecting an increase of elderly people: those over 65 number about 10 percent of the population. The average family is shrinking in size, while the numbers both of households and of single persons multiply. Although the state of the national economy, which generally flourished in the 1950s and 1960s, has made an emigration policy unnecessary, a department of emigration is still maintained in the Ministry of Social Affairs and Public Health, and certain subsidies are still granted. Emigration to Canada, the United States, and Australia, which amounted to more than 30,000 persons per year in 1956 and 1957, has fallen to about 9,000 a year. South Africa still attracts between 1,700 and 1,800 persons yearly, and New Zealand attracts between 500 and 600.

As a result of the postwar government policy mentioned earlier, emigrants exceeded immigrants by about 10,000 each year from 1947 to 1954. During the years from 1955 to 1964, however, the economy and labour potential of western Europe attracted an increasing number of Spaniards, Yugoslavs, Turks, and Moroccans, so that the balance remained static. The latest figures indicate an immigrant surplus, a situation that reflects, in part, the growing number of immigrants from the former Caribbean colonies of Surinam and the Netherlands Antilles, who, as citizens of the kingdom, have free access to The Netherlands.

Concentration of population in the two western provinces

Nearly half the population lives in the two western provinces of Zuid-Holland and Noord-Holland and in the central province of Utrecht, in which the concentration is as high as 2,300 persons per square mile (895 per square kilometre). The four largest cities—Amsterdam, Rotterdam, The Hague ('s-Gravenhage), and Utrecht—are located in this area. In contrast, the three northern provinces—Groningen, Friesland, and Drenthe—are sparsely settled, with an average density of over 450 persons per square mile.

Figures on internal migrations suggest continuous emigration from Groningen and Friesland, in which industrialization has been relatively unsuccessful, accompanied by movement from Zuid-Holland and Noord-Holland toward Utrecht and the less densely populated provinces of Drenthe, Overijssel, Gelderland, and Noord-Brabant. The southernmost province, Limburg, suffers from a decaying coal-mining industry, and its inhabitants are increasingly forced to seek their living elsewhere. Although the current estimate of a total 17,100,000 inhabitants by the year 2000 is lower by 800,000 people than the 1967 estimate, The Netherlands will still have to absorb a growth of nearly one-third in a single generation. Attention will therefore have to be concentrated on regional planning and economic development, and both will demand a high rate of private and public investment. This burden, along with the support of those above 65, will fall on the working population. On the other hand, there will be relatively fewer schoolchildren. Some people have advocated an official birth-control policy, but traditional religious attitudes may prevent its fulfillment.

THE NATIONAL ECONOMY

Position in the world. Since World War II, The Netherlands has become a highly industrialized nation occupying a central position in the economic life of western Europe. Although agriculture now accounts for less than 7 percent of the national income, it remains a highly specialized contributor to Dutch exports. Because of the scarcity of mineral resources—with the important exception of natural gas—the country is dependent on large imports of basic materials. Given this situation, a continued trade deficit of something over 10 percent has to be offset by a favourable balance in transport and transit; in these areas the nation's fleet has become a major international carrier.

Dutch trading partners

Trade relations are mainly with Europe and North America, which supplied, in the early 1970s, over 80 percent of all imports, while receiving nearly 90 percent of all exports. The European Economic Community is, of course, the dominant factor in foreign trade, and, whereas in 1958 (just before the Common Market was set up) only 41.5 percent of Dutch exports went to West Germany, Belgium and Luxembourg, France, and Italy, in 1970 these nations accounted for over 60 percent.

Natural power sources. With increasing use of oil and natural gas, coal, which is cheaper when imported from abroad, is now little mined. Between 1958 and 1970, the number of coal miners fell from 48,000 to about 12,000—though rising productivity kept coal production about 40 percent of the 1958 amount. Coal mining is completely concentrated in southern Limburg.

The production of crude oil (a little over 1,600,000 tons a year) covers only a small part of Dutch requirements. The wells are located in southeastern Drenthe, near Schoonebeek, and in Zuid-Holland.

The discovery of natural gas during the 1950s has had a tremendous influence on the development of the Dutch economy. The gas field near Slochteren, in Groningen, holds proven reserves of more than 5,830,000,000,000,000 cubic feet (165,000,000,000,000 cubic metres); by 1971, annual production there and at some lesser fields had risen to some 88,000,000,000,000 cubic feet (2,000,000,000,000 cubic metres). About one-third of this production was exported to Germany, Belgium, and France, helping to improve the balance of payments in the area in which The Netherlands has usually had its largest deficit. An aluminum factory using natural gas as fuel was set up at Delfzijl, in Groningen. It became the core of an important industrialization project in a traditionally agricultural area.

The use of coal for producing coke is no longer an economical proposition in The Netherlands, and coke-oven gas has been superseded by natural gas as fuel for the chemical industry of south Limburg. Domestic natural-gas consumption for cooking and heating is also continuously rising.

Intense development of dairying and horticulture

Agriculture. Of the country's 9,000,000 acres (3,600,000 hectares), 5,300,000 are under cultivation: 3,300,000 acres as grassland, 1,700,000 acres for arable farming, and 300,000 acres for horticulture, especially tulips. Dutch cattle farming is highly developed: the milk yield per acre of grassland and the yield per cow are among the highest in the world. About 40 percent of the total milk production is exported after being processed into such dairy products as butter, cheese, and condensed milk. Large-scale crop cultivation is hardly possible in The Netherlands, and most fodder as well as cereals for human consumption are imported from such countries as Canada and the United States.

Horticulture carried on under glass is of special importance. The export of hothouse tomatoes, cucumbers, and lettuce increased sixfold from the 1950s to the late 1960s, and The Netherlands now contains almost half of the total European horticultural area under glass.

During the period from 1950 to 1966, the country's agricultural labour force decreased by half, and the number of farms dropped from 210,000 to about 145,000; in horticulture the number of holdings remained constant. During the same period, the total output of Dutch agriculture doubled—a clear indication of a rise in productivity. Fishing now accounts for only about 1 percent of the national income.

Industry. Dutch industrial development started relatively late, in 1870, and production rose even during the depression of the 1930s. Further development became a priority after World War II, when ascending population figures and growing farm-labour surpluses necessitated tens of thousands of additional jobs each year. A spectacular contribution to the solution of the employment problem was made by the chemical industry, whose annual output increased 10-fold between the late 1940s and the early 1970s—the greatest growth rate of any sector of Dutch industry.

Metal manufacturing, however, remains the most important industry. The biggest plant is the Royal Netherlands Blast Furnaces and Steel Works, at IJmuiden, with a capacity of 4,000,000 tons of crude steel per year. The electronics industry is also important: one large corporation alone accounts for one-tenth of all Dutch exports. The food, drink, and tobacco industries are a strong second, based as they are on the highly productive agriculture sector. Dutch industry has also been able to redevelop commercial aircraft since World War II, and automobile manufacturing has been expanded. In contrast, textile employment decreased over the 1960s, and several companies have been forced to close down entirely.

Banking

Finance. Commercial banking in The Netherlands is in the hands of a few large concerns. The Algemene Bank Nederland and the Amsterdam-Rotterdam Bank handle 60 percent of Dutch financial business between them, while the Coöperatieve Centrale Raiffeissen-Bank en Aangesloten Banken and the Coöperatieve Centrale Boerenleenbank specialize in agricultural credit. The more than 200 independent savings banks are centred on the state-owned Post Office Savings Bank. Since 1948 the central bank, Nederlandsche Bank, has also been state owned. Its function, defined by the 1948 Banking Act and the 1956 Credit Control Act, is to supervise the entire system. An independent agency, it has authority to strengthen traditional monetary controls.

The Dutch economy nevertheless remains basically in private hands. Postwar industrial development has been consciously stimulated by government policy, and state subsidies have been granted to attract industry toward the relatively underdeveloped northern provinces, as well as Limburg and certain other pockets of economic stagnation. Despite these subsidies, the western provinces remain the centre of new industry, especially in the services sector.

State ownership, employer organizations, and the role of labour. The state completely owns such corporations as Netherlands Railways and the Dutch State Mines and is a large-scale participant in others: the Royal Steel Works, the Royal Dutch Airlines (KLM), De Nationale Investeringsbank (Herstelbank), and the Gas Union, which distributes natural gas. The state thus has a direct, continuous influence on the management of some sectors of the economy, and especially on investment policy. Dutch employers are organized in three separate but closely cooperating organizations, one Catholic, one Protestant, and one nondenominational. Labour has a similar tripartite organization, comprising Catholic, Protestant, and Socialist groups, with some other, independent fringe organizations. Although the state has wide legal powers for intervening in wage disputes, government policy has not been able to put an effective check on inflationary rises in wages and prices. Consequent increases in the cost of living have been on the order of 7 percent annually from the late 1960s onward. A strong anti-inflationary policy was announced by the government formed after the elections of April 1971.

TRANSPORTATION

Transportation is of special importance in The Netherlands, since the country functions as a gateway for goods traffic between western Europe and the rest of the world. Goods flow through Dutch harbours, continuing their passage by river vessel, train, truck, pipeline, and—a recent development—by modern container units.

Shipping and air traffic. The maritime traffic of The Netherlands is about equal to the land traffic, and indeed the whole southern part of the North Sea may be likened to an immense traffic square, fed as it is by the Thames, Rhine, Maas, and Scheldt, with links into the hinterland of the Continent that make it the greatest commercial artery of the world after those of North America. Rotterdam has the country's best equipped modern harbour. Europoort, the region between Rotterdam and the sea, can easily be reached by the biggest oceangoing ships; it serves as an approach to Rotterdam harbour, itself handling more tonnage than any other harbour in the world. Rijnmond (the mouth of the Rhine) and IJmond (the

mouth of the IJ) are also equipped to receive big ships. In oil processing, too, Rotterdam is the world's biggest centre, having expanded from an annual capacity of 1,200,000 tons in 1930 to 137,200,000 in 1970. A trench 1,500 feet wide and 75 feet deep extends eight miles into the North Sea to facilitate the entry of supertankers with 200,000-ton capacities. The overall goods traffic in the sea harbours of Rotterdam and Amsterdam in fact increased sixfold over the 1951–70 period. The number of ships of the Dutch merchant fleet, which is among the 12 largest fleets in the world, decreased by 32 percent from 1960 to 1971, and the total tonnage decreased by 12 percent. The number of rivercrafts is probably unsurpassed by any other country.

Royal Dutch Airlines (KLM) initiated a scheduled service between Amsterdam and London in 1920 and now has a worldwide network. One subsidiary operates an airline in the West Indies, while another runs a modest domestic network between Amsterdam and the outlying provinces. Schiphol, Amsterdam's airport, and Zestienhoven, the airport at Rotterdam, both are of international importance. The Dutch government conducts a school for civil aviation and pilot training.

Inland transportation. As might be expected in so thickly settled and small a country, the road network is comprehensive. There are more than 57,000 miles (92,000 kilometres) of paved roads, half of which have separate lanes and two-level crossings. A rapid rate of expansion was planned for the 1970s and beyond, especially to handle the increasing number of private cars, already one to every six inhabitants.

Despite the competition offered by railroads, motor freight, containers, and pipelines, it appears that the important waterways will never be surpassed for traffic in freight. For this reason, much attention and financial support are devoted to the waterways in order to meet the growing international demand for efficient goods transport.

The continued importance of waterways

The Netherlands has about 3,500 miles of inland waterways linked with Belgian, French, and German systems. Besides such natural waterways as the rivers Maas, Rhine, Waal, and Lek, many artificial waterways—the Juliana Kanaal, the Amsterdam–Rijn Kanaal, and the Maas–Waal Kanaal—connect the major ports on the coast with the hinterland. The state-owned railroads are modest but well developed and in total length are about average for Europe. The combined effect of inland navigation and freight traffic on roads has prevented the expansion of goods traffic by rail. More than half of the rail network is electrified; elsewhere, steam has been replaced by diesel.

ADMINISTRATION AND SOCIAL CONDITIONS

The Netherlands and the former colonies of Surinam and the Netherlands Antilles form the Kingdom of The Netherlands, a constitutional monarchy—though Surinam and the Antilles are, in practice, autonomous and have their own governmental system. The monarchy is hereditary in both the male and female line, though the latter succeeds only in default of male heirs. By the early 1970s, the monarch had in fact been a queen since 1890.

Constitutional framework. The constitution, which dates from 1814, maintains that the head of state is inviolable, but it also embodies the concept of ministerial responsibility; it further provides that no government can remain in power against the will of parliament. The States-General (Staten-Generaal), as parliament is officially known, consists of two chambers: a directly elected Second Chamber of 150 members and a First Chamber, whose 75 members are elected by the members of the councils of the 11 provinces. Both chambers share legislative power with the government (officially known as the crown, defined as the head of state acting in conjunction with the ministers) and control government policy, but, whereas the First Chamber has only the power of veto in the legislative process, the directly elected Second Chamber, controlling the government, plays a dominant role.

Every four years, after elections for the Second Chamber have been held, the government resigns and a process of bargaining starts between various parliamentary leaders who hope to form a government that will control a majority in parliament. It usually takes a few months before a *formateur,* as the architect of such a coalition is known, can accept a royal invitation to form a government; the head of state then formally appoints the ministers. In the event of political crises resulting in the fall of the government before the end of a four-year period, the same process of bargaining takes place. The monarch, however, has the right to dissolve one or both chambers, at which time new elections are held.

Formation of the government

Local government. In local government, the most important institutions are the municipalities, of which there are 865. Their jurisdiction extends over the entire country (except for some areas of recently reclaimed land). Each municipality is run by a directly elected council of between seven and 45 members, depending on the size of the population. This council is presided over by a *burgemeester* (mayor), who is appointed by the government and serves as chairman of the executive, members of which are elected by and from the council. Where the councils' own ordinances are applicable, the municipalities are autonomous, and in many instances national legislation or provincial ordinances provide for the cooperation of municipal authorities.

The country is also divided into 11 provinces for purposes of local government—Noord-Holland, Zuid-Holland, Zeeland, Utrecht, Noord-Brabant, Limburg, Gelderland, Overijssel, Drenthe, Groningen, and Friesland. Their administrative system has the same structure as the municipal one: directly elected councils (*staten*) who elect the members of the executive, except for the chairman, who is appointed by the government. The main function of the provinces consists of controlling the municipalities within their borders, as well as controlling the district water-control boards (*waterschappen*), the public authorities that are responsible for water control within certain definite areas.

Political life. The Second Chamber, the provincial councils, and the municipal councils are elected according to a system of proportional representation. In general elections for the Second Chamber, it can take as little as 0.66 percent of the overall vote to get one of the 150 seats in the chamber. As a result, a large number of parties and political movements are represented in parliament. The three Christian centre parties (one Catholic and two Protestant) have slowly evolved a form of cooperation that included a common platform for the 1971 parliamentary elections. The Labour Party, the Democrats 1966 (D66—a party of constitutional reform and progressive, non-ideological politics), and the Radical Political Party (a progressive splinter, mainly from the Catholic People's Party) have also coalesced for electoral purposes, presenting a common program and a list of potential ministers as well. These two blocs have recently occupied, between them, more than two-thirds the total number of seats, thereby creating a certain measure of order in Dutch party politics.

Objections to the political system

Because of the complicated party system and the time-consuming and complicated process by which a government comes into being, constitutional and party reforms are advocated by many people. Dissatisfaction with "the system" expresses itself by widespread utterances of frustration about official politics, often embodied in extra-parliamentary movements.

Justice and the armed forces. In The Netherlands, the ordinary administration of justice is entrusted exclusively to appointed judges; trial by jury is unknown. There are 62 cantonal courts (*kantongerechten*), which exercise jurisdiction in a whole range of minor civil and criminal cases. More important cases are handled by one of the 19 district courts (*rechtbanken*), which also can hear appeals over cantonal court decisions. Appeals against decisions from the district courts are heard by one of five courts of appeal (*gerechtshoven*).

The Supreme Court (Hoge Raad) ensures a uniform application of the law, but it cannot suspend a law as being contrary to the constitution. In the legislative pro-

cess itself, the government and the parliament together pass judgment on the constitutionality of a bill under consideration. Laws that are contrary to an international agreement to which The Netherlands is a party can be abrogated by the courts.

The Dutch armed forces consist of an army, a navy, and an air force. All male citizens become liable to military service at the age of 18. Since 1967, the normal period of obligatory service has been fixed at 16 months, with an additional two months for officers and noncommissioned officers. The Netherlands is a member of NATO. The Dutch armed forces also are responsible for the defense of Surinam and the Netherlands Antilles.

The social sector. *Education.* The Dutch educational structure consists of a public and a private system. Private schools, as long as they conform to legally determined standards of such things as curriculum, examinations, and qualifications of personnel, are financially subsidized up to the highest level, according to the same rules in force for the public system. With a few exceptions, private schools are run by religious organizations, either Protestant or Catholic. Higher education is provided by three state universities: Leiden (established in 1575), Groningen (1614), and Utrecht (1636); other universities include that of the city of Amsterdam, which is the largest (1632), and two private universities, the Protestant Free University (Vrije Universiteit) in Amsterdam (1880), and the Catholic University of Nijmegen (1928).

In addition, higher technical education at the university level takes place in special institutions in Delft, Eindhoven, and Enschede. Private institutions for the teaching of economics at university level are established in Rotterdam (nondenominational) and Tilburg (Catholic). All these are financed by the state, and, although different rules have been considered, the right of entrance is determined by final examinations in secondary schools.

Housing. Since World War II, housing policy has been one of the most controversial topics of political and social life. Because of war damage and a stagnant building trade, a considerable housing shortage had developed by the early 1950s. The rate of population growth, moreover, had accelerated, and rising living standards meant that people expected more space per person and generally higher quality in housing facilities. Estimates of the existing housing shortage had to be revised upward continuously, but, with a building program of about 130,000 dwellings per year, an end to the shortage was in sight in the early 1970s.

The government's role in housing

Construction is heavily subsidized in The Netherlands. Since 1945, more than four out of every five new dwellings have been built with some form of public support. Subsidies are paid to municipalities and building associations, which are mainly concerned with the housing needs of lower income groups, or to private persons who conform to certain building standards. In urbanized areas, rent control is still maintained. Local authorities have power to set up a system of housing allocation, a power particularly exercised in metropolitan areas.

Social welfare. The Netherlands has an extensive system of social insurance. For instance, the state has direct supervision of old-age, widows', and orphans' pensions, to which all citizens are entitled. The enforcement of the Health Insurance Act, the Working Incapacity Insurance Act, and the Unemployed Benefit Act is entrusted to special associations set up by employers' and employees' organizations. The last two acts cover all employees, whereas participation under the Health Insurance Act is compulsory only for employees below a certain wage level, determined yearly according to the general level of wages and prices. Employees and self-employed persons also receive children's allowances, though rules and amounts differ for each group.

Since 1968, a special act has covered certain specialized or prolonged medical expenses for all citizens. About 70 percent of the population is covered by the Health Insurance Act, and most other persons are more or less covered by some form of private health insurance. A guaranteed minimum income is also maintained.

CULTURAL LIFE AND INSTITUTIONS

The cultural climate in The Netherlands is varied and lively, though the official life of the arts is mainly an upper class affair. There are nevertheless some signs of malaise, not only in concert life but also in the theatre and the fine arts. The interest of the public is declining, and the awarding of rather extensive subsidies by the administration has caused unrest among the public as well as among the artists themselves, many of whom are looking for new means of support. There is also a growth from a kind of artistic underground in which the young have begun to create new possibilities—with an international and anti-establishment flavour. These "subcultures" may not be recognized as part of the official arts, yet they are a significant development, often characterized by the fashions followed by the young.

The fine arts. There are 32 state-supported museums in the nation, the most famous of which are the Rijksmuseum at Amsterdam, the Mauritshuis at The Hague, and the Stedelijk Museum, also in Amsterdam; the first is noted for its magnificent collection of works by the great 17th-century Dutch master Rembrandt van Rijn, and the last is known for its collection of paintings by the late-19th-century painter Vincent van Gogh. Modern museums, with their progressive policies, attract large sections of the public. There are nearly 400 public collections of art and culture.

Connected with various cultural institutions are the Preservation Service for Monuments, which restores valuable houses and buildings and protects archaeological treasures; the State Office for the Documentation of the History of Art; and the Central Laboratory for Art and Science.

The history of painting could scarcely be written without including, besides those of Rembrandt and van Gogh, the names of the great painters of Holland, such as Jan van Eyck, the founder of the Flemish school in the 15th century; the allegorical Hieronymus Bosch in the 16th; portraitists such as Frans Hals and landscapists such as Jan Vermeer, Aelbert Cuyp, and Salomon van Ruysdael in the 17th; the 17th-century still-life artists such as Willem Heda and Willem Kalff; and the geometrically inclined Piet Mondrian in the 20th. Interest in painting in The Netherlands is still widespread, and such artists as Kees van Dongen, Willem de Kooning, and Karel Appel are internationally famous, as much in demand among collectors of contemporary works as classical masters are by the great museums of the world. Sculpture, on the other hand, has always been overshadowed by the more prominent pictorial developments. Thanks to a complicated system of public assistance and scholarships, young artists can indulge in their experiments with the certainty of a minimum income, while the government and municipalities regularly buy their works to adorn various administrative centres.

The problems of Dutch theatre and literature

Dutch theatre and literature have always been handicapped by the very tiny proportion of the human race that speaks Dutch: some 17,000,000 in Europe (among them the Flemings of Belgium); some 6,000,000 Afrikaans speakers in South Africa; and over 500,000 Dutch citizens abroad. This limits the possibility of Dutch writing making a worldwide impact; except for the translation of some Dutch novels and poems, Dutch literature, though very much alive, has received little of the attention accorded the universal visual vocabulary of Dutch painting.

Theatre companies are all private foundations, though the state compensates 40 percent, and the municipalities 60 percent, of any loss incurred by theatres. Players' salaries are legally determined, and performances of Dutch plays are encouraged, though the administration is not concerned with artistic qualities. Television has had some adverse effect on theatre life in The Netherlands.

Young Dutch film makers, less handicapped than their writing colleagues, have chalked up many successes abroad, usually with documentaries about Dutch painters. There is also a Netherlands Film Academy, which is building up a reputation far outdistancing the very limited production of feature films.

Musical life, on the other hand, is intense. Although private orchestras in The Netherlands are supported by the government, the latter makes no attempt to interfere in the operation of these organizations or the choice of repertory. The Amsterdam Concertgebouw orchestra is world-famous, and Dutch composers are encouraged. Other organizations, such as the three Dutch ballet companies, several choirs, and music schools, are also subsidized.

The press and broadcasting. The first European newspapers were printed in Amsterdam in 1620, and the Dutch press has a reputation for high-quality reporting; yet, despite ample advertising, it is plagued by financial depression. This situation stems from rising costs of newsprint and printing and the competition of radio and television in both news reporting and advertising. By 1971, half of the Dutch newspapers were operating at a deficit. Closedowns and mergers of old and respected newspapers (such as *Algemeen Handelsblad,* founded in 1828, and *Nieuwe Rotterdamse Courant,* founded in 1844) seem hardly able to check the crisis. During the previous 10 years, the number of newspaper publishers had sunk from 51 to 31. In the latter 1950s, there were 162 newspapers, with a daily circulation of 2,700,000; in 1971 there were fewer than 100 newspapers, though daily circulations had risen to about 4,000,000.

The Dutch broadcasting system is more complicated and may be considered unique, but above all it is democratic. Seven organizations, all under private initiative and with ideological aims, account for about 80 percent of radio broadcasting and 60 percent of television. These Catholic, Protestant, Christian, Socialist, and neutral stations all operate within the framework of the Netherlands Broadcasting Foundation (NOS), which is responsible for the actual transmission and for the joint programs filling the rest of the time. Church societies, political parties, and small representative groups are granted some reserved broadcasting time.

The government itself has no influence on the programs, and even permission to advertise is granted to a separate foundation, with a limited allocation of time. All broadcasting is financed by a licensing fee and by the yield from television and radio advertisements. These sums are paid into the Ministry of Cultural Affairs, Recreation and Social Welfare, which in turn pays the cost of the transmitters and allots the broadcasting systems a fixed amount per hour for radio and television programs.

THE OUTLOOK

The Netherlands is undergoing a period of intensive change. Although a growing population necessitates a policy of continuous economic growth, the combined demands on available space made by industry, traffic, housing, and recreation confront the authorities with complex decisions that can only be made within a framework of regional planning. At the same time, such decisions will have to take into account the country's evolution from a hierarchical democracy, built around religiously based reverence for authority, to a participatory democracy. The party system and the constitution also will undoubtedly have to be adapted to this change in social organization.

These problems can only be solved within a European context, and Dutch foreign policy, which has been based on the necessity for European integration since the end of World War II, will doubtless continue in that direction. Supranational policies are increasingly dictated in such fields as industrial development, the regulation of traffic, prevention of pollution, and protection of the natural environment. Actually, The Netherlands, densely populated and already highly developed economically, can hope to become something of a pioneer in solving the problems that confront industrialized Western civilization in the last quarter of the 20th century.

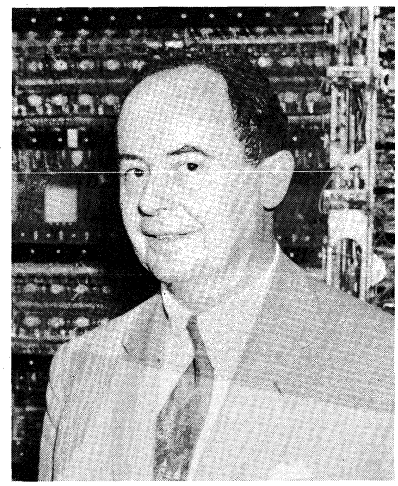
BIBLIOGRAPHY. The most extensive source of information on The Netherlands is *The Kingdom of The Netherlands* (1971), an official publication. The *Digests of the Kingdom of The Netherlands* are separate publications on the economy, the system of social security, and the constitutional organization in The Netherlands; the Government Information Service updates these publications annually. A complete survey of geographic conditions is published by the CARTOGRAPHIC INSTITUTE (BOOTSMA) under the title *Complete Geography of The Netherlands* (1971). Specialized works on drainage and water control are JOHAN VAN VEEN, *Dredge, Drain, Reclaim: The Art of a Nation,* 5th ed. (1962); see also two publications of the GOVERNMENT INFORMATION SERVICE: *The Zuyder Zee Works* (1967) and *The Delta Project* (1967). On demographic problems only works in Dutch are available; PIETER VAN DAALEN, *Dringen in Nederland* (1965); and J.P. VAN ROOIJEN, *Het Bevolkingsvraagstuk* (1961), more or less cover the field. HILBRAND BOSCHMA, *Fauna von Nederland* (1927); and H. HEUKELS, *Schoolflora voor Nederland* (1886, reprinted 1934), are good, if dated, works on Dutch flora. For a description of economic life the following works should be consulted: *The Textile Industry in Europe* (OECD, 1962), FOLKERT DE ROOS, *De Algemene Banken in Nederland* (1968); C.P.A. GEPPAART, *Onevenwichtigheden in de belastingwetgeving* (1968); *Politique des Transports aux Pays-Bas* (Éditions Techniques et Économiques, 1967). Dutch law and politics may be studied from the before-mentioned *Digests* and also from ERNST VAN RAALTE, *Het Nederlandse Parlement* (1958; Eng. trans., *The Parliament of the Kingdom of The Netherlands,* 1959). R.L. MORLAND, *Local Government in The Netherlands* (1958), can be a guide in that particular field. JOHN P. WINDMULLER, *Labor Relations in The Netherlands* (1969); and *Manpower and Social Policy in The Netherlands* (OECD, 1967), are the best introductions to Dutch labour politics; educational developments are well covered by *Educational Policy and Planning in The Netherlands* (OECD, 1967). The office for the documentation of art history publishes a *Bibliography of Dutch Art* (The Hague). *Broadcasting in The Netherlands* (NOS, 1971), explains the Dutch system of radio and television broadcasting.

(J.M.Lu./J.P.A.G.)

Neumann, John von

A mathematician, John von Neumann made important contributions to the sciences of quantum physics, logic, and meteorology that had practical applications in national defense and in the development of high-speed computing machines. His mathematical theory of games of strategy had a significant impact on economics.

Alan W. Richards



Von Neumann.

Von Neumann was born December 3, 1903, in Budapest, Hungary. Many legends about him, from childhood on, tell of his phenomenal speed in absorbing ideas and solving problems and of his equally phenomenal memory that retained everything he once thought through. He studied chemistry at the University of Berlin, and, at Technische Hochschule in Zürich, received the diploma in chemical engineering in 1926. The same year he received the Ph.D. in mathematics from the University of Budapest, with a dissertation about set theory. His axiomatization has left a permanent mark on the subject; and his definition of ordinal numbers, published when he was 20, has been universally adopted.

Von Neumann was *Privatdozent* ("lecturer") at Berlin

in 1926–29 and at the University of Hamburg in 1929–30. During this time he worked mainly on quantum physics and operator theory. Largely because of his work, quantum physics and operator theory can be viewed as two aspects of the same subject. He had a basic insight concerning vectors: the geometry of vectors in infinite-dimensional Euclidean space has the same mathematical characteristics as the structure of the states of a quantum-mechanical system.

In 1930 von Neumann was visiting lecturer at Princeton University; he was appointed professor in 1931. In 1932 he gave a precise formulation and proof of the "ergodic hypothesis" of statistical mathematics. His book on quantum mechanics, *Mathematische Grundlagen der Quantenmechanik*, published in 1932, is still a standard and one of the most inspiring treatments of the subject. In 1933 he became a professor at the newly founded Institute for Advanced Study, Princeton, keeping that position for the rest of his life. Meanwhile, he turned his attention to the challenge made in 1900 by a German mathematician, David Hilbert (*q.v.*), who proposed 23 basic theoretical problems for 20th-century mathematical research. Von Neumann solved a special case of Hilbert's fifth problem, the case of compact groups (see TOPOLOGICAL GROUPS AND DIFFERENTIAL TOPOLOGY).

