Pressing. With many oil-bearing seeds and nuts, rendering will not liberate the oil from the cellular structures in which it is held. In these cases the cell walls are broken by grinding, flaking, rolling, or pressing under high pressures to liberate the oil. Many different mechanical devices have been used. The most primitive method is to crush seed in mortars until the oil exudes. In India, the ghani, a bullock-powered mortar and pestle, is used to extract oil from rapeseed and various local nuts and seeds as a cottage-industry type of operation. After the seeds are ground for several hours, the liberated oil is soaked up in rags and removed by hand wringing. There are more than 100,000 ghanis, supplementing the output of modern mills that use mechanical presses or solvent extraction. The lever and wedge, one step more advanced and employed for centuries, is still used in some places. The Romans developed a screw press, described by Pliny, for the production of olive oil. Centuries ago, the Chinese employed the same series of operations followed in modern pressing mills; viz., bruising or grinding the seeds in stone mills, heating the meal in open pans, and then pressing out the oil in a wedge press. The Dutch, or stamper, press invented in the 17th century was used almost exclusively in Europe for pressing oilseeds until the early part of the 19th century, when the hydraulic press was developed. The yield of oil from the hydraulic press was considerably higher than that from earlier processing methods because of the much higher applied pressures. In open presses, the ground seed material was confined in cloths of human hair or, less commonly, camel hair. Pressures on the cake varied from 1,000 to 2,000 pounds per square inch, and in the closed-type press, in which the oil-containing material was confined in a strong perforated steel cage during the pressing operation, pressures of 6,000 pounds per square inch or more were attained. Under ideal conditions the oil content of the hydraulic-press cake can be reduced to about 3 percent, but in practical operation a 5 percent level is average. The modern screw press replaced many of the hydraulic presses because it is a continuous process, has greater capacity, requires less labour, and will generally remove more oil. As ground seed is fed continously into the mechanical press, a worm screw increases the pressure progressively as the material moves through a slotted barrel. Pressures from 10,000 to 30,000 pounds per square inch are attained, and the oil is squeezed out through the slots, leaving a cake containing 3 to 3.5 percent oil under optimum processing and 4 to 5 percent oil under average conditions.

The general sequence of modern operations in pressing oilseeds and nuts is as follows: (1) the seeds are passed over magnetic separators to remove any stray bits of metal; (2) if necessary, the shells or hulls are removed; (3) the kernels or meats are converted to coarse meal by grinding them between grooved rollers or with special types of hammer mills; and (4) they are pressed in hydraulic or screw presses with or without preliminary heating, depending on the type of oil-bearing material and the quality of oil desired. Oil expressed without heating contains the least amount of impurities and is often of edible quality without refining or further processing. Such oils are known as cold-drawn, cold-pressed, or virgin oils. Pressing the coarse meal while it is heated removes more oil and also greater quantities of nonglyceride impurities such as phospholipids, colour bodies, and unsaponifiable matter. Such oil is more highly coloured than cold-pressed oils. Residual meals are concentrated sources of high-quality protein and are generally used in animal feeds. Because certain meals (*e.g.*, castor-bean meal and tung-nut meal) are toxic, they are generally used in fertilizers. In some primitive areas most press cakes are used as fertilizers because of decomposition before or after processing.

Quality variations in pressed oils

Solvent extraction. Cakes obtained by pressing operations still retain 3 to 15 percent of residual oil. When the value of the oil is considerably greater as oil than as a part of the meal, it is desirable to obtain more complete extraction with solvents. Modern commercial methods of solvent extraction use volatile purified hydrocarbons, especially the various grades of petroleum benzin (commonly known as petroleum ether, commercial hexane, or heptane). In large-scale operations, solvent extraction is a more economical means of recovering oil than is mechanical pressing. In the United States and increasingly in Europe, there are many instances of simple petroleum benzin extraction of seeds, mainly soybeans. For seeds or nuts containing a higher oil content than soybeans it became customary to press the material in screw presses to remove a large proportion of the oil before extraction. Since this prepressing also ruptures the cellular structures of oil-bearing materials, most of the residual oil is easily removed with solvents.

A typical extraction system consists of (1) cleaning to remove tramp iron, dirt, foreign weed seeds, and stones; (2) removing hulls or cortex in cracking, aspirating, or screening operations; (3) cracking or rough grinding the kernels, meats, or prepressed cake; (4) steaming (tempering or cooking) of the meats; (5) flaking the small pieces between smooth flaking rolls; (6) extracting the oil with solvent; (7) separating the meal, or marc, from the oil-solvent solution, called miscella; and (8) removing the solvent from both the miscella and the marc. The marc may be toasted or pelletized, or both, for use in animal feeds. Most extracted meals contain less than 1 percent of residual oil. The amount varies depending upon the amount of prepressing, the type of material being extracted, and the efficiency of the extracting system.

An interesting combination of solvent extraction and rendering is the process in which a chlorinated solvent is mixed with wet fresh tissue and the mass is heated to the boiling point of the mixture of solvent and water. When condensation of the vapour occurs, the mixture separates; water is drawn off, and the solvent is returned to the extraction system. The resulting product consists of a dry (low-moisture) extracted meal and miscella containing most of the fat. The high cost of chlorinated solvents is a disadvantage, but the process has promising potentialities because of the feasibility of preparing extracted animal or fish meals that have not been subjected to high temperatures. With a rapidly rising world population there has been concern about protein malnutrition, particularly among children in the developing countries. Fish protein concentrate, FPC, a product prepared by solvent extraction and moisture removal from whole fish, has been suggested as a possible source of highly nutritious protein that could be made available from underutilized fisheries resources. In one process, isopropyl alcohol is used to extract oil from chopped or minced fish; the alcohol simultaneously dehydrates the flesh and extracts the oil; a second process uses a chlorinated solvent (ethylene dichloride) to accomplish oil extraction and dehydration; and a third makes use of petroleum naphthas rather than chlorinated solvents. Acceptance of FPC as a protein supplement would increase production of fish oils.

Fish protein concentrate

Solvent extraction was first practiced in Europe, using batch extractors for the recovery of additional oil from the residues obtained from mechanical pressing. The

greater efficiency of solvent extraction encouraged direct application to oilseeds, and the batch extractor gradually gave way to continuous units in which fresh flakes are added continuously and subjected to a counterflow of solvent. One of the earliest continuous extractors, and a type still considered to be one of the best, was the Bollman or Hansa–Mühle unit from Germany, in which solvent percolates through oilseed flakes contained in perforated baskets moving on an endless chain. After the extraction cycle is complete, the baskets of extracted flakes are dumped automatically and then refilled with fresh flakes to initiate another cycle. Many extractor designs have been proposed, but only a few have found wide acceptance. In the DeSmet extractor, popular in Europe and in a number of developing countries, a bed of flakes on an endless horizontal travelling belt is extracted by solvent percolation. The Blaw–Knox Rotocell has become the most popular extractor in the huge United States soybean industry. The flakes are conveyed into wedge-shaped segments of a large cylindrical vessel. Solvent percolating through the cells falls into the bottom of the extractor housing, where it is picked up by a series of pumps and recirculated countercurrent to the flakes.

Most European extraction plants have been smaller than those in the United States. They are usually multipurpose and can alternatively process several types of oilseeds, depending on the availability of raw materials and the market demands. In contrast, most extraction plants in the United States process only one kind of seed. Historically, oilseed processing was carried out by squeezing or crushing; today processors are still called "crushers," even though almost all processing is by solvent extraction. The size of the crushing plant is increasing rapidly. In 1951 there were 193 soybean extraction plants in the United States with an average capacity of 160 tons per day; in 1969 there were 132 units, with an average capacity of 580 tons, and new installations usually have capacities of 1,000 to 2,000 or more tons per day. World trends indicate a gradual transition to fewer mills with larger individual capacities.

PROCESSING OF EXTRACTED OIL

The extent of processing applied to fats depends upon their source, quality, and ultimate use. Many fats are used for edible purposes after only a single processing step; *i.e.*, clarification by settling or filtering. Most cold-pressed oils (for example, cold-pressed olive, peanut, and some coconut and sunflower oils) can be used in food products without further processing. Tremendous quantities of butter and lard are used without special treatment after churning or rendering. The growing demand for bland-tasting and stable salad oils and shortening, however, has led to extensive processing techniques. But in the less industrialized countries, processing often is limited by lack of facilities, a shortage of technically trained engineers, and added costs for chemicals, which are often in short supply.

Refining. The nonglyceride components contribute practically all of the colour and flavour to fats. In addition, such materials as the free fatty acids, waxes, colour bodies, mucilaginous materials, phospholipids, carotenoids, and gossypol (a yellow pigment found only in cottonseed oil) contribute other undesirable properties in fats used for edible purposes and, to some extent, for industrial applications. Many of these can be removed by treating fats at 40° to 85° C (104° to 185° F) with an aqueous solution of caustic soda (sodium hydroxide) or soda ash (sodium carbonate). The refining may be done in a tank (in which case it is called batch or tank refining) or in a continuous system. In batch refining, the aqueous emulsion of soaps formed from free fatty acids, along with other impurities (soapstock), settles to the bottom and is drawn off. In the continuous system the emulsion is separated with centrifuges. After the fat has been refined, it is usually washed with water to remove traces of alkali and soapstock. Oils that have been refined with soda ash or ammonia generally require a light re-refining with caustic soda to improve colour. After water washing, the oil may be dried by heating in a vacuum or by filtering through a dry filter-aid material. The refined oil may be used for industrial purposes or may be processed further to edible oils. Usually, the refined oils are neutral (*i.e.*, neither acidic nor alkaline), free of material that separates on heating (break material), lower in colour, less viscous, and more susceptible to rancidity.