Von Neumann algebras

In the second half of the 1930s the main part of von Neumann's publications, written partly in collaboration with F.J. Murray, was on "rings of operators" (now called Neumann algebras; see ANALYSIS, FUNCTIONAL). Of all his work, quite probably these concepts will be remembered the longest. Currently it is one of the most powerful tools in the study of quantum physics. An important outgrowth of rings of operators is "continuous geometry." Von Neumann saw that what really determines the character of the dimensional structure of a space is the group of rotations (see ALGEBRAIC STRUCTURES) that the structure allows. The groups of rotations associated with rings of operators make possible the description of space with continuously varying dimensions. In that context, for example, it makes sense to describe a space of dimension ¾. Hitherto, mathematicians had represented a given space only in terms of whole numbers. Abstracting from the "concrete" case of rings of operators, von Neumann formulated the axioms that make these continuous-dimensional spaces possible.

About 20 of von Neumann's 150 papers are in physics; the rest are divided more or less evenly between pure mathematics (mainly set theory, logic, topological group, measure theory, ergodic theory, operator theory, and continuous geometry) and applied mathematics (statistics; numerical analysis; shock waves; flow problems; hydrodynamics; aerodynamics; ballistics; problems of detonation; meteorology; and two nonclassical aspects of applied mathematics, games and computers). His publications show a discontinuous break from pure to applied around 1940.

During World War II, he was much in demand as a consultant to the armed forces and to the civilian agencies concerned with the problems of war. His two main contributions were his espousal of the implosion method for bringing nuclear fuel to explosion and his participation in the development of the hydrogen bomb. His political and administrative decisions were not usually on the liberal side. He continued to advocate atomic-bomb tests after the war.

The "minimax theorem"

The mathematical cornerstone of von Neumann's theory of games is the "minimax theorem," which he stated in 1928; its elaboration and applications are in the book he wrote jointly with Oskar Morgenstern in 1944, *Theory of Games and Economic Behavior*. The minimax theorem says that, for a large class of two-person games, there is no point in playing. Either player may consider, for each possible strategy of play, the maximum loss that he can expect to sustain with that strategy and then choose as his "optimal" strategy the one that minimizes the maximum loss. If a player follows this reasoning, then he can be statistically sure of not losing more than that value called the minimax value. Since (this is the assertion of the theorem) that minimax value is the negative of the one, similarly defined, that his opponent can guarantee for himself, the long-run outcome is completely determined by the rules.

In computer theory, von Neumann did much of the pioneering work in logical design, in the problem of obtaining reliable answers from a machine with unreliable components, the function of "memory," machine imitation of "randomness," and the problem of constructing automata that can reproduce their own kind. One of the most striking ideas, to the study of which he proposed to apply computer techniques, was to dye the polar ice caps so as to decrease the amount of energy they would reflect —the result could warm the Earth enough to make the climate of Iceland approximate that of Hawaii.

Among the many awards that von Neumann received are honorary doctorates from Princeton, Harvard, and Istanbul; a term as president of the American Mathematical Society; and memberships in several national scientific academies, including the United States National Academy of Sciences. President Eisenhower appointed him to the Atomic Energy Commission in 1955. He received the Enrico Fermi award in 1956, knowing that he was incurably ill. He died of cancer in Washington, D.C., on February 8, 1957.

The "axiomatic method" is sometimes mentioned as the secret of von Neumann's success. In his hands it was not pedantry but perception; he got to the root of the matter by concentrating on the basic properties (axioms) from which all else follows. His insights were illuminating and his statements precise.

BIBLIOGRAPHY. Von Neumann's *Collected Works* were published in six volumes between 1961 and 1963. A memorial issue of the *Bulletin of the American Mathematical Society* (vol. 64) was devoted to his life and works (May 1958). His last, incomplete, written work, *The Computer and the Brain* (published posthumously in 1958), has a touching preface by his widow.

Neuropteran

At one time the term neuropteran referred to many groups of insects that are now placed in other orders, so that, in a strict sense, the order Neuroptera now includes only the lacewings. Frequently, however, two other closely related insect groups are included also as neuropterans. These are the snakeflies (Raphidiodea), so-called for their body shape, and the dobsonflies and alderflies (Megaloptera). For completeness of discussion, therefore, all three groups, considered here as three separate orders, are included in this article.

General features

All three orders may have evolved from an early mecopteran (scorpionfly) ancestral stem, prior to the Trichoptera–Lepidoptera offshoot (see TRICHOPTERA). Carnivorous insects of varied structure and habit, both freshwater and terrestrial members of the three orders, are widely distributed with the exception of the snakeflies (which are confined to the Northern Hemisphere). Many members are important in the biological control of other insects and mite pests; others are "flies" of interest to anglers. Some of the most elegant and dainty insects are lacewings. There are more than 500 species of alderflies and dobsonflies, 80 species of snakeflies, and 4,000 species of lacewings.

The size of lacewings varies from 1.5 to over 35 mm in length and 2 to over 50 mm in anterior wing length. Lacewings are characterized by their many-veined pairs of wings, which give them a lacy appearance. Dobsonflies and alderflies, while similar in general appearance, have wings that appear heavier than those of lacewings; 15 to 30 mm in body length, their anterior wing length varies from 20 to more than 50 mm. Snakeflies are of medium size, 10 mm or more in body and anterior wing length, with wings similar to those of lacewings.

The Megaloptera and Raphidiodea differ from the Neuroptera in their prognathous adult heads (mouthparts anterior) and biting larval mandibles; the neuropterans have hypognathous adult heads (mouthparts ventral) and unique piercing–sucking larval jaws (composed of mandibles plus maxillae).

Natural history. *Life cycle of Neuroptera.* Neuropteran eggs may be laid loosely in light soil, cemented directly to a surface, or cemented on the end of a stalk. During the cementing process, the female places the tip of the abdomen on a surface and exudes a viscid fluid; she raises her abdomen slowly to draw the fluid into a slender filament. The fluid rapidly hardens, and the egg is attached by its posterior end to the top of the stalk.

Larvae hatch after 5–14 days unless the egg is in the overwintering stage. In some families a thickened portion of skin is used by the larva to break the egg; in others the egg splits. There are generally three larval stages in Neuroptera. The first lasts a few days, the second a few days or for the winter months, while the third varies, depending on the species, from weeks to months.

Neuropteran larvae are carnivorous and free-living with the exception of the aquatic family Sisyridae; these larvae are parasitic on freshwater sponges. Typically, a neuropteran larva sucks out the contents of its prey, leaving only a hollow skin. Although many lacewing larvae are nocturnal and need no camouflage, other species carry debris on bodies adapted for this purpose. In one family debris floats onto the hairs and is caught, while in another the larva takes debris in its jaws and places it on its back. In still another family larvae lie lightly covered in the soil; the lacewing larvae known as antlions dig conical pits in light, dry soil or sand. They vigorously throw out soil with their heads, then lie in the pit, body covered and jaws ready to grasp an ant or any other prey that may fall in. Should a captive attempt to escape by climbing a pit wall, the antlion will use its head to toss soil and cause the prey to fall back into the pit.

Larval feeding

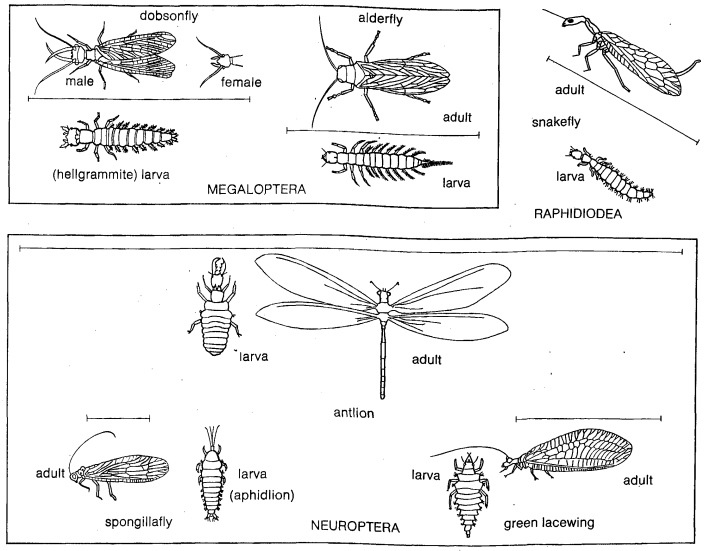
The neuropteran larva spins a double cocoon by exuding whitish or yellowish silk through its anus. First, a loosely woven cocoon is spun and fastened to a surface; then the larva spins a second tightly woven cocoon inside the first. This double construction is typical of neuropterans; the walls of the two cocoons may be closely attached or apart, depending on the species. The larva may spend the prepupal stage of several days or months within the cocoon before the pupal molt occurs. The limbs of the pupa are free. In a few species the pupa bursts from the cocoon, but most species use their functional mandibles to emerge. Adults appear either as the pupa leaves the cocoon or after it has reached a suitable position. Some species have two or more broods a year, although the life cycle does not exceed 12 months. Mating may occur anytime during the lifespan of the adult female; sometimes she holds fertilized eggs until weather conditions are suitable.

Life cycles of Megaloptera and Raphidiodea. Megalopteran females lay eggs above water level in masses of 3,000 or more. Larvae crawl into the water where they are very active. Commonly, alderfly larvae are associated with muddy bottoms of ponds and slow-moving streams, dobsonfly larvae with fast-flowing streams or rivers. The larvae are predaceous, usually nocturnal, and may leave the water to search for prey or to molt. Before pupation the larvae leave the water to form cells in damp, coarse soil beneath stones or debris. The pupa crawls from its earthen cell before the adult emerges. Raphidiodean females use slender ovipositors to lay eggs in the cracks of tree bark, and immature stages are found there.

Reproduction

Usually mating occurs at night. Sperm are passed either directly as spermatozoa or in a spermatophore that may project from the female after mating and be eaten by her, either wholly or in part. While megalopterans lay eggs in masses of several thousands, raphidiodeans lay them singly, and neuropterans lay 600 or 700 singly, separately in groups, or in batches.

Ecology. All of the larvae and adults are carnivorous and predaceous (except the parasitic Sisyridae), devouring enormous numbers of mites, insect eggs and larvae, ants, thysanopterans, psocopterans, and homopterans (especially aphids). For example, chrysopids consume large numbers of aphids and are a potent natural control mechanism. Larval feeding is continuous except during molts. Adults may also feed on dead insects, and females may feed on their own eggs and on spermatophores. The neuropteran family Sisyridae may have evolved from the closely related family Osmylidae whose larvae probe streamside mosses for prey.

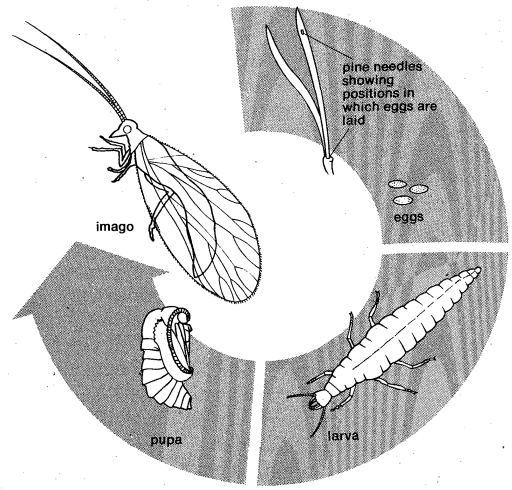


Diversity among neuropterans.
Line scales indicate approximate size of each insect.
From *Invertebrate Identification Manual* by Richard A. Pimentel, © 1967 by Litton Educational Publishing, Inc.; reprinted by permission of Van Nostrand Reinhold Company

Megalopteran larvae, a source of food for freshwater fish, are used as bait by anglers. Spiders capture both adults and terrestrial larvae in their webs. Neuropteran eggs and larvae are preyed upon by other neuropterans, other predaceous insects (*e.g.*, coccinellid, or ladybird beetle, larvae), ants, birds, and bats.

Form and function. *Adults.* Antennae are multisegmented in neuropterans and filiform in Megaloptera and Raphidiodea. The head is squarish or transverse in Megaloptera and Neuroptera, elongate in Raphidiodea; prognathous (mouthparts anterior) heads are typical of Megaloptera and Raphidiodea, hypognathous (mouthparts ventral) of Neuroptera. The four wings, which are similar in size, large or elongated, and translucent, contain many veins and crossveins and are sometimes coloured in brown or green shades. The ten-segmented abdomen lacks appendages (cerci); however, terminal claspers may occur. In both sexes, the last abdominal segment may be reduced, modified, or bear a pair of dorso-lateral groups of trichobothria (short, stiff sensory bristles). In females, abdominal terminalia are also variable; Raphidiodea have a long, thin ovipositor.

Immature stages. The larval head, prognathous in all three groups, may bear as many as seven simple eyes on each side or none. Megalopteran larvae have large man-



Life cycle of the brown lacewing *(Hemerobius stigma).*

Larval jaws

dibles, raphidiodean small, while larval jaws, the outstanding feature of neuropterans, may be short or long, straight or curved. In all neuropteran species each jaw is a sucking tube, mandible above and maxilla below, the two fitting together but separable. Since there is no true mouth, liquid food is sucked by a pharyngeal pump through the two jaws directly into the pharynx. The aquatic megalopteran larvae have lateral gill filaments and either a median caudal filament or anal prolegs; Raphidiodea lack abdominal processes. The terminal abdominal segments of neuropterans are modified into an anal proleg, with or without processes, which also functions as a spinneret (an organ for producing silk from internal glands); in several families the abdomen has special hairs or bristles (macrotrichia) for holding debris for camouflage.

Some pupae resemble adults, particularly the snakeflies. The hooks or ridges, aligned both forward and backward and evident on the dorsum of the abdomen of some pupae, may be used to maintain a position within the cocoon rather than to escape from it; mandibles and limbs are often used to aid in the escape.

Locomotion. Most larvae have walking legs except in those whose legs are modified for burrowing (Ithonidae and Myrmeleontoidea). The aquatic dobsonfly larvae have a pair of terminal abdominal prolegs that are important in moving in strong currents. The legs, abdominal filaments, and median tail filament of alderfly larvae bear long hairs, or setae, which help to propel them through their slow-moving water habitats. Snakefly larvae wriggle rapidly backwards to escape danger. Most neuropteran larvae have the tenth abdominal segment modified into a single anal foot for use in locomotion; a pair of hooked processes also assist in holding. Members of the three groups typically are weak fliers.

Evolution and Paleontology. The closely related dobsonflies, alderflies, and snakeflies may have arisen from a common stem that diverged from the ancestral mecopteran (scorpionflies) stem early in the Carboniferous Period (about 325,000,000 to 345,000,000 years ago); the Neuroptera may have diverged from the ancestral mecopteran stem later in the Carboniferous.

Fossil representatives of the modern families Sialidae and Corydalidae are represented in the Oligocene Baltic amber (about 26,000,000 to 38,000,000 years old). The present-day Raphidiidae are represented in the Oligocene Baltic amber. The present-day neuropteran family Psychopsidae was existent as early as the Triassic Period (about 190,000,000 to 225,000,000 years ago) in Australia. Other present-day neuropteran families, Coniopterygidae, Osmylidae, Sisyridae, Hemerobiidae, Chrysopidae, Myrmeleontidae, first occurred in the Oligocene Baltic amber, the Ascalaphidae in the Lower Miocene of France (about 36,000,000 years ago), and the Nemopteridae in the Miocene of Colorado.

Classification. *Distinguishing taxonomic features.* The adults of the orders Megaloptera, Raphidiodea, and Neuroptera have similar mouthparts, wings, and genitalia; they differ in shape of head and thorax. The presence of simple eyes (ocelli) and the morphology of antennae, head, wings (including venation), legs, and body, are criteria used to distinguish families.

Larval characters associated with the aquatic habit, such as abdominal filaments, separate Megaloptera and Sisyridae (Neuroptera) from terrestrial Neuroptera and arboreal Raphidiodea. The normal mandibles of Megaloptera and Raphidiodea separate these groups from Neuroptera, whose jaws are combined mandibles and maxillae. The form of the head, neck, mouthparts, legs, and body are used to separate neuropteran families.

Annotated classification. This is a combination of American and English classifications accepting three separate orders.

ORDER MEGALOPTERA

Adults medium to large; head prognathous; biting mouthparts; antennae threadlike (or filiform); 2 pairs of large, similar wings, held rooflike or nearly flat over abdomen in repose. Larvae elongated; biting mandibles; lateral abdominal gill filaments present; aquatic.

Family Sialidae (alderflies)

Wing expanse 20–40 mm; simple eyes (ocelli) absent; 4th tarsal joint of lower leg dilated and bilobed. Larvae with 7 pairs of lateral, segmented, abdominal filaments, median caudal filament; larvae without anal prolegs.

Family Corydalidae (dobsonflies)

Wing expanse 40–100 mm; 3 ocelli; 4th tarsal joint cylindrical; male mandibles sometimes enlarged. Larvae (called hellgrammites) with 8 pairs of unsegmented or imperfectly segmented, lateral, abdominal filaments; terminal filament absent; 2 anal prolegs.

ORDER RAPHIDIODEA (snakeflies)

Adults small to medium; head prognathous, elongated, tapering posteriorly; biting mouthparts; antennae filiform; prothorax elongated, cylindrical; 2 pairs of similar elongated wings, held rooflike over abdomen in repose; female with long, slender ovipositor. Larvae elongated; head and prothorax large, polished; biting mandibles; abdominal filaments and prolegs absent; arboreal.

Family Raphidiidae

Three ocelli; antennal joints smaller at bases.

Family Inocellidae

Ocelli absent; antennal joints cylindrical.

ORDER NEUROPTERA (lacewings)

Adults small to large; head hypognathous; biting mouthparts; antennae varied; 2 pairs of similar wings, held rooflike over abdomen in repose. Larvae elongated or broad; piercing–sucking jaws, elongated mandibles above, elongated maxillae below, form a hollow tube; abdominal filaments absent, except aquatic Sisyridae: paired abdominal prolegs absent; 10th abdominal segment modified as an anal proleg and/or spinneret.

Superfamily Ithonoidea

Adults large, mothlike; larvae with straight jaws, modified for subterranean predatory feeding.

Family Ithonidae (moth lacewings)

Adult wing expanse 30–79 mm; head small, closely set on prothorax; antennae long, filiform; costal areas of wings not broad. Larvae burrowing; legs adapted for digging, tibia fused to tarsus; mouthparts short, straight; maxillae enlarged.

Superfamily Hemeroboidea

Adults small to large; antennae filiform or moniliform (beadlike); posterior wings shorter than anterior; elongated larvae with jaws straight or curved.

Family Hemerobiidae (brown lacewings)

Adults small; antennae long, moniliform; ocelli absent; wings with few crossveins, hairy; female without projecting ovipositor. Larvae (called aphis wolves) elongated, with short incurved jaws; body smooth, fine hairs; free living on vegetation.

Family Sympherobiidae (brown lacewings)

Adults small, closely related to Hemerobiidae. Larvae spindle-shaped; head small; antennae short; jaws short, stout, slightly incurved.

Family Dilaridae (pleasing lacewings)

Small; antennae of male coarsely comb-shaped; head with 3 ocelli or ocellus-like tubercles; wings with numerous crossveins.

Family Psychopsidae (silky lacewings)

Adults large mothlike species; antennae short, wings broad. Larvae elongated, flat; head broad posteriorly, closely attached to prothorax; jaws incurved, large, sicklelike; often arboreal, under bark.

Family Osmylidae (osmylidflies)

Adults medium to large; head wider than long; antennae filiform, short; 3 ocelli; wings often with brown markings; claws with many teeth. Larvae elongated; long, slender, straight jaws, slightly upcurved; in margins of freshwater.

Family Polystoechotidae (large lacewings)

Adults medium to large; wing expanse 40–75 mm; antennae short. Larvae with short, sharp, incurved mandibles, maxillae stout, blunt; labial palpi, sensory appendages on labium (lower lip); leg 5-jointed; tarsal claws simple, slightly curved; knobbed structures (called empodia) between terminal elongated claws.

Family Sisyridae (spongillaflies)

Adults small, brownish, closely related to Osmylidae; ocelli absent. Larvae moderately elongated; hairy; antennae long, bristle-like; mandibles and maxillae elongated, with bristle-

like piercing structures; labial palpi absent; 1 tarsal claw per leg; aquatic; parasitic on freshwater sponges.

Family Chrysopidae (green lacewings, stinkflies)

Adults small to medium, yellowish, green, or grey, sometimes with markings; wing expanse 31–65 mm; head small, antennae long, filiform; iridescent golden eyes. Larvae (called aphid lions) moderately elongated, broad; long, sharp, incurved jaws; hairy; legs with long, trumpet-shaped empodium between claws; many with dorsal lumps on body, carry packets of debris dorsally; found on vegetation.

Family Apochrysidae (fragile lacewings)

Fragile, closely related to Chrysopidae; antennae filiform.

Family Berothidae (beaded lacewings)

Small, slender; antennae long, filiform; wings hairy, sometimes with seedlike scales; larvae thysanuriform, with short, straight jaws.

Family Trichomatidae

Small, slender, closely related to Berothidae; wings and body with long hairs.

Family Mantispidae (mantispids)

Adults small to large; wing expanse 10–55 mm; antennae short; prothorax greatly elongated; wings narrow; forelegs predatory. Larvae have 2 forms; 1st stage with squarish head; antennae with 3–5 joints; short, straight jaws; labial palpi with 3 or 7 joints; legs with 2 claws and empodium; active hunters; in presence of food reserves larvae become white, parasitic grubs with small heads and atrophied legs.

Superfamily Nemopteroidea

Adults highly specialized, related to Myrmeleontoidea; head prolonged in rostrum; posterior wings narrowed, elongated to twice anterior wing length. Larvae short, broad; with incurved jaws; varied in form, distinct from other neuropterans.

Family Nemopteridae (thread-winged or spoon-winged lacewings)

Adults delicate; head snoutlike; antennae short; posterior wings greatly elongated, ribbonlike or threadlike; often expanded distally to appear spoonlike. Larval antennae long, filiform; jaws incurved; mandibles with or without internal teeth; with or without an elongated neck formed by anterior portion of prothorax; if present, neck may be thin, cylindrical, 3 times length of head; remainder of thorax and abdomen broad, flattened; legs long, with 2 curved claws, empodium absent; free-living in dust, some cave dwelling.

Superfamily Myrmeleontoidea

Adults medium to large in size; antennae varied. Larvae short, broad; jaws incurved; mandibles with inner teeth.

Family Myiodactylidae

Adults resemble Osmylidae; antennae long, cylindrical.

Family Nymphidae (slender lacewings)

Adults slender; long, cylindrical antennae; wings long, slender. Larval neck slender; jaws incurved, mandibles with single internal tooth near midway.

Family Myrmeleontidae (antlions)

Adults with long, slender wings; bodies partly covered with fine hairs; dragonfly-like; antennae short, weakly clubbed or flattened distally. Larvae (called antlions or doodle bugs) short and broad; head small; neck bent to allow rapid upward and backward movement of head; mandibles strong, incurved; 3 internal teeth; posterior legs modified for backward burrowing, tibia fused to tarsus; abdomen hairy, plump, modified posteriorly for backward burrowing; lie in soil surface or at bottom of a self-made pit.

Family Stilbopterygidae (shiny wings)

Adults large, swift fliers; shining wings and bodies; dragonfly-like; antennae short, strongly clubbed; eyes large; larvae large, black, shiny; found in vegetable refuse.

Family Ascalaphidae (owlflies)

Adults large, dragonfly-like species, 40–50 mm in length; some rapid fliers; antennae long, slender, strongly clavate distally; eyes large, divided; head with long, fine hairs. Larval head squarish; mandibles elongated; 1 or several inner teeth; neck short, narrow; posterior legs with tibia fused to tarsus; body fringed.

Superfamily Coniopterygoidea

Tiny, somewhat separated from other Neuroptera; body, wings covered with white waxy powder; larvae straight-jawed; labrum large, covering the other mouthparts.

Family Coniopterygidae (dustywings)

Adult wing expanse 3–10 mm; antennae long, filiform wings similar or posterior wings reduced; wing venation reduced. Larvae, 5 simple eyes each side; 5-jointed antennae; jaws short or long, needlelike; legs with padlike empodium.

Critical appraisal. Standard English and American systems differ in their classification of Megaloptera and Raphidiodea as distinct orders.

The standard English classification is order Neuroptera, suborder Megaloptera, superfamily Sialoidea, family Corydalidae, family Sialidae, superfamily Raphidiodea, family Raphidiidae, and suborder Planipennia (true Neuroptera). In other systems, the suborder Megaloptera is termed suborder Sialodea, the combination Raphidioptera is used for Raphidiodea, and the name Neuroptera is used for a superorder containing the orders Megaloptera, Raphidioptera, Planipennia. The modern tendency is to separate the three main groups in the separate orders Megaloptera, Raphidiodea (or Raphidioptera), and Neuroptera (Planipennia), as in the classification above.

Although larvae of most families have been described, further breeding and detailed studies of life histories and morphology of immature and adult forms are required.

Neutron

The neutron is one of two subatomic particles present in the nucleus of every atom (except of hydrogen), the other being the proton. These two particles, called nucleons, interact through the so-called nuclear force and bond in various proportions to form the different atomic species of the elements.

The mass of a neutron is slightly greater than the mass of the proton, and almost 2,000 times that of an electron; the proton has the basic positive electrical charge, whereas the neutron has no overall electrical charge. The neutron possesses an intrinsic angular momentum (a concept that relates the distribution of mass in a body and its angular velocity) and a magnetic moment; that is, it behaves like a minute magnet in ways that suggest that it is an entity of moving electrical charges. It appears, therefore, to have a rather complex structure. The free neutron, one not incorporated into a nucleus, is subject to radioactive decay of a type called beta decay. It can disintegrate, or decay, into a proton, an electron, and an antineutrino, a particle with no charge and no mass. Because of its beta decay, the neutron does not exist in nature in its free state but must be produced artificially. Because free neutrons are electrically neutral, they pass unhindered through the electrical fields within atoms and, therefore, constitute a penetrating form of radiation, interacting with matter almost solely through the relatively rare collisions with atomic nuclei.

Shortly after the discovery of the neutron in 1932, it was found that many elements may undergo a nuclear transformation, called fission, when bombarded by neutrons. In the same fission process a new "generation" of neutrons is produced. In 1942, it was demonstrated that neutrons were produced in the fission process in sufficient numbers to sustain a chain reaction in the world's first atomic pile (later called a nuclear reactor) at Chicago. This development led to the construction of the atomic bomb and to general realization of the tremendous capabilities of nuclear energy. After World War II, the neutron was shown to have great potentialities in nonmilitary fields. Subsequent developments led to the large-scale production of electrical power from nuclear energy and its use as the motive power for ships. The absorption of neutrons by nuclei exposed to the large neutron in-

tensities available in reactors has resulted in the production of large amounts of radioactive isotopes utilized in many fields, mainly as tracers, minute quantities of which can be followed, by the use of radiation detectors through various chemical, biological, and industrial processes. Radioisotopes are used in medicine to study normal tissue, to diagnose disease, and in some cases to treat various forms of cancer.

In addition, the neutron is an important tool in pure research. Since it is a basic constituent of all matter, knowledge of its properties and its structure is essential to an understanding of the structure of matter. Nuclear reactions induced by neutrons are valuable sources of information about the nucleus; an understanding of its interactions with matter reveals important data about the characteristics of the basic nuclear force.

HISTORY

In 1911, the British physicist Sir Ernest Rutherford demonstrated that most of the mass and all of the positive charge associated with an atom is concentrated in its centre. He proposed a basic model for the atom in which the positive charge resides in the nucleus (with a radius of 10^{-12}–10^{-13} centimetre), and the negative charge consisting of the electrons is distributed over a sphere with a radius comparable to the radius of the atom (about 10^{-8} centimetre). At that time, although the actual composition of the nucleus was unknown, it had been proposed that it might contain some electrons in addition to protons. As the properties of nuclear particles became better understood, it became clear, however, that free electrons could not exist within a space as small as that of a nucleus.

In experiments performed between 1918 and 1930, atoms of one element were transmuted into atoms of another by the use of high-speed alpha particles, the nuclei of helium atoms. In 1930, Walther Bothe and H. Becker, working in Germany, reported that a penetrating radiation resulted from the bombardment of beryllium with alpha particles. This radiation was interpreted as gamma radiation of very high energy—more penetrating than had been observed up to that time. Further studies of the properties of this radiation by Irene and Frédéric Joliot-Curie in France led to the discovery in January 1932 that its intensity was increased by passage through a screen containing a large hydrogen content. The Joliot-Curies first suggested that the protons in the screen were ejected in the process of gamma ray (γ-ray) scattering, but the kinetic energy associated with the gamma rays had to be unreasonably large in order to account for the observed effect.

Discovery

James Chadwick, working during this time at the Cavendish Laboratory in England, found that the radiations from the bombardment of beryllium by alpha particles could transfer kinetic energy to other light nuclei as well as they could to hydrogen. Late in February 1932, Chadwick published a paper in which he suggested that the protons (hydrogen nuclei) and other light nuclei were recoiling from elastic collisions with a particle of mass approximately equal to that of the proton. Charged particles react electrically with the atoms of matter into which they penetrate and are soon stopped; the postulated particle had to be electrically neutral in order to explain its high penetrating power. Chadwick called it the neutron, as suggested by Rutherford. Later in 1932 he showed that its mass is only slightly larger than that of the proton. It was then concluded that the atomic nucleus is composed only of protons and neutrons, both of which should be regarded as fundamental particles.

Within a few years after Chadwick's discovery, a large number of investigators throughout the world were studying the properties and interactions of the neutron. Its mass was more accurately determined. It was discovered that the (α, n) reaction, in which alpha particle bombardment results in the emission of a neutron, occurred for other light nuclei besides beryllium; and the inverse reaction (n, α) was also shown to exist. The latter indicated the neutron's ability to induce transmutations. In 1934, the Joliot-Curies produced artificially radioactive nuclei in an (α, n) reaction, and in the same year Enrico Fermi and his coworkers in Italy showed that radioactivity could be induced in a variety of elements through bombardment by neutrons. Further work by the Italian scientists indicated that neutron-induced radioactivity could be increased by reducing the velocities of the neutrons. In other words, it was found that slower neutrons were more likely to be captured by nuclei. This recognition was of great importance to the understanding of neutron reactions and led to the use of slow neutrons as the main tool in the investigation of nuclear structure until after World War II.

PROPERTIES OF NEUTRONS

Absence of charge. Perhaps the most important of the fundamental properties of the neutron is its effective lack of an electric charge. The proton, in comparison, has one unit of positive charge. As a result of this difference, neutrons and protons interact quite differently with matter. For example, a proton passing through matter interacts much more strongly because of the electrical forces between its charge and the negatively charged electrons in the atom and the positively charged nucleus and loses its kinetic energy rapidly. A neutron, on the other hand, loses kinetic energy only in its relatively rare collisions with an atomic nucleus. It therefore constitutes a highly penetrating type of radiation.

Mass. The most accurate determination of the mass of the neutron is obtained in nuclear reactions in which the masses and energies of all of the particles except the neutron mass are known. The first accurate determination was performed in Cambridge, England by the physicists Sir James Chadwick and Maurice Goldhaber in 1935, in a reaction in which a deuteron (an atomic nucleus of deuterium, a heavy isotope of hydrogen) was decomposed into a neutron and a proton by the absorption of gamma radiation (electromagnetic waves with very high frequencies). At the present time, the mass of the neutron is taken to be 1.67466×10^{-24}g, or 1.008665 atomic mass units. In comparison, the proton mass is 1.67236×10^{-24}g, or 1.007276 atomic mass units, and the mass of the hydrogen atom (one proton plus one electron) is 1.67327×10^{-24}g, or 1.007825 atomic mass units. (One atomic mass unit = 1 amu = $\frac{1}{12}$ of the mass of the C^{12} atom = 1.66028×10^{-24}g.)

Radioactivity. Because the mass of the neutron is larger than that of the proton, the free neutron can decay into a proton with the emission of an electron and an antineutrino.

Half-life

In this process, called beta decay of the neutron (from the symbol β for the type of electron emitted in radioactive decay), the maximum energy of the electron is 7,820,000 volts. Neutron beta decay was first observed in 1948. The most recent value for the half-life of the free neutron is 11.7 minutes (*i.e.*, one-half of any quantity of neutrons decays in 11.7 minutes). When a neutron is bound in a nucleus, however, electron emission is generally impossible, and the neutron is therefore stable.

Spin, magnetic moment, and statistics. The neutron has a spin; that is, it behaves somewhat as a top spinning on its axis, with the difference that only certain discrete values of the angular momentum associated with this spinning motion are possible. Not all possible values are allowed to the spin; only those that are multiples of a basic value, the quantum of action. As with the proton and electron, the value of the neutron's spin is ½ (in units of $h/2\pi$, in which h is Planck's constant, a physical constant that has the dimensions of energy times time. It must, furthermore, obey the Pauli exclusion principle, which says that two neutrons in the same atom cannot occupy the same quantum state. (The behaviour of a large number of neutrons is governed by the rules of one of the forms of quantum statistical mechanics, called the Fermi-Dirac statistics.)

The neutron acts like a small magnet, with north and south magnetic poles, when placed in a magnetic field; that is, it has an intrinsic magnetic dipole moment. The first accurate measurements of the neutron's magnetic moment were by Luis Walter Alvarez and Felix Bloch, United States physicists, in 1940. The presently accepted value is −1.91315 nuclear magnetons (one nuclear magneton = 0.505038×10^{-23} erg per gauss). The negative

sign means that the magnetic moment points in a direction opposite to that of the spin. The existence of a magnetic moment for the neutron is not consistent with the predictions of the theory developed by a British physicist, Paul Adrien Maurice Dirac, to explain the behaviour of electrons, and which should be applicable to all charged particles with spin ½. The neutron's magnetic moment is, therefore, considered to be anomalous, which implies that the neutron, being electrically neutral, must have a somewhat complex intrinsic structure of positive and negative charges.

Wave properties and classification. On the basis of the laws of quantum mechanics, which were developed to account for the fact that in some situations subatomic particles behave like waves, a wavelength can be associated with the neutron. In a general way, wave phenomena should be observed in the interaction between neutrons and matter when the wavelength is comparable to the size of the system with which it interacts. The wavelength is inversely proportional to the square root of its energy, and for computational purposes the value of the wavelength for a neutron with kinetic energy E can be written as

$$\lambda = \frac{2.86 \times 10^{-9}}{\sqrt{E}} \text{(centimetre)},$$

in which E is in units of electron volts. (The unit, electron volt [eV], which is equal to 1.6×10^{-12} erg, is an energy unit of convenient size in the world of elementary particles. Two commonly used multiples of this unit are 1 MeV $= 10^6$ eV $=$ 1,000,000 electron volts, and 1 keV $= 10^3$ eV $=$ 1,000 electron volts.) It is useful to classify neutrons according to their energy and wavelength, although any specific scheme is somewhat arbitrary. It is common to describe neutrons with energies in the range from 0 to 1,000 eV as slow, 1 to 500 keV as intermediate, 0.5 to 10 MeV as fast, and greater than 10 MeV as very fast. The slow neutron category can conveniently be subdivided into cold neutrons (energies below 0.002 eV), thermal neutrons (a most probable energy of 0.025 eV), and epithermal neutrons (energies greater than 0.5 eV). The wavelengths associated with these energies can be found by application of the above formula.

Structure. Valuable information about the properties of the basic nuclear force has been obtained from data on the scattering of neutrons by protons. According to current theory, many of these properties can be interpreted in terms of a picture in which both the neutron and proton are thought of as being surrounded by a "cloud" of charged or neutral pions, subatomic particles that react strongly with neutrons and protons, and are sometimes called pi mesons. When two nuclear particles (either two neutrons, a neutron and a proton, or two protons) are in close contact with each other, these pions are interchanged (transmitted) from one to the other and thus act as the "glue" that binds nuclear systems together. On the basis of such a theory, the neutron can exist part of the time as a proton and a negatively charged meson separated by about 10^{-13} centimetre. It therefore has an internal structure consisting of circulating electric charge that can give rise to its magnetic dipole moment. This picture implies furthermore that the neutron should have a small electrostatic interaction (electric attraction or repulsion) with electrons. The scattering of slow neutrons by atomic electrons has indicated the existence of various effects, the largest of these being due to the interaction between their magnetic moments. No effect specifically attributed to the internal structure of the neutron has, however, been observed in such experiments. Recent studies of the scattering of very energetic electrons from targets of hydrogen and deuterium, nevertheless, verify that the neutron has a complex internal structure that involves charged pions, although the details of the actual distribution of the charge are not at present well understood.

The neutron star. A major development in the field of astrophysics was the discovery (1967) of rapidly pulsating objects called pulsars that are sources of radio waves in space. Although the physical nature of these sources of radiation is not entirely certain, it has been thought that they might be so-called neutron stars. In the theory of stellar evolution, the neutron star is the name given to a star in one of its final stages of life. It is a small object (radius about six miles) and extremely dense. Although the exact constitution is unknown, it is thought to consist primarily of free neutrons held together, and thus stabilized against beta decay, by immense gravitational forces. If this conjecture concerning the pulsars is correct, then these stars constitute the first direct evidence of the existence within the universe of matter consisting almost completely of free neutrons.

NEUTRONS AS COMPONENTS OF NUCLEI

On the basis of present theory, the nucleus of any atom more massive than the lightest isotope of hydrogen is composed of one or more neutrons and protons. These particles, along with electrons, are the fundamental building blocks of the chemical elements. According to the neutron-proton model, the number of protons in the nuclear core is equal to the number of electrons in the atom and is therefore equal to the atomic number Z. The mass number A of the atom, defined as the closest integer to the actual atomic weight, is equal to the sum of the number of neutrons and protons in the nucleus since each of these particles contributes approximately one unit of atomic weight. The number of neutrons, N, in the nucleus is then equal to the difference between the mass number and the atomic number (*i.e.*, $N = A - Z$). Isotopes of an element all have the same number of protons and electrons, but differ from each other in mass number, and thus contain different numbers of neutrons. For example, the three stable isotopes of hydrogen each contain one proton; normal hydrogen has no neutrons and $A = 1$, deuterium has one neutron and $A = 2$, and tritium has two neutrons and $A = 3$.

The protons and neutrons in the atomic nucleus are bound together by the strong nuclear force. The strength of this binding, the so-called binding energy, can be deduced from the actual nuclear masses by use of the relationship describing the equivalence of mass and energy derived on the basis of the special theory of relativity. Thus, if ΔM is the decrease in mass that occurs when a number of neutrons, protons, and electrons combine to form an atom, the binding energy is

$$\Delta E = (\Delta M) \times c^2,$$

in which c is the velocity of light. The magnitudes of nuclear binding energies are very large indeed. For the case of an atom of helium, for example, the binding energy is 28 MeV, which means that it takes 28,000,000 electron volts energy to dissociate the helium nucleus into its four constituent particles. By comparison, it takes only a few electron volts to separate an electron from an atom. The tremendously higher energy involved in the case of nuclear transformations arises from the exceedingly strong forces that exist between the particles in the atomic nucleus.

Similarity to proton

In some circumstances it is useful to stress the similarities between the neutron and proton rather than their differences. In this respect, the neutron and proton can be regarded as two different manifestations of a single entity called the nucleon. The nucleon is therefore similar to an entire atomic nucleus, in that it can exist only in discrete quantum states; that is, it exists only in certain states characterized by definite values of charge and total internal energy. The neutron, with zero charge, is a state of the nucleon at a slightly higher energy (due to its slightly larger mass) than the proton, which is the nucleon state of +1 unit of charge.

NEUTRON PRODUCTION

For experimental purposes, free neutrons must be produced artificially. They can be released in nuclear reactions initiated by either charged particles or gamma radiation and in the nuclear fission process.

Energy. Neutron sources based on nuclear reactions provide monoenergetic neutrons (numbers of neutrons having the same energy) as well as neutrons having a broad continuous spectrum of energies. In any reaction, energy is either released or absorbed. Which occurs in a

particular case can be determined from a knowledge of the rest masses (a particle at rest has less mass than one in motion, due to relativity) of the atomic nuclei involved in the reaction along with the known energy-mass equivalence as expressed in the relationship, $E = mc^2$. If the energy associated with the sum of the nuclear masses of the projectile and the target is greater than the sum of the masses of the neutron and the final nucleus, then the reaction is exoergic and energy is released. If not, the reaction is endoergic, and energy must be absorbed in order for neutrons to be emitted. In endoergic processes the energy necessary for the reaction must be supplied by the kinetic energy of the relative motion of the target and projectile.

Yield. The yield of neutrons in a reaction depends on the nature and kinetic energy of the incoming nuclear particle. In a quantitative determination of the yield, it is necessary to know the reaction cross section. This quantity represents the probability that the nuclear particles will interact. In an elementary sense the cross section is the target area presented by a nucleus to an incoming particle, although this picture should not be taken too literally since the cross section depends not only on this area but also on the energy of the incident (incoming) particle and on the angle at which the final particles are emitted. The unit of cross section is called the barn (one barn $= 10^{-24}$ cm^2). The yield of a neutron-producing reaction is the number of neutrons produced for each particle incident on the nucleus.

Reactions initiated by charged particles. Most nuclear reactions that lead to the production of neutrons involve the bombardment of light atomic nuclei by incident protons, deuterons (heavy-hydrogen nuclei), or alpha particles. Other light projectiles such as ^{3}H (tritium) nuclei and ^{3}He (helium-3) particles are also used. These nuclear particles are usually accelerated to high kinetic energies in various kinds of nuclear accelerators, such as the Van de Graaff generator, the Cockroft-Walton generator, the cyclotron, and the proton synchrotron.

Symbols

A shorthand notation has developed for use in specifying nuclear reactions. The target nucleus and product nucleus are indicated by the chemical symbol of the element with a superscript giving the mass number A of the nucleus. (For example, ^{12}C represents the carbon isotope of mass 12.) The smaller incoming and outgoing particles are denoted n for neutron, p for proton, d for deuteron, α for alpha particles, and γ for gamma rays. Thus, the reaction ^{7}Li$(p, n)^7$Be means that one atom of lithium, mass 7, absorbs a proton, p, and emits a neutron, n, which leaves one atom of beryllium, mass 7.

Those reactions that yield the most copious supplies of monoenergetic neutrons are proton–neutron (p, n) and deuteron–neutron (d, n) reactions. The most common (p, n) sources are lithium and tritium, and these reactions are usually written: ^{7}Li$(p, n)^7$Be reaction (*i.e.*, $^7\text{Li} + p \rightarrow {}^7\text{Be} + n$) and ^{3}H$(p, n)^3$He reaction. Both processes are endoergic. High yields of monoenergetic neutrons with energies up to 4 MeV can be supplied from accelerated proton beams.

Most deuteron–neutron (d, n) reactions are exoergic; that is, energy is released in the interaction. These reactions can therefore supply neutrons of higher kinetic energy. The ^{2}H$(d, n)^3$He and ^{3}H$(d, n)^4$He reactions are frequently used for the production of monoenergetic neutrons at various energies between 2 and 30 MeV. Both of these reactions yield copious amounts of neutrons even at small deuteron kinetic energies.

Neutron yields in reactions induced by accelerated alpha particles are generally lower than in the reactions discussed above. Nevertheless, under certain conditions, the ^{9}Be$(\alpha, n)^{12}$C reaction, for example, is a useful source of monoenergetic neutrons. This reaction is, moreover, the principal process responsible for neutron production in radioactive materials used as neutron sources. In such sources the neutrons are produced in the bombardment of beryllium by the alpha particles emitted by naturally radioactive elements. In contrast to accelerator-produced neutrons, the neutrons emitted from radioactive sources are not monoenergetic.

Neutrons constitute an appreciable fraction of cosmic radiation as observed at sea level. Both slow neutrons and the very fast neutrons that arise from nuclear disintegrations in the atmosphere have been observed. From a practical point of view, such neutrons do not constitute a useful supply of neutrons at sea level because of their low intensities.

From the point of view of a radiation health hazard, it is fortunate that the intensities are low at sea level. These neutrons do, however, change some nitrogen atoms of the atmosphere into radioactive carbon atoms that have been found useful in radiocarbon dating (see DATING, RELATIVE AND ABSOLUTE).

Reactions initiated by gamma radiation. Neutrons can be produced in reactions initiated by gamma (γ) rays whose energy is greater than the energy with which the neutron is bound in the nucleus. This means that for most nuclei the γ-ray energy must be greater than about MeV. For beryllium and deuterium, however, the thresholds for neutron production by γ-ray absorption are 2.225 MeV and 1.66. MeV respectively. Some radioactive neutron sources utilize these low (γ, n) thresholds. Depending upon the particular radioactive material, approximately monoenergetic neutron sources with energies from 25 keV to about 1 MeV have been constructed.

A high-intensity (γ, n) neutron source can be obtained from the acceleration of large electron currents in linear accelerators, betatrons, and synchrotrons. When accelerated electrons strike targets made of heavy elements, they give rise to intense X-rays. The energy spectrum of this radiation is continuous up to a gamma-ray energy equal to the kinetic energy of the accelerated electrons. For electrons accelerated to energies in excess of the neutron-binding energies of nuclei, copious supplies of neutrons can be produced. The neutrons produced in such a source are not monoenergetic. The spectrum is relatively broad and resembles the energy spectrum that is obtained in the nuclear fission process.

Neutron energies in a reactor

Fission reactions. The nuclear reactor, or pile, is a very useful source of neutrons, especially of slow ones. The basic reaction involved is nuclear fission, during which neutrons are emitted. In the fission of uranium-235, ^{235}U, for example, an average of 2.5 neutrons are produced per fission. The spectrum of neutron energies is very broad—up to at least 8 MeV, with an average value of about 1.5 MeV. This is not, however, the energy distribution observed either inside or emerging from a nuclear reactor, because of the various slowing-down processes of neutrons in the reactor's moderating material (see below). The kinetic energies of the neutrons from a pile are classified as fast neutrons, epithermal and intermediate-energy neutrons, and thermal neutrons. From a practical viewpoint, the reactor is not a useful source of fast neutrons (although strong sources of fast neutrons can be obtained by bombarding ^{235}U by slow neutrons from the reactor), but both intermediate and thermal neutrons from a reactor are used extensively in nuclear studies.

NEUTRON CONTROL AND MANIPULATION

Moderation and diffusion. Beams of slow neutrons are usually obtained from a nuclear reactor, in which the fission reaction produces neutrons with kinetic energies up to 8 MeV. The process of reducing their energies into the slow range involves successive interactions with the many nuclei in the large mass of material (usually graphite or water) within the reactor. The career of a neutron in such a medium is usually divided into two parts. The first phase, called neutron moderation, is the process by which the neutrons are slowed down by elastic scattering collisions (see below) with the nuclei of the medium until they have attained thermal energies. A knowledge of the distribution of neutron energies and neutron positions within the moderating material during the slowing-down process is important to the design of nuclear reactors, as well as to the subsequent use of the neutrons. The second phase, referred to as thermal neutron diffusion, involves the subsequent collisions that the neutron encounters until it is finally captured by an atomic nucleus or it escapes from the medium. In this phase the loss of energy of the neu-

trons in collisions with nuclei is as probable as energy gains, and their behaviour is very similar to that of atoms in a gas. The individual neutron energies are distributed around an average value according to the so-called Maxwell distribution, a statistical distribution based on the principles of the kinetic molecular theory. Their behaviour is described by a diffusion equation, which is directly analogous to the basic differential equation of heat conduction.

Absorption. In the interaction between neutrons and bulk matter, the disappearance of the neutrons from the medium is governed by the probability of neutrons being absorbed by the nuclei of the medium. This probability is a mathematical one and is expressed as the cross section for the capture of neutrons; the larger the cross section, the greater the probability of absorption. For slow neutrons, the capture cross sections vary inversely as the square root of the kinetic energy, or velocity, of the neutron (so-called $1/v$ law, v being the neutron velocity), except at capture resonance (see below), where the probability for neutron absorption can become extremely large. Strong selective absorption by a nucleus over a narrow energy region, called resonance absorption, is superimposed over the $1/v$ absorption for slow neutrons.

Velocity selectors. The neutrons emerging from a mass of moderating material have a continuous distribution of kinetic energies in the thermal and intermediate energy regions. Some experiments require devices to separate neutrons of specific energies from the continuous spectrum emitted by the source. Such devices are called monochromators or velocity selectors. Mechanical velocity selectors, also called choppers, are utilized for neutrons in the thermal and somewhat higher energy range. A chopper is basically a high-speed rotating shutter designed to allow the passage of neutrons of only one specific velocity. Crystal velocity selectors select neutrons of a specific low energy by the process of reflecting neutrons from a single crystal of a metallic material that absorbs high-energy neutrons. A polycrystalline substance can also be used to filter out all short-wavelength neutrons to produce cold neutrons; that is, neutrons with kinetic energies less than 0.002 eV.

Choppers

Velocity selection can also be achieved by neutron time-of-flight techniques. Such methods have been utilized over a broad energy range that extends from thermal energies up to the fast neutron region. A short burst of neutrons is produced and their velocities determined by the measurement of the time taken to travel a known distance. Neutron sources can be pulsed charged-particle accelerators, which produce the neutron bursts in nuclear reactions, or reactors in which the emergent beam is broken into pulses by use of mechanical choppers. Flight times are measured by electronic techniques; by the use of multichannel methods, various neutron velocities can be selected simultaneously.

Neutron optics. Slow neutrons have wavelengths of about 10^{-8} centimetre, about the same size as the distances between atoms in crystals. They are, therefore, well suited for studies of the structure of crystals—that is, the pattern of the atoms in ordered matter. In the scattering of neutron waves by crystalline materials, the scattered wave interferes with the incident wave in much the same manner as in the case of X-ray scattering. The scattered intensities in different directions vary as a result of the particular relationship between the neutron wavelength and the location of the atoms in the crystal. The intensity patterns exhibited in this diffraction process can be analyzed to give details of the atomic structure of the material. The structure of organic crystals and of crystals with magnetic properties have been studied extensively by neutron-diffraction methods.

As with light waves, neutrons can also be reflected or refracted in passing across the boundary between two media. Slow neutrons, however, show these optical phenomena in the interaction with various metals—bismuth, lead, beryllium—rather than with optically transparent materials. Just as light exhibits the phenomenon of total reflection by a mirror, the total reflection of neutrons will also be observed if the neutron is incident on a neutron "mirror" (beryllium for example) at extremely small glancing angles. Such techniques allow the determination of the neutron index of refraction of a medium and have yielded valuable information on the interaction between neutrons and nuclei.

NUCLEAR REACTIONS PRODUCED BY NEUTRONS

When a neutron collides with an atomic nucleus, a variety of nuclear reactions can occur. The lack of charge enables even very low energy neutrons to initiate such reactions. In comparison, the positively-charged proton can interact with the nucleus only when its energy is high enough to overcome the repulsive force between its charge and the charge on the nucleus. The probability that a particular reaction will happen depends on the nature of the nucleus and the kinetic energy of the incident neutron. It is determined by the cross section for the reaction.

Energy dependence of cross sections. The manner in which a neutron interacts with a nucleus to initiate a reaction depends upon its kinetic energy. For slow neutrons the wavelengths are larger than nuclear sizes and therefore the probability for interaction is very large. When the neutron is captured it shares its energy with all the nucleons in the target and a compound nucleus is formed with a total energy, called energy of excitation, equal to the initial kinetic energy of the neutron plus the binding energy of the neutron in the compound nucleus. The compound nucleus, which can be thought of as a system at a high temperature, subsequently "cools down" by emitting a neutron, a γ ray, or a charged particle, and the final nucleus is left in one of its allowed quantum states. Which particle will be emitted depends on the properties of the compound and final nuclear states. For incident neutron energies, such that the total excitation energy corresponds to the actual energy states of the compound nucleus, a compatability called nuclear resonance occurs, and the probability for capture becomes very large. The cross section for absorption or for a particular mode of decay exhibits peaks in energy, which are fairly well defined. The occurrence of resonance behaviour increases for intermediate and higher energy neutrons. These neutrons have wavelengths comparable in size to nuclear dimensions and are therefore useful probes of the details of nuclear structure. In the fast and very fast energy region, neutron wavelengths become smaller than the average distance of separation of the nucleons in the nucleus, and there is a good chance that the neutron will pass through (or close to) the nucleus without being captured at all. The cross sections do not appear to depend sensitively on the internal structure of the nucleus. An almost perfect analogy is the scattering and absorption of light by a semitransparent medium. In this sense, the nucleus acts like a "cloudy crystal ball." At these energies, furthermore, the neutron has a good chance of interacting with only a single nucleon, which is then emitted in what is called a direct nuclear reaction. If it is absorbed to form a compound nucleus, the nuclear temperature is so high that individual capture resonances are not observed. Instead, the system behaves as if many quantum states are excited at the same energy, and the chance that many particles will be emitted in the decay becomes large. Some of the nuclear reactions induced by neutrons are discussed in the following sections.

Elastic scattering and total cross sections. The simplest process that occurs when a neutron strikes a nucleus is elastic scattering. It occurs for all nuclei at all neutron energies. In this process, the sum of the kinetic energies of the nucleus and the neutron after the collision is equal to the kinetic energy of the neutron before the collision. (It is assumed that the target nucleus is initially at rest and thus has no kinetic energy.) Experimentally, the nucleus in its lowest state of internal motion experiences a recoil, and the neutron with reduced energy is re-emitted in a different direction.

Elastic scattering is the dominant neutron reaction at intermediate and high energies for light- and medium-weight nuclei. At those energies at which the cloudy-crystal-ball model (see above) of the nucleus becomes important, the reaction is sensitive to the shape of the nucleus,

and the effective sizes of nuclei (*i.e.*, their radii) can be determined from measured scattering cross sections.

Total cross section

A given nucleus generally has a different cross section for each type of nuclear reaction that can take place, and the sum of the cross sections for all processes is called the total cross section. Thus, the total cross section is a measure of the number of neutrons that are removed from an incident beam in passage through matter. The difference between the total cross section and the scattering cross section is the absorption cross section.

Radiative capture. At low neutron energies, in the thermal and near-thermal region, the most probable reaction following neutron capture is the emission of gamma rays. At those energies for which resonances occur, the cross sections are exceedingly large. For indium, for example, the capture cross section at a resonance at 1.4 eV is more than 100 times that at nearby nonresonant energies. As the neutron energy is increased into the intermediate region, the neutron–gamma (n, γ) reaction becomes less probable because of increased competition with resonant elastic scattering, at least for light nuclei. For heavier elements, on the other hand, radiative capture is still the predominant process. Much of present knowledge of the energy-level structure of medium-weight and heavy nuclei has been obtained in studies of the (n, γ) reaction.

Emission of neutrons. Inelastic scattering results from a collision in which the incident neutron transfers some of its kinetic energy into internal energy of the target nucleus and a neutron is re-emitted at very much reduced energy. Such a process requires that the kinetic energy of the incident neutron be greater than the energy of the lowest excited state of the nucleus. Depending on the particular target nucleus, the neutron must have a minimum energy of between about 0.05 and 5 MeV before inelastic scattering can occur. After the inelastic process has taken place, the target nucleus can decay to a state of lower energy by the emission of γ rays.

In the very fast neutron energy region (kinetic energies of 10 MeV or higher), neutron-induced reactions frequently lead to the subsequent emission of two neutrons. In light nuclei, this (n, $2n$) reaction takes place almost as often as neutron scattering or charged-particle emission. For heavy nuclei, the emission of two neutrons is considerably more probable than is charged-particle emission.

Emission of charged particles. Reactions that are initiated by neutrons and result in the emission of one charged particle are the inverse of those in which neutrons are produced by charged-particle bombardment. The most frequently encountered neutron-induced reactions are those in which protons and alpha particles are emitted. The process of proton emission occurs only after the absorption of energy (that is, the process is endoergic, except for a few lightweight target nuclei), and the cross sections for such reactions are appreciable only for fast neutrons for which the available energy for the charged particle is large. In (n, α) reactions energy is often released and hence they can be initiated by slow neutrons.

Fission reactions. Nuclear fission is a mode of disintegration in which a heavy nucleus is split into two fairly massive intermediate-weight fragments with the release of a large amount of energy (about 200 MeV). One or more neutrons can also be released in the process. Some elements fission spontaneously or, as with many uranium and plutonium isotopes, fission can be induced by slow neutrons. For such heavy elements, fission occurs with a high probability after the capture of a neutron. For example, the fission cross section for the uranium-235 isotope, ^{235}U, is about 83 percent of the total slow neutron absorption cross section. For some heavy nuclei, however —notably ^{238}U and ^{232}Th—fission occurs only after the capture of neutrons with kinetic energies greater than about 1.5 MeV.

Other reactions. At ultrahigh neutron energies (between 50 and 500 MeV), multiple particle emission can take place. The reaction appears to proceed in two stages. In the first, the incident neutron interacts with individual nucleons in the nucleus, and these are emitted by a direct reaction. In the second step, the remaining nucleons in the system redistribute their energies to form a very highly excited compound nucleus, which decays by the emission of gamma rays and one or more nuclear particles.

DETECTION OF NEUTRONS

Methods of detection

In experiments that involve neutrons, one of the most important problems is their detection. Since the neutron is electrically neutral, it does not produce direct ionization. Neutron detection must therefore be based on secondary effects that result from their reactions with nuclei. For fast neutrons, the most important detection techniques make use of the ionization by light nuclei recoiling after elastically scattering neutrons. Other methods for detecting both fast and slow neutrons rely on neutron-induced charged-particle reactions in which the ionization produced by the charged particle is detected on the observation of fission fragments from neutron-induced fission or on a measurement of the radioactivity induced in a suitable nucleus by neutron capture or some other neutron reaction.

The design of apparatus for neutron detection involves a number of considerations. The technique to be used is selected on the basis of the application, the efficiency with which the secondary radiation is collected, the response to neutrons as a function of their energy, the sensitivity to background effects, and the response to neutrons sharply defined in energy.

Detection of fast neutrons; recoil detectors. In the process of elastic scattering, the positively charged target nucleus struck by a neutron with kinetic energy E will recoil with an energy E' as shown by the formula in which m and M are the masses of the neutron and recoiling nucleus, respectively, and θ is the angle between the directions of motion of the recoil nucleus and the incident neutron:

$$E' = \frac{4\,mM}{(m+M)^2} E\cos^2\theta.$$

For most efficient detection, a large recoil kinetic energy is desirable. The formula shows that the largest recoil energies occur when m and M are equal, so that scattering from protons (that is, from hydrogen nuclei) is preferred, since the mass of a proton is almost identical with that of a neutron. The main disadvantage to recoil proton detection is that the recoil particles will have all energies from 0 to E for incident monoenergetic neutrons with energy E.

Typical proton recoil detectors are ionization chambers and proportional counters filled with hydrogenous gases, scintillators made of hydrogenous compounds, photographic emulsions, and cloud and bubble chambers. A single gas recoil counter is useful for the simple detection of neutrons. To determine the neutron energy as well, combinations of two or more recoil counters have been used to measure both the energy of the recoiling proton and its direction of emission. The simultaneous detection of energy and angle of emission of the recoil proton is possible in photographic emulsions and in cloud and bubble chambers, since in these devices the path travelled by a charged particle appears as a visible track. In recent years, fast-neutron recoil counters based on the scintillation method of detection have been widely used. These devices are usually organic crystals or organic liquids and plastics. The light output from the scintillators, which is generated from the passage of a recoil proton, is amplified by a photomultiplier tube and its associated electronic circuitry. Recent advances in such techniques have made it possible to reduce the sensitivity of the device to background radiations, particularly γ rays. These counters are well adapted to the investigation of complex neutron spectra by methods that utilize velocity selection by time of flight.

Scintillation counters

Detection of fast neutrons. *By nuclear reactions.* In order for a neutron-induced reaction to be useful as a detector over a fairly wide energy range, the reaction cross section should be large and should vary smoothly with neutron energy. There should, furthermore, be few if any alternative reactions. Generally, therefore, the choice is limited to reactions involving light nuclei. Both the $^3He(n, p)^3H$ and $^6Li(n, {}^3H)^4He$ reactions satisfy these requirements in the fast-neutron region moderately well,

although there are some background effects. Both have been employed as fast-neutron detectors—^{3}He as a gas-filled proportional counter, and ^{6}Li in the form of a thin foil. The $^{10}B(n, \alpha)^{7}Li$ reaction, which is widely applied for neutron detection at low energies, has a prohibitively small sensitivity to fast neutrons. If, however, proportional counters containing boron bifluoride, BF_3, gas are immersed in a moderating medium such as paraffin, a detector that has a uniform response for neutrons from very low energies up to about 5–6 MeV can be constructed. This "long counter" is used widely in applications that involve the simple detection of neutrons.

The fission reaction utilizing uranium, ^{238}U, and thorium, ^{232}Th, as targets can serve as detectors for fast neutrons with energies greater than about 1.5 MeV. Since the energy release in the fission reaction is extremely large, the ionization pulses from the fragments are great enough to be distinguished from any background effects, and efficient neutron detection is possible.