Batch and continuous refining

Other refining techniques that have been employed include the use of sulfuric acid instead of alkaline agents. This technique removes or destroys many of the impurities in the oils without removing the free fatty acids. For industrial oils, such as linseed oil, that are not required to be low in fatty acids, acid refining is sometimes advantageous. Steam refining, consisting of blowing clean steam through oil at high temperature and under vacuum, may sometimes be used on oils (*e.g.*, coconut oil) that contain few phospholipids or other impurities; or it may be used on oils that have been treated with acetic anhydride to remove the phospholipids and other impurities. Steam blowing removes most of the free fatty acids. Other refining agents that have been used include ammonia, magnesium and calcium oxides, ion-exchange resins, and certain organic bases.

Water refining, usually called degumming, consists of treating the natural oil with a small amount of water, followed by centrifugal separation. The process is applied to many oils that contain phospholipids in significant amounts. Since the separated phospholipids are rather waxy or gummy solids, the term degumming was quite naturally applied to the separation. The separated phospholipid emulsion layer from oils such as corn (maize) and soybean oils may be dried (commercially, these products are called lecithin) and used as emulsifiers in such products as margarine, chocolate products, and emulsion paints. The degumming of crude soybean oil, which has an average phospholipid content of 1.8 percent, provides the primary source of commercial lecithin. To obtain products of lighter colour, hydrogen peroxide may be added as a bleaching agent during the drying of lecithin. The degummed oil may be used directly in industrial applications, such as in paints or alkyd resins, or refined with alkalies for ultimate edible consumption.

Bleaching. If further colour removal is desired, the fat may be treated with various bleaching agents. Heated oils are treated with fuller's earth (a natural earthy material that will decolorize oils), activated carbon, or activated clays. Many impurities, including chlorophyll and carotenoid pigments, are adsorbed onto such agents and removed by filtration. Bleaching often reduces the resistance of oils to rancidity, because some natural antioxidants are removed together with impurities. When many oils are heated to more than 175° C (347° F), a phenomenon known as heat bleaching takes place. Apparently the heat decomposes some pigments, such as the carotenoids, and converts them to colourless materials.

Destearinating or winterizing. It is often desirable to remove the traces of waxes (*e.g.*, cuticle wax from seed coats) and the higher melting glycerides from fats. Waxes can generally be removed by rapid chilling and filtering. Separation of high melting glycerides, or stearine, usually requires very slow cooling in order to form crystals that are large enough to be removed by filtration or centrifuging. Thus linseed oil may be winterized to remove traces of waxes that otherwise interfere with its use in paints and varnishes. Stearine may be removed from fish oils in order to separate the solid glycerides that would detract from its use in paints and alkyd resins. At the same time, fish stearine is more suitable than whole oil for edible purposes. Cottonseed and peanut oils may be destearinated to produce salad oils that remain liquid at low temperatures. Tallows and other animal fats may be destearinated for simultaneous production of hard fats (high in stearic acid content for special uses such as in making candles) and of liquid oil called oleo oil.

Removing traces of wax

For many industrial purposes, fatty acids are required rather than glycerides. Saponification of tallow yields the mixed fatty acids. If these are crystallized and then pressed, a crude grade of oleic acid, termed red oil, is removed, leaving a solid residue termed single-pressed stearic acid. Repetition of melting–crystallization cycles

yields additional red oil and higher quality saturated acids termed double-pressed and triple-pressed stearic acids. Red oil is impure (approximately 75 percent) oleic acid, and despite the name "stearic acid," the solid product contains a ratio of approximately 60 parts of palmitic acid to 40 parts of stearic acid.

Hydrogenation. For many edible purposes and for some commercial applications it is desirable to produce solid fats. Many shortenings and margarines contain hydrogenated (hardened) oils as their major ingredients. The development of margarine and shortening products resulted from the invention of a successful method for converting low-melting unsaturated fatty acids and glycerides to higher melting saturated products. The process consists of the addition of hydrogen in the presence of a catalyst to the double (unsaturated) bonds. Thus oleic or linoleic acid (or their acid radicals in glycerides), which are normally liquid at room temperature, can be converted to stearic acid or the acid radical by the addition of hydrogen.

Limited use was made of this hydrogenation technology in Europe; the greatest potential use for the process lay in the United States, where a vast production of cottonseed oil, a by-product of the Southern cotton industry, awaited developments that would permit its conversion to a plastic fat. The hardening of cottonseed oil in the early 1900s gave birth to the shortening industry. Practical hydrogenation then spread to all countries where margarines and shortenings are produced from liquid oils.

In commercial practice, hydrogenation is usually carried out with vigorous agitation or hydrogen dispersion with a narrow range of catalyst concentration (about 0.05 to 0.10 percent of finely divided nickel suspended on kieselguhr, or diatomaceous earth) in a steel pressure-reaction vessel. The ordinary ranges of temperature and pressure are from 100° to 200° C (212° to 392° F) and from atmospheric pressure to 60 pounds per square inch, respectively. These conditions can be controlled to make the hydrogenation reaction somewhat selective; *i.e.*, to add hydrogen to the linolenic (three double bonds) and linoleic (two double bonds) acid radicals before adding to the oleic (one double bond) acid radicals. The most unsaturated fatty-acid groups are most easily hydrogenated and thus react first with the hydrogen if conditions are right. Copper-containing catalysts are especially selective in the hydrogenation of vegetable oils. If very hard fats with low amounts of unsaturation are desired and selectivity is unimportant, higher temperatures and pressures are employed to shorten the reaction time and to use partially spent catalyst that would otherwise be wasted. After hydrogenation, the hot oil is filtered to remove the metallic catalyst for either reuse or recovery.

Rearrangement of molecular structure

During the catalytic treatment another reaction also takes place—isomerization (rearrangement of the molecular structure) of unsaturated fatty-acid radicals to form isooleic, isolinoleic, and similar groups. Because these isomers have higher melting points than do the natural acids, they contribute to the hardening effect. The unsaturation of natural oils has the *cis* configuration, in which hydrogen atoms lie on one side of a plane cutting through the double bond and alkyl groups lie on the other side. During hydrogenation some of the unsaturation is converted to the *trans* configuration, with like groups on opposite sides of the plane. The *trans* isomers are much higher melting than the natural *cis* form. Simultaneously with the change of some of the unsaturation to the *trans* configuration there is a migration of double bonds along the chain. Thus isomers of oleic acid may be formed with the double bond in any position from carbon atom 2 to carbon atom 17. Many of these isomerized acids are higher melting than the natural oleic acid. Infrared analysis is useful for quantitative measurement of changes occurring during hydrogenation.

Partial hydrogenation of soybean oil selectively converts the highly unsaturated linolenic acid to linoleic and oleic acids, which are more stable to oxidation and better in flavour stability. Simultaneously, isomerization of double bonds coupled with limited increases in the saturated-acid content increases the melting point, so that the product becomes semisolid. Liquid oils possessing much better flavour stability than the original oils can be separated by winterizing such partially hydrogenated products. During the late 1960s hydrogenated–winterized soybean oil became an important commercial product.

Deodorization. Odourless and tasteless fats first came into high demand as ingredients for the manufacture of margarine, a product designed to duplicate the flavour and texture of butter. Most fats, even after refining, have characteristic flavours and odours, and vegetable fats especially have a relatively strong taste that is foreign to that of butter. The deodorization process consists of blowing steam through heated fat held under a high vacuum. Small quantities of volatile components, responsible for tastes and odours, distill, leaving a neutral, virtually odourless fat that is suitable for the manufacture of bland shortening or delicately flavoured margarine. Originally, deodorization was a batch process, but increasingly, continuous systems are being used in which hot fat flows through an evacuated column countercurrent to the upward passage of steam. In Europe, a deodorization temperature of 175°–205° C (347°–401° F) is common, but in the U.S., higher temperatures of 235°–250° C (455°–483° F) are usually employed. About 0.01 percent of citric acid is commonly added to deodorized oils to inactivate trace-metal contaminants such as soluble iron or copper compounds that otherwise would promote oxidation and the development of rancidity.

Characteristics of cooking oils

Olive oil is invariably marketed in undeodorized form. The natural flavour is an important asset, and olive oil, as is true of butter, commands a premium in the market because of its distinctive and prized flavour. The common cooking oils of Asia—soybean, rapeseed, peanut, sesame, and coconut—are consumed in their crude form as expressed from oilseeds. In contrast, deodorized oils are in particular demand in the United States and Europe. For many years the only important vegetable oil consumed in the United States was cottonseed oil, which in its crude form has such a strong and unpleasant flavour that further processing was an absolute necessity in order to render it edible. Because of widespread sale of neutral-flavoured cottonseed oil products over many years, a general preference was developed for odourless and tasteless fats.

Another reason for the practice of deodorizing edible oils in Europe and America relates to differences in oil quality by occidental and oriental extraction techniques. In China and Southeast Asia, edible oils have been produced principally by small, relatively crude equipment. The yield of oil is relatively low, and a minimum amount of nonglyceride substances is expressed from the seed, with the result that the flavour of the oil is fairly mild. In Europe and the United States, oil extraction is carried out in large factories that operate on an extremely competitive basis. Very high pressure expression or solvent extraction is used, and in order to improve yields the seeds are heat-treated prior to extraction. Oils obtained in high yield under such conditions are stronger in flavour than oils prepared by low-pressure expression, and the refining and deodorizing steps are required to improve palatability. The improvement in yields more than compensates for the added costs of refining and deodorizing.

When fats are hydrogenated for manufacture of margarine and shortening, they develop a characteristic sweet, but rather unpleasant, "hydrogenation odour" that must be removed from edible fats by deodorization.

EDIBLE FAT AND OIL PRODUCTS

The oil and fat products used for edible purposes can be divided into two distinct classes: liquid oils, such as olive oil, peanut oil, soybean oil, or sunflower oil; and plastic fats, such as lard, shortening, butter, and margarine. The physical nature of the fatty material is unimportant for some uses, but the consistency is a matter of consequence for other products. As a dressing on green salads, for example, a liquid oil is used to provide a coating on the ingredients; a plastic fat such as lard or butter would be unsuitable. Spreads for bread, foods that require a highly developed dough structure, or icings and fillings

Table 4: Fat Content of Typical Foods

food	fat (%)	food	fat (%)	food	fat (%)
Fruits	0.1–20	Cereals	0.2–7	Fish	0.2–30
Banana	0.2	Rice		Haddock	0.2
Pineapple	0.2	Polished	0.4	Tuna	4
Orange	0.2	Brown	2.0	Salmon	10–15
Apple	0.6	Barley	1.0	Cod	18
Avocado	17	Rye		Meat	5–60
Olive	20	Flour	1.0	Beef	10–40
Vegetables	0.1–2.0	Whole	1.7	Lamb	10–40
Potato	0.1	Wheat		Pork	15–60
Beet	0.1	Flour	1.0	Poultry	2–35
Asparagus	0.2	Whole	2.0	Nuts	40–70
Cabbage	0.2	Corn		Peanuts	45
Carrot	0.2	Meal	1.0	Almonds	55
Tomato	0.2	Whole	4.0	Pecans	70
Onion	0.3	Oats, meal	7.5	Miscellaneous	
Peas		Dairy, eggs	3–85	Cocoa	12–25
Green	0.4	Milk, whole	3.5	Chocolate	50
Dry	1.3	Cheese, cottage	4	Mayonnaise	75–80
Beans		Cheeses (cheddar, Parmesan, Swiss)	25–35	Dressings	25–60

Lima	0.5	White	0.6		
Navy	1.8	Yolk	33		
		Whole	10		
		Butter	80		

with a plastic structure, require plastic fats rather than liquid oils.

Sources of edible products

For reasons related both to history and climate there are pronounced geographical patterns of consumption of fats and oils. The ancestors of the present inhabitants of central and northern Europe obtained their edible fats almost exclusively from domestic animals. The food habits and the cuisine depended on the availability of plastic fats; and butter, lard, margarine, and shortening continue to be their primary fatty-food materials. In contrast, population pressures in the older civilizations of the Orient and the Mediterranean countries of southern Europe, northern Africa, and the Near East have long since made extensive raising of livestock impractical, necessitating that the edible oils of these regions be derived primarily from intensively cultivated vegetable crops. In the tropics, conditions are relatively unfavourable for livestock but are well suited to culture of a variety of oil-bearing plants, many of which flourish in the wild state. In contrast to most high-population-density tropical areas, cattle abound in India.

Dehydrated butter or ghee is an important item of Indian cookery, and a hydrogenated shortening called vanaspati is designed to reproduce the coarsely crystalline plastic texture of ghee.

More than 90 percent of the world production of fats and oils is used in edible products, and the objective of most processing steps is to convert crude fats of low palatability or undesirable physical form into refined products that meet the regional requirements for food fats. In the highly industrialized areas of Europe and the United States, the annual consumption of visible fats—such as lard, butter, shortening, or salad oils that have been separated from the original animal or plant source—varies from 40 to 55 pounds per person in various European countries to 52 pounds per person in the United States. For the world as a whole, the average available supply is 23 pounds per person; and in many areas of South America, Africa, and Southeast Asia, the annual consumption is ten pounds or less per person.

About 40 percent of the dietary fat in the developed countries comes from isolated fats and oils, with 60 percent obtained from basic foods, whereas in the less developed countries most of the dietary fat is obtained from fruits, cereals, vegetables, dairy products, and meats, and relatively little is consumed in the form of isolated fat products. The quantities of fats and oils in conventional food supplies vary over wide ranges. Most fruits and vegetables have from 0.1 to 2.0 percent of fat, with the exception of avocados and olives, which are exceptional in their high fat content (Table 4). Cereals range from 1 to 7 percent, and nuts may contain as much as 70 percent of fat.

INDUSTRIAL USES

Historically, soap has been the largest industrial outlet for fats and oils. Leaching of wood ashes provided the alkaline agent for the first soaps, but as the chemical industry developed, such soft potassium soaps gradually gave way to hard soaps based on sodium hydroxide. Modern soap processing is a sophisticated industry making use of carefully proportioned blends of animal and vegetable fats to achieve the proper balance of foaming ability, detergency, and desirable physical form. After World War II, synthetic detergents manufactured from petroleum products supplanted much of the soap, especially in the United States.

Some hard fats, tallows, and beeswax are still used in candle manufacture, but petroleum waxes also took over a large share of candle production. Considerable quantities of specialty oils and sulfonated oils are used in leather dressing and textile manufacture.

Some oils have properties of medicinal value. Castor oil, for example, has a strong purgative action; fish-liver oils are sources of vitamins A and D; and others such as lard, olive oil, and almond oil serve as vehicles in pharmaceutical preparations. Chaulmoogra oil, which contains unique fatty acids with a cyclic (cyclopentenyl) structure, has been used in treatment of Hansen's disease (leprosy).

Linseed, tung, and other drying oils and large quantities of soybean oil, sunflower oil, and safflower oil are used in paints, varnishes, and alkyd resins. The latex-emulsion paints containing products derived principally from petroleum oil began to find widespread acceptance for interior finishes in the United States in the late 1940s. This trend, which spread to other countries in the 1950s and included emulsion paints for outside use, displaced large volumes of the drying oils in protective coatings. Competition of products from petroleum encouraged (and forced) the development of new products and new markets for glyceride oils. Among the new derivatives were drying-oil products that could be thinned with water. A new industry based on the manufacture of chemicals from fats was started just before World War II and grew rapidly after the war. Soapstocks from the refining of fats and oils were acidified to split out a dark-coloured crude grade of fatty acids, termed acidulated soapstock. Distillation of such soapstock acids provided large quantities of distilled fatty acids with a light colour. Supplementing these acids, both animal and vegetable fats, with and without hydrogenation, were hydrolyzed with water in high-pressure autoclaves. The separated acids were fractionated by vacuum distillation, by solvent segregation, or by both. This made available commercial quantities of relatively pure, single fatty acids. From the fatty acids dozens of products, such as long-chain alcohols,

Development of new glyceride oil products

amines, amides, esters, nitriles, and ketones, were made. These chemicals could be used for many applications directly or as chemical intermediates in the manufacture of other products, such as detergents, plasticizers, special lubricating oils, polyamide resins, and special thixotropic (gel) paints. Modifications of the glycerides themselves, through such chemical processes as epoxidation, copolymerization, rearrangement, chlorination, vinylation, and acetylation, led to more new industrial products.

WORLD PRODUCTION

The principal countries and regions producing various oil-bearing materials (seeds, nuts, and the like) are listed in Table 3. In many cases the fats are not extracted in the countries of origin; instead, the raw materials are exported. Thus Marseille and Rotterdam became centres for copra processing, and Liverpool, Hull, and Hamburg-Harburg developed into centres of oilseed expression. The development of industry in tropical countries and the high cost of transportation, however, have led to the increased production of oils and fats in the countries of origin.

During the two decades from 1950 to 1970 there was a marked increase in the world production of fats and oils (Table 5). Population increased by 44 percent, from 2,517,000,000 in 1950 to an estimated 3,630,000,000 in 1970, but during the same 20 years production of fats and oils increased by 73 percent. Production of edible vegetable oils more than doubled, led by huge increases in soybean, sunflower seed, and rapeseed oils. Palm oils showed a modest increase, but large plantings in the 1960s suggest an increase in production in the early 1970s. Production of industrial oils was static and animal fats increased about proportionally to the increase in human population. During the 1960s a large-scale fish-processing industry developed in Peru, based on the abundant anchoveta (a small anchovy) of the highly nutrient coastal waters. Whale-oil production is decreasing because of overfishing. In 1970, the U.S. Department of the Interior placed the sperm whale on the endangered-species list and prohibited sperm-oil imports.

Table 5: Estimated World Production of Fats and Oils
(000,000 short tons)

	1950	1960	1970*
Edible vegetable oils			
Cottonseed	1,565	2,450	2,655
Peanut	1,835	2,770	3,435

II. Waxes

Waxes differ from fats chemically in that they are fatty-acid esters of monohydroxy alcohols instead of glycerol. A few are esters of dihydroxy alcohols. Moreover, their physiological function as a protective coating on cuticles of leaves and fruit appears to be different from that for fats, because waxes rarely occur as cell constituents. The waxes are difficult to saponify, in contrast with the relative ease of saponification or hydrolysis of glycerides. Many of the waxes melt at high temperatures (*i.e.*, between about 35° and 100° C, or 95° and 212° F) and form hard films that can be polished to a high gloss; therefore, they are used in many kinds of polishes. Their other physical properties are similar to those of the fats. They are soluble in the same solvents and leave grease spots on paper. Latex emulsions consisting of polymers of vinyl and acrylic compounds have partially replaced polishes based on natural waxes, particularly for use on floors.

Constituents of waxes

The fatty acids found in waxes are almost always saturated. They vary from lauric to octatriacontanoic acid ($C_{37}H_{75}COOH$). Saturated alcohols from C_{12} to C_{36} have been identified in various waxes. Several dihydric (two hydroxyl groups) alcohols have been separated, but they do not form a large proportion of any wax. Also, several unidentified branched-chain fatty acids and alcohols have been found in minor quantities. Several cyclic sterols (*e.g.*, cholesterol and analogues) make up major portions of wool wax.

Only a few vegetable waxes are produced in commercial quantities. Carnauba wax, which is very hard and is used in some high-gloss polishes, is probably the most important of these. It is obtained from the surface of the fronds of a species of palm tree native to Brazil. A similar wax, candelilla wax, is obtained commercially from the surface of the candelilla plant, which grows wild in Texas and Mexico. Sugarcane wax, which occurs on the surface of sugarcane leaves and stalks, is obtainable from the sludges of cane-juice processing. Its properties and uses are similar to those of carnauba wax, but it is normally dark in colour and contains more impurities. Commercial production of other waxes such as rice wax and grain-sorghum wax proved unsuccessful. Other cuticle waxes occur in trace quantities in such vegetable oils as linseed, soybean, corn (maize), and sesame. They are undesirable because they may precipitate when the oil stands at room temperature, but they can be removed by cooling and filtering. Cuticle wax accounts for the beautiful gloss of polished apples.