By radioactivity. Fast neutrons can be detected by radioactivation techniques. Either the fast neutrons are slowed down to thermal energies and then captured in a material that becomes radioactive, or the fast neutrons themselves produce radioactivity in a nuclear reaction. Processes such as (n, p) and $(n, 2n)$ reactions, which are sensitive only to neutrons in the MeV range, frequently lead to radioactive final nuclei and can serve as such fast-neutron detectors. The radioactivity is detected after neutron irradiation by measuring the subsequent alpha, beta, and gamma radiation with suitable counters.

Detection of slow neutrons. *By nuclear reactions.* The most widely usable detector for slow neutrons is based on the reaction $^{10}B(n, \alpha)^{7}Li$ reaction. In this reaction, a large amount of energy is released. Hence the ionization caused by the alpha particle is easily observed, and background radiations can be eliminated. The cross section at thermal energies is very large and is a smooth function of energy up to about 1 keV.

The standard detector for slow neutrons has for many years been the BF_3 gas proportional counter or a similar counter with ^{10}B used as a wall coating of the counter tube. For time-of-flight experiments with slow neutrons, however, improved time resolution (because of faster time response of scintillators) can be obtained by the use of various boron scintillators, including scintillating liquids with boron dissolved in them. Other scintillating materials which contain ^{6}Li are also used for slow-neutron applications. The $^{6}Li(n, {}^{3}H)^{4}He$ reaction, which has been mentioned in connection with fast-neutron detection, has a large cross section for thermal neutrons as well. Although their efficiencies are lower than for boron counters, detectors with good time resolution have been constructed.

Some heavy nuclei have very large cross sections for fission by slow neutrons. Fission detectors consisting of thin foils of ^{233}U, ^{235}U, and ^{239}Pu are efficient detectors of neutrons in this energy range.

By radioactivity. The neutron radiative-capture process can be used as a detector of slow neutrons. In this application, either the γ rays following neutron capture are detected or (if the final nucleus is radioactive) the induced activity can be measured. To measure the radioactivity, the most important requirements are that the half-life be in a convenient range (a few minutes to several days) and that the capture cross section be large. Capture in manganese, indium, and iodine, for example, satisfy these requirements and are frequently used.

Nevada

Located in a mountainous region that includes vast semi-arid grasslands and sandy alkali deserts, Nevada is a part of the Old West that in 1864 became the 36th state of the United States. Its name was derived from the Spanish *nevada* ("snow clad"), a reference to the high mountain scenery of the Sierra Nevadas on its southwestern border with California. Other neighbouring states sharing many of the geographical features that make Nevada the nation's most arid state are Oregon and Idaho to the north, Utah to the east, and Arizona to the southeast. The 1970 population of about 489,000 living amid 110,540 square miles (286,299 square kilometres) made Nevada, after Alaska and Wyoming, the most sparsely populated state in the nation. During the 1960s, however, its percentage gain in population was the largest of the 50 states. Its capital, Carson City, remained the smallest state capital in the nation.

Location and general character

The Nevada of the 1970s appears far removed from the days when Virginia City was a fabled frontier town, thriving upon the rich silver mines of the Comstock Lode. Many frontier qualities persist, though subtly transformed into a sophisticated urban environment. The prospector digging against odds to find a bonanza has been replaced by the fortune seekers in the gambling casinos of Las Vegas and Reno, and the erstwhile "saloon diversions" have evolved into the lavish nightclub entertainment.

While the great majority of Nevadans live in the two main cities—more than one-half of them in the Las Vegas metropolitan area and one-fourth in that of Reno—the vast undeveloped lands of the state provide a largely unknown resource for the future. Combined with the major scientific activity related to the federal government's atomic-research facilities, the modern cities and desert reaches make Nevada a fascinating and unique phenomenon among American states. For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; NORTH AMERICA; NORTH AMERICAN DESERT; and SIERRA NEVADA RANGE.

THE HISTORY OF NEVADA

Anthropological evidence indicates that prehistoric Indian settlements existed in Nevada more than 20,000 years ago. Cave-dwelling tribesmen left picture writings on rocks in southern Nevada, and Basket Makers and Pueblo Indians also flourished there. Explorers of the early 1800s found Mohave, Paiute, Shoshoni, and Washoe Indians at various locations within Nevada.

Explorers and settlers. Missionaries and fur traders were in the vanguard of exploration. The missionary travels of Francisco Garcés from New Mexico to California in 1775–76 were imitated by other Spanish Franciscans. In 1825 Hudson's Bay Company trappers explored the northern and central region, and two years later Jedediah Smith led a party of Americans into the Las Vegas Valley and across the Great Basin. By 1830 the Old Spanish Trail brought traders from Santa Fe and Los Angeles, and in 1843 and 1845 John C. Frémont's military explorations publicized the Great Basin and the Sierra Nevada region. During the 1840s American pioneers followed the Humboldt Valley-Donner Pass route to the Pacific Coast, and the Forty-Niner Gold Rush greatly expanded migration through Nevada to California.

Nevada, which came under United States sovereignty through the Mexican Cession of 1848, was a part of California until it was incorporated into the newly organized Utah Territory in 1850. In 1849 a settlement was made at Genoa (then Mormon Station) in Carson Valley, but population remained meagre until the discovery of the Comstock Lode in 1859. From that time on Nevada ceased to be merely a highway for gold seekers on the way to California. Thereupon Virginia City became the most famous of all the Western mining camps, and

Discovery of mineral wealth

the rapid influx of prospectors and settlers resulted in the organization of Nevada Territory in 1861.

Simultaneously, the American Civil War gave strategic importance to the new territory. President Lincoln realized that Nevada's mineral wealth could help the Union, and he also needed a Northern state to support the proposed antislavery amendments to the Constitution. Although Nevada Territory had only about one-fifth of the 127,381 persons required for statehood, Nevadans were encouraged to seek admission to the Union. Congress accepted the proposed state constitution and voted for statehood in 1864.

Mining and cattle-ranching decades. Throughout its early decades Nevada's economy was dependent on mining and ranching. The rich Comstock mines reached a maximum annual output of $36,000,000 in silver in 1878. During the 1870s, however, the federal government limited the role of silver in the monetary system, causing a decline in silver prices, the closing of many mines, and the decay of thriving communities into ghost towns.

As mining declined, cattle ranching became a major industry. But beef prices were unpredictable, high railroad rates were burdensome, and severe winters often killed thousands of cattle. In the late 1880s many cattlemen were forced into bankruptcy. Depressed in mining and ranching, the state's population dropped from 62,000 in 1880 to 47,000 in 1890.

Prosperity returned only after the turn of the century, when rich silver ores were discovered near Tonopah, major copper deposits around Ely, and a major gold strike occurred at Goldfield. Thousands of miners answered the lure of those bonanzas, and railroads built extensive branch lines to bring in equipment and haul out the ore. Accessible railroads and reduced rates also encouraged cattlemen to renew large-scale production. Irrigation of fertile river valleys produced sizable hay crops. Thus assured of winter feed, ranchers further expanded herds in the upland regions. World War I demands for Nevada's beef and metals kept the boom going, but the failing markets of the 1920s brought the return of depression.

During its first three decades, Nevada was strongly oriented to Republican control. Reflecting the lax standards in national politics, the state was often manipulated by corrupt politicians. Mineowners and ranchers frequently subsidized government officials, and there were accusations that rich men had bought seats in the United States Senate. Monetary issues became paramount in the 1890s, and the Free Silver Party swept four consecutive state elections. By 1900, however, the traditional two-party system was again in control, and since then Nevada has voted consistently in line with national trends.

Creation of a modern economy. During the Great Depression of the 1930s, when agriculture and mining were in acute distress, Nevada began its transition to a modern economy. After legalization of gambling in 1931, as well as establishment of a six weeks' residency to qualify for divorce, the state developed resort and tourist-oriented businesses. Construction of Hoover Dam on the Colorado River substantially aided the economy of southern Nevada, and its cheap hydroelectric power opened the way for manufacturing. The importation of hydroelectric power from Bonneville Dam on the Columbia River and piped-in natural gas also has brought industrial development in the northwestern region.

Advent of the resort and scientific communities

In the 1950s the establishment of the Nevada Test Site by the federal Atomic Energy Commission expanded employment opportunities and stimulated the development of technical industries within the state. Overshadowing the new industrialization, and fundamentally responsible for the current prosperity, is the diversification and expansion of the tourist trade to include not only the gaming and entertainment facilities of the Reno and Las Vegas areas but also the scenic and recreational opportunities throughout the state.

THE LANDSCAPE

Surface features and waters. Most of Nevada lies within America's Basin and Range Province, or Great Basin, whose topography is characterized by rugged mountains, flat valleys with occasional buttes and mesas, and sandy desert regions. More than 30 north–south mountain ranges cross the state; the highest elevations are Boundary Peak, at 13,140 feet (4,005 metres) and Wheeler Peak, at 13,061 feet (3,981 metres). The southern area of the state is within the Mojave Desert, and the lowest elevation, 470 feet, is in the Colorado River Canyon.

The state's rivers depend for the most part on the melting of winter snows and spring rainfall, and almost all drain into lakes that have no outlets or into shallow sinks that in summer evaporate into alkaline mud flats. The Humboldt, the largest of Nevada's rivers, provides the only major east–west drainage system. The Truckee, Carson, and Walker rivers, which rise in the Sierra Nevadas, serve extensive irrigation and reclamation projects. The Muddy and Virgin rivers in southern Nevada are related to the Colorado River system.

Several lakes provide scenic and recreational attractions. Lake Tahoe on the California–Nevada border is particularly notable for its clarity, depth, and scenic beauty. Pyramid, Walker, and Winnemucca lakes are remnants of an ancient sea. In relation to its area, however, Nevada has comparatively little surface water. The increasing demands of urbanism, industry, and agriculture are exhausting both underground and surface resources, and scarcity of water is an increasing concern. The impounded waters of Lake Mead, extending for 117 miles behind Hoover Dam, provide significant relief for the southeastern area.

Scarcity of water

Climate. The high Sierras along the western boundary often cause clouds of Pacific origin to drop their moisture before reaching Nevada, thus producing a semi-arid climate. The driest regions are in the southeast and near Carson Sink, where annual rainfall seldom exceeds four inches (100 millimetres). The northeast averages eight–nine inches of precipitation, whereas that of the northwestern mountains often reaches 24 inches. Temperatures vary as widely. In the north July temperatures average 70° F (21° C) and in the south 86° F (30° C). In January the averages range from 24° F (−4° C) in the north to 40° F (4° C) in the south. The northern and eastern areas have long, cold winters and short but relatively hot summers, whereas in southern Nevada the summers are long and exceedingly hot, the winters brief and mild. Regional differences are pointed up by variations in the growing season: Las Vegas has 239 days; Elko, only 103; and Reno, 155.

Vegetation and animal life. Despite aridity and rugged terrain, Nevada shows considerable variety in vegetation. In the lower desert areas, mesquite, creosote, greasewood, yucca, and more than 30 varieties of cacti abound, while sagebrush and Joshua trees flourish at the higher elevations. Throughout the state, particularly after the spring rains, more than 2,000 varieties of wild flowers have been identified. Mountain forests contain pine, fir, and spruce as well as juniper and mountain mahogany. The piñon pine is characteristic in the high mountain regions, and the rare bristlecone pine—one of the oldest living species of trees—is native to the Toyaibe Range.

The animal population includes those best adapted to temperature extremes and lack of moisture. Among the larger animals are bighorn sheep, several varieties of deer, and the pronghorn antelope. Rabbit and other rodents are abundant; the desert harbours such reptiles as geckos, horned toads, tortoises, and sidewinder rattlesnakes; and predators such as coyote and bobcat are common. The permanent bird population is limited, but there are seasonal visitations by a great variety of migratory birds. Game birds include sage grouse, pheasants, and quails; and Nevada's rivers and lakes contain large quantities of bass, trout, crappy, and catfish.

THE PEOPLE OF NEVADA

Ethnic and religious groups. The great majority of Nevadans are of European ancestry, about 95 percent of whom were born in the United States. Some 6,000 persons trace their ancestry to Basques recruited as sheep-

herders from their ancient Pyrenean homeland, and about 3,000 Mexican-Americans live in the southeast. Descendants of the Paiute, Shoshone, and Washoe Indians live on several reservations. Blacks, mostly in the Las Vegas and Reno areas, make up less than six percent of the state's populace.

The two predominant religious groups are the Mormons, who migrated westward from neighbouring Utah, and Roman Catholics, each with about one-fifth of the population. Other Protestant denominations and a Jewish minority account for the remainder of the religious adherents.

Contemporary demography. During both the 1950s and 1960s, Nevada's population grew by more than 70 percent, though it remains only 47th in size among the 50 states. In spite of a birthrate slightly above, and a death rate slightly below, the national averages, this growth was largely the result of a steady influx of people from other states. The impact of this immigration has been felt most strongly in Las Vegas and surrounding Clark County, which more than doubled in population in each decade after 1940, and in Reno and surrounding Washoe County. In 1970 about 80 percent of the Nevadans were urban, 73 percent of them engaged in the booming and diversifying economies of those two metropolitan areas.

Immigration and urbanization

THE STATE'S ECONOMY

Although the traditional bases of Nevada's economic life, mining and agriculture, remain important, they were far overshadowed in the 1970s by manufacturing, governmental activity, and especially tourist-related services. The state's labour force in 1970 enrolled nearly one-half of the population, indicating an extraordinarily low percentage of dependent persons, and the per capita income was the fourth highest in the nation.

Mining, agriculture, and forestry. One of the richest mineral regions of the nation extends eastward from California across Nevada and into Arizona. Even with 75 percent of its lands unexplored for its resources, in 1970 Nevada ranked high in mineral production, which provided one-third of the total value of goods produced in Nevada. Copper is the most commercially valuable of the metals, and the state's annual output ranks fifth in the nation. The Ruth Mine in White Pine County is the largest open-pit copper mine in the world. Manganese ore is mined in the southeast, and tungsten, antimony, and iron deposits in central and northwestern Nevada. The Cordero Mine in Humboldt County is the second largest source of mercury in the United States, and total mercury production ranks second only to that of California. Nevada's silver output ranks seventh in the nation, and commercial production of gold occurs only at the Carlin Mine in Eureka County, second in yield nationally. Petroleum was discovered in Nye County in 1954.

Continuity of the traditional economy

Nevada's agriculture is largely dependent upon irrigation. Even in the river valleys, farmers and ranchers pump additional underground water for their crops and livestock. About 600,000 acres are classified as croplands, compared with more than 7,000,000 acres utilized for fenced pastures, meadowlands, and open-range grazing. In recent decades farms and ranches have increased in acreage while declining in number.

Farms are devoted mainly to forage crops or truck farming, though southeastern farms also produce cotton. Livestock ranching, however, is the main source of agricultural income. The large cattle and sheep ranches are chiefly in Elko, Humboldt, and Lander counties, where many ranchers graze their herds for part of the year on leased public lands. Most of the beeves are shipped to California or the Middle West for fattening prior to marketing. Dairy and poultry farms have become important in western and southeastern Nevada, and horse ranches are also being developed in the same regions.

Approximately 12,000,000 acres, or 17 percent of Nevada's total acreage, is devoted to forests and woodlands. More than 5,000,000 acres have been designated as national forests, and private holdings support only a small-scale lumber industry. Aside from lumber production, the forests are of importance for the conservation of water and wildlife and in providing recreational opportunities.

Manufacturing and electrical resources. Throughout the 1960s manufacturing expanded and diversified, and industrial employment rose by nearly 60 percent. Most of the larger enterprises were located in Clark or Washoe counties. In order of value the leading product groups are: primary metals; cement, stone, glass, and ceramic clay; foodstuffs, including meat and dairy products; fabricated metals and machinery; printing and publications; and lumber and wood products. The primary industry is copper smelting, and the largest industrial complex is located in Henderson, where major factories process titanium ore and produce industrial chemicals.

Nevada's electric power capacity for industrial and domestic use doubled between 1955 and 1966. Approximately one-half of the electricity is generated by hydroelectric plants. Although Hoover and Davis dams are major power sources, federal allocations do not adequately serve the energy needs of the state. Steam-generating plants near Las Vegas provide supplementation for southern Nevada, while northwestern Nevada imports hydroelectric power from California.

Federal government. About 87 percent of Nevada's land is owned by the federal government. Following establishment of the Nevada Test Site by the Atomic Energy Commission in the 1950s, a complex of research and development enterprises, mainly in the aerospace, civil-defense research, biomedical environmental protection, and electronics fields, grew up in the Las Vegas area. By the 1970s they had come to rival the similar industries in California and in the Boston and Washington, D.C., areas. The test site itself is a major centre for underground nuclear detonation and for 15 years, until 1972, for nuclear rocket development. Thousands of military personnel are stationed also at Nellis Air Force Base and Fallon Station (Naval Auxiliary Air Station).

The tourist-related industries. In 1970 tourism and its related activities brought Nevada 20,000,000 visitors, contributed 30 percent more income than mining, agriculture, and manufacturing combined, and employed about one-third of the work force. Although millions of persons visited Lake Mead and other recreational and scenic areas, the focus of the tourist industry was on several attractions that are unique to Nevada among the American states.

Legalized gambling and related lures

The 24-hour-a-day gaming casinos bordering the "Strip" in Las Vegas are the most publicized aspect of the legalized-gambling industry. Most such activities are conducted within the law and have contributed to the state's treasury, but there also have been intermittent investigations into the involvement of underworld crime syndicates in Nevada gambling. Important adjuncts to the casinos are the luxury hotels and nightclubs that have made Las Vegas—and, to a lesser extent, Reno and Lake Tahoe—a major centre of live entertainment in the nation.

In addition, Nevada law long has permitted divorces after only brief residence and marriages without waiting periods. Nevada's divorce law attracts thousands of persons annually from across the country, while the ease of marriage is taken advantage of mainly by persons from neighbouring states. The existence of legal prostitution is a unique circumstance in the sparsely populated rural counties of central Nevada.

Labour and unions. The labour organizations of the 1870s and 1880s were related to the mining and railroad industries, but a series of unsuccessful strikes and the radical reputation of the Industrial Workers of the World retarded the movement in the 1900s. Recovery came very slowly, and not until 1939 did more than 30 percent of the Nevada work force hold union membership. Nevertheless, substantial state legislation supported the working population. In 1913 workmen's compensation insurance was initiated, state employment offices were established in 1923, and unemployment compensation was begun in 1937.

In recent decades union organization has had a substantial resurgence. Restaurant workers and the entertainers

have built large, influential unions paralleling those of the teamsters, operating engineers, plumbers, carpenters, and sheet-metal workers. By 1970 labour-union membership had exceeded 50,000, and most Nevada urban workers—excluding the 17,000-plus employees of the gaming industry—were covered by union contracts.

Transportation. Its vast size makes Nevada heavily dependent upon air transportation. The state is served by seven national airlines and numerous supplemental carriers. There are 81 airports and airfields, and both Las Vegas and Reno have been designated as international ports of entry.

Three major railroads cross the state, while short lines serve as feeders where truck competition has not caused discontinuance. Nevada's public roads include primary and secondary highways as well as municipal and rural roads. Two of the nine federal highways are part of the interstate system. Several national bus lines and trucking lines serve the state.

The three major transportation and trade centres are Reno (the principal distributive centre for northwestern Nevada and northeastern California), Elko and Ely (in northeastern Nevada), and Las Vegas (the commercial centre for southern Nevada and nearby areas of Utah and Arizona). Warehousing and trucking industries flourish because of Nevada's strategic geographical location and the "free port" tax exemption for goods continuing in transit.

ADMINISTRATION AND SOCIAL CONDITIONS

State and local government. Nevada is governed under its original constitution, adopted in 1864 but since amended in many respects. The chief officials, including the governor, lieutenant governor, attorney general, secretary of state, controller, and treasurer, are elected to four-year terms. In addition to the usual departments and agencies supervising areas of public concern, the state Equal Rights Commission oversees areas of discrimination of various kinds, while the Gaming Control Board oversees operations of the gambling industry.

Executive, legislative, and judicial branches of government

Nevada's bicameral legislature comprises a Senate of 20 members elected for four-year terms and an Assembly of 40 members elected for two-year terms. It convenes in January of odd-numbered years.

The highest judicial body is the Supreme Court, composed of a chief justice and four associate justices. There are also 12 district courts, subdivided into departments on a population basis. Cities and townships have courts staffed by municipal judges and justices of the peace. All judicial offices are subject to nonpartisan elections.

Local government comprises 17 counties, 16 cities and towns, and 57 townships. Since Nevada traditionally has been rurally oriented, the county remains the primary unit of local administration. Each county has a public administrator, board of commissioners, district attorney, sheriff, and other officials. Cities and towns are incorporated under charters granted by the legislature, most of them with a mayor–council form of government.

Finance. Nevada's fiscal policies have been markedly conservative. The constitution rigidly limits both taxation and indebtedness. The bonding capacity cannot exceed one percent of the total assessed valuation of real property in the state, and the maximum tax rate on real estate is $5 on each $100 of valuation. Even more unusual is the absence of state taxation upon inheritances and all types of income.

Special taxation, however, provides about 70 percent of governmental income, with the balance coming from federal grants and subventions. A general sales tax is the chief source of state revenue, followed by various levies upon gambling and privilege excises. Principal expenditures are for education, health and welfare, and highways.

Political life. Nevada's politics has been middle-of-the-road. Through 1970 the Republicans and Democrats each have carried the state 13 times in presidential elections, and the state's electoral vote has been cast for the victor in every presidential campaign since 1912. State elections have shown a similar pattern. Of the 20 governors elected since statehood, nine were Democrats, three were Free Silverites, and nine were Republicans. The legislature usually is divided, with Democrats frequently in control of the Assembly, and Republicans customarily having a majority in the Senate. In the 1960s legislative overrepresentation of the rural counties offset the numerical advantage of the Democrats, but the redistricting that became effective in 1972 opened the way for a major shift in political control.

Education. The public school system is controlled by an elected eight-member Board of Education, which delegates administrative responsibilities to an appointive superintendent of public instruction. Local school districts, coextensive with the counties, receive supplementary funding from the state. School attendance is compulsory for those between the ages of seven and 17; in 1970–71 more than one-fourth of the state's population was enrolled in public schools.

Institutions of higher education

The University of Nevada originally was established at Elko in 1874 under the provisions of the Morrill Land-Grant College Act; 12 years later it was moved to Reno. In 1951 an extension branch was established in Las Vegas, which since has become the autonomous University of Nevada, Las Vegas. Elko Community College is within the university system, and the 1971 legislature established similar two-year colleges for the western and southern regions. To supplement campus instruction, the Desert Research Institute and the Agricultural Experiment Stations provide statewide research services.

Welfare, health, and housing. Nevada's social welfare programs and its custodial institutions are administered by the Department of Health, Welfare, and Rehabilitation. Old-age and welfare allotments are given to those qualified on the basis of need, and public assistance is available for the blind and other handicapped individuals. Support payments are provided for dependent children, and a state orphanage is located near Carson City. The state mental hospital is in Sparks, and in 1970 a mental-health facility was established in Las Vegas. Penal and rehabilitation institutions include the state prison in Carson City, a girls' training centre at Caliente, and an industrial school for boys at Elko.

Health care, housing, and public safety are responsibilities of local government or private enterprise. In 1971 Nevada had 20 general hospitals, which provided slightly more than 2,000 beds for patients, and there were 109 physicians and 47 dentists per 1,000 of population. An open-housing law was passed by the 1971 legislature, and limited beginnings were made in low-cost public housing.

CULTURAL LIFE AND INSTITUTIONS

Arts and entertainments. Nevadans traditionally have mingled rural conservatism and the individualism of the Old West. During its first century the population was relatively small and dispersed, and cultural values remained those of an agrarian society. With the sophisticated resort industries and the influx of residents, however, Las Vegas and Reno developed marked metropolitan characteristics. Not only has the economy diversified but cultural activities have burgeoned. Recognizing this trend, the 1967 legislature established the Nevada State Council on the Arts to coordinate and stimulate cultural activities.

Both major cities have well-established programs in the performing arts. The universities sponsor lectures, concerts, and theatrical productions, while the tourist industry regularly features the most famous entertainers from America's show business. Both Reno and Las Vegas support symphony orchestras and have commercial and public art galleries. Varied handicrafts are promoted by the Artists and Craftsmen's Guild of Nevada and by the Handweavers and Spinners Guild. Traditional Indian arts and crafts have been revived on reservations and in urban colonies.

Preservation of the past. Nevada's frontier heritage is commemorated by annual pageants and festivals, which provide natives with both sentimental nostalgia and additional commercial opportunities. Perhaps the best known is Helldorado Week in Las Vegas each May, for which

townspeople wear Western garb and mobilize a series of rodeos and parades. A unique ethnic event is the Basque Festival in Elko, and the Reno Rodeo is an outstanding Fourth of July celebration. The entire state observes its anniversary, Admission Day, on October 31, highlighted by a picturesque parade and costume ball in Carson City.

Old West festivals

Nevada has five museums and 43 libraries. The Nevada State Museum, located in the old federal mint building in Carson City, emphasizes the mining industry and mineral collections. Anthropological artifacts are featured at the Lost City Museum in Overton, at the University Museum in Las Vegas, and at the Southern Nevada Museum in Henderson. The Mackay School of Mines Museum, on the Reno campus of the state university, is oriented to metallurgical, mineralogical, and geological specimens. The Nevada Historical Society, also in Reno, has pioneer mementos, the most complete holding of Nevada newspapers, and a sizable historical reference library. The library of the University of Nevada, Reno, has the largest collection of books in the state, while the Nevada State Library at Carson City is notable for excellence in legal fields.

Scenic and historic sites. State and federal governments maintain six historic monuments, three major parks, and several developed recreational areas. The Valley of Fire State Park, near Overton, is widely known for its brilliantly coloured rock formations, Indian pictographs, and petrified forest. Mormon Station Historic State Monument, in Genoa, includes the site of the first permanent settlement in Nevada, and Cathedral Gorge, near Caliente, displays red and gold rocks that resemble church spires. The famed Death Valley area lies on the border between Nevada and California, and Lehman Caves National Monument, near Baker, has underground pools and unique limestone formations.

Communications media. Of the 31 newspapers published in Nevada, 23 appear as weekly journals. The largest dailies are the *Las Vegas Review Journal,* the *Las Vegas Sun,* Reno's *Nevada State Journal,* and the *Reno Evening Gazette.* Nine television channels and 32 commercial radio stations blanket the state.

Prospects. Nevada's future appears to be related closely to an ever accelerated growth and diversification. A continuing influx of population and industrial expansion will have a special impact on the southern region. Consequently, Las Vegas and Clark County will increasingly dominate the politics and economy of the state. Problems that already loom conspicuously on the horizon include: conservation and augmentation of water resources, control of environmental pollution, elimination of disadvantages for ethnic minorities, a broader base for state and local taxation, and governmental consolidation for the metropolitan areas. It is likely that, during the 1970s, Nevada will move farther from its rural past and continue to develop in the patterns of urban America.

BIBLIOGRAPHY. The FEDERAL WRITERS' PROJECT, *Nevada: A Guide to the Silver State* (1940), provides a thorough but dated overview of the state. For a comprehensive bibliography, see RUSSELL R. ELLIOTT and H.J. POULTON, *Writings on Nevada* (1963). The best historical survey is JAMES W. HULSE, *The Nevada Adventure,* rev. ed. (1969); but still useful are JAMES G. SCRUGHAM (ed.), *Nevada: A Narrative of the Conquest of a Frontier Land,* 3 vol. (1935); and RICHARD G. LILLARD, *Desert Challenge* (1942). For special topics, see ELEANORE BUSHNELL, *The Nevada Constitution,* rev. ed. (1968); JOHN A. BRENNAN, *Silver and the First New Deal* (1969); RUSSELL R. ELLIOTT, *Nevada's Twentieth-Century Mining Boom* (1966); MARY ELLEN GLASS, *Silver and Politics in Nevada* (1970); JOHN KOONTZ, *Political History of Nevada,* 5th ed. (1965); ELIOT LORD, *Comstock Mining and Miners* (1883); STANLEY W. PAHER, *Nevada Ghost Towns and Mining Camps* (1970); and WILLIAM WRIGHT, *The Big Bonanza* (1947).

(R.J.Z.)

New Brunswick

New Brunswick is a Canadian province located on the eastern seaboard of the North American continent. One of the four original provinces making up the national Confederation in 1867, it ranked eighth of the ten Canadian provinces in population a century later. Together with Nova Scotia and Prince Edward Island, it forms the regional grouping known as the Atlantic (Maritime) Provinces. Though it has contributed heavily to the national life of Canada, its importance has receded as the country has expanded toward the west and north. Economically, it has failed to keep pace with the more central provinces of Ontario and Quebec. On the other hand, its beautiful natural environment—an attraction for tourists, hunters, and fishermen—has remained relatively unspoiled. It has an oblong shape, about 200 miles from north to south and 150 miles from east to west. Its area is 28,354 square miles (73,437 square kilometres), and it extends from 45° to 48° north latitude and from 63° to 69° west longitude. To its west, across the United States border, lies the state of Maine; to the north it is bounded by Quebec, on the east by the Gulf of St. Lawrence and Northumberland Strait, and on the south by the Bay of Fundy. Separating the latter features, the narrow neck of the Isthmus of Chignecto joins the province to Nova Scotia. (For related information see CANADA; CANADA, HISTORY OF.)

HISTORY

The province was first known to Europeans as a portion of a seaward region called Acadia, inhabited by Micmac and Malecite Indians of the Algonkian-speaking group. French traders and settlers made but slight impact on this mainland part of Acadia until, in the mid-18th century, British expansion on the neighbouring Nova Scotian peninsula compelled the French authorities to make a precautionary military move. A French fort at Beauséjour, on the 17-mile-wide Chignecto Isthmus, became the point of the principal confrontation and fell to British assault in 1755. The expulsion of the French-speaking Acadian people followed immediately, and for several years the British hunted down parties of refugees in the inner recesses of New Brunswick's forests and rivers.

By a British proclamation of 1763, the area later to be known as New Brunswick was incorporated into Nova Scotia. Development was slow. A sprinkling of New England settlers continued to move to the St. John River, where the first English settlement had taken place at Maugerville in 1762. A few hundred Acadians returned, establishing themselves on the northern and eastern coastlines. The American Revolution had important consequences for the area when some 14,000 Loyalists, mostly from the middle states of the new republic, settled on the banks of the St. John and St. Croix rivers. This decisive event was followed by the separation of the area from Nova Scotia and the establishment of the province of New Brunswick in 1784.