Beeswax, the most widely distributed and important animal wax, is softer than the waxes mentioned and finds little use in gloss polishes. It is used, however, for its gliding and lubricating properties as well as in waterproofing formulations. Wool wax, the main constituent of the fat that covers the wool of sheep, is obtained as a by-product in scouring raw wool. When it is purified it is called lanolin and is used as a pharmaceutical or cosmetic base because it is easily assimilated by the human skin. Sperm oil and spermaceti, both obtained from sperm whales, are liquid at ordinary temperatures and are used mainly as lubricants.

III. Essential oils

The volatile oils of the plant kingdom are called essential oils because they were considered to represent the very essence of odour and flavour. As a practical definition, an essential oil is a more or less volatile material isolated by a physical process from an odoriferous plant of a single botanical species. The oil bears the name of the plant from which it is derived; for example, rose oil or peppermint oil.

Distillation is the most common method for isolation of essential oils, but other processes—including enfleurage (extraction by using fat), maceration, solvent extraction, and mechanical pressing—are used for certain products. Younger plants produce more oil than older ones, but old plants are richer in more resinous and darker oils because of the continuing evaporation of the lighter fractions of the oil.

Function of essential oils

The function of the essential oil in a plant is not well understood. Odours of flowers probably aid in natural selection by acting as attractants for certain insects. Leaf oils, wood oils, and root oils may serve to protect against plant parasites or depredations by animals. Oleoresinous exudations that appear when the trunk of a tree is injured prevent loss of sap and act as a protective seal against parasites and disease organisms. Few essential oils are involved in plant metabolism, and some investigators maintain that many of these materials are simply waste products of plant biosynthesis.

Out of the vast number of plant species, essential oils have been well characterized and identified from only a few thousand plants, and of these only 150 to 200 have been processed commercially for their fragrant products. The oils are stored as microdroplets in glands of plants. After diffusing through the walls of the glands, the droplets spread over the surface of the plant before evaporating and filling the air with perfume. Characteristically, the most odoriferous plants are found in the tropics, where the solar energy is greatest. Many of the essential oils are processed in remote tropical areas under exceptionally primitive conditions.

HISTORY

The history of essential oils is closely intertwined with that of flavours and spices. The first records of essential oils come from ancient India, Persia, and Egypt; and both Greece and Rome conducted extensive trade in odoriferous oils and ointments with the countries of the Orient. Most probably these products were extracts prepared by placing flowers, roots, and leaves in fatty oils. In most ancient cultures, odorous plants or their resinous products were used directly. Only with the coming of the golden age of Arab culture was a technique developed for the distillation of essential oils. The Arabs were the first to distill ethyl alcohol from fermented sugar, thus providing a new solvent for the extraction of essential oils in place of the fatty oils that had probably been used for several millennia.

The knowledge of distillation spread to Europe during the Middle Ages, and isolation of essential oils by distillation was described during the 11th to 13th centuries. These distilled products became a specialty of the medieval pharmacies, and by about the year 1500 the following products had been introduced: oils of cedarwood, calamus, costus, rose, rosemary, spike, incense, turpentine, sage, cinnamon, benzoin, and myrrh.

Distillation was considered as serving to separate the essential from the crude and nonessential with the help of fire, and it met almost ideally the definition of a "chymical" process as expounded by the noted Swiss physician and alchemist Paracelsus (Theophrastus Bombastus von Hohenheim, 1493–1541). Paracelsus maintained that the objective of alchemy was the development of medicines, rather than transmutation of base materials to gold. It

The *quinta essentia*

was his theory that there is a most sublime extractive, the *quinta essentia* (quintessence), which represents the effective part of every drug, and that isolation of this extractive should be the goal of pharmacy. His theories stimulated physicians and pharmacists to seek essential oils by distillation of a range of aromatic leaves, woods, and roots; and the very name essential oil recalls the Paracelsian concept of the *quinta essentia.*

Starting from the time of Marco Polo, the much-prized spices of India, China, and the Indies served as the impetus for trade with the Orient. Quite naturally, such spices as cardamom, sage, cinnamon, and nutmeg were subjected to the pharmacists' stills. By the middle of the 18th century about 100 essential oils had been introduced, although there was little understanding about the nature of the products. As chemical knowledge expanded in the late 1800s and early 1900s, many well-known chemists took part in the chemical characterization of essential oils. Improvement in knowledge of essential oils led to a sharp expansion in production, and use of the volatile oils in medicine became quite subordinate to uses in foodstuffs, beverages, and perfumes.

In the United States, oils of turpentine and peppermint were produced before 1800; within the next several decades oils of four indigenous American plants became important commercially; namely, sassafras, wormwood, wintergreen, and sweet birch.

Since 1800 many essential oils have been prepared and characterized, but only a few have attained commercial significance.

METHODS OF PRODUCTION

The first step in the isolation of essential oils is crushing or grinding the plant material to reduce the particle size and to rupture some of the cell walls of oil-bearing glands. Steam distillation is by far the most common and important method of production, and extraction with cold fat (enfleurage) or hot fat (maceration) is chiefly of historical importance (see below).

Steam distillation. Three different methods of steam distillation are practiced. In the oldest and simplest method a vessel containing water and the chopped or crushed plant material is heated by a direct flame, and the water vapour and volatile oil are recovered by a water-cooled condenser. This original method is being replaced by a process in which the plant material is suspended on a grid above the water level, and steam from a second vessel is introduced under the grid. The volatiles are condensed and the oil is separated. In the third process, the vessel containing the plant material on a grid is heated to prevent condensation of steam, so that dry distillation is attained.

The first and, to a lesser extent, the second methods are subject to significant oil losses because of water solubility of some components. To avoid such losses, the distillate remaining after the essential oil is skimmed off may be redistilled or, alternatively, the water distillate may be added back to the next charge in the distillation vessel. Yields in a single distillation vary, depending on the plant material. The yield from most flowers is less than 0.05 percent; many roots such as angelica or grasses such as citronella have yields in the 0.1 to 1.0 percent range; yields from seeds may be as high as 16 percent (nutmeg); and oleoresins may produce from 10 percent (olibanum, the Biblical frankincense) to 75 percent (gurjun balsam).

In many tropical areas, aromatic plants grow wild or are cultivated as a garden crop. Distillation of the oil is usually a family industry and most often a side occupation. The harvesters produce small quantities of an oil that they then sell to brokers or village buyers who consolidate these products and forward them to exporters. For such processing the simple water stills are used because they are low in cost, easy to operate, and portable, so that they can be moved readily to follow the plant material. Oil of star anise in Vietnam, oil of lemongrass in India, or oil of cananga in Java are produced in this way. In contrast, the highly organized essential-oil industry of southern France uses more complex and permanent facilities. With better transportation the plant materials can be gathered from wider areas, and the lack of portability is more than compensated for by the higher yields obtained from scientifically monitored equipment.

Enfleurage. In the Grasse region of southern France, flowers were extracted with cold fat (enfleurage) long before the introduction of extraction with volatile solvents. This process is applied to flowers that do not yield an appreciable quantity of oil by steam distillation or whose odour is changed by contact with boiling water and steam. A highly purified mixture of tallow and lard is spread on both sides of the chassis, a rectangular wood

Use of the chassis

frame (about 5 × 50 × 40 centimetres, or 2 × 20 × 16 inches) containing a glass plate. When piled one above the other the chassis form airtight compartments with a layer of fat on the upper and lower surface of each glass plate. Each morning, flowers are carefully spread over the fat surface, and the chassis are assembled in a cool, dark room and left for a period varying from 24 hours (for jasmine) to 72 hours (for tuberose). During this time most of the flower oil is absorbed by the fat. The petals are then removed (defleurage), and the process is repeated until the fat is saturated with oil. The final product is called pomade (*e.g.*, pomade de jasmine, pomade

de violet), the most saturated being Pomade 36, because the chassis has been treated with fresh flowers 36 times during the process.

Originally the pomades were used directly; later they were extracted with alcohol. The alcoholic washings are called Extrait 36 when made from Pomade 36, and they reproduce to a remarkable degree the natural flower perfumes. If the alcohol is evaporated, the oil residue, or absolute, is called *absolu de pommade* or *absolu d'enfleurage*.

The process is very expensive, and it is now limited to a few flowers, such as jasmine or tuberose, that continue their physiological activity after picking and thus give higher yields by the cold processing of enfleurage than they would in hot extractions, which stop perfume production.

Maceration. The physiological activity of most flowers stops soon after picking. In this case, it is possible to shorten the long enfleurage process by extracting the flowers by molten fat for one to two hours at a temperature ranging from 45° to 80° C (113° to 176° F). The fat is filtered after each immersion, and after ten to 20 extraction cycles the pomade is sold as such, or it may be extracted with alcohol to yield the extract or the absolute.

Extraction. Since both enfleurage and maceration are rather expensive processes, the essential-oil specialists of Grasse shifted almost completely to extraction for the recovery of essential oils from plant materials that could not be processed by steam distillation. Petroleum naphthas, benzene, and alcohol are the primary solvents. The solvents dissolve not only essential oils but also waxes, fats, pigments, and other cell components. Re-

moval of solvent leaves a semisolid concrete. The concrete is used directly for some applications, but more commonly it is extracted with alcohol, followed by chilling to precipitate waxes, and filtration. Finally, the wax-free alcohol solution is desolventized under reduced pressure to yield the essential oil, the so-called absolute.

Expression. This procedure is applied only to citrus oils. The outer coloured peel is squeezed in presses, and the oil is decanted or centrifuged to separate water and cell debris. The method is used for oil of sweet and bitter orange, lemon, lime, mandarin, tangerine, bergamot, and grapefruit. Much oil is produced as a by-product of the concentrated-citrus-juice industry.

CHEMICAL COMPOSITION

The development of chromatographic procedures, especially gas–liquid chromatography and thin-layer chromatography, as routine analytical techniques during the 1950s and 1960s facilitated the precise identification and determination of the chemical constituents of essential oils.

Constituent compounds of essential oils

Terpenes are by far the most important components, but individual oils may contain appreciable quantities of straight chain, aromatic, or heterocyclic compounds. Thus allyl sulfides are characteristics of oil of garlic, traces of indole and anthranilic acid esters are found in orange oil, straight chain alcohols and aldehydes are recognized in oil of violets, and phenols and other aromatic compounds are common to many oils.

Terpenes, the dominant constituents of essential oils, are built up from units of the simple five-carbon molecule isoprene. Both hydrocarbons and oxygenated compounds such as alcohols, aldehydes, ketones, acids, esters, oxides, lactones, acetals, and phenols are responsible for the characteristic odours and flavours.

In some oils one or only a few components predominate: thus oil of wintergreen contains about 98 percent of methyl salicylate; orange oil, about 90 percent of *d*-limonene; bois de rose, 90 percent of linalool; and cassia, up to 95 percent of cinnamaldehyde. In most oils there is a mixture of anywhere from a few dozen to several hundred individual compounds. Trace components are very important, since they give the oil a characteristic and natural odour.

Essential oils are generally expensive, with prices ranging from several dollars per kilogram on the low side to several thousand dollars per kilogram. The high price of the natural oils coupled with their limited availability has encouraged a search for substitutes. Great progress has been made in the synthesis of individual components such as geraniol, citral, linalyl acetate, and the like. These synthetics have been combined with natural oils to extend supplies, and they have also been blended together in an attempt to duplicate the oils themselves. Such reconstituted oils usually lack certain of the odour notes of the natural products, because of absence of trace ingredients, often unidentified, that may be present in the natural oils. They also tend to have a more "chemical" odour, because of trace impurities in the synthetics that are different from the components of natural oils.

PRODUCTION AND ECONOMICS

Essential oils are used in three primary ways: as odorants they are used in cosmetics, perfumes, soaps, detergents, and miscellaneous industrial products ranging from animal feeds to insecticides to paints; as flavours they are present in bakery goods, candies, confections, meat, pickles, soft drinks, and many other food products; and as pharmaceuticals they appear in dental products and a wide, but diminishing, group of medicines.

The world production of most essential oils is in the range from a few tons per year to a few thousand tons. Pine oil from steam distillation of pine stumps and turpentine from distillation of pine oleoresin are exceptional, with annual volumes of 100,000 and 300,000 tons, respectively; but these products are used primarily as solvents, and neither is used directly by the essential-oil industry, although oil of turpentine is a starting point for the manufacture of synthetic camphor, terpineol, geraniol, nerol, citronellol, linalool, citral, neral, and menthol, all of which are used in flavours or perfumery.

Annual exports by France are approximately 4,000 metric tons, with a value of $40,000,000–$50,000,000. Imports into the United States during 1969 were obtained from 74 countries and had a value of $56,000,000, almost balanced by exports of essential oils from the U.S., with a value of $51,000,000. Table 6 lists the more important essential oils together with the source and approximate world production.

Oil Shales

During the several stages of formation of sedimentary rocks following the deposition of sediments in a swampy or marine environment, there is much interaction of organic and inorganic substances. When the influence of the organic substances becomes pervasive, the resulting sedimentary rock is called organogenic, meaning that it is in large part of organic origin. The organogenic sediments, or bioliths as they are termed, encompass the oil shales or kerogenites. These are layered, cleavable (fissile), dark shales that are rich in hydrocarbons and fossil organic substances.

Processing and uses

Though the inflammable character of oil shale has been known for centuries, its use as industrial fuel was long discouraged by the lower costs of coals and petroleum. The industrial processing of oil shales goes back 100 years all over the world, but the processing of shale oil took on economically important dimensions only in the 1920s. The production of oil from oil shale is costly; first, because shale oil cannot be refined by conventional means, and second, because oil from shale is deficient in hydrogen and hydrogen therefore must be added during the

refining process. Shale oil also contains relatively large amounts of sulfur and nitrogen, the removal of which during the refining process is quite expensive. With the introduction of special shale-processing methods, however, the economic efficiency of both crude-oil processing and that of shale oil becomes almost identical.

Oil shales are worth processing for three purposes: fuel-gas production; the development of a chemical industry based on shale-oil refining; and the extraction of the fissionable materials uranium and thorium and other trace elements (elements that occur in oil shales in very small amounts) from shale. Uranium and thorium together with other such industrially important metals as germanium, vanadium, cobalt, nickel, copper, silver, chromium, molybdenum, and others can be found in the largest quantities in sediments derived from swamp environments and in oil shales.

It was estimated by Victor Goldschmidt in 1933 that the quantity of sedimentary rocks in the earth's crust amounts to 300,000,000 cubic kilometres. The oil-shale and asphaltite reserve is about 10^{13} tons, and their uranium concentration has been estimated as 0.01 percent. As for crude oil, the present world stock is 50×10^9 tons, with 250×10^9 tons more estimated to be in an unproved crude-oil reserve. The quantity of oil contained in oil shale is believed to amount to another 300×10^9 tons.

One part of the trace elements molybdenum, vanadium, copper, zinc, boron, manganese, and arsenic in organic sediments is of biogenic origin; another part accumulated during the diagenesis (chemical and physical changes that accompany the transformation of sediments to solid rock) of organic substances, partly due to sorption and partly by chemical precipitation. In humic rocks, those metals that migrate as cations in the aqueous solutions of the soil or that are reduced to cations by the reductive effect of humic acids become concentrated. Because of the cation sorption property of the humic acids, the concentration of metals in humic rocks can be 10^4 times as great as metal concentrations in subsoil water. A uranium concentration of this magnitude can be observed in the United States and in Sweden even today, derived from the natural waters that originate in granitic detrital areas and that seep through peat layers rich in humic acids.

This article treats the nature and distribution of oil shales, their probable genesis, and the environmental factors of greatest significance. For further information on lithology, see SEDIMENTARY ROCKS and SHALES; for discussions of environments of deposition and diagenetic changes see also articles on CLAY MINERALS; COALS; PETROLEUM; and NATURAL GAS; for information on the status of associated technologies see PETROLEUM REFINING and PETROLEUM AND GAS EXTRACTION.

ORGANIC CONTENT OF OIL SHALES

Bitumens and bituminization

A predominant part of the organic content of oil shales is formed by bituminous materials. The word bitumen is a collective term denoting the mixture of liquid and solid hydrocarbons that either occur in nature or can be extracted from natural substances without decomposition. Bitumens are colloidal systems, sols, that contain resinous or carbonaceous particles of an average molecular weight of 300 to about 3,000. Most oil-shale bitumens, also called pyrobitumens and kerogenes, are insoluble. The term kerogen was applied for the first time in the description of the shales in Scotland, when it was used to refer to the organic mineraloid of indefinite chemical composition that is the source of the oil when distilled. The term kerogenite is applied not only for kerogen-bearing sedimentary formations of shaly structure but also for other ones containing kerogen. The formation of bitumen takes place in nature in the metamorphism of fossil organic substances under definite chemical and physical circumstances; the term bituminization is used in geochemistry for the designation of the progressive development of hydrocarbons in organogenic materials.

On land or in areas periodically flooded by water the organic sediment can, either continuously or periodically, get into contact with the oxygen of the atmosphere. The end-products of this limited oxidation (*i.e.*, carbonization) are humus or coal (carbonaceous rocks). Humite coals are the products of the peaty sediments of accumulated terrestrial vegetation. Water plays an important part in material transport as well as in covering the organic sediment with layers of mineral sediment. The organic material of sapropel coals (formed from thick deposits of the organic remains of marine plants and animals) is of aquatic origin. They accumulate as underwater sediments in larger pools of stagnant water that are overgrown with coal-forming vegetation and inhabited by algal colonies. In dry seasons, when shallow waters dry up, they perish, leaving behind yellowish or brown elastic remains. Sediments of this kind can be found in the southern part of Lake Balkhash, in the U.S.S.R.; in the coastal regions of Lake Coorong in southern Australia; in Mozambique; and in the area north of Lake N'hangella.

Today carbonic sedimentation takes place in areas where the oxidation of organic substances is limited and the rate of bacterial decomposition is low. These formations are characteristic of cold and moderate climatic conditions. In the tropics, however, where temperatures are high, intensive bacterial activity and a rapid oxidation of organic substances are dominant.

Generation of crude oil

A large part of the living organisms of the oceans can assimilate hydrocarbons photosynthetically from dissolved CO_2, carbon dioxide; and on their perishing and sedimentation, these hydrocarbons form the starting material of sapropel oil and bitumen (oil algae). Oxygen is excluded from the very beginning of the metamorphism of aquatic sediments. A maximum bacterial activity is characteristic of the bituminization process under anaerobic (lacking in oxygen) conditions (enrichment in hydrocarbons) and the end-product of the process is petroleum or crude oil. The "pure" processes of carbonization and bituminization depend on the environmental conditions and also may be present in a complex form. The mixed appearance of inorganic sediment-forming components and the end-products of coalification and bituminization is representative of this fact. Figure 1 shows the main carboniferous sediment types with different concentrations of these three components and their nomenclature.