Early settlement

Early Loyalist enthusiasm was soon diminished. In the last years of the 18th century, the war of the French Revolution prevented the British government from giving New Brunswick the kind of encouragement its people expected, and not until about 1808 did the terms of trade alter in favour of the province and the population start to grow. This was primarily a result of the decision of the British government to grant tariff preferences to the timber resources of the North American colonies, a situation brought about by Napoleon's control of Baltic products. The Loyalist expectation of a society of landed gentlemen, living from the fruits of agriculture, gave way to the realization that New Brunswick possessed little arable land and the subsequent development of an economy based on the forests.

Material progress continued rapidly until the mid-19th century, reaching a climax during the so-called age of wood, wind, and water, when the province gained a reputation for the quality of its ships and sailors. Responsible home government was granted by Britain in 1848. The Reciprocity Treaty with the United States (1854) and opportunities offered by the U.S. Civil War stimulated trade and shipping. New Brunswick entered into confederation with Canada in 1867 only with reluctance, largely because of its general satisfaction with its status as an almost completely self-governing colony within the British Empire.

Union with Canada

New Brunswick has had an unspectacular history in its existence as a province of Canada. Forest products have continued to be the basis of its economy, and secondary industry has failed to develop to significant proportions. In comparison with national growth, wealth and population have progressed but slowly. Until the restrictions by American immigration authorities in the 1920s, large numbers of young people left for New England, where economic prospects appeared brighter. Since the 1940s there has been a comparable exodus to central Canada. By the 1970s, average income in the province was about two-thirds that of Canada as a whole.

THE LANDSCAPE

Forests cover some 87 percent of the province, a proportion that has been increasing since 1950. Pine, once profuse, has steadily diminished, and the principal growths today are maple, birch, spruce, fir, and tamarack (American larch). Much reforestation has taken place. The climate, with temperatures ranging from −30° F (−34° C) in winter to 90° F (32° C) in summer, and with 40 to 45 inches (1,000 to 1,125 millimetres) of rainfall and up to 100 inches of snow annually, nourishes rapid forest growth. New Brunswick is also a land of lakes, rivers, and small streams. The St. John and St. Croix rivers drain the western half of the province, the east being served by the Restigouche, Miramichi, and Petitcodiac. Ranges of hills, reaching a maximum altitude in Mt. Carleton, 2,690 feet (820 metres), cross the province from west to east in both the north and south.

Most of the soil of New Brunswick is acid, stony, and poorly drained, although there are occasional pockets of good cattle-raising country, and the upper St. John Valley is noted for the production of potatoes. Villages are market centres or sites for sawmills. The population has become increasingly urbanized, the proportion exceeding 50 percent by the 1970s. Of the rural dwellers, less than 10 percent are engaged in farming. The largest city, Saint John, with a metropolitan area population exceeding 130,000, is a manufacturing centre, national port, and terminus of Canada's two great railways. Moncton, with a population of nearly 50,000 by the early 1970s, is a manufacturing and communications centre. Fredericton (25,000), the provincial capital since 1785, is the commercial centre of central New Brunswick.

Patterns of settlement

The dense forests of the province shelter an increasing moose population. During the autumnal open season, thousands of deer are pursued by brightly-coated hunters, many of them from the sprawling urban areas elsewhere on the continental seaboard. Rivers and streams abound in fish, but by the 1970s the famous Atlantic salmon had greatly diminished in number, the victim of pollution from industrial plants and from the aerial spray directed against the spruce budworm that infested the forests.

THE PEOPLE

New Brunswick is notable for its large French-speaking minority, principally descendants of those returning Acadians of the 18th century who settled on the northern and eastern shores of the province. In the northwest these have been substantially reinforced by French Canadians from Quebec. Against strong historical odds, the Acadians have not only preserved their identity in an English-speaking environment but have, over the years since confederation, increased from 16 to nearly 40 percent of the population. Northern and eastern counties are predominantly French-speaking. Settlement has followed the coastline and rivers, the northern interior being almost barren of population.

Origins

The first English-speaking groups moved in during the 18th century, from the New England region farther south. Between 1810 and 1850 the population grew rapidly, from 30,000 to 193,800. This was a result of the introduction of English, Scots, and Irish groups, who came with the intention of farming but were for the most part absorbed into forest industries. Numerically most important and most identifiable, especially in Saint John and on the Miramichi, were the Irish. Following confederation small colonies of Scots (and one of Danes) were established on the upper St. John. Since 1945 the population has become slightly more cosmopolitan, the most notable addition being a contingent of Dutch. Indians, scattered through the province on reservations, numbered less than 4,000 by 1970. A black minority, from colonial times, amounted to 5,500, some of them descendants of slaves of the Loyalists.

The admittedly modest natural resources of the province and the heavy emigration attendant upon the greater opportunities available elsewhere have been responsible for a slowing of natural population growth, a factor given fresh emphasis in recent years. At the 1971 census the total population was 635,000, an increase of about 18,000 over the census figures of 1966. This was in spite of a comparatively high birth rate of 19.9 per 1,000 and a death rate of 7.9. As a result of its high birth rate, and unlike the other Atlantic Provinces, which had a high proportion of elderly people, New Brunswick was close to the national average.

New Brunswick, by the early 1970s, had nothing to approach the national minority problems afflicting the bilingual communities of Quebec and the racial strife of the metropolitan areas of the nearby United States. Historically, relations between the two main national groups within the province have been amicable, though in recent years, under the stimulus of the Assumption Society and other cultural organizations, Acadians have become more conscious of an underprivileged status in the operation of the economy, in government, and in education. Inequalities have, to a great extent, been removed by a government that, for ten years after 1960, had an Acadian premier and a majority of Acadian ministers. The University of Moncton (1963; originally founded as St. Joseph's University in 1864), has become an important Acadian cultural centre, and French has been made an official second language of the province, with minimal protest from the English-speaking majority. The economic and cultural plight of the Indian and black minorities began to generate some attention during this period.

Minority consciousness

Religiously, the province is roughly 51 percent Roman Catholic. The largest Protestant denominations are the Baptist (18 percent), which gained many adherents in the early 19th century, the Anglican, and the United Church of Canada (each about 14 percent).

THE ECONOMY

Two-thirds of provincial production is based on forest industries and the manufacture of pulp and paper, a proportion tending to grow in recent years. Seven large paper mills and a multitude of sawn-lumber establishments account for the principal exports. Many farmers contribute to the industry by maintaining woodlots, pulpwood frequently being an important cash crop. On the Bay of Fundy and along the northeastern coast, fishing is a major industry, with lobsters being the most valuable product. By 1970, total landings exceeded $16,000,000 annually. The most spectacular development of the 1960s and early 1970s has been the advance of mining for base metals in the northeast, value being almost $100,000,000. Production of electric power from hydro- and steam-generating sources, greatly encouraged by government in hope of attracting secondary industry, amounted by 1970 to nearly 4,000,000 kilowatt-hours. Owing to the seasonal factors on which most industries are based, the rate of unemployment, at times reaching 10.8 percent, is considerably above the national average.

The long-recognized fact that New Brunswick is an underprivileged region has impelled governmental activity to raise average income closer to the national standard. The traditional method has been to alleviate isolation of the province from large markets by favourable adjustment in freight rates. Results, however, have been insignificant, and more recently the federal government has embarked on heavy spending programs, a notable example of which is the June 1970 agreement of Canada's Department of Regional Development to spend $62,000,000 over a two-year period on what is called infrastructure—improvement of roads and construction of new facilities for communication—all in the hope of

Development measures

sparking industrial development. Saint John and Moncton have been designated growth areas to receive special attention. This planning operation has been supplemented by work of The New Brunswick Development Corporation, a provincial agency whose principal ambition is to build a multi-industry complex at Saint John, based on the possibility of a greatly increasing share of North America's seagoing traffic. The port's deepwater facilities offer hope that new-type containerized cargo vessels will enable it to expand its trade, perhaps at the expense of New York and Montreal.

TRANSPORTATION

The two great national railway systems, Canadian National and Canadian Pacific, have slowly yielded their primacy to transportation by road and air. The port of Saint John, however, still depends on rail traffic for its main sustenance, principally by means of the Canadian Pacific line running through Maine to Montreal. Passenger service has steadily diminished as a result of the development of airports at Saint John, Moncton, and Fredericton, supplemented by half a dozen smaller centres in the north. An autobus service accounts for most internal passenger traffic. As a major port, Saint John accounts for a high proportion of Canadian external trade, especially in the winter season when Montreal is closed off by ice in the St. Lawrence. Small freighters transport produce of the northern lumber and mining industries to Europe and elsewhere.

From the 1950s on, the road system has been modernized. In recent decades emphasis has been given to improvement of secondary roads and to improved snow clearance in the winter season.

ADMINISTRATION AND SOCIAL CONDITIONS

Government follows the constitutional forms of a Canadian province within the framework of the British North America Act. The one-chamber legislature at Fredericton, consisting of 58 members and representing 15 counties and six cities, has control over education and other internal services but shares jurisdiction with Ottawa over several matters. The executive consists of the premier and 13 cabinet members. Since 1945 the area of provincial jurisdiction has tended to enlarge at the expense of the federal. Under the constitution elections are to be held every five years but in practice take place every four years. Major political parties are the Liberal and Conservative, third parties never having succeeded in making an important impact. Liberals held power from 1960 to 1970, a Conservative government taking office in November of the latter year.

Control over many social services—family allowances, old-age pensions, unemployment insurance—is in whole or part shared with the federal government. Approximately 50 percent of provincial revenues are derived from Ottawa by subsidy, under the British North America Act and subsequent federal-provincial agreement. For the development of its program of social welfare, the provincial government is heavily dependent on Ottawa for financial assistance and has been compelled to raise rates of taxation to levels higher than those in most Canadian provinces.

By its Equal Opportunity Programme (1967), the government sharply curtailed powers of municipal administration, taking exclusive control over assessment of properties and collection of taxes, the object being to equalize living standards throughout the province. Six cities, 21 towns, and over 90 incorporated villages are dependent for revenues on provincial grants. School boards, administration of justice at the local level, and welfare assistance are all under the control of provincial officers to a much greater extent than formerly applied. For the 1970s, centralization has been the formula in vogue.

Great disparities in standards of living between wealthier counties of the St. John Valley and those of the predominantly Acadian northern and eastern shores have been a target for governmental action. In spite of heavy expenditure, plans to move poverty-stricken residents of Gloucester County, an area of chronic unemployment, to more favoured locations have produced negligible results. Yet the opening of new trade and technical schools in all sections gives hope for the future. Marginal farms, once prosperous, have become deserted, and more and more people are becoming dependent on secondary industry and its ancillaries; yet their material condition has not greatly improved. A general complaint has been that thousands of young people, educated by the government at heavy cost, have left the province. To meet inflationary conditions, the Minimum Wage Act of 1965 has steadily been modified in an upward direction, and the cost of living is almost that of the national average. A socialized medical system came into operation on January 1, 1971. Housing construction is dependent on interest rates set by federal authorities at Ottawa. Perhaps because of their close contact with a beautiful natural environment, a general awareness of depressed living conditions has not, as yet, become coupled with bitter and widespread social discontent.

Depressed areas

The Canadian Armed Forces maintain Camp Gagetown, a training base and staging area for army personnel, in the lower St. John valley. Containing, as it does, some 5,000–10,000 troops and their dependents, it is an important ingredient in the provincial economy. At Chatham there is a base for fighter craft of the air force.

CULTURAL LIFE AND INSTITUTIONS

For a small province, New Brunswick enjoys a remarkable and varied cultural life. At Fredericton, home of the first native Canadian school of poetry, that of William Bliss Carman (1861–1929), a celebrant of nature, and Sir Charles Roberts (1860–1943), a regionalist influenced by Ralph Waldo Emerson, the tradition is strongly sustained. The Lord Beaverbrook Art Gallery at Fredericton—a legacy of the newspaper magnate, who spent his formative years in the province—contains many old masters, housing treasures of English and Canadian schools of painting, including the famous Krieghoff Collection. Many artists of national reputation, attracted by the magnificent setting, reside in the province. Theatre New Brunswick, endowed by the Beaverbrook Foundation and directed from The Playhouse at Fredericton, carries on year-round activity. There are many regional festivals of music, the most distinguished being those of the Acadians, who have produced choral groups that have been highly successful in international competition. Sculpture in wood and work in the ceramic arts are vigorously pursued. The province maintains an agency to foster cultural activity.

Education

Four universities—those of New Brunswick at Fredericton and Saint John (established 1785 and the oldest in Canada); Moncton, which is bilingual; Mount Allison, at Sackville; and St. Thomas, Fredericton—all support creative arts. New Brunswick and Moncton are under public control. Mount Allison is a private corporation, while St. Thomas, working in association with New Brunswick, is Roman Catholic. All are financially supported by the provincial government. The New Brunswick Museum, Saint John, oldest in Canada, contains many treasures reminiscent of pioneer days. The Provincial Archives are located at Fredericton. The historic past is commemorated by the construction of King's Landing, 20 miles north of Fredericton, a replica of a pioneer village; while at Ft. Beauséjour a massive work of archaeological investigation and a national historic park remind visitors of the 18th century conflict between French and British.

By the early 1970s there were five daily English-language newspapers and one French-language newspaper. Their services are supplemented by eight weeklies. The Canadian Broadcasting Corporation has television stations at Saint John and Moncton, the latter providing service in French. An independent station operates at Moncton. Ample radio broadcasting is provided from a dozen stations.

PROBLEMS AND PROSPECTS

Since 1867, material progress in New Brunswick has been disappointing, but largely in relation to development elsewhere in North America. Confederation failed to provide

large markets for provincial produce in the interior of the continent. The larger and more centrally located secondary industry of Ontario and Quebec gave cruel competition to provincial energies, sometimes bringing them close to economic extinction. The decline of wooden shipbuilding brought an end to the major role New Brunswick had played in overseas markets, and the rise of the pulp and paper industry in the 1920s failed to compensate for lost advantages. Since 1937 the federal government has accepted the principle that wealthier provinces should assist the less fortunate ones. Consequent federal action up to the decade of the 1970s has enabled the province to keep from losing further ground, although hopes for a substantial reversal of fortunes spring eternal in the local consciousness. In the early 1970s, these were based on brighter prospects for the future of those Atlantic ports enjoying deepwater facilities. The recent increase of income from the tourist trade also brought the belief that this, too, might become a principal provincial asset.

Newcomb, Simon

Simon Newcomb was perhaps the greatest American astronomer of the 19th century, although in depth and originality of mathematical invention he was excelled by George W. Hill, his associate for 15 years. Newcomb was born in Wallace, Nova Scotia, on March 12, 1835. His father, an itinerant country schoolteacher, taught Simon to count at the age of four, and before he was five he was spending several hours a day making calculations in addition and multiplication; before he was seven he had finished the arithmetic book, including the extraction of cube roots.

Newcomb.

Newcomb had little or no formal education. At the age of 16 he was apprenticed to a quack herb doctor in Salisbury, New Brunswick. After two or three years he ran away to join his widowed father who had settled in the United States, in Maryland. In the libraries at Washington, D.C., Simon found the first full opportunity to indulge his intellectual curiosity. After avidly exploring many technical fields he concluded that his principal talent lay in mathematics. He was especially attracted to the *American Ephemeris and Nautical Almanac*, an annual handbook for astronomers, containing predicted positions of the principal celestial objects and other astronomical phenomena. Of this work he says, "Its preparation seemed to me to embody the highest intellectual power to which man had ever attained." He thereupon applied for employment in the American Nautical Almanac Office, then at Cambridge, Massachusetts, and became a computer there in 1857. He also enrolled in the Lawrence Scientific School of Harvard University, receiving a degree in 1858. In 1861 he applied for and received a commission in the corps of professors of mathematics in the United States Navy and was assigned to the United States Naval Observatory at Washington, where he worked for more than ten years determining the positions of celestial objects with the meridian instruments and for two years with a then new 26-inch refractor telescope.

Major work: solar-system motions

In 1877 Newcomb was put in charge of the American Nautical Almanac Office, then in Washington, where almost at once he commenced the great work that he had had in his mind for some years, and that was to occupy the greater part of the rest of his life: the calculation of the motions of the bodies in the solar system. Reaching the compulsory retirement age for captains in 1897, he later received the then unusual distinction of retirement with the rank of rear admiral. He died in Washington on July 11, 1909, and was buried in Arlington National Cemetery.

In 1884 Newcomb had obtained the additional appointment of professor of mathematics and astronomy, which he held until 1893, at Johns Hopkins University, Baltimore, Maryland, continuing, however, to live in Washington. For many years he was editor of the *American Journal of Mathematics*. He was one of the founders of the American Astronomical Society and was its first president (1899–1905). Newcomb received honorary degrees from ten European and seven American universities and was a member of 45 foreign societies. He was awarded the gold medal of the Royal Astronomical Society (1874), the Huygens Gold Medal of the Holland Society of Science (1878), the Copley Medal of the Royal Society (1890), the Bruce Gold Medal of the Astronomical Society of the Pacific (1897), the Schubert Prize of the Imperial Academy of Sciences, St. Petersburg (1897), and the Sylvester Prize of the Johns Hopkins University (1901). He was elected a member of the National Academy of Sciences in 1869, serving as home secretary, 1881–83; vice president, 1883–89; and foreign secretary, 1903 until his death.

Newcomb's most important work appeared in the *Astronomical Papers Prepared for the Use of the American Ephemeris and Nautical Almanac*, a series of memoirs that he founded in 1879 with the object of giving "a systematic determination of the constants of astronomy from the best existing data, a reinvestigation of the theories of the celestial motions, and the preparation of tables, formulae, and precepts for the construction of ephemerides, and for other applications of the same results." Of 36 articles filling approximately 4,500 quarto pages in the first nine volumes, he was sole or principal author of 25. Among them were his tables of the Sun, Mercury, Venus, Mars, Uranus, and Neptune, and Hill's tables of Jupiter and Saturn, which were in use throughout most of the world for calculating daily positions of the objects from 1901 to 1959, and even afterward for the Sun, Mercury, Venus, and Mars. This series of *Papers* is remarkable for its sustained high quality. Hardly anything in them has proved to be incorrect, and at mid-20th century they were still worthy of the attention of any student of celestial motions.

Development of system of astronomical constants

Possibly Newcomb's most far-reaching contribution was his inauguration, jointly with A.M.W. Downing, then superintendent of the British Nautical Almanac Office, of a worldwide unified system of astronomical constants, which was later to lead to the outstandingly successful scheme of international collaboration among the princi-

pal almanac makers of the world that survived two World Wars with increasing vigour. Newcomb and Downing were impressed by the "confusion which pervaded the whole system of exact astronomy, arising from the diversity of the fundamental data made use of by the astronomers of foreign countries and various institutions in their work" (Newcomb, *Reminiscences of an Astronomer*, 1903). A conference of the directors of the national ephemerides of the United States, Great Britain, France, and Germany, was held in Paris in May 1896. It resolved that beginning with 1901 a certain set of constants, substantially Newcomb's, should be used by all the ephemerides. The decision even included some work of Newcomb's that was not to be finished for several years. Although Newcomb was attacked by some astronomers at home for decisions that were in their opinion premature, time has proved the wisdom of his course. A similar conference, held at Paris in 1950, decided unanimously that the system of constants adopted in 1896 was still preferable to any other for practical use.

BIBLIOGRAPHY. NEWCOMB wrote a number of books, including *Popular Astronomy* (1878), *The Stars* (1901), *Astronomy for Everybody* (1902), and *Compendium of Spherical Astronomy* (1906), some of which have been translated into as many as seven foreign languages. He also wrote on finance and economics and published some fiction. An autobiography, *Reminiscences of an Astronomer*, was published in 1903. A bibliography of his life and works (541 titles) is given by R.C. ARCHIBALD, *Mem. Natn. Acad. Sci.*, 17:19–69 (1924).

(G.M.Ce.)

Newfoundland

The most easterly portion of the North American continent, Newfoundland is a Canadian province thrusting into the bleak North Atlantic Ocean far from the nation's industrial heartland. Its position gives it strategic importance in transportation and communications between North America and Europe. The Strait of Belle Isle separates the island of Newfoundland to the south from mainland Labrador, which comprises nearly three-fourths of the province's total area. The wildly jagged and seasmashed coasts that, with all indentations, stretch for more than 10,000 miles (16,000 kilometres) form an apt symbol of the staunch independence of its people, who refused to become Canadians until 1949. Above the continental shelf fringing the coasts, but especially about the Grand Bank to the south of the island, are some of the world's finest and most extensive fishing grounds. Their existence has been the single most crucial factor in shaping the history and the character of the province from its founding to the present. (For information on related topics, see CANADA; CANADA, HISTORY OF; and NORTH AMERICA.)

HISTORY

The official discoverer of Newfoundland was the Genoese-Venetian navigator Giovanni Caboto (*c.* 1450-*c.* 1498/1499), better known to history as John Cabot, who reached the island in 1497 while sailing under the English flag. The Grand Bank doubtless had been known to fishermen earlier, but Cabot's enthusiastic reports opened the way for international rivalries over the region. Early in the 16th century, English, French, Basque, and Portuguese fishermen were contesting for catches; by 1600 England and France were the chief rivals for Newfoundland.

Early restrictions on settlement. Several attempts made at colonization during the 17th century met the inveterate hostility of the English fishermen, and, after 1634, of the English crown. In 1699 Parliament prohibited settlement of the island except as necessary to maintain the cod fishery. This remained the basic governing directive for Newfoundland for more than 150 years, during which time the island became virtually a private fiefdom ruled by commercial fishing interests.

The rationale for this policy was twofold. First, under the prevailing concepts of international trade, known as the mercantile theory, the fishing of the Grand Bank remained a mother-country industry rather than that of a colony, with definite economic advantages accruing to England. Second, the region was looked upon as a "nursery for seamen," a training ground for the crews that were to maintain England's maritime superiority into the distant future. This latter idea also led the French in 1662 to found Placentia on the southeast coast as the seat of a royal governor and a base of operations. From Placentia the French destroyed every English settlement on the island in actions which took place in 1696, 1705, and 1708. Treaties in 1713 and 1783, the latter marking the armistice ending the American Revolution, recognized British sovereignty but granted French fishermen the right to land and dry their catches along portions of the northern and western coasts. This "French shore problem" remained a thorny one for the islanders until 1904.

French raids

During the 17th and 18th centuries the island's population increased despite repressive legislation, the denial of property rights and social services, and a particularly vicious judicial system managed by the captains of fishing vessels. Britain found it necessary to appoint a naval governor in 1729 and to establish a proper judicial system in 1792. Both governor and court remained only for the summer fishing season, however, and not until 1824, with the appointment of a resident governor and council, was a settled colony finally acknowledged.

In 1832 local agitation led to the addition of a popularly elected assembly. In 1855 the island was granted full responsible government after a campaign that reignited a bitter underlying sectarianism. As the hold of the transient fishermen over the island's life weakened toward the end of the 18th century, many of the prosperous fishermen settled in as merchants, and government officeholders increased in number. Large groups of labourers were imported for the cod fishery, 11,000 coming in the peak year of 1814–15 alone. These immigrants, mainly Irish Catholics, continued to stand for the rights of fishermen and servants against the new and largely Protestant middle class, creating a sectarian spirit that persisted in Newfoundland's political life well into the 20th century.

Sectarian rivalries

Toward confederation. Between 1864 and 1869, Newfoundland was involved in discussions leading to Canadian confederation. The idea of actually joining the confederation, however, was rejected at the polls both then and after negotiations were reopened in 1895. New radical social policies were heralded with the formation of the People's Party by Edward Morris in 1907 and the Fishermen's Protective Union by William Coaker in 1908. The political rivalry of Morris and Coaker was submerged in the common efforts of World War I.

For nearly 150 years, rights to the coasts of Labrador, an ill-defined geographical entity, were hotly debated. By 1825, British tribunals had given Newfoundland jurisdiction over the Atlantic face, Canada over the coasts on the Gulf of St. Lawrence. But the inland boundaries and administration of Labrador were to remain unsettled until 1927, when Newfoundland was awarded the huge inland region in a definition that said that the "coasts" reached to the headwaters of rivers emptying eastward into the Atlantic.

The depression that afflicted the Western world after 1929 completely overwhelmed Newfoundland's already struggling economy, which had been overtaxed by the war and by the cost of building a transisland railway. In 1933 a royal commission recommended the suspension of the existing government and the inauguration of government by a commission appointed by and responsible to the government of the U.K. In 1934, Newfoundland came under the rule of such a government. The commission was finally able to re-establish the colony's finances on a firmer foundation.

Following World War II a national convention was elected to recommend possible forms of future government to be voted upon by the people. The convention failed, however, to recommend anything beyond a continuation of the existing government or a return to the pre-1934 constitution. The British government, nevertheless, added the confederation question to the ballot. The first of two referenda held in 1948 was inconclusive; the second gave a clear majority to confederation. On March 31, 1949, Newfoundland entered the Canadian Union.

Confederation contested

THE PHYSICAL ENVIRONMENT

Landscapes. Newfoundland and Labrador must be treated as two separate physiographic regions. The island is roughly triangular in shape with two large peninsulas hooking into the sea from the northwest and southeast corners. It is part of the Appalachian geological province of North America, in which the landforms run from southwest to northeast. The land in the west of the island rises abruptly from the sea or from a narrow coastal plain to a maximum height of 2,651 feet (808 metres) to form the edge of a plateau that slopes away to the northeast to elevations that do not generally rise above a few hundred feet. The plateau region is gently undulating and dotted with thousands of lakes and ponds; the coastal terrain is hilly and rugged. The submersion of coastal areas has created numerous bays and offshore islands.

Labrador lies north and east of the province of Quebec on the Labrador-Ungava Peninsula. Geologically, it is part of the edge of the Canadian Shield, the rugged mass comprising some of the world's oldest rock. In the Torngat Mountains in the extreme north, the land rises abruptly from the sea to heights of over 5,000 feet. Deeply indented and dissected by many rivers, first glaciated then flooded, the coastline presents a rugged, forbidding front to the Atlantic. Inland, the plateau is undulating and lake spotted.

Climate. In general, Newfoundland has cold but not severe winters and warm to cool summers. The mean July temperature of the coast ranges from 40° F (4.4° C) in northern Labrador to 59° F (15° C) on the island's south coast. In the southern interior the July mean is just above 60° F (16° C). January means in the southern portion of the island are above 20° F (−6.7° C), on the coast of Labrador approximately 10° F (−12.2° C) and 0° F (−17.8° C) in the south and north, respectively, and in interior western Labrador about −15° F (−26° C). Extreme low temperatures in southern Newfoundland rarely reach 0° F, but in western Labrador readings below −40° F (−40° C) are not uncommon. The annual precipitation varies from 55 inches (1,397 millimetres) in the southern parts of the island to about 17 inches (432 millimetres) at Cape Chidley. In the northern regions, as much as half of the annual precipitation occurs as snow, and snowfalls of more than 100 inches a year are not uncommon. In the south, the snowfall usually accounts for only 20 percent of the total precipitation.

Midlatitude storms, moving across Canada and up the Atlantic seaboard, have a pronounced effect on Newfoundland's climate. Warm air drawn in on the southern side of the disturbances contributes to the high precipitation in the southern part of the island. Northeast and east winds prevail in advance of each storm, blow across the cold Labrador Current, keep coastal summers cool, and retard the coming of spring. Northwest winds, following in the wake of each storm, carry in cold Arctic air that forces temperatures even lower than the latitude and marine location would suggest. To the south of the island the cool air of the Labrador Current mixes with the warmer air over the Gulf Stream to produce frequent dense fogs, which are most common over the Grand Bank and along the south and southeastern portion of the coast.

Forest cover

Plant and animal life. With the exception of the tundra region of northern Labrador and the barren reaches of higher altitudes and of some coastal regions, much of the province is forested. The principal species are conifers, of which balsam fir and black spruce are the most abundant. In most parts of the province, but particularly on the island, conifers are mixed with such leaf-bearing species as the paper and yellow birches and a wide variety of hardwood shrubs. The best stands of forest occur in areas of deep and well-drained soils, while in less-favoured areas much of the forest growth is stunted. In others, repeated fires and subsequent erosion have created barrens that produce a great variety of small woody plants, many of them producing edible fruit. Where glacial action has created poor drainage conditions, there are extensive boglands of organic material that vary in thickness from a few inches to 30 feet.

The moose is the most plentiful of the large wild animals found in the province. Other species include the caribou, the black bear, and the polar bear, and several species of seals. Small fur-bearing animals are typical of the northern coniferous forest and the tundra of Labrador.

Large seabird colonies inhabit the islands and headlands along the coast. Migratory ducks and shorebirds and wading birds in great numbers frequent the coast in their varying seasons. Inland, the principal game species are ptarmigan and snipe. Several species of ducks and geese maintain breeding populations. Birds of prey such as the peregrine falcon, the osprey, and the bald eagle find a respite from the environmental deterioration that has afflicted them in other habitats.

THE REGIONS OF NEWFOUNDLAND

The Avalon Peninsula. Newfoundlanders see their province as comprising nine regions, distinct in their natural settings and evidences of human presence. The most densely populated part of the island, the Avalon Peninsula on the southeast coast, contains the capital city, St. John's. Most of the coastal terrain is barren, the result of human deforestation. Apart from St. John's and a few small towns such as Harbour Grace, Carbonear, and Placentia, most of the peninsula's villages typically are located on a safe harbour and have evolved without any reference to town planning. The houses are generally of two-story frame construction, brightly painted, and surrounded by small gardens and meadows. They are located in sheltered positions often adjacent to such waterfront premises as stores, stages, wharves, and the fish-drying platforms called flakes. The helter-skelter arrangement of houses and other domestic buildings and of gardens, meadows, pastures, and woodlands, though sometimes shocking to persons accustomed to the precise streets, squares, and blocks of orthodox North American towns, represents, to others, a delightfully picturesque and romantic nonconformity. Only after about 1950 was the idea of the "planned community" introduced into town design throughout the island.

Patterns of settlement

Bonavista and Notre Dame bays. Northward from the Avalon, in the region of Bonavista and Notre Dame bays on the north coast, the landscape is somewhat softened. The exposed headlands and offshore islands are still barren, but in the deeper bays and estuaries the size and variety of the forest cover attest to deeper soils. The rocky shoreline is interrupted by stretches of sandy beach, and the fishing village occasionally is replaced by a farming community. Many densely forested islands shield the mainland from the worst effects of the northeast winds and create hundreds of miles of virtually landlocked waters. Many old communities such as Fogo and Bonavista cling to the more exposed locations, where the exigencies of the fishery demanded that they be built. These are being outstripped in growth, however, by the newer towns located in more favourable settings and engaged in the more recent industrial developments in paper manufacture, sawmilling, transportation, and distribution.

The Great Northern Peninsula. The region of the Great Northern Peninsula stretches northward toward the Labrador coast. On the west, magnificent sandy beaches and a narrow coastal plain dissected by numerous lakes and rivers are set against the scenic Long Range Mountains, which rise abruptly to heights of over 2,600 feet. On the eastern slope of the Long Range are good stands of commercial forest. Settlements in this region are more widely spaced along the coast than in other regions, with St. Anthony the largest town.

The west coast. The west coast region stretches southward from Bonne Bay, at the base of Great Northern Peninsula, to Cape Ray on the Cabot Strait. The northern section is well forested, while from St. George's Bay to the Codroy Valley the terrain is the best suited to agriculture in the province. The principal population centres are Corner Brook, a city based on a large pulp and paper complex, and Stephenville, originally developed in conjunction with a U.S. air base that is being converted to a centre for light industry.

The south coast. The most spectacularly rugged section of the island's coastline is probably the south coast, stretching from Cape Ray eastward to Fortune Bay. Here, the land generally rises abruptly from the sea, and the rivers are short and turbulent, but the head of Bay d'Espoir and the rivers and valleys that enter it are well forested. Many small settlements that once dotted the coast have been abandoned, and the population is now centred in fewer but larger communities such as Channel-Port-aux-Basques at the western extreme of the region, which is a major transshipment centre for freight and is the port of entry for rail and road traffic from mainland Canada.

The Burin Peninsula. Almost all settlement is coastal and directly related to the fishery in the Burin Peninsula region. The larger towns are Grand Bank, Fortune, and Marystown, all centres for the fresh-fish-processing industry, and St. Lawrence, which produces Canada's total supply of the mineral fluorspar, an important agent in metallurgy.

The island interior. The interior region is largely uninhabited. The pulp and paper industry at Grand Falls, however, has fostered the development of such towns as Windsor and Bishop's Falls, while mining and international air traffic have led to the growth of the towns of Buchans and Gander respectively.

Coastal and western Labrador. Labrador is composed of two very different regions. The coast south of the Hamilton Inlet, like the island of Newfoundland, is settled with scattered fishing villages. North of the inlet the five permanent settlements have predominantly native Indian and Eskimo populations. The only large towns are Goose Bay and Happy Valley, which developed around a military airfield. In western Labrador the twin mining towns of Labrador City and Wabush are modern, well planned, and prosperous, and Churchill Falls is the site of one of the world's greatest hydroelectrical developments. Here, as everywhere in the province, fishing provides a major recreation for all classes and ages.

THE PEOPLE AND THEIR WAY OF LIFE

Dominance of British peoples

Population composition. Newfoundland's people represent an extremely homogeneous group. Of the 522,000 at the 1971 census, about 95 percent are of British origin, the English, Irish, and Scottish and Welsh making up percentages of 75, 17, and 3, respectively. Nearly 4 percent are of French and Channel Island extraction. The native Indian and Eskimo peoples together comprise only 0.3 percent of the total. The homogeneity is accentuated by the fact that the vast majority of those persons of English ancestry trace their origins to the four western counties of Devon, Dorset, Somerset, and Cornwall. Historically, such cleavage as has existed has been along denominational rather than linguistic or ethnic lines. The three principal denominations are Roman Catholic, Church of England, and United Church of Canada, representing about 36, 29, and 21 percent of the total population, respectively. The birthrate has been falling steadily since 1950, reaching 24.0 per 1,000 of population in 1970, while the deathrate for the same year was 5.9 per 1,000. The net result is at present a natural increase of about 2 percent. Well over half of the population is below 25 years of age.

Since the beginning of the 20th century, emigration to the U.S. and, more recently, to other Canadian provinces has removed some of the pressure of the population. The exodus has probably, on occasion, reached 15,000 in a single year.

There were about 1,300 coastal villages, of which fewer than 100 had more than 500 inhabitants. The 20th-century trend toward urbanization has been accentuated by a vigorous government policy of resettlement designed to concentrate the people in fewer but larger and, in theory, more viable communities. Though hundreds of small villages remain, about 54 percent of the population is classified as urban, with nearly half of that number living in the metropolitan areas of St. John's and Corner Brook.

The provincial economy. *Mineral and forest products.* Newfoundland has been fortunate in being able to meet changing demands for products through exploitation of its rich mineral, forest, and marine resources. Historically, the fisheries brought Newfoundland into being, and until the beginning of the 20th century they were virtually the only industry. During the late 19th century mineral deposits were found both on the island and in Labrador, and the demands for paper gave great impetus to forestry. Mining has assumed the major role, its exports totalling nearly four times the value of pulp and paper products, more than five times that of fish products. This striking preponderance of mineral production is a direct consequence of the exploitation of western Labrador's vast iron reserves.

Power resources. The enormous hydroelectric-power resources of both the island and Labrador have been of the utmost importance in Newfoundland's industrial development. The Churchill Falls development in western Labrador, the first phase of which was completed in 1972, produces upwards of 7,000,000 horsepower of electrical energy. This great potential, as well as Newfoundland's position midway on the main shipping routes between North America and Europe, is crucial in planning the province's economic future. Attempts are being made to develop industries that require inexpensive electrical power and ease of ocean shipping and whose products can be marketed both in Europe and in North America. A phosphorus plant constructed at Long Harbour in the late 1960s represented a major step in this direction.

Energy potential

Modern fishery. Technical innovation has changed the nature of the fisheries. For centuries, the industry revolved about salted, dried codfish, caught in inshore waters and prepared for market primarily by many small family-run facilities. The majority of today's catch, comprising a wide variety of species, is taken by large trawlers in offshore waters and fresh frozen in large plants located strategically along the coast.

These developments reflect an increasingly complex and more broadly based economy. Secondary manufacture is of growing importance, and there is a rapid associated growth of service related industry. The relative values of these components of the economy are increasing rapidly, as is the absolute value of total production.

Transportation. Until the closing years of the 19th century, the sea was about the only highway facilitating transport and communication around the coast. A narrow-gauge railway was built later from St. John's to Channel–Port aux Basques along a route that touched the innermost parts of the major bays. Subsequently, branch lines were developed to serve regional centres of population and to connect with coastal steamships that carried passengers, freight, and mail to the hundreds of villages not served by the railway. Today a road system reaches nearly all communities, and a first-class paved highway crosses the island, more or less following the rail line. Some of the secondary roads are paved, but most have gravelled surfaces.

Connections with the mainland

The island is linked to mainland Canada by rail, car, and passenger ferries operating between Channel–Port aux Basques and Argentia on the south coast and North Sydney, Nova Scotia. National, international, and regional air service is provided by various lines.

Scheduled flights to tiny settlements throughout Labrador are of special importance during the frozen winters. In addition, a railway runs south from the western towns of Labrador City and Wabush to Sept-Îles, Quebec, on the Gulf of St. Lawrence. Further small road networks exist around principal population centres, and a short stretch of road runs alongside the Strait of Belle Isle.

Administration and social conditions. In most ways, administrative organization and social conditions in Newfoundland are typical of those in other Canadian provinces, though there was generally a slower development of institutions because of the unique history of the province.

Governmental organization. Under the terms of union with Canada, Newfoundland is represented in the Canadian Parliament by six senators and seven members of the House of Commons. The provincial government, completely autonomous in those areas reserved to its jurisdic-

tion by the British North America Act of 1867, consists of a lieutenant governor representing the crown and a unicameral legislature of 42 members elected by universal suffrage. The government is organized on the British parliamentary model. The executive council, or cabinet, is chosen from among the elected members of the party representing the majority in the House of Assembly. The Liberal Party has won every election since confederation, with the official opposition, the Progressive Conservative Party, unable to win more than 6 of the 42 electoral districts.

Local government was slow to evolve in Newfoundland. Not until 1888 was the first municipal government elected in St. John's, and the next town council was not created until 1938. By the 1970s, most of the settlements were incorporated as towns or as components of rural district organizations. Elected councils are empowered to levy taxes, and, under the general aegis of the provincial Department of Municipal Affairs and Housing, are responsible for the management of local concerns.

Justice. The Supreme Court of Newfoundland consists of a chief justice and other judges, sitting in St. John's but travelling annually on circuit to other parts of the province. Inferior district courts are established in federal electoral districts, and magistrates' courts serve many local communities.

Education. As in much of Canada, Newfoundland's educational system is a mixture of state and church activity. Historically, educational services were provided by the churches, which were then permitted to retain administrative controls even when the government assumed the major financial burden. The rights thus acquired were, at the time of confederation, enshrined in the provincial constitution, with the result that the provincial Department of Education was divided into five virtually autonomous denominational divisions. Throughout the province, more than 300 school boards duplicated schools and services, creating an increasing public outcry and, finally, a determination by the principal denominations themselves to rationalize their operations. In 1969 the Department of Education was reorganized along functional lines, school districts were consolidated with a drastic reduction in the number of school boards, and the principal Protestant denominations integrated their services. The individual denominations, however, continue to maintain their own centralized administrative offices and to exercise certain functions for which they are still totally responsible. Vocational, technical, and trade schools are nondenominational in character and are operated by the provincial government. Founded as Memorial University College in 1925, the Memorial University of Newfoundland, in St. John's, is the province's single university. It is nondenominational and managed by an autonomous board of regents.

Educational consolidation

Health and social services. The provincial government administers virtually all health services, which under the Medical Care Act are free to all residents. With few exceptions, members of the medical profession participate in the Medical Care Plan. Newfoundland differs from most other Canadian provinces in that few private agencies exist to provide services to the aged and children and to the variously disadvantaged. A notable exception is the International Grenfell Association, which since the beginning of the century has operated a hospital at St. Anthony and provided medical, educational, orphanage, and other social services on the Labrador coast and in the northern portions of the island.

Elsewhere, almost all such services are provided by the provincial government. This reflects both the very recent development of municipal institutions, the great dispersal of settlement, and the small population of most communities. Thus the police force that serves St. John's is not a municipal force but one that is, in theory, responsible for the whole of the province. In fact, however, they are assisted outside St. John's by the Royal Canadian Mounted Police, who operate under contract to the provincial government.

Quality of life. The same problems of population distribution and geography also combine to keep the cost of living somewhat higher and wage rates somewhat lower than in other parts of Canada. But statistics do not tell the whole story, for an inherent factor within a standard of living is the somewhat intangible notion of quality of life. Thus a cash income that statistically indicates subsistence below the poverty level might represent a comfortable living to a Newfoundland fisherman owning his own home, fishing equipment, and premises, as well as a few acres of cultivated land.

Cultural life and institutions. The insular location of Newfoundland and the internal isolation of hundreds of small communities have combined to preserve distinctive cultural characteristics that have long since disappeared in the land of their origin. Thus a most distinctive feature of Newfoundland is the local speech, which preserves much of the flavour of its West Country origins in 17th-century England. Over several centuries of comparative isolation, it has been modified only by the influence of the Irish who at one time constituted half the total population. But there is really no such thing as a Newfoundland accent, for there are almost as many dialects as there are bays. The differences between these dialects and "standard English" are not merely in accent but in vocabulary, in sounds, and in syntax.

Though isolation produced distinctive language patterns and usages, it created as well the necessity for local entertainment. This factor, perhaps in combination with the Irish traditions of bards and minstrels, has encouraged the development of the art of the storyteller and the preservation and creation of an immense body of folk music and song. Indeed, Newfoundland has been categorized as a living archive of folklore, folktale, and folk song. With a few notable exceptions, however, Newfoundlanders have not been exceptionally productive in the visual arts. Why the imaginative flair and inventiveness so apparent in the field of folk music has not carried over into other art forms can be no more than speculated upon. Professional theatre was driven out by television, but amateur groups have maintained the increasingly healthy theatre-going tradition.

Folk culture

St. John's has always been well served by newspapers, although the score or more that appeared during the 19th century and flourished for greater or lesser periods of time have now been replaced by two dailies, the *Evening Telegram* and the *Daily News*. A version of the *Evening Telegram* known as the *Western Star* is published in Corner Brook, and several gossipy weeklies serve other outpost regions.

But Newfoundland's distinctive culture has begun to recede before the impact of mainstream North American influences, which were first experienced acutely when World War II caused a large influx of military personnel. The increase in the amount of radio and television transmission and the influx of large numbers of professional people from elsewhere have hastened the process of change. A particular and pressing care of the university and of the Folk Arts Council is to prevent a total loss of the distinctive elements of the folk culture, to keep them not as museum pieces but as vital force in the province's life.

Prospect. By comparison with the materially more advanced provinces of Canada, Newfoundland is an underdeveloped region. But it is, nevertheless, a region rich in natural resources, not the least of which may lie beneath the sea that covers the extensive areas of continental shelf adjacent to the coasts.

The task of building the infrastructure of a modern society after centuries of neglect is costly in terms both of money and of time. Few peoples are more passionately attached to their homes than are Newfoundlanders to their ruggedly beautiful land. Few North Americans are more conscious of their history. They are now challenged by the task of preserving the distinctive elements of their identity while creating a modern and prosperous society. Progress has been rapid, however, and there is every reason to believe that continued sound economic policies and governmental stability will join with the determined individualism of the Newfoundlanders in bringing the richness of the past into an even more bountiful future.

BIBLIOGRAPHY. D.W. PROWSE, *A History of Newfoundland from the English, Colonial and Foreign Records* (1895), is the standard general history of Newfoundland but is now somewhat dated and is weakest in its treatment of the 19th century. J.D. ROGERS, *Newfoundland*, vol. 5, pt. 4 of *A Historical Geography of the British Colonies* (1911), is a delightfully written general history that complements Prowse. A.H. MCLINTOC, *The Establishment of Constitutional Government in Newfoundland, 1783–1832* (1941); and GERTRUDE GUNN, *The Political History of Newfoundland, 1832–1864* (1966), are detailed and scholarly works that capture the essence of Newfoundland politics during the struggle for and the early years of self-government. The historical beginnings of the fisheries, for many years the *raison d'être* of Newfoundland, are admirably covered in R.G. LOUNSBURY, *The British Fishery at Newfoundland, 1643–1763* (1934, reprinted 1969); while the economist's position is stated in H.A. INNIS, *The Cod Fisheries*, rev. ed. (1954), which is a veritable mine of information. Little of a definitive nature has been written to cover the 20th century, but ST. JOHN CHADWICK, *Newfoundland: Island into Province* (1967), is a useful survey while R.I. MCALLISTER (ed.), *Newfoundland and Labrador: The First Fifteen Years of Confederation* (1966); and the NEWFOUNDLAND GOVERNMENT, *Historical Statistics of Newfoundland and Labrador* (1970), provide essential basic data. R.A. MACKAY (ed.), *Newfoundland: Economic, Diplomatic and Strategic Studies* (1946), is a valuable collection of papers on miscellaneous aspects of Newfoundland's role in international affairs; and G.S. GRAHAM, *Empire of the North Atlantic* (1950), fits the island into its North Atlantic context. The development of educational services in Newfoundland is a fascinating story told in F.W. ROWE, *The History of Education in Newfoundland* (1952). Two dominant aspects of Newfoundland folk life are illustrated in KENNETH PEACOCK, *Songs of the Newfoundland Outports*, National Museum of Canada Bull. No. 197, 3 vol. (1965), a valuable collection of folksong; and H. HALPERT and G.M. STORY (eds.), *Christmas Mumming in Newfoundland* (1969), a group of fascinating essays by sociologists, historians, folklorists, and anthropologists.

(L.H.)

New Guinea, Mountain Ranges of

The mountains of New Guinea extend from northwest to southeast throughout the length of the world's second-largest island. They form a lofty and almost impenetrable cordillera (mountain chain) that constitutes an impediment to linguistic and cultural unity among its peoples. From 50 to 150 miles (80 to 240 kilometres) wide, and frequently higher than 12,000 feet, the massive complex of ranges runs approximately 1,500 miles (2,400 kilometres) through the Indonesian province of Irian Barat (West Irian) in the western half of the island, and, in the eastern half, along the frontier between the Australian-administered UN Trust Territory of New Guinea to the northeast and Australian-administered Papua to the southwest (jointly administered as Papua New Guinea).

Spectacularly steep, rain-drenched, and often crowned with snow, the mountains stand as a heavily-wooded fortress guarding impassable ridges, broad highland valleys, and plateaus that occur at altitudes of about 5,000 feet. On the northern coast another mountain complex that is nearly parallel but lower—reaching heights between 3,000 and 7,000 feet—rises abruptly from the Pacific Ocean. Large undulating, stable plains, part of the Australian continental shelf, dominate southern New Guinea.

The mountains. The Arfak Mountains in the northwestern Vogelkop Peninsula, which have a maximum elevation of about 10,000 feet, form the westernmost part of the system. Their southeastern foothills cross the isthmus between Geelvink and Bintuni bays to reach the main part of the island. Here the central cordillera rises to form a great mountain backbone that extends without interruption for 1,100 miles. From west to east the chain is composed of the Snow Mountains (Pegunungan Maoke, comprising the Nassau and Orange ranges), the Star Mountains, and the Hindenburg, Victor Emmanuel, Central, Bismarck, Kubor, Kuper, and Owen Stanley ranges. On approaching their New Guinea terminus at Milne Bay, the mountains diminish in height and width. A partly drowned extension between the Coral and Solomon seas appears to the southeast of New Guinea as the Louisiade Archipelago.

The western ranges

The western ranges are generally higher than those in the east and include many peaks that extend above the snow line, which occurs at about 14,000 feet. The highest point on the island is the summit of Mount Carstensz (Puntjak Sukarno), which reaches a height of 16,404 feet. Other important summits include Mount Idenburg (15,750 feet), Wilhelmina (15,585 feet), and Leonard Darwin (13,887 feet). An enormous glacier-capped ridge extends for approximately 8 miles between Mounts Carstensz and Idenberg. Gigantic cliffs border the ridge on both its northern and southern sides, presenting a breathtaking face of clear ice with a maximum vertical drop of 10,000 feet. Although the snowfield of Mount Carstensz was reached as early as 1909 by the Dutch explorer H.A. Lorentz, it was not until 1962 that its summit was climbed by an expedition led by the Austrian Heinrich Harrer.

In eastern New Guinea, Mount Wilhelm at 14,793 feet rises in the centre of the Bismarck Range. Extinct volcanoes, notably mounts Giluwe (14,330), Hagen (12,392), and Ialibu (11,369) and the Doma Peaks (11,700), are other dominant peaks. The Great Papuan Plateau, a plain made of volcanic debris, surrounds the smooth, symmetrical cone of Mount Bosavi (7,863).

The parallel northern system is—from west to east—composed of the Pegunungan Gauttier and Pegunungan Van Rees mountains, and the Torricelli and Finisterre ranges. The continuity is broken by deep troughs of these ranges, through which the inland lake-plain that lies between the central and coastal ranges can be reached. The plain, which is 100 feet above sea level, is drained by the Mamberamo, Sepik, and Ramu rivers; the river mouths are surrounded by broad swampy lowlands that contrast with the otherwise rugged character of the northern coast.

Geology. The cordillera lies in a zone of weakness in the earth's crust separating the relatively stable Australian continent from the basin of the Pacific Ocean. The ranges formed an axis of geological activity from 225,000,000 to 2,500,000 years ago. Formed of essentially young rocks that have been intensively folded, the ranges show evidence of violent movements of the earth's crust. Original folding that took place from 136,000,000 to 65,000,000 years ago was compounded by more severe folding that occurred from 65,000,000 to 2,500,000 years ago. Marine beds were uplifted to a maximum height of 16,000 feet, while at the same time, downward movements produced the depressions to the north and south of the central highlands; parts of the lands that had been raised also became isolated, forming island chains. Lakes Paniai, Tage, and Tigi, which were formed by folding that took place across the course of the Arabu River, lie at a height of about 5,750 feet in the region around Enarotali in the west.

With wind and water erosion occurring at a rapid rate, the mountains are much cut into hills and valleys; they have long, straight slopes and a thick vegetation cover. Chemical erosion is caused by the heat and rain and the rain forest cover encourages intense bacterial activity.

To the south the foothills are made of limestone, which permits water to filter through, thereby forestalling stream erosion; outcropping limestones consequently often form prominent ridges. Elsewhere the alluvium resulting from erosion is coarse; flooded streams occasionally transport boulders as large as 30 to 40 feet in diameter.

Although frosts occur above 10,000 feet, significant frost weathering is not usually observed below 12,000 feet. Glaciated landscapes indicate that a snow line existed at heights of 11,500 to 12,000 feet from 2,500,000 to 10,000 years ago; glaciation has nevertheless been a minor factor in landscape development.

Active volcanoes

Volcanic activity in recent times has been limited to the coastal region of the north and east; Mount Lamington, in the Owen Stanley range of eastern New Guinea, erupted in 1951, killing or injuring 4,000 people, and other eruptions have occurred on smaller islands in the Bismarck Sea. Volcanic activity has also recently occurred on the Vogelkop Peninsula.

Drainage. The central highlands form the watershed of a complex drainage system that includes several large rivers. From west to east these rivers are the northern

Tariku, the Taritatu, the Sepik, the Ramu, and the Markham rivers, and the southern Pulau, the Digul, and the Fly. From its source in the Star Mountains, the Sepik meanders for 700 or 800 miles to the northern sea. The Ramu and Markham rivers flow in opposite directions from a watershed in the middle of a valley between the Finisterre and Bismarck ranges. All these rivers carry huge amounts of alluvium. The largest Papuan river, the Fly, begins its more than 600-mile course in the Victor Emmanuel Range; at the river's mouth, which is 33 miles wide, a flood plain is being built up at a rate that approximately matches the rate at which the southern coast is subsiding.

Soil. Except for volcanically active areas, such as the Vogelkop Peninsula and the northeastern coast, the soils are heavily weathered and leached. Steep slopes usually support deep acid soils, commonly brown clays derived from plants. Peaty soils occur at high altitudes as well as in swampy areas. Shallow dark clays coat the steep limestone slopes; deep dark clays cover limestone floors packed with funnel-shaped cavities, and slumps (masses of material that have slipped down from high slopes). Olive ash soils, derived from plants, occur at moderate altitudes.

Climate. The climate is tropical and is dominated by two prevailing wind systems—the northwest monsoon wind, which blows from December to March, and the southeast trade wind, which prevails from May to October. The average site experiences ten inches of precipitation monthly; the amount is subject to only slight seasonal variation, although rainfall is heaviest during the northwest monsoon. In many districts higher than 5,000 feet, rain is practically incessant. Because the mountains occupy a central position between the moist air masses of the Bismarck Sea in the northwest and the Coral Sea in the southeast, every wind brings moisture that falls as rain when it reaches the mountains.

Rainfall and temperature

Temperature in the more-populated valleys varies between 50° and 80° F (10° and 27° C) with a daily range of 10° to 55° F (6° to 31° C). Intermontane plateaus, between the mountains, such as the upper Chimbu Plateau (which lies at an altitude of about 6,000 feet between the Finisterre Range to the east and various ranges to the west), average 10° F (6° C) less. Ground frosts are common at elevations above 10,000 feet.

The type of climate varies with altitude. A tropical monsoon climate predominates below 3,500 feet, developing into a wet, tropical mountain climate up to an altitude of 6,000 feet. A wet–cool mountain climate with persistent cloudiness occurs between 6,000 and 11,000 feet; above 11,000 feet a high mountain-steppe climate prevails.

Vegetation. With its dry plains, humid jungles, and freezing windswept peaks, New Guinea has a highly diversified plant life. An amazing wealth of approximately 3,000 different species of orchid, many of which are peculiar to the locality, enriches the vegetation. Near the foot of the mountains the undergrowth contains screw pine and creeping bamboo. Along the lower mountain valleys, at heights of from 3,000 to 5,000 feet both oaks and laurels mingle with valuable evergreen trees. Mountain forests of evergreen and oak are found at altitudes between 5,000 and 9,000 feet; the forest floor is carpeted with moss and fern, while Rhododendron and over 200 plants of the ginger family provide bright colours. Up to 8,000 feet hunters and cultivators have frequently reduced the forest to grassland. A moorland of low scattered bushes with fern and cycad is characteristic of the highest altitudes.

Animal and bird life. The diversity in climate and vegetation has produced a correspondingly varied animal life. Mammals are related to those of Australia, and consist of marsupials (animals carrying their young in pouches), rats, mice, bats, spiny anteaters (which lay eggs), crocodiles, and wild boars. Both venomous and harmless snakes occur. Rivers are poor in freshwater fish. Frogs and tree frogs abound. The most spectacular birds are the colourful birds-of-paradise, of which there are approximately 80 species. Formerly slaughtered for their feathers, they are now protected. The cassowary, a large, flightless bird, is domesticated for its feathers. Sulfur-crested cockatoos (*i.e.*, with lemon-coloured crests) are prominent among the 46 parrot species, and the crowned pigeon is also found.

Birds-of-paradise

The inhabitants. The mountain tribesmen are predominantly Negritos, who represent remnants of an early, widespread migration from southern Asia. The island probably first received human migrants about 25,000 years ago. Radio-carbon dating of stone tools found at Chimbu and Goroka has established that human settlement occurred in the highlands at least 10,000 years ago. The official population density is estimated at about 17 persons per square mile in the Australian territories, and about five per square mile in West Irian, but densities are undoubtedly highest in highland valleys.

Human adaptation to the environment, recurrent Melanesian intrusions, and genetic variations produced many different groups. Montane isolation in the mountains has led to the development of cultural and linguistic differences. Most of the people, however, are animists practicing agriculture on land tracts that are constantly changed, and cultivating bananas, sugarcane, taro (a stemless plant with a starchy edible root), and tobacco. Sweet potatoes, introduced in about 1600, permitted a more vigorous agriculture to develop at altitudes too high for the traditional crops grown at the 5,000-foot level. Skillful cultivation enables slopes standing at angles as steep as 70° to be used without causing surface erosion. Pigs are domesticated for religious ceremonies as well as to establish group prestige. The casuarina tree, which has a valuable hard wood, is planted for fuel and is also used for fencing in the few places where population pressure has resulted in semi-permanent cultivation. The main tribal groups are the Ekaris and Monis of the Arfak Mountains; the Tapiro, Pesechem, and Nogullo of the Nassau Range; and the Kukukukus and the Wabago of eastern New Guinea. The Enga language, spoken by 130,000 eastern highlanders, is the most widely used of more than 1,000 Papuan and Malayo-Polynesian languages that are spoken.

Mapping. Although progress has been hampered by persistent cloud cover, by 1970 about 85 percent of the mainland had been adequately photographed from the air for mapping purposes.

Transport. In West Irian few mountain passes occur below 13,000 feet. Rivers, gorges, and mountain barriers have formed serious obstacles to normal movement. Until 20 years ago, neighbouring groups were usually strangers and, therefore, enemies. The airplane has, to some extent, served to overcome both natural and human barriers to communication. There are approximately 60 airstrips on the island, some of which bear heavy traffic. At Goroka, in the U.N. Trust Territory of New Guinea, about 850 landings a month are recorded.

Overland transport remains poor, particularly in West Irian, where the only road networks are in the coastal lowlands. In eastern New Guinea most of the roads can only be traversed by four-wheel-drive vehicles or by tractors. The largest and best-maintained road system is the Highlands Highway, which extends 400 miles west from Lae on the east coast of the Trust Territory and crosses the 8,175-foot Daulo Pass.

Economic resources. While gold, oil, and copper have long been mined at coastal locations, the difficulty of access has delayed exploitation of the rich mineral, timber, and hydroelectric resources of the mountains. Small amounts of timber are obtained in the eastern districts. In the Trust Territory of New Guinea there is a small hydroelectric plant at Goroka, and another hydroelectric project is planned on the upper Ramu River.

(O.R.)

New Guinea, Trust Territory of

The United Nations Trust Territory of New Guinea, under Australian administration, includes the northeast quarter of the island of New Guinea (east of longitude 141° E), the islands of the Bismarck Archipelago, Bougainville and Buka islands, and about 600 small offshore islands. It is bounded to the west by West Irian (part of Indonesia), to the north and east by the Pacific Ocean, and to the south by Papua. The territory has a total area of 92,160 square miles (238,700 square kilometres) and a population of nearly 1,800,000 in 1970. The administrative capital, Port Moresby, is on the south coast of Papua, an Australian external territory. Papua and the Trust Territory of New Guinea are administered jointly. The territory is visited every three years by a UN visiting mission, which monitors Australia's fulfillment of its international trusteeship. (For Papua, see AUSTRALIAN EXTERNAL TERRITORIES; for an associated physical feature, see NEW GUINEA, MOUNTAIN RANGES OF; for further historical aspects, see OCEANIA, HISTORY OF.)

Relief, drainage, and soils. The most prominent physiographic feature of the territory is a complex system of ranges running roughly northwest to southeast through the centre of the island of New Guinea, approximately along the border between the trust territory and Papua. This Central Cordillera is broadest between the towns of Kainantu, to the east, and Wabag, to the west, where plains 4,000 to 6,000 feet high are flanked by high mountain ridges. The highest mountain is Mt. Wilhelm, in the Bismarck ranges; it rises to 14,793 feet (4,509 metres). North of the Central Cordillera is a fault trough through which drains the Sepik River (some 700 miles long and navigable for more than 300 miles) and the Ramu and Markham rivers. North of the fault trough, a northern chain of mountains runs parallel with the main cordillera, but it is not so wide, lofty, or continuous. Only in the Saruwaged Ranges of the Huon Peninsula do peaks exceed 13,000 feet. Raised coral reefs are a feature of the north coast of New Guinea. Some reefs on the Huon Peninsula rise to 2,000 feet above present sea level.

The main islands of New Britain, New Ireland, Manus, and Bougainville are hilly and mountainous, with valleys and gorges inland. Like the northern coast of New Guinea, some parts of their coastlines have been subject to uplifting during the last 10,000 years, but there are many coastal plains (for example, in West New Britain) and coastal mangrove swamps. The numerous lesser islands are of volcanic or coral origins.