From F. Pettijohn, *Sedimentary Rocks* (1949); Harper & Row

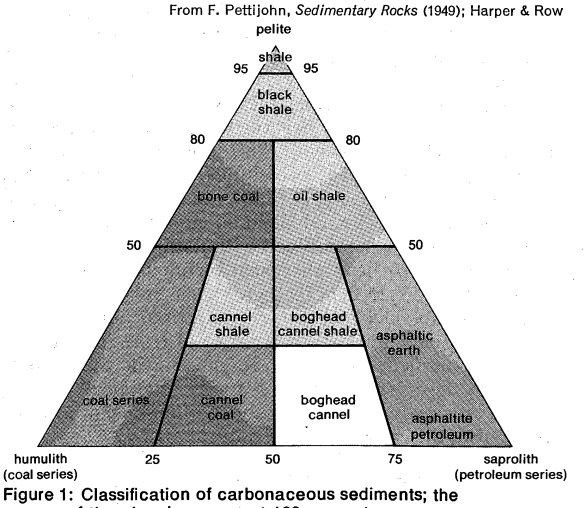

Figure 1: Classification of carbonaceous sediments; the apexes of the triangle represent 100 percent.

PROPERTIES OF OIL SHALES AND RELATED COALS

Kerogenic shales, which may be regarded as the "parent rocks" of crude oil, contain transitional bituminous substances that possess certain qualities of both petroleum and coal. They are brown to black, of low specific weight, inflammable, and burn with a sooty flame; if heated above 350–400° C, they yield oil. Their external structure is laminar and in a stratigraphic section, alternating darker and lighter strata correspond to the periodic changes of organic content. They are quite resistant to the oxidizing effect of air. Chemically, they are various mixtures of clay, shale, limestone, and organic substances. From the point of view of mineral composition, they mainly consist of silica, iron, aluminum, calcium, magnesium, and sodium carbonates, silicates, oxides, and sulfides.

Organic substances are contained in shales in the following main forms: soluble liquid hydrocarbons, soluble asphalt, and insoluble kerogen, or pyrobitumen. The organic content appears mainly in the form of mineraloid kerogen, which is insoluble. In superior shales the kerogen content can amount to 20 or 30 to 50 percent. The exact chemical composition of kerogen still has not been established. It is certain, however, that the kerogen substance of the various shales is polymerized in the same way; they are stereopolymers in which carbonyl, carboxyl, and phenolic hydroxyl groups can be found. The reason for the high insolubility can be explained by the giant-sized macromolecules of kerogen. The elemental composition of kerogen is as follows: carbon 69–80 percent; hydrogen 7–11 percent; nitrogen 1.2–2.5 percent; sulfur 1–8 percent; oxygen 9–17 percent. In a thin section, kerogen can be recognized through the presence of colloidal globules or macerated plant or algae remains.

The chemical composition of shale oil is still controversial. Kerogens probably consist of aliphatic groups, which can be regarded as ethers, formed by the combination of hydrocarbons and perhaps alcohol derived fatty acids.

Figure 1 demonstrates that with an increase of the kerogen content of oil shales, they turn first into torbanites and boghead coals, and then gradually into cannel coal. In this way, these formations can be conveniently distinguished from the members of the peat–anthracite series.

Boghead coals

Boghead coals differ from normal coal because, upon destructive distillation, they yield paraffins and olefins whereas coal yields aliphatic hydrocarbons. There are abundant torbanite occurrences in France, New South Wales, South Africa, and in the northern part of the United States. The torbanite of Scotland seems to be quite homogeneous and compact and seldom reveals interlayers. The organic mineraloid in it shows yellowish transparency and can be regarded as the remains of *Pila scotica* algal colonies. The Permo-Carboniferous kerogen shale of New South Wales is largely made up of the alga *Reinschia australis*. At Satmar, South Africa, where a large torbanite occurrence was under exploitation in the 1970s, the microscopically recognizable fossil algal remains are known as *Botriococcus brauni*. This formation is a good example of the close association of torbanite with a different kind of coal. Torbanites generally contain no massive plant remains, which indicates that they have not been formed from normal peat. Their high ash content indicates their aquatic origin. The organic content of a highly pure boghead coal occurrence in Australia known as coorongite is provided exclusively by *Elaeophyton coorongiana*, oil algae.

Sapropelic coals (algal coals) can be the component parts of coal formations of any geological age. The oil algae recognized in Tertiary bogheads created large one-celled colonies with very thick, bituminous cell walls. In coastal regions these are usually known as balkasite and coorongite. Marahunite, named for Marahu, Brazil, its place of occurrence, is also a kind of brown coal, occurring primarily in Cretaceous or Pliocene formations. A marahunite colony consists of a soft streak of several metres width. The Australian wollongongite and hartleyite, as well as the Siberian closterite, the latter having received its name from the *Closterium* algae, also belong to the populous category of the bogheads. Boghead coals occur in France, Saxony, Poland, and North America in Carboniferous rocks. In the boghead of Poland, eualginite dominates. In shallow and frequently drying waters, mushroom colonies develop and turn alginite into eualginite. It is a common peculiarity of the bogheads that they are rich in nitrogen and pyrite sulfur and that no testacean fossils occur in them. Boghead coals yield dark green shale oil, rich in paraffins, when they are heated up to 460° C in closed retorts.

Cannel coals

A characteristic type of Carboniferous coal is cannel coal, also referred to as spore-pollen coal. It burns in a long, soft, sooty flame and its name refers to the fact that it will even catch fire from the flame of a candle. To the naked eye, cannel coal resembles boghead. Antraxylon predominates among its components, and microscopic spores, algal remains, or even huminitic components may occur. In Carboniferous cannels the quantity of soluble bitumen and distillable tar content is very high, and these give off numerous gaseous products during combustion. Tertiary spore-pollen coals do not have the same tar-yielding ability. It is thought that the origin of cannel begins with the sinking of spores in shallow pools and small still lakes at neutral pH (pH = 6–8) and under aerobic conditions. Following the filling of these pools and lakes, anaerobic conditions probably prevailed. Although the spore content is characteristic of cannels, in certain boghead cannels a considerable amount of algae is present. Algae are completely missing or are insignificant in common cannels. No sharp distinction can be made between cannel and boghead coals on the basis of algal or spore content, because they are extremely similar with respect to their elemental chemical composition.

Dysodile, or paper coal, constitutes a typical transitory stage between algal coal and spore-pollen (boghead-cannel) coal. It occurs in Germany, Brazil, in the Etna region of Italy, and in Bohemia (Cypres Shale). It is grayish yellow, laminated, thin, and flexible and contains the remains of animal organisms. Its composition is like that of oil shales.

Fimmenite may be regarded as an even purer kind of spore-pollen formation, dating back to the Eocene period. In the Geisel Valley of Germany, it is known as pollen coal. Both carbonization and bituminization occur during the formation of the oil-shale–boghead-cannel coal sequence.

ORIGIN OF OIL SHALES

The diagenesis of coal formation is relatively well known because the consecutive members of the carbonization process in the peat–anthracite sequence are well illustrated in nature. As far as the diagenesis of petroleum is concerned, however, the several empirical rules available primarily refer to the final kerosene state and have little to do with the process of crude-oil formation. In the early stage of the diagenesis of organic substances, bacterial activity is most important because it eliminates most of the nitrogen and oxygen from the organic substance and thus transforms it to a chemical composition closely connected with crude oil. It has been proved that methane in recent sapropelic sediments, for example, is the result of anaerobic bacterial activity. At present, there is no proof that the formation of the higher members of the hydrocarbon series is due to anaerobic bacterial activity.

Diagenetic factors

The reactions that produce liquid hydrocarbons from organic substances contained in shale are somewhat better known. The catalytic effect of clay minerals (*q.v.*) plays an important role. Controlling this process in natural environments is difficult. It is suspected that natural radioactivity may be instrumental in oil formation. Laboratory experiments have been carried out to reconstruct the diagenesis of natural oil. Assuming that change of temperature is the main diagenetic factor, a sample of brown coal was heated slightly in order to expedite bituminization. Afterwards, the end-products of the laboratory experiment were successfully identified with the paraffins of the Gippsland crude oil. Thus it was proved that the crude oil of the Gippsland Basin is likely to have been formed *in situ* from low ranking Cretaceous or Eocene coals.

General opinion holds the crucial differences among the various kinds of organic sedimentary formations to be not so much the result of different mechanisms of sedimentation but rather of the chemically distinctive features of the organic ingredients, distinctive character of their decomposition, and the conditions of their diagenesis. The most significant parameters of diagenesis of organic substance exercise their influence during the entire period of metamorphism. In the depositional period, a rise in temperature causes the dehydration of an organic substance. The effect of dehydration on the increase of reaction speed is generally known in terms of the speed of bacterial effects and of catalytic reactions. Heat effects often will render the bitumen content of oil shales into oil even under natural conditions because of the cracking of hy-

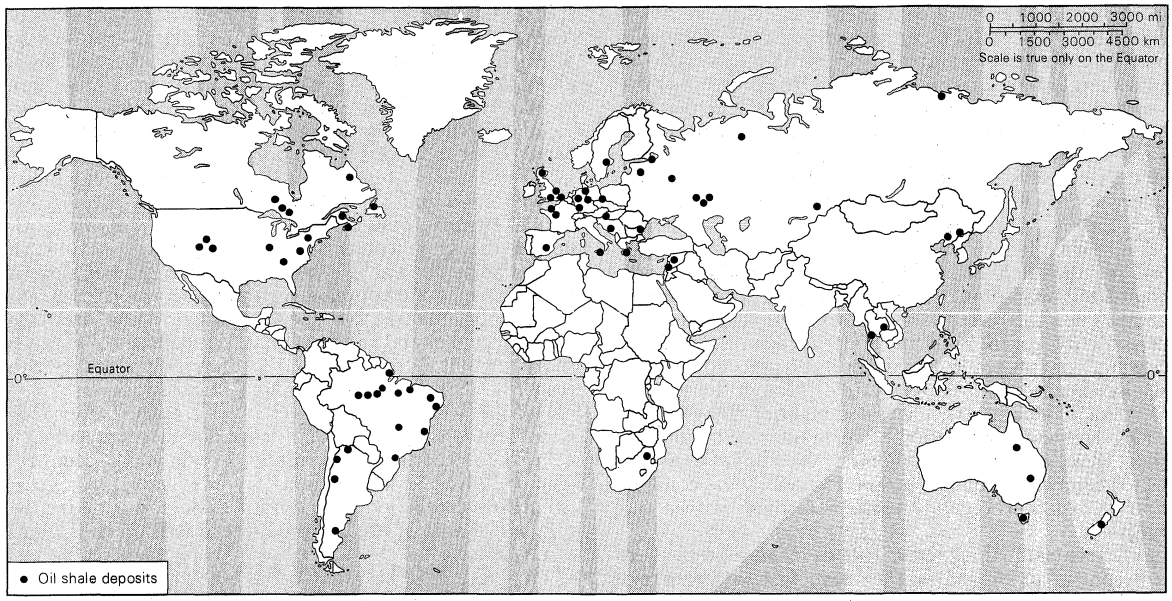

Figure 2: World distribution of oil-shale deposits. No deposits are known in Antarctica.

drocarbon chains. At temperatures above 350° C, oil shales yield gaseous products. The presence of porphyrins in kerosene and bituminites, however, makes it likely that temperatures could not have exceeded 200° C in the course of their diagenesis. In geochemical processes, the temperature and the time factor can replace each other to a certain degree on the basis of their interdependence in reaction speed.