Volcanic and seismic activity

The territory is geologically unstable and subject to much seismic and volcanic activity; 32 volcanoes (mainly in the Bismarck Archipelago) either have erupted in the last 80 years or are in a latent volcanic stage in which they produce hot vapours and gases.

Soils generally are very leached and infertile. Some exceptions are the volcanic soils in New Britain and Bougainville and the alluvial soils of the Markham and Ramu valleys.

Climate, vegetation, and animal life. About half of the territory receives more than 100 inches of rainfall a year, but some mountainous parts probably receive well in excess of 300 inches. Relatively dry zones receiving less than 70 inches annually occur in the lower Sepik and Markham valleys. Maximum rainfall typically occurs between January and April; between May and August, normally a relatively dry period, a markedly wet season nevertheless occurs in the southeast parts of the Huon Peninsula, New Britain, and Bougainville.

Temperature varies little throughout the year. In coastal areas average monthly maximum temperatures are about 86° F (30° C) and average minimum temperatures about 73° F (23° C). Daily temperature variation is about 10° to 15° F (6° to 8° C). In the highland valleys temperatures are lower and extremes are greater. On the tops of the highest mountains snow occasionally falls.

Lowland rain forest is the dominant vegetation cover. There is also a wide range of other plant communities, including coastal mangroves and strand forest, lowland grassland, woody and herbaceous swamps, moss forests in the mountains at about 9,000 feet, and tussock grasses on the peaks above 13,500 feet.

The animal life is closely related to that of Australia. Among mammals, marsupials such as the tree kangaroo and the phalanger (also a tree dweller) predominate. The spectacular birds-of-paradise occur in sparsely populated areas.

History. On the basis of associated evidence in Australia, which was joined to New Guinea at certain periods in the Pleistocene Period (which lasted from about 2,500,000 to about 10,000 years ago), it is probable that man entered the New Guinea region about 50,000 years ago. Diverse hunting and gathering activities persisted until about 6,000 years ago, when evidence of simple subsistence horticulture appears. Great differences in existing languages and agricultural systems indicate that coastal and inland groups were never closely related.

Portuguese and Spanish navigators sighted the north coast of New Guinea in the early part of the 16th century. Until German trading firms started operations in the New Guinea islands in the 1870s, only the coast was mapped, and very little was known about the interior of the mainland or of the islands.

German, Australian, and Japanese occupations

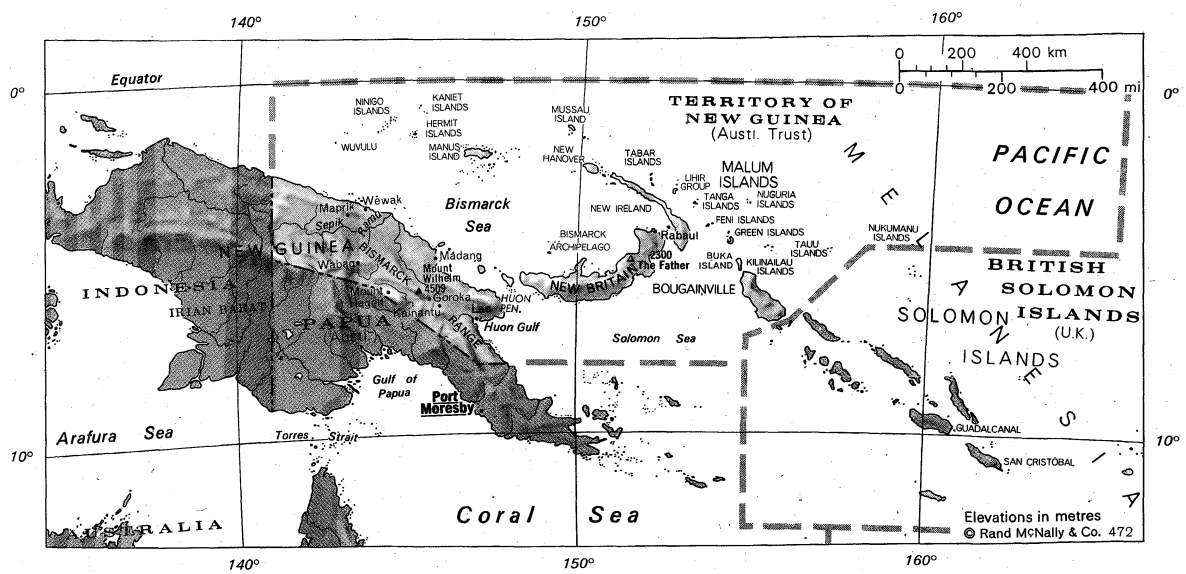
In 1884 Germany formally took possession of the territory, which was administered by the German New Guinea Company until 1899, when the German imperial government assumed control. In 1914, on the outbreak of World War I, the territory was occupied by Australian troops and remained under military administration until it became an Australian mandate of the League of Nations in 1921. By 1923 a strip extending only about 50 miles inland from the coast was under effective Australian control. It was not until the 1930s that the densely populated highland valleys were discovered. During the 1930s the foreign-owned coconut plantations were adversely affected by the economic depression, and the economy of the country was based largely on the export of gold from the Bulolo Valley.

Between 1942 and 1945, during World War II, the islands and lowland areas of the territory were occupied by Japan. Since 1946 the territory has been administered by Australia under the United Nations trusteeship system.

People, population, and culture. The indigenous people, officially "Australian protected persons," are ethnically diverse. Broadly, the so-called Papuan is representative of this interior, and the Melanesian is representative of the coasts and islands. There is, however, also some mingling with Micronesian and Polynesian peoples.

Two radically different indigenous language types exist —Austronesian or Melanesian, and non-Austronesian or Papuan. Some 200 related Austronesian languages occur, mainly in the islands and along the New Guinea coast. The 500 non-Austronesian languages have small speech communities, but the largest is the Enga, in the Wabag area, which has some 140,000 speakers. Because of the multiplicity of tongues, Pidgin English (Neo-Melanesian) has developed as an effective lingua franca.

In 1970 the estimated indigenous population was about 1,763,000 and was increasing at a rate of about 2.4 percent annually. The average population density of the



TRUST TERRITORY OF NEW GUINEA

whole territory is about 19 persons per square mile, but they are unevenly distributed. About 30 percent of the population are in the highlands, with some concentrations of between 200 and 500 persons per square mile. Other clusters occur in north New Britain and in the Maprik area of the Sepik District. The main towns

Principal towns

are Lae (population 35,000 in 1971), Rabaul, Wewak, Madang, Goroka, and Mount Hagen. Only about 5 percent of the total population are urban. The nonindigenous population, mainly Australian, numbered just over 20,000 in 1966, and about 70 percent lived in the towns. Many indigenous groups have rich and varied forms of artistic expression and an extensive ceremonial and ritual life.

The economy. Agriculture is the most important element in both the subsistence and commercial sectors of the economy. Yams, taro, sago, and bananas are the lowland staple foods, and sweet potato is the main highland food. Commercial cash crops account for 85 percent of the foreign exchange earned by the territory. The crops are grown on plantations owned by the nonindigenous population or by indigenous smallholders. The main crops are coffee, cocoa, and copra, which together account for more than half of the total exports. Other important cash crops are pyrethrum (a plant used in the making of insecticides), tea, rubber, and oil palm. Gold, produced principally in the Wau-Bulolo area of the Morobe District, is declining in importance, but huge deposits of low-grade copper have been found in the Panguna area of Bougainville. Copper concentrate is expected to become a major source of income. It is estimated that there is a 900,000,000 ton reserve of copper ore at Panguna. Production began in 1972.

Besides revenue raised internally, mainly from import tariffs and direct taxation, the territory receives a non-repayable grant from the Commonwealth of Australia.

The main road system is the Highlands Highway, which runs for 400 miles westward from Lae. There are smaller road networks in the Sepik District and in New Ireland; limited road systems radiate out from the main towns. Coastal trade is important in moving agricultural produce to the main ports, but aircraft have played an important role in opening up and developing the territory. Aircraft are the main method of travel within the territory, and most of the inland centres and outstations are served by small planes.

Highways, coastal shipping, and air traffic

Administration. The territory consists of 12 districts and 50 subdistricts and is administered jointly with Papua by an administrator, appointed by the Australian government and based in Port Moresby. The main legislative body is the House of Assembly, which consists of 84 elected members and ten appointed; any ordinance passed by the House, however, must have the assent of the administrator and—in some cases—the governor general of Australia.

New Hampshire

New Hampshire, one of the 13 original states of the United States, is situated with its five fellow New England states at the extreme northeastern corner of the nation. With an area of 9,304 square miles (24,097 square kilometres), it is bounded on the north by the Canadian province of Quebec, on the east by Maine and an 18-mile-long stretch of the Atlantic Ocean, on the south by Massachusetts, and on the west by Vermont. The capital is Concord, located in the south central part of the state.

Stability and progress

Though the essence of New Hampshire may be symbolized by its underlying granite bedrock, by the stern visage of the rock profile known as the "Old Man of the Mountain" looking out from Cannon Mountain in Franconia Notch, and by its more than three centuries of staunch Yankee tradition, New Hampshire contains within itself a number of contradictions. The 1970 census showing 737,681 inhabitants ranked it only 42nd among the 50 states, but a 21.5 percent population growth in the 1960s made it the third-fastest-growing state east of the Mississippi River. It is generally thought to be a rural state, but about 40 percent of its residents' wages and salaries were received from manufacturing in 1970, making it by this measure the fifth most industrialized state in the nation. In 1964 New Hampshire became a national pioneer when a statewide sweepstakes went into effect, its income earmarked for education. This innovation was necessitated, however, by the lack of either a general sales tax or a state income tax, two measures the citizens and state legislature have been loath to accept.

On the side of tradition, New Hampshire seems very much a region tied to the past, to the land, and to the conservative way of life. Many of its residents can trace their New Hampshire ancestry for generations. The names of many of its towns and 1,300 lakes and ponds—Sunapee, Winnipesaukee, and Kearsarge, for example—are picturesque reminders of the Indians who inhabited northern New England before the coming of the white man in the 17th century. Its towns are governed by the town meeting, a last bastion of direct democracy in which the citizens themselves vote on the measures that will direct local affairs for the coming year. Despite these echoes from the past, its industries produce space-age materials. For more information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; and NORTH AMERICA.

HISTORY

The English colony. The region that was to become New Hampshire was included in a series of grants made by the English crown to one John Mason and others in the 1620s. A fishing and trading settlement was established in 1623, and in 1629 the name New Hampshire, after the English county of Hampshire, was applied to a grant for a region between the Merrimack and Piscataqua rivers. The towns of Dover, Portsmouth, Exeter, and Hampton were the main settlements in the early decades.

From 1641 to 1679 the region was administered by the colonial government of Massachusetts. Following decades of territorial and religious dispute between Massachusetts and Mason's heirs, New Hampshire became a separate royal province in 1679. Bitter boundary feuds with Massachusetts and with New York over that part of the New Hampshire grant that became Vermont continued almost until the American Revolution. Most famous of the colonial governors was Benning Wentworth, who held the post from 1741 to 1767, the longest tenure of any royal governor in any of the colonies.

In 1767 the colony had its first census and counted about 52,700 inhabitants. In 1769 it was divided into five counties, to which five others have been added since 1800. New Hampshire soldiers played an active part in the colonial wars between Great Britain and France from 1689 to 1763. By the end of the colonial period the seat of government was at Portsmouth, and there were 147 chartered towns in the province.

Revolution and statehood. In December 1774 there was armed resistance to the British at New Castle, where Ft. William and Mary was seized by colonists. Gunpowder and other munitions were taken. New Hampshire people were overwhelmingly in sympathy with the aims of the revolutionary leaders. The state furnished two major generals to the Continental Army, three regiments of regular troops, and hundreds of short-term militiamen. Officially becoming a state in 1776, it issued its own Declaration of Independence some weeks before the national Declaration of July 4, 1776. Gen. John Stark of Derryfield led the Continental forces in a major victory at Bennington, Vermont, in 1777. New Hampshire's vote was the ninth and decisive one in ratifying the Constitution of the United States in 1788.

Role in forming the nation

Following the establishment of the new nation, the state grew rapidly. Agriculture, notably sheep raising, flourished and manufacturing developed along the fast-flowing rivers, particularly in Manchester. When the railroads appeared in the northeast, an extensive rail network was constructed. Portsmouth and its surrounding towns were shipbuilding centres. In 1846 Manchester became the first incorporated city in the state. On the national scene New Hampshire was the birthplace of such noted statesmen as Daniel Webster and Pres. Franklin Pierce.

Contributions to war and politics. New Hampshire played an active part in the Civil War and, following that conflict, voted regularly for Republican candidates until the New Deal of the 1930s. The progressive movement had an impact upon the state in the early 20th century, and the economic depression of the 1930s left scars that were only slowly effaced. In both world wars and in the Korean and Vietnamese conflicts, the state's men played significant roles, and the shipbuilding and naval facilities at Portsmouth were of special value.

Because it holds the earliest presidential primary in the nation, New Hampshire has furnished the first testing ground for many successful candidacies, including those of Dwight D. Eisenhower in 1952, of John F. Kennedy in 1960, of Lyndon B. Johnson in 1964, and of Richard M. Nixon in 1968. In 1905 Portsmouth was the site of the peace conference that ended the Russo-Japanese War, and in 1944 the state was host to the Bretton Woods Conference that founded the International Bank for Reconstruction and Development and the International Monetary Fund. The U.S. Air Force constructed a huge Strategic Air Command base at Newington in 1957, and the Portsmouth Naval Shipyard, in Kittery, has continued to specialize in building and repairing submarines.

THE NATURAL AND HUMAN LANDSCAPE

Physical environment. The basic physical features of New Hampshire are the result of the last glacial age (10,000 to 64,000 years ago), during which the "Wisconsin ice sheet" moved like a huge bulldozer across New England from the northwest to the southeast. Loose sand, silt, clay, and gravel were deposited as masses of glacial till that, near the town of Greenland, is 395 feet in depth. The mountain notches of New Hampshire—Carter, Crawford, Dixville, and Franconia—are the result of this glacial action, as are the potholes and cirques, amphitheatre-like recesses, found in the state. The great glacier left deposits in the form of many deltas and hillocks of stratified deposits. New Hampshire's lakes are also the results of glacial action.

Glacier-formed topography

Rivers and soils. New Hampshire has five main river-drainage basins. The largest is that of the Merrimack River in the central part of the state. Second in size is the Connecticut River drainage basin along the western border. The remainder of the state feeds the Saco and the Androscoggin rivers, as well as several smaller streams, including the Piscataqua, that are known collectively as the coastal rivers.

Mountains. The mountains are the most striking feature of New Hampshire's landscape. There are about 1,500 classified elevations, including eight mountains rising more than a mile in altitude, 61 rising more than three-quarters of a mile in height, and 157 with an elevation of a half-mile or more. The best known is Mt. Washington at 6,288 feet, the third-highest peak in the U.S. east of the Mississippi River. The mean elevation of the state is about 1,000 feet above sea level.

Climate. New Hampshire's climate is highly varied. In the winter the temperatures may drop below 0° F (−17° C) for days at a time. Summers are relatively cool, and the mean annual temperature is about 40° F (4.4° C). The annual precipitation is approximately 40 inches and is rather evenly distributed over the four seasons.

Vegetation and animal life. Even today, more than 80 percent of New Hampshire remains under forest cover. The majority of the trees found in the eastern U.S. are indigenous to New Hampshire. The most valuable single species of tree has always been the white pine, which has been characterized as "nature's chief gift to New England." Invaluable for masts in the era of sailing ships, these great trees also furnished useful lumber.

The wooded areas also support a flourishing wildlife. Whitetail deer are numerous, and moose are occasionally seen. There is a hunting season for deer each year, but the killing of moose is prohibited. Beavers, once almost exterminated, have been protected in recent years and are making a comeback. Black bears are relatively common, while smaller mammals like rabbit, squirrels, raccoons, foxes, and mink are still plentiful. There is an abundance of bird life, including such species as grouse, woodcock, pheasants, and ducks.

Until recent years, many varieties of fish were available in both coastal and interior waters. State rearing stations keep the interior lakes and rivers well stocked for fishing. During the 1960s, however, there was much concern about the effects of pollution on the under-water world, and strenuous efforts, both public and private, are underway to prevent further contamination of lakes, streams, and coastal waters.

Patterns of human settlement. Six quite distinctive regions exist, each with its roots deep in New Hampshire's history. The heavily forested White Mountain area in the north is popular with mountaineers and tourists in summer and winter alike. The lakes region centring on Lake Winnipesaukee is a favoured locality for summer camps and resorts and for water sports. The seacoast region around Portsmouth, Dover, Exeter, and Hampton has many maritime activities. The south central, or Merrimack, region, surrounds Manchester, the most heavily industrialized section of the state. The Dartmouth–Sunapee Lake region in the west central portion is dotted with educational institutions and summer homes. Finally, the area around Mount Monadnock, in the southwestern corner of the state, is noted for many small industries and such attractions as the MacDowell Colony, a residential retreat in Peterborough for artists in many fields, and for the Cathedral of the Pines in Rindge, an outdoor shrine dedicated to America's war dead. Each of these regions is officially organized and finances its own promotional activities.

Historic regions

The population of the state in 1972 was distributed among 13 cities, 224 incorporated towns, and 24 unincorporated places. The 11 percent of the state's area that comprises the massive White Mountain National Forest is almost uninhabited.

THE PEOPLE OF NEW HAMPSHIRE

Demographic trends. In the first U.S census, in 1790, New Hampshire had a population of 141,885. Since then each decennial count recorded a growth, except for that of 1870, when there was an extensive post-Civil War exodus to the new states of the Middle West. In the first census the urban population of the state was 3.3 percent, but in 1970 almost 60 percent of the state's 737,681 inhabitants were classified as urban. The people of the state were concentrated to a large extent in the southern and southeastern regions, and the larger urban centres were all located south of the White Mountains. In the area nearest to Boston, Massachusetts, New Hampshire was becoming a kind of "bedroom suburb" for thousands of persons who commuted to that metropolis each day. In the expanding population, persons over 65 years of age totalled 11 percent of the citizenry in 1970, a figure among the highest in the nation.

The vital statistics of the state revealed that the lowest birthrate in modern times was in 1933 and that the highest was in the years just after World War II. The highest death rate in the 20th century was in 1918, the year of the worldwide influenza epidemic.

Ethnic and religious origins. In the colonial period, the majority of the people were of English origin, but in 1719 there began a significant influx of Scotch-Irish who were largely Presbyterian in faith. Settling in the south central and southwestern portions of New Hampshire, they named their principal towns Derry, Londonderry, Antrim, and Dublin. These Scotch-Irish were energetic pioneers, excellently suited for fighting Indians, the British, or any other enemy who confronted their adopted country. They gave yeoman service in the Revolution and all subsequent wars.

Immigration and religion

New Hampshire never had a state church, even in colonial times. Rather, it had a unique system of "town churches" in which any officially recognized denomination could be designated at the annual town meeting as the one to receive public tax support. Prior to the American Revolution, there were five possible denominations from which to choose: Congregational, Baptist, Presbyterian, Quaker, and Church of England. In 1819 this system was discarded by the Toleration Act passed by the legislature. Since then all churches have been privately supported, and any denomination may function freely.

In the 19th and 20th centuries, new waves of immigration came into the state from central Europe, from the Balkans, and from countries peripheral to Russia, such as Poland and Finland. These newcomers brought with them their native customs and varied religious faiths. The first Roman Catholic congregation was established in 1828, the first parochial school in 1859, and a statewide diocese in 1884. The first Jewish congregation was organized in 1892, and the first Greek Orthodox Church in 1905. One of the only two Shaker communities still functioning in the U.S. is located in Canterbury. The Cathedral of the Pines attracts thousands of visitors each year to its impressive site. The New Hampshire Council of Churches, organized in 1945, developed broad ecumenical policies in which many faiths take part.

From the beginning, the people of New Hampshire have been mostly white. In 1970 black citizens made up less than 0.4 percent of the population, and citizens of Asian origin were even fewer. The largest group not directly descended from origins in the British Isles was the French-Canadian, or "Canado-Americaine," who first began to arrive in the years immediately after the Civil War, chiefly from Quebec. They are attracted mainly to such industrial cities as Manchester, Nashua, Laconia, and Berlin. By the end of World War I, New Hampshire had the largest percentage of citizens of French-Canadian origin of any of the states.

French-Canadian population

THE STATE'S ECONOMY

New Hampshire manifested some striking economic trends in the 1960s. The historic shoemaking, woodworking, apparel, and textile industries showed a marked drop in productivity and employment opportunities, while space-age industries grew rapidly. Among nonmanufacturing industries that also grew significantly were communications and public utilities, insurance and banking, medical and health-service establishments, miscellaneous business services, and wholesale and retail trades. Employment in New Hampshire was less affected by the recession that began in 1969 than were most other parts of the nation, and at the end of 1970 the state's unemployment rate was the lowest in New England. Per capita personal income in the state in 1970 was $3,608, ranking New Hampshire 26th in the nation in the average earning power of its people.

Agriculture, forests, and fisheries. Agricultural acreage decreased by two-thirds between 1910 and 1970, but, with an even greater decrease in the number of farms, the acreage per farm has increased. Poultry and poultry products are the chief source of income, followed by dairying and vegetable farming. Two-fifths of the harvested timber was for sawlogs, one-fifth for pulpwood to supply paper and newsprint industries, and most of the remainder for firewood. With only Rockingham County

on the coast, the state ranks low in commercial fishing yields but has marketable catches of lobsters, oysters, clams, and deep-sea fish.

Manufacturing, mining, and tourism. Electrical- and electronic-goods manufacturing has largely supplanted the textile and garment industry, much of which after 1945 either closed or moved to the South in search of cheaper labour and greater proximity to raw materials. Paper and wood products comprise another important industry. The only large industrial centre north of the White Mountains is Berlin, with large paper and pulp mills.

There are many rock quarries, chiefly of granite, throughout New Hampshire, but modern construction methods have reduced the demand for stone and depressed the industry. Other native minerals that have commercial value include garnet, zircon, beryl, and bog iron. In 1955 the state legislature established an Industrial Park Authority to attract new business into New Hampshire. Supplemented by the endeavours of individual cities and towns and by various private organizations, the authority has been successful in modernizing the industrial and business life of the state. An organized effort began in 1925 to publicize New Hampshire as a tourist area, and this effort has steadily expanded since that date. The great popularity of winter sports after World War II made New Hampshire as attractive to visitors in the cold months as it has been in the summer. Tourism became a major economic aspect of life in the Granite State.

Transportation. At its maximum extent, in 1920, the New Hampshire railroad network comprised 1,252 miles of trackage; 50 years later it was barely half that figure. Hundreds of miles of right-of-way had been abandoned, and there was no passenger service except on a six-mile-long cog railway on Mount Washington. This line had opened in 1869, the first such construction of its kind in the world. A century and more later it was still carrying tourist passengers behind steam locomotives during the summer season.

As the railroad disappeared, the bus and highway systems of the state greatly increased. In 1970 state highways totalled more than 4,100 miles; local roads, over 10,000 miles; and the interstate-highway system, over 210 miles, some of it still under construction. Air service to the chief cities of the state was maintained at a decreasing level. Most of the nearly 40 airports were privately owned, and only a few of the principal cities had either regularly scheduled airline service or adequate runways and landing aids.

ADMINISTRATION AND SOCIAL CONDITIONS

Constitution and governmental structure. The constitution of New Hampshire, the second oldest among the 50 states, was adopted in 1784. Every seven years the voters of the state may vote on the question of holding a convention to consider modifications of the basic law. Proposals that pass these conventions must be approved by two-thirds of the voters at a popular referendum. Fifteen such conventions have been held in the state's history, and a large number of modifications have been adopted, but a considerable portion of the original constitution remains in effect.

Executive power. Since 1784 New Hampshire has had 72 governors, some of whom in the early years were re-elected repeatedly. The normal incumbency in modern times has been two terms of two years each, but a determined effort is under way to establish a four-year gubernatorial term. The governor is assisted in his duties by a five-man council, an institution that is found elsewhere in the United States only in Maine and Massachusetts. Members, elected every two years from five geographical districts in the state, must approve all appointments to state offices and to judicial posts.

Legislature. The state legislature, the General Court, comprises at least 400 members elected every two years. The lower body, the House of Representatives has between 375 and 400 delegates and in the English-speaking world is believed to be exceeded in size only by the United States House of Representatives and the British Parliament. The state Senate has a modest membership of 24. In 1971 the Citizens Conference on State Legislatures, a privately funded study group, ranked the New Hampshire legislature 39th from the top in terms of effectiveness as a lawmaking body.

Judiciary and police. The state's judicial functions take place in three levels of courts, municipal and district courts, county superior and probate courts, and the state Supreme Court. All justices are appointed by the governor and his council and serve during good behaviour or until they are 70. The state police, in addition to their usual duties, are at the disposal of the governor for emergency assignments. Local police are under the jurisdiction of the municipal authorities.

Local government. The traditional town meeting, held annually on the first Tuesday in March, is the keystone of local government in New Hampshire. One of the last vestiges of pure democracy in the world, the town meeting is basic to community life in New Hampshire. Presided over by an elected moderator, the voters ballot on each article in the town warrant for the year. If adopted, these articles become the guide to town action for the ensuing 12 months. The meeting chooses the executive of the town and one of three selectmen, each of whom serves for three years. The meeting also selects such departmental heads as fire chief, treasurer, town clerk, road agent, and members of various special boards and commissions. In some towns the selectmen are empowered to choose a town manager, who conducts the day-by-day affairs of the community. Cities are governed by mayor–council, council–manager, or commission systems.

The annual town meeting

Politics. New Hampshire has always been a two-party state, and third-party candidates traditionally have had little success with Granite State voters. For decades prior to the Civil War, New Hampshire was overwhelmingly Democratic, but from then to the depression of the 1930s it was dominated by the Republicans. In recent years, however, the voters have opted on several occasions for Democratic presidential candidates—Woodrow Wilson, Franklin D. Roosevelt, and Lyndon B. Johnson—and have sent several Democrats to Congress.

Patterns of taxation and state aid. Taxes in New Hampshire present a confusing picture. New Hampshire clung tenaciously to its distinction of having neither a general sales tax nor a comprehensive state income tax. More than 60 percent of state income was derived from taxes on alcoholic beverages, tobacco, legalized racetrack betting, and the sweepstakes that went into effect in 1964. Such taxes admittedly were designed to draw heavily on the immense volume of tourism. The overwhelming burden of local income was derived from property, with non-property local taxes trivial.

The resultant problem of state aid to local units of government was an increasing and an abrasive one. Whereas, nationally, state aid provided nearly 30 percent of all local general revenue, in New Hampshire it provided only 7 percent. This resulted in such figures as New Hampshire's 1970 rank of 32nd in state aid to welfare services, 42nd in state aid for local education, 47th in support of its state university, and 49th in programs of state aid for vocational rehabilitation. Its health and welfare services, especially to the mentally retarded, were augmented in the 1960s, but there was agitation for further improvement.

Financial difficulties

Despite intricate and complex formulas for state aid devised by successive legislatures, the absence of any broad-based changes in the tax structure of the state kept the fiscal picture gloomy in the early 1970s. A 3 percent general sales tax proposed by the governor in 1971 polarized opinion into grudging support and vehement opposition, but it failed to pass the legislature.

Education. New Hampshire has had a public-school system since 1647, when, as a part of Massachusetts, it was required to provide different kinds of schools depending on community size. The statewide system is under a board of education headed by a commissioner. Each town is constituted a school district, with its main support coming from local property taxes. The land-grant college that became the state university was found-

ed in 1866 in Hanover and moved to Durham in 1893. Affiliated colleges are located at Plymouth and Keene. During the 1960s six state vocational colleges and a technical institute were established; an educational-television system based at the state university went into operation in 1959.

Best known among the private institutions of higher learning is Dartmouth College at Hanover, a liberal arts college that observed its bicentennial in 1969. Other private colleges include St. Anselm's College (1889) at Manchester, Mount Saint Mary College (1934) at Hooksett, and Rivier College (1933) at Nashua, the last two for women only. Since 1945, eight new four-year liberal arts colleges, all privately financed, have been founded in the state. In addition to these, there are several private junior colleges, the oldest of which is Colby College-New Hampshire (1928) at New London.

CULTURAL LIFE AND RECREATION

The arts. New Hampshire has several outstanding cultural institutions. The MacDowell Colony was founded as a memorial to the composer and Peterborough resident Edward MacDowell (1861–1908) by his widow in 1907, and it since has been a mecca for musicians and writers. In 1964 the 86-acre former home of the noted sculptor Augustus Saint-Gaudens (1848–1907) at Cornish was designated as a National Historic Site. Manchester has the Currier Gallery of Art and an institute of arts and sciences; Dartmouth College a distinguished fine arts centre; Nashua an arts and science centre; and several towns have smaller galleries, art centres, and museums. Summer theatres flourish in a dozen or more of the state's resort areas.

Sporting and historic sites. Recreation and tourism are important parts of the cultural pattern of the state. New Hampshire has more than 30 ski areas, many of which operate their lifts in the summer for sightseers. There are more than 200 youth camps and more than 60 golf courses. Numerous historical sites throughout the state include many restored colonial homes and Ft. William and Mary at New Castle. There are more than 40 state parks and over 800,000 acres of publicly owned forest preserves.

PROSPECTS

Despite its conservatism, New Hampshire has shown evidence of facing the future with a willingness to seek new ways. By the early 1970s, more than half the towns in the state had established conservation commissions to protect the ecology. The New Hampshire Council on the Aging sought to assist in geriatric matters. Hundreds of "tree farms" total more than 500,000 acres. There was a Center for Continuing Education at the university in Durham and a State Council on the Arts.

One of the assets with which New Hampshire can face the future is the stabilizing force of historical continuity, which may allow it to evaluate the direction of needed innovation. In almost every town and city there are families whose successive generations have lived on the same property, even in the same house, for a century or more. There are other less concrete traditions of the land that modernity and sophistication cannot erode. It was not by accident that Thornton Wilder's famous play *Our Town* (1938), depicting many universal aspects of human experience, was set in rural New Hampshire. It was not wholly fortuitous that the noted American poet Robert Frost (1874–1963) lived most of his life in the state. It is not coincidence that "Old Home Week" has been proclaimed by the governor every year since 1913.