This rivalry of the temperature and time factors is the reason ancient organic sediments can occur in the earth's crust with a lower degree of carbonization than more recent organic sediments. In the course of organic diagenesis, in the processes of bituminization and carbonization, certain age features can be recognized, but as far as the mechanism of the processes is concerned time and temperature are interdependent.

The role of pressure cannot be dismissed in the transformation of organic substances into coal and bituminous rocks. The uninterrupted, joint presence of all diagenetic factors, combined with environmental influences of organic and inorganic origin, lead to the formation of kerogenites of extremely varied nature. The exceptional feature of the Green River Shales in North America, for instance, is that they are not laminated. Because it is principally dolomitic limestone, the designation limestone kerogenite would describe it better. The structure of the rock is characterized by consecutive darker and lighter bands, which accord with the seasonal stratification of organic and inorganic substances. In periods of excessive rainfall, the dissolved carbonates formed highly calcareous layers, which straddle the oil-shale layers that were formed in the basins of Eocene Lake Uinta, Lake Goshute, and others (see TERTIARY PERIOD). The basins underwent considerable horizontal as well as vertical changes.

Environmental influence on oil-shale characteristics

The rocks of the Green River Formation are studied extensively because of their hydrocarbon content, especially ozokerite, albertite, gilsonite, and wurtzilite, which are naturally occurring solid or asphaltic pyrobitumens. Gilsonite forms thick branched veins that emanate from oil shale over long time periods. The migration of liquid gilsonite can be observed even today, where this bituminous substance diffuses into sandstone in the southern part of the Uinta Basin, Colorado. In other places, ozokerite has been found in brecciated (fractured and broken) inorganic sediments. The asphaltic sediments of the Uinta Basin show a crucial difference from the younger sediments of the basin, a difference related to different conditions of sedimentation.

The lower strata of the water of modern seas are progressively less rich in oxygen, particularly in places that are free from turbulences and currents. Life is absent in such zones, and the organic component of the sediments sinks down from the upper, better-aerated layers. The Paleozoic black shales containing graptolites (ancient marine organisms) of such origin are partly oil bearing and date back to the Devonian, Carboniferous, and Lower Jurassic periods; they are of essentially identical quality. Posidonia Shales, lithologically and from the point of view of the character of their fauna, represent equally anaerobic sedimentary conditions. Bottom-living forms are characteristically absent, and the fauna consists principally of cephalopods, together with lamellibranchs such as Posidonia, believed to be a form living attached to free-swimming cephalopods or to floating seaweed. Jet is often recognized in them as an isolated carbonic substance, proved to be a material of woody texture. These sediments, rich in floating or swimming organisms and essentially devoid of bottom dwellers, suggest that in Württemberg anaerobic conditions prevailed on the Jurassic sea bottom.

The environmental factors of recent sediment formation can be studied in the sediments of the Mexican seacoast. Both sapropelic and humitic sediments are formed, the further destiny of which is determined in nature by the wide-ranging variation of carbonization and bituminization, as these processes are determined by different environmental conditions.

OCCURRENCE AND DISTRIBUTION OF OIL SHALES

Some of the most significant oil-shale occurrences and their basic characteristics are described below. This survey is not exhaustive, as indicated by the world distribution map (Figure 2).

Lothian Shale. Important shale kerogenite beds can be found in the calcareous sandstone formations of West Lothian, in Scotland. The exceedingly thin stratification of the shale is not discernible to the naked eye.

The rock comprises finely dispersed spore and cuticle remains; yellowish or reddish ball-like forms in the shale have been verified as unicellular algae embedded in an argillaceous (clay-rich) matrix, which is impregnated with bituminous substances. This oil shale most likely accumulated in either shallow water or well-oxygenated lagoons.

Kolm Shale. Spore coal with an ash content of about 30 percent occurs in Cambrian shales. It is abundant in bituminous substances and exemplifies the cellular occurrence of bitumens. The shale layer is radioactive, the uranium content is 50–100 parts per million, and at some places is as much as 200 grams per ton.

The stratigraphic age of the lenticular shales containing the Kolm lenses is Upper Cambrian, based on the presence of the trilobite *Peltura scarabaeoides.* In Swe-

den, oil shale is the raw material base of the uranium industry. The most significant centre of processing is to be found in Göteborg. The shale comprising the Kolm lenses contains an average 10 percent of kerogen and 3 percent of the clay-limestone component.

Chattanooga Shale. A highly radioactive black shale is found in the Antrim-Chattanooga-Woodford area of the United States. Its bitumen content is usually high. In some areas intense gasification has been detected. It is thought by some workers that the formation of natural gas may be due to radioactivity (as a heating mechanism), although the irregular occurrence of the gas is not compatible with the general, evenly distributed, high radioactivity of the material.

Copper Shale. Black clay shale with high copper, sulfur, and bitumen content containing 0.5–3 percent copper, as well as silver, zinc, lead, iron, molybdenum, vanadium, and a small amount of other metals, occurs at several places in Germany, where it formed in shallow bays during the Zechstein Period. River-carried sulfates were changed into sulfides by reduction processes and then precipitated from the solution. The thickness of the layer is 25 to 30 centimetres. Its most important occurrences are at the foot of the Harz Mountains, at the fringes of the Thuringian Forest, in Hessen and Baden-Württemberg, and in Upper Bavaria and Westphalia in the Posidonian Shales. The sulfide minerals are finely dispersed in the clay that is saturated with bitumen. Of the German copper production, 90 percent is covered by the oil-shale raw material. Molybdenum also is extracted from it. Its kerogen content is relatively low (10 percent); its inorganic component consists of 30 percent clay, 25 percent limestone, and 6 percent pyrite, and the average silicate content is 28 percent.

Tasmanite. A distillable, shaly coal found in Tasmania in Carboniferous coal beds with an average thickness of 1–2 m (3.3–6.6 ft) mainly consists of carbonized polliniferous grains. Tasmanite contains a resinlike polycyclic compound with a molecular weight of about 1,400: $C_{90}H_{134}O_{15}(OH)_2$. The pyrolitic products of this compound are liquid hydrocarbons with 72.62 percent C, 9.18 percent H, and 18.21 percent O. The components of tasmanite are, respectively: kerogen 25 percent, clay 9 percent, carbonate 1 percent, pyrite 0.1 percent, and silicates 65 percent.

Green River Oil Shale. The oil-shale layers in the basins of the Piceance, Uinta-Washakie, and the Green Rivers cover exactly 42,000 square kilometres (16,216 square miles). The sedimentary layers extend over the states of Wyoming, Utah, and Colorado. At present they form the world's largest known natural hydrocarbon reserve.

The oil reserve in this territory is an estimated 270 $\times 10^9$ tons. Particularly exploitable layers, rich in oil, can be found in the Piceance Basin in northwestern Colorado, where a ton of oil shale yields 95 litres (.60 barrels) of oil. In the oil-shale layers of the Green River, the organic substances, varying from zero to 80 percent, consist mainly of fungus spores, but there are also spore and pollen grains of higher order plants. The Green River Formation itself is situated on a lacustrine bed, following a lenticular pattern, in a layer of 460 to 610 metres (1,500–2,000 feet) thick, flanked by marly sediments of the Wasatch and Bridger formations. The formation is of Eocene age, and the shape of the layers suggests that the lake underwent major vertical and horizontal changes during this time interval.

In the U.S., apart from oil shale, other oil-impregnated sediment reserves are estimated at 500,000,000 tons.

Satmar Torbanite. There is a torbanite occurrence at Satmar, South Africa, eight miles north of Ermelo. The layer is 135 centimetres (53 inches) thick. The upper 51 centimetres (20 inches) make up a coal layer of moderately laminated structure, which changes vertically into torbanite. The torbanite layer proper is only 36 centimetres (14 inches) thick. The microscopic investigation of the torbanite layer revealed that the layer proper is made up of the fossil remains of huge algal colonies of *Botryococcus braunii* or *Elaeophyton coorongiana.*

Kuckersite. A special boghead coal on the territory of the Estonian S.S.R., termed kuckersite, dates back to Ordovician-Silurian time. It is a relatively soft, light brown rock of maritime origin; its algal material is *Gloecapsomorpha prisca,* but its fauna numbers 230 maritime species. Kuckersite usually occurs together with bituminous shaly limestone. Its kerogen content is of uniform composition, with an 18–20 percent content in the upper layers and 40–50 percent in the lower ones. The Baltic oil-shale field extends over several basins with its layers almost completely horizontal and at a depth of 5–10 (16–33 feet) or 100–200 metres (330–660 feet). The total thickness of its six occurrences is 4–5 metres (13–16 feet), which, on the territory of the Estonian S.S.R., is made up of six shale layers (about 3.0–3.2 m [9.8–10.5 ft]), and four levels at Leningrad and Gdov (about 1.8–2.0 m [5.9–6.6 ft]). Its heating value approximates 3,500 calories per kilogram. At distillation it yields 18–20 percent crude oil. The Baltic oil-shale reserve amounts to an estimated 14 $\times 10^9$ tons, of which 10.5 $\times 10^9$ tons are in the Estonian S.S.R. The growth of the Estonian oil-shale production for a recent 25-year period is as follows (in millions of tons): 1940, 1.9; 1950, 3.5; 1955, 7.0; 1960, 9.2; 1965, 15.8.