New Jersey

Although it is a major social, economic, and political force in its own right, New Jersey often is looked upon as a stepchild among the heavily industrialized and populated Eastern Seaboard states of the United States. Only four states in the nation are smaller than its 7,836 square miles (20,295 square kilometres), but only seven had more inhabitants in the 1970 census than the nearly 7,170,000 New Jerseyites counted. As a geographical entity and as a human collective, New Jersey nonetheless suffers from a massive lack of identity among American states. For some 300,000 of its citizens who commute to New York, on the north and northeast, and to Pennsylvania, on the west, New Jersey is a vast "bedroom state." For its transportation system, one of the most extensive and busy in the world, it is primarily a funnel for goods and people moving between New York City and points north and Philadelphia, Delaware, and points south. For hundreds of thousands of out of staters it offers long stretches of fine beaches along the Atlantic Ocean on the east and south, although the name and image of the resort Atlantic City may be better known than those of the state itself.

Contradictory nature of the state

Above all, New Jersey is rife with contradiction and anomaly. Its people fiercely fight off the challenges of state government to complete home rule by powerful municipal administrations, which have contributed heavily to the almost uniform depression and decay of its cities. Whereas it has produced some of the most able and respected American governors in the 20th century, its politics have been astonishingly corrupt, and, in recent years, it has achieved notoriety as a major haven for organized crime. It is a wealthy state but beset with fiscal problems, and its citizens tax themselves heavily for public education but consistently refuse to spend money on higher education.

New Jersey is called the Garden State because of its many prosperous truck farms, yet it is among the most urbanized and crowded of states. The urban glut of its northeast contrasts sharply, however, with the rugged hills of the northwest and the enormous stretches of pine forest and rolling, lush horse country. It is one of America's most important industrial centres, but it has paid the price in environmental pollution, in dirt and noise, and in congested roads and slums. In sum, New Jersey is a curious amalgam of the urban and rural, the poor and wealthy, the progressive and backward, the parochial and cosmopolitan. Although it was one of America's 13 original states and the third to ratify the constitution, the New Jersey of the late 20th century has many earmarks of a political body unable to come to terms with itself. (For information on related topics, see UNITED STATES; UNITED STATES, HISTORY OF THE; and NORTH AMERICA.)

THE HISTORY OF NEW JERSEY

The colony. Before the Europeans came, the Lenni Lenape (or Delaware) Indians spent the summer at the shore feasting on fish and collecting the shells they made into wampum. This is what the Florentine explorer Giovanni da Verrazano found in 1524, when he became the first white man to touch shore in New Jersey. Almost a century passed before colonization began with the arrival in 1609 of the English navigator Henry Hudson, who

sent a party to explore Newark Bay. The first settlers were English, Scots–Irish, Swedes, and Dutch. The colony was brought under English rule in 1664, although for the next five years the Dutch disputed that claim. In 1676 the province was divided into East and West Jersey, the former going to Sir George Carteret and the latter to a group of Quakers. The division continued until 1702, when all of the province reverted to James II.

Unlike other colonists, who suffered from the harshness of English rule, the early New Jerseyites were of such an independent and misanthropic nature that it was the royal governors who did much of the suffering. Until 1738, New Jersey and New York were ruled by a single governor. When Lewis Morris took office as the first governor of New Jersey alone, one member of the Assembly advised his colleagues on how governors should be treated: "Let us keep the doges poore and wee'll make them do as we please."

Revolution and statehood. Typically, considerable division of sentiment occurred within the state over the American Revolution, and Tory activity was heavy. The most significant battle of the conflict was fought in New Jersey on December 26, 1776. Gen. George Washington and his hungry, ragged troops crossed the Delaware River from Pennsylvania in longboats, surprised the garrison of German mercenaries in Trenton, and captured the city. A week later, Washington won another vital battle at Princeton, routing Lord Cornwallis, commander of the British army. The victories breathed new life into the Revolution, and an army of colonials near despair was transformed into an effective fighting force. Between the Revolutionary and Civil wars, New Jersey underwent tremendous industrial development, largely abetted by the construction of canals and, later, railroads. The railroads, particularly the Camden and Amboy (forerunner of today's Penn Central), played a crucial role in the state's political life, dominating and controlling legislators and governors during the "robber baron" era of industrial expansion in the 19th century. Accommodating tax laws of that era gave New Jersey the epithet "The Mother of Trusts": one-half of the nation's largest corporations made their headquarters in the state. Public dissatisfaction with the power of the trusts and public utilities helped pave the way for the election of Woodrow Wilson as governor in 1910.

During the Civil War, Southern sympathizers operated almost openly in New Jersey, although the state contributed nearly 90,000 troops to the Federal army. Industrial growth continued through and after both world wars, and, until after the middle of the 20th century, the growing decay of the cities was lost sight of amid the general prosperity that industry brought with it.

THE NATURAL AND HUMAN LANDSCAPE

The natural environment. *Topography.* New Jersey comprises four distinct physical regions—the rugged hill country of the northwest, where the Appalachians slice across; the rolling horse country just below the hills; the central plain of the northeast, where the major cities and suburban towns lie; and the coastal plain of the south. In the thinly populated northwest, the soil is heavy and contains much limestone and sandstone. The highest elevation, at High Point, is 1,803 feet (550 metres) above sea level. Southward, the hills become lower and gentler, and the soil contains considerable granite; this gives way to soil dominated by shale. The central plain is a mixture of loams and marl, while the coastal plain is composed mainly of sands and loam. The most striking features of the state are its beaches, the hills of the northwest, and the marshy meadowlands of the northeast.

The diverse physical regions

Lakes and ponds cover about 315 square miles of the state's surface. New Jersey's major river, which it shares with Pennsylvania, is the Delaware. The Hudson River separates the state from New York. Other major rivers are the Passaic and the Hackensack, both in the northeast, and the Raritan, which runs west to east and is generally regarded as the boundary between North and Central Jersey. Hopatcong Lake in Sussex and Morris counties is the state's largest.

Climate. The climate is moderate, although there is a marked difference in temperatures between the northwest and the southeast. In the north, the average temperature is 50° F (10° C)—in winter, 28° F (−2° C) and in summer, 70° F (21° C). In south, the annual average is 55° F (13° C)—in winter, 35° F (2° C) and in summer, 71° F (22° C). Rainfall averages 46 inches a year—36 inches (914 millimetres) in South Jersey and 50 inches (1,270 millimetres) in North Jersey.

Vegetation and animal life. Virtually all of the plant life common to the northeastern United States can be found in New Jersey, and in the marshes and Pine Barrens of south New Jersey many rare plant species grow, including some insect-ingesting plants. The Barrens are dominated, however, by many varieties of pine and white cedar. Oak, elm, birch, ash, sweetgum, maple, walnut, and chestnut trees are found in river valleys. Plants common to the state include wild azalea, rhododendrum, honeysuckle, mountain laurel, wintergreen, and cardinal flower.

The Hackensack Meadows and the Great Swamp in Morris County are dominated by grasses. Whereas the ecology of the Swamp is sound, centuries of dumping, filling, and dredging have destroyed much of the plant and animal life of the Meadows. Plume grass is the main plant in the Meadows, but it is of negligible value to fowl or fish. Muskrats abound in both marshes. The increasing suburban development of New Jersey has encroached on wildlife habitats, although bear and wildcats can still be found in the Barrens and mountains. Deer are plentiful, as are opossums and muskrats. Other animals encountered include rabbits, squirrels, chipmunks, woodchucks, and many varieties of snakes. All of the birds common to the Northeast are found in New Jersey, as are many migratory varieties.

Traditional regions. *The Jersey Shore.* The most distinctive of New Jersey's regions is its 127-mile-long shore, much of it composed of long and narrow sandbars separated from the mainland by bays and inlets that form part of the Intracoastal Waterway, an interconnected water highway that stretches all the way to Florida. Cape May, at the southern tip of the state, was America's first summer resort, and both that community and Long Branch in Monmouth County were known as the playgrounds of presidents during the 19th century. Today, the quality of the Shore ranges from the urban garishness of Asbury Park to the opulence of Deal and Mantoloking. In such resorts as Wildwood and Atlantic City, the night life plies its revels until dawn, whereas such other towns as Avalon, Ocean City, and Beach Haven are basically family resorts. The Jersey Shore at its best can be found in its two state parks, Sandy Hook in the north and Island Beach in the south. There, the dunes are still topped with coarse but fragile grass, and the osprey still build their nests. The marshes teem with wildlife, and the trees are bent and twisted by wind and salt spray.

Human uses of the land

The metropolitan area. Five northeastern counties in the New York metropolitan area—Essex, Hudson, Passaic, Bergen, and Union—contain nearly one-half of New Jersey's population. Four of the state's six largest cities —Newark, Jersey City, Paterson, and Elizabeth—are located here. The Newark–Hudson County–Elizabeth complex appears to many travellers as one endless, smoky, industrial city: dingy, smelly, but throbbing with commercial life.

Beyond the cities lie the suburbs. Most are pleasant and prosperous, but some are old and showing the first signs of the blight that began to eat away at the cities decades ago. Industrial construction in suburban communities was increased tremendously in recent years, but many suburban towns, especially in Bergen County, remain bedroom communities of New York City and of the New Jersey cities. Newark's population of almost 400,000 doubles every day as the work force pours in. The state remains dominated, however, by the two giants just beyond its borders. An estimated 160,000 New Jerseyites cross the Hudson to New York by rapid-transit trains, by the main line of the Penn Central, or by bus and automobile through the Holland and Lincoln tunnels or across

the George Washington Bridge. North Jerseyites watch New York television, root for New York athletic teams, and patronize New York theatres and restaurants. The same situation exists in Camden, Burlington, Gloucester, and Salem counties where 95,000 persons cross the Delaware to jobs in Philadelphia and environs.

For all of this, however, New Jerseyites have an antipathy for these two big cities. Many citizens of the Garden State grew up in New York or Philadelphia, and, although they retain a lively interest in events there, they profess a profound gladness at being out of the city, with its crime and its financial and housing problems. This attitude is shared by those who never lived in the cities but who grew up in their shadows.

South and Central Jersey. Just below Trenton, the state capital, begins South Jersey, comprising all or most of eight counties, roughly one-half of the state's area but less than one-fourth of the population. Although the climate is drier than in the north, the loamy soil is well suited to vegetable farming, and most of the land not covered by forest or marsh is farmed. Less than 1 percent of the state's population is engaged in farming, but farm income per acre is the highest in America.

Central Jersey, all of five counties and part of three, is largely plain, but hilly areas occur in Hunterdon and Somerset counties. Middlesex and Mercer counties, especially the former, are heavily industrialized. Princeton University is located in Mercer County and the borough of Princeton, which combines the charm of the campus with a rich colonial past to create one of the nation's loveliest towns. Rutgers, the State University is in nearby New Brunswick. Hunterdon and Somerset counties are a pleasant mixture of farm and woodland.

The northwest. The four counties of the northwest take in a mixture of small town, affluent suburb, and rugged countryside, although two major cities, Passaic and Paterson, are in Passaic County. The area contains numerous dairy farms and parks and recreation areas.

The Meadowlands. Although relatively small, the New Jersey Meadowlands loom large in the state's future. Stretching from Perth Amboy to Hackensack, they cover some 19,000 acres (8,000 hectares), 12,000 of which are undeveloped. The lack of development results from disputes between the state and private interests over ownership and from the many problems of construction in a marshy area. Located as it is in the centre of the world's busiest metropolitan area, however, the value of the Meadowlands is immense. In the late 1960s, New Jersey put together the machinery to develop this area through the New Jersey Meadowlands Commission. Initial plans call for a sports complex and ultimately a new city between the Passaic and Hackensack rivers. In 1971 the New York Giants professional football team signed contracts to play in the new arena by 1975, and the possibility existed that the New York Yankees baseball franchise would follow them.

Disputes over land development

THE PEOPLE OF NEW JERSEY

Ethnic composition. New Jersey's first settlers were the English, Scots–Irish, Swedes, and Dutch, but its population today more nearly reflects the immigration patterns of the 19th and 20th centuries: Germans and Slavs, Russian and European Jews, Irish and Italians. New Jersey was a prime destination for the waves of blacks that left the South during and after World War II; by 1970 they made up 10.7 percent of the population. The state has a sizable Puerto Rican population, and Cubans who left their country after the Castro revolution and settled in North Jersey, mainly Hudson County, comprise the latest group to make its presence felt.

Italian-Americans are now the state's largest ethnic group. They are the predominant Caucasian bloc in the cities, although the cities also contain sizable Polish, Hungarian, and other eastern European groups. The Italian-Americans and blacks dominate the political and cultural life of the cities—a situation that often has brought the two groups into competition and conflict.

Demography. The population is unequally distributed. Roughly three of every four New Jerseyites live north of Trenton, and 60 percent of the population lives within 30 miles of New York City. The 18.2-percent growth during the 1960s was a drop from the 25.5-percent figure recorded in the 1950s. Population density was, however, the greatest in the nation.

The most striking demographic trend in New Jersey, as in the nation as a whole, is the movement of the white population away from the cities and the concurrent proportional growth of the urban black population. Between 1960 and 1970, the populations of Newark, Jersey City, Trenton, and Camden showed marked decreases, while those of Paterson and Elizabeth inched upward. Urban Hudson County was the only county to post a loss in population, though slight. Newark, with a population of some 380,000, remains the state's largest city and one of only a handful of American cities with a black majority; in 1970 Newark became the first major city in the Northeast to elect a black mayor. The exodus from the cities is directed, as elsewhere in the nation, toward suburban and rural regions. Areas only a few years ago considered rural are becoming suburban or even urban in character. In the 1960s the population of rural Ocean County jumped more than 90 percent, and other rural counties experienced growth of close to or more than 50 percent. This process is solidifying New Jersey's position as the most urbanized of states after California: about 89 percent of New Jerseyites live in areas designated by the Bureau of the Census as urban. Three counties—Essex, Union, and Hudson—are 100 percent urban, and four more—Bergen, Camden, Middlesex, and Passaic—are more than 95 percent urban.

Patterns of suburban and rural migration

The flight of the white middle class from the cities has been accompanied by an emigration of industry and commerce. Old, outmoded factories are left behind for sleek new buildings out of town, and huge suburban shopping centres have replaced the downtown department stores. This shift means more jobs in the suburbs and rural areas, and the jobs create a commensurate demand for housing. In the end, the homes and apartments probably will go where the jobs are—in the suburbs. The cities and towns bordering these areas will become increasingly black, a situation that is potentially explosive because of the continuing decay of the cities and the poor quality of housing and services the cities can supply. Clearly, the future promises great pressures for, as well as great resistance to, low-cost, integrated housing in the suburban counties.

THE STATE'S ECONOMY

Alexander Hamilton's attempt in 1791 to build the nation's first industrial town at Paterson was a failure. He had the right idea, however, for New Jersey was destined to become an industrial giant. The state now ranks seventh nationally in per capita income and seventh in value added by manufacturing.

Between 1960 and 1970, total buying income in New Jersey increased by 90 percent and retail sales by 12 percent. The work force increased by 22 percent, or 548,000 people, and value added by manufacture by 65 percent. New Jersey's gross state product in 1970 was $40,000,000,000, and total personal income was $33,000,000,000. Average income per household was just under $15,000. One of three New Jersey workers is in manufacturing, compared with a national average of 25 percent. The New Jersey worker earns about 2 percent more than the national average.

Economic activities. One of New Jersey's largest and most prestigious industries is research. New Jersey has the highest number of engineers and scientists per capita in the nation, and New Jersey firms spend 10 percent of the nation's research dollars. Although it is not reflected in the manufacturing statistics, a close correlation exists between research and heavy industry. America's greatest inventor, Thomas Edison, was a New Jerseyite, and he established the nation's first research laboratory in Menlo Park in 1876. There he created the electric light, the phonograph, and all manner of electrical gadgets, as well as pioneering the technology of the motion-picture industry. Edison's primitive laboratory of a century ago has been succeeded by the David Sarnoff Research Center,

Leadership in scientific research

the Bell Telephone and Western Electric laboratories, the Institute for Advanced Study at Princeton, the James Forrestal Research Center, and many more sleek, modern centres dotting the landscape of Central Jersey. New Jersey's major manufacture is electronics products, closely followed by chemicals, in which it leads the nation. It holds high national ranking in the production of clothing, electrical machinery, toys, sporting goods, and stone, glass, and clay products. The state is not noted for its mineral deposits, but the iron found in the South Jersey bogs provided much of the shot and cannon used during the Revolution. Minerals mined today include trap magnetite, iron, uranium, and zinc, as well as sand and gravel.

The spread of industry and housing is costing New Jersey much of its farmland, the most valuable per acre in the nation. Slightly more than 1,000,000 acres remain under cultivation, and gross farm income runs well over $250,000,000 a year. The resort industry is a big factor in New Jersey's economy, especially in the south, where a bad year at the Shore hurts the economic well-being of the entire region. Resorts account for some $2,000,000,000 a year, most of this coming during the summer months at the Shore. But Atlantic City, with its huge Convention Hall and fine old hotels, does a thriving winter convention business. Because of its many industries, the New Jersey economy is highly diversified and usually reflects the health of the national economy. At the end of the 1960s, the unemployment rate was climbing rapidly, reaching over 7 percent by the summer of 1971. The long-dormant housing industry was showing signs of recovery, however, and the New Jersey Economic Policy Council predicted slow but steady economic growth.

The State Division of Economic Development, along with the major utilities and business organizations, conducts an effective program of selling New Jersey to industry. During the late 1960s and early 1970s, the state attracted many new industries, especially corporate headquarters from New York City, largely through its greater space, better transportation, and favourable tax rates.

Transportation. Since colonial days, when New Jersey's toll roads linking Philadelphia and New York were a major industry, transportation has been the lifeblood of New Jersey's economy. The role of transportation in New Jersey can best be appreciated in the Newark area. There, 12 lanes of the New Jersey Turnpike, the busiest in the world, converge with the main line of the Penn Central Railroad, Newark Airport, Port Newark, and Port Elizabeth to provide a steady stream of goods and humanity in a hurry. It is perhaps the busiest transportation centre in the world. The economy of northern New Jersey is bound tightly to that of New York City, and the commercial traffic between the two states is the heaviest in the nation.

Port of New York Authority

In 1921 the states of New York and New Jersey formed the Port of New York Authority—a bistate commission empowered to finance and operate transportation facilities in the New York metropolitan area. The Port Authority, as it is known, is a public corporation operating Newark and Teterboro airports in New Jersey and La Guardia and Kennedy in New York, as well as the Lincoln and Holland tunnels, three bridges, huge piers, bus and rail lines, truck terminals, and two giant towers of the World Trade Center rising above Lower Manhattan.

A similar but much smaller transit complex exists in the Camden area, linking the South Jersey area with Philadelphia. There is a deepwater port at Camden on the Delaware and high-speed transit to Philadelphia. In addition to the turnpike, which travels the length of the state from the George Washington Bridge in the north to the Delaware Memorial Bridge in the south, the Garden State Parkway stretches 173 miles north to south, and the Atlantic City Expressway links that city with the Camden area. Before World War II, New Jersey had one of the finest road networks in the nation. A pay as you go fiscal policy kept the state from building roads fast enough, however, and the highways in North Jersey grew crushingly congested during the 1950s and 1960s. A bond issue approved in 1968 has helped ease the traffic problem, but it seems unlikely that the state can ever catch up with demands. There are about 43,000 miles of railroad track in New Jersey, the most per square mile in the nation. Ten railroads and seven trunk lines cross the state. New Jersey also has more airports per square mile than any other state, with 3,000 aircraft based at its 83 airports and 194 heliports. The largest and busiest field is Newark Airport, which services more than 7,000,000 passengers a year.

New Jersey's transportation future appears to lie in the area of mass transit, a theme that dominated the 1969 gubernatorial election campaign. In 1971 the Governor realized his first breakthrough when the Port Authority agreed to build a new rail line joining suburban Union County with Penn Station in Newark and with Newark Airport.

ADMINISTRATION AND SOCIAL CONDITIONS

New Jersey, on December 18, 1787, became the third state to ratify the United States Constitution. In the early days of the republic it maintained a tradition of legislative superiority, a condition that was somewhat modified in favour of the governor when a new constitution was adopted in 1844. Even then, however, New Jersey's chief executive was one of the weakest in America. Its people were distrustful of big state government, fearful that a strong central government would trample on municipal powers. By the end of World War II, the people were ready for a change. The result was the constitutional convention of 1947, which gave the governor strong new powers and created what is generally regarded as the strongest court system in the United States, with enormous powers vested in the chief justice.

Constitutional framework of government

Governmental structures. New Jersey governors serve terms of four years, and they are permitted re-election to a second term. No other state official runs on a statewide basis, so the governor has no rivals in the executive branch. He appoints, with the advice and consent of the Senate, virtually all top state officers and members of state boards, authorities, and judiciary, and he has the authority to supercede county prosecutors. By virtue of his broad executive and administrative powers, the vast patronage at his disposal, and his unequalled access to the press, radio, and television, the governor of New Jersey is as strong a chief executive as there is in the nation. A two-thirds majority of both legislative houses is necessary to override his veto. The governor can be checked and occasionally defeated by a rebellious legislature or political leaders, but, in the final analysis, governors seldom lose wars, only battles. In the state legislature, reapportioned in 1966 to conform to the "one man, one vote" principle, the Senate is composed of 40 members and the General Assembly of 80. Assemblymen are elected every two years, while senators run for one two-year term and two four-year terms each decade. As late as 1971 the state Supreme Court had failed to approve the reapportionment plan, although it was permitted to stand for the election of that year.

Local government

New Jersey's 21 counties are administered by boards of freeholders, elected on a county-wide basis. The boards vary in size from five to nine members, depending on the size of the county. In addition to these elected officials, the various levels of local government are supplemented by service commissions, boards, and authorities, many of which enjoy wide independence and even autonomy. Attempts to merge municipalities, reduce the number of school districts by consolidation, or strengthen county government have failed because of the fear of compromising local power and prerogatives.

Political life. In national elections, New Jersey is a "swing" state. It leans Republican, and it was the only major industrial state in the Northeast carried by Richard M. Nixon in 1968. In 1969 New Jersey elected its first Republican governor in 16 years, William T. Cahill; he succeeded Richard J. Hughes and Robert B. Meyner, each of whom served eight years in office. In only two of these years, 1966 and 1967, the Democrats controlled both houses of the legislature, a feat they last accomplished more than 50 years earlier when Woodrow Wilson was governor, a post he used as his springboard to the

presidency. Although there were signs that civic bossism was in the first stages of decline as the 1970s opened, New Jersey's political system was long dominated by powerful county leaders who drew their power from the patronage and contracts that they dispensed through control of the courthouse or city hall. The most notorious of these bosses was Frank Hague, who operated as the absolute ruler of Jersey City and Hudson County from 1917 to 1947. For three decades Hague dominated the Democratic Party and heavily influenced the Republicans. His philosophy of government was best summed up in his famous reply to critics: "I am the law in Jersey City."

Financial policies. For decades New Jersey politicians boasted that the state spent less per capita than any other in America. Whether this can be attributed to frugality or to the ignoring of social needs is a matter of debate. New Jersey collected the fourth-lowest per capita tax in the United States as late as 1966, when a 3 percent sales tax was enacted that in 1970 was raised to 5 percent. By 1971 informed opinion was virtually unanimous that New Jersey would have to enact a personal-income tax within a few years. Since New Jersey consistently has avoided the imposition of a broad-based tax for so long, it has been forced to rely heavily on the real-estate tax levied by municipalities to cover their own expenses and those of school districts and counties. At the same time, the state paid comparatively little aid to the local school districts. The result is a property tax in some communities, especially in the cities, that is among the highest in the nation. The state showed signs in the early 1970s of plunging into a tax-reform program, but then there was the difficult question as to whether enough time remained to halt the downward plunge of such major cities as Newark and Trenton.

Social services. Most of the services rendered the citizens of New Jersey come from the state, although most of the major counties maintain institutions of one kind or another, and much funding comes through federal agencies. The state has for several years faced a chronic shortage of hospitals, prisons, and various other institutions, although much has been done to correct the situation since the 1960s.

Higher education

New Jersey has long had a reputation for shirking its responsibilities to higher education, sending 55 percent of its college students out of the state for an education during the 1960s. Indeed, there was no state university at all until New Jersey took over full responsibility for Rutgers University in 1945. Under the leadership of Governor Hughes, the process of converting the six state colleges from strictly teacher-preparation institutes to full-fledged liberal arts schools was begun in the late 1960s. A medical school was begun in Newark during the decade, and in the 1970s construction was scheduled to begin on two new universities. New Jersey is also the home of Princeton University, one of the nation's most prestigious institutions.

Housing, especially in the core cities, is one of New Jersey's most difficult problems. In 1970 it was estimated that some 500,000 housing units in the state were substandard, and, in common with most Northern states, New Jersey was saddled with staggering and spiralling welfare costs.

CULTURAL LIFE AND INSTITUTIONS

The living arts. New Jersey has never been noted as a cultural giant because the vast majority of its citizens are well served by such attractions as the New York theatre or the Philadelphia Orchestra. Still, there are 18 symphony orchestras in the state, all but the New Jersey Symphony Orchestra small and community-oriented. In 1968, however, New Jersey helped correct its reputation as a cultural backwater with the opening of a beautiful new amphitheatre at the Garden State Arts Center, home of the New Jersey Symphony Orchestra. Located on Telegraph Hill off the Garden State Parkway in Monmouth County, the facility has proved to be an extraordinary success, and its programming of music, drama, and dance has been exceptionally well received.

There are 11 summer theatres in New Jersey, most of them located near vacation areas. The McCarter Theater, on the Princeton University campus, is open year round and offers high-quality plays and musical presentations.

Artistic and historical preservations. New Jersey has an unusually high number of museums, 120 in all, many operated in conjunction with historic sites or buildings. The New Jersey State Museum (with a planetarium), located in the state capitol complex in Trenton, the Rutgers Art Gallery, the Newark Museum, and the Princeton University Art Museum are among the better known.

New Jersey's rich traditions are manifested in such historic homes and sites as Washington's winter headquarters in Morristown, where he wrote his farewell address to the Continental Army; Morven, the official governor's residence in Princeton; the restored colonial villages of Batsto and Allaire; the Camden home of poet Walt Whitman; and many others that attract thousands of tourists each year.

Communications. New Jersey depends entirely on New York and Philadelphia network stations for its national television and local news. A state-operated public television system, on ultrahigh frequency, was initiated in 1971. The state's largest newspaper is the *Newark Star-Ledger*. The *Newark Evening News* and the *Newark Sunday News* were the most influential journals, but a long strike in 1971 forced the sale of the Sunday paper and a cutback in daily operations. Other papers include the *Record* of Hackensack and the *Sunday-Record-Call*, the *Trenton Times* newspapers, and *Courier-Post* of Camden.

PROSPECTS

The major challenge facing New Jersey in the years ahead is the regulation of growth so that pollution, congestion, and noise can be controlled and the dwindling supply of land utilized widely. The heavy concentration of population in the northeast makes water supply a special problem, and reservoir sites are scarce.

Problems of growth

Strong leadership will be needed at the state and local levels if the mistakes made in the cities are not to be repeated in the suburbs. If its cities are decaying, facing bankruptcy, and torn by racial turmoil, the situation is not unique to New Jersey, and only national action is likely to cure their ills.

Perhaps New Jersey's most severe and immediate problem is housing. Low- and middle-income housing in the suburbs is badly needed, but restrictive zoning laws and building codes prevented such construction in the 1960s. State and local officials seemed to achieve a new awareness of this problem in the early 1970s, however, and a series of court cases pointed to an end to these practices.

Most students of government and many political and governmental leaders believe that New Jersey will have to face up to governmental reorganization in the years ahead. They argue that there are too many individual municipalities and school districts and that the result is waste, duplication, and inefficiency. Leaders of county government say that the counties are the logical place to concentrate services on a regional basis, but state laws permit the counties little flexibility or responsibility.

In the early 1970s all of these problems were being debated in the state legislature, and the needs were clearly recognized. Local opposition to change, however, remained strong.

BIBLIOGRAPHY

Geography: *The Geology of New Jersey*, bulletin no. 14 of the state Department of Conservation and Economic Development (1915), covers the geography and geology of the state in great detail, as does the *Topographic Atlas of New Jersey*, which contains large maps showing railroads, canals, highways, mines, and quarries.

History: THOMAS FRANCIS GORDON, *The History of New Jersey, from Its Discovery by Europeans, to the Adoption of the Federal Constitution* (1834), gives the best account of the state's role in the Revolutionary War. FRANCIS B. LEE, *New Jersey As a Colony and State*, 4 vol. (1902); IRVING STODDARD KULL (ed.), *New Jersey: A History*, 6 vol. (1930–32); and WILLIAM STARR MYERS (ed.), *The Story of New Jersey*, 5 vol. (1945), are all thorough and detailed works.

Population: The best recent study of the state's ethnic background is JOHN E. BRUSH, *Study of the Population of New Jersey*, 2nd ed. (1958). See also HERSCHEL LEE SCHENECK, *Indians of New Jersey* (1951).

Economy: ADELAIDE ROSALIA HASSE, *Index of Economic Material in Documents of the States of the United States, New Jersey, 1789–1904* (1914), is a prime source for information on New Jersey's industrial economy during the 19th century. HOMER HOYT, *An Economic Survey of the State of New Jersey* (1950); and JOHN T. CUNNINGHAM, *Made in New Jersey* (1954), are also useful. For a current picture of the state's economy, the DEPARTMENT OF LABOR AND INDUSTRY, *Facets of New Jersey*, a periodically updated series of pamphlets, is the best and most concise account.

Culture: The FEDERAL WRITERS' PROJECT, *New Jersey: A Guide to Its Present and Past* (1939), contains an excellent section on the arts. LOLITA L.W. FLOCKHART, *Art and Artists in New Jersey* (1938), also contains valuable information.

Government: The NEW JERSEY LEAGUE OF WOMEN VOTERS, *Spotlight on Government* (1969), is a comprehensive, one-volume study of the state government. *Fitzgerald's Legislative Manual*, published annually, contains a wealth of biographical information on governmental leaders plus election returns, the organization of state departments, lists and memberships of agencies, authorities and commissions, the text of the state constitution, and many other important pieces of information. The New Jersey Tercentenary Commission in 1964 published a 26-volume *New Jersey Historical Series* covering a wide variety of topics. DUANE LOCKHARD, *The New Jersey Governor: A Study in Political Power* (1964), part of the series, is an especially readable and analytical source of information on modern government.