There are additional important oil-shale occurrences in some other areas of the U.S.S.R.: in the eastern part of the Kazakh S.S.R. (Zaysan), in the territories to the east of Lake Ladoga and Lake Tsud, in the Caucasus, in the Ukraine and in western Siberia, and also in the Volga Basin.

Chinese deposits. The largest oil-shale occurrences are in Fushun and Huatian, in northeastern China, where the largest coal basins also are located. The oil-shale deposits contain 6–10 percent oil. In Manchuria, large-scale coking of bituminous coals has been started. In a similar way, oil shales are also cokified in other parts of the country, too. The quantity of exploitable oil in the Chinese oil fields amounts to an estimated 1 $\times 10^9$ tons. In 1955 the amount of processed shale oil was less than 1,000,000 tons; in 1965 it increased to 9,300,000 tons.

Brazilian deposits. Brazil has tremendous oil-shale reserves in the states of São Paulo and Paraná. These oil shales, of Tertiary formations, rank among the most significant occurrences in the world. The investigation of the Brazilian deposits and the final estimation of their contained reserves was underway in the 1970s.

BIBLIOGRAPHY. A great deal of information concerning the characteristic properties of oil shales, their sources, and special problems of exploitation may be found in the proceedings of meetings, such as the "Proc. Fifth Symposium on Oil Shale," *Colo. Sch. Mines Q.,* vol. 63, no. 4 (1968); and *Oil Shale and Cannel Coal,* vol. 2 (1951), devoted to the proceedings of the Second Oil Shale and Cannel Coal Conference. The transitional character of kerogene rocks, their limnological and their stratigraphical properties are treated, together with the general features of coal sediments and petroleum, in the following works: B. NAGY and U. COLOMBO (eds.), *Fundamental Aspects of Petroleum Geochemistry* (1967); A.I. LEVORSEN, *Geology of Petroleum,* 2nd ed. (1967); W. FRANCIS, *Coal: Its Formation and Composition* (1954); and D.W. VAN KREVELEN, *Coal: Typology, Chemistry, Physics and Constitution* (1961).

Data on world distribution, exploitation, and technology, with many references, are included in H.S. BELL, *Oil Shales and Shale Oils* (1948); and N.I. ZELENIN *et al.,* "Chemistry and Technology of Oil Shales," in Russian (1968); and F. MAYER, *Erdöl Weltatlas* (1966). A large source of modern information on oil shales is presented periodically in the following journals: *Oil and Gas Journal* (weekly); *World Oil* (14/yr.); *Zeitschrift für Angewandte Geologie* (monthly); *Erdöl-Erdgas-Zeitschrift* (monthly); and *Erdöl und Kohle* (monthly). Each year maps, production figures, and geological data for all known oil and gas pools in the entire world are published in August by *World Oil* and in December by the *Oil and Gas Journal.*

(M.Sz.)

Okavango River

The Okavango River, the fourth longest river in southern Africa, runs for 1,000 miles (1,600 kilometres) from Angola, where it is known as the Cubango, to the Kal-

ahari. Flowing generally southeastward from the point where it rises, it forms part of the Angolan–South West African border before it crosses South West Africa's narrow Caprivi Strip to enter Botswana, where it empties into the vast Okavango Swamp in the desert. The river—formerly sometimes called the Okovango—derives its name from the Okavango people of South West Africa. David Livingstone, the Scottish missionary and explorer, and the first European known to have seen the Okavango, reached the swampy delta in 1849.

Although it often brings water to a parched land, the river's resources remain largely unused, and its banks are only sparsely settled. In the early 1970s various plans for the utilization of its immense water resources were being considered, in part with the assistance of the United Nations Development Programme. They included irrigation schemes for the river's middle course, the diversion of water from the swamps for industrial development, and the establishment of the Okavango Swamp as a wildlife sanctuary and tourist attraction. (For a related physical feature, see KALAHARI.)

The river's course. *The upper course.* The river rises as the Cubango just south of Vila Nova, Angola, on the Bié Plateau, at an altitude of 5,840 feet. The turf-clad granite plateau surface receives an annual rainfall of 52 inches and is also the source of other smaller headstreams, including the Cuchi River, an important tributary.

The Cubango River

For the first 230 miles of its course, the Cubango flows over hard granite, gneiss (a coarse-grained rock in which bands containing granular minerals alternate with bands in which schistose materials predominate), and metamorphosed rocks that were formed during the Precambrian Era, more than 570,000,000 years ago. The river is frequently broken by rapids. Its generally uneven and occasionally rugged course suggests that in this area the river flows over underlying older rocks, whereas at an earlier time it may have traversed an overlying, younger surface. Below the Cuchi confluence near the town of Caiundo, the riverbed narrows abruptly from about 900 feet to about 300 feet. There, the fury of the falling waters gives the rapids their name of Richo Riacantento, or Eye of the Rock.

The middle course. To the south of Caiundo, the river passes from the hard-rock surface to the Kalahari sand and the character of its valley changes. The river channel cuts through the western side of a valley floor less than a mile wide and bounded by cliffs of compacted sand capped by ancient river gravels. As it flows toward the South West African frontier, the river continues to erode its valley to depths occasionally exceeding 200 feet. Its channel is often bounded by almost vertical cliffs in which layers of hard silcrete (a quartzite) and calcrete (a limestone) are exposed. An interesting and somewhat puzzling feature in this stretch is the Tandaué Chana, a dry channel that runs parallel to, and some 10 to 15 miles to the west of, the Cubango. The channel is a relic of former flow patterns during times of flood. It turns abruptly eastward and joins the river before it reaches the international boundary.

Below its confluence with the Cuito River, the Cubango has removed the sand cover from parts of the underlying rocks to expose great areas of lavas between 190,000,000 and 136,000,000 years old. Near Andara, in the Caprivi Strip, ancient quartzites also have been exposed. At the end of this rocky stretch the river, again flowing to the southeast, once more passes onto the Kalahari sand surface at Popa Falls, after which it is known as the Okavango.

The lower course. Below the falls, the river enters its swamp tract in Botswana territory. For the first 70 to 80 miles it flows between a well-defined sand scarp on the northeast and a low rise in the sandveld surface to the southwest. During this stretch, the width of the swamp increases from a minimum of about one mile in the north to a maximum of seven miles in the south. This relatively narrow section then comes to an abrupt end, after which the river spreads out to form a triangular-shaped delta, the base of which extends for about 150 miles. It forms a drainage line—its parts known as the Thamalakane River and the Ngabe River—that drains southwest toward Lake Ngami and northeast to the Mababe Depression. Flow from the Thamalakane occurs sporadically through the Boteti (or Botletle) River to Lake Xau (Dow) to the southwest and to the Makgadikgadi Depression in the west; this flow may not occur for years at a time.

The delta. The delta region is known as the Okavango Swamp and covers an area of about 6,500 square miles (16,835 square kilometres). It is divided into two relatively distinct sections by Chief's Island, which stretches for about 40 miles in a southeasterly direction and is about ten miles wide. The main channel issuing from the river is called the Ng-gokha River and divides at the island into an eastward continuation of its own channel to the north and the Taokhe (or Taoge) and Boro channels to the west. The Taokhe, the westernmost channel, is almost entirely choked by a dense growth of papyrus, while the Boro is the main distributary to the Thamalakane River. To the northeast of Chief's Island, the Ngokha divides into the Borokha-Santantadibe Channel to the east and the Moanachira Channel that forms the northeastern limit of the swamp and flows into the Mababe Depression.

The Okavango Swamp

Peoples. In Angola, between Caiundo and Cuangar, the dry, sandy thornbush country through which the river flows is virtually uninhabited, and vast areas are uncharted. The riverbanks, however, are thinly settled by the Kwangare tribes, who live mainly by fishing and subsistence agriculture. A few small bands of Bushmen roam the territory between the Cuito and Cuando rivers. The South West African territory on the river's banks is inhabited by the Okavango people, who engage in agriculture and stockbreeding. The Kaba (Bayei), Bagereku, and Mbukushu tribes live on the islands in the swamp and practice hunting and some agriculture.

Since 1884, the delta has been recognized as part of the Batawana Tribal Preserve. An important administrative problem has been the control of the tsetse fly. Infesting the southern delta, the fly has pushed the pastoral Batawana southwest into Ngamiland.

Hydrology. The river is subject to changes in flow along its length because of seasonal variations, the reception of tributaries, evaporation, and absorption into the riverbed. In its upper course, the rate of flow varies between 700 and 3,000 cubic feet per second. At Caiundo and Cuangar, both situated on the middle course, the rate of flow varies from 1,765 to 2,120 cubic feet per second in the dry season to 10,600 in the wet season. Its annual average discharge is 105,930,000,000 cubic feet. At Runtu (Rundu) above the Shimpuru Rapids, the average annual discharge increases to between 141,260,000,000 and 459,100,000,000 cubic feet. Below the confluence with the Cuito River, the maximum annual average discharge again increases to 635,670,000,000 cubic feet. Along the river's lower course at Shakawe, however, the rate of flow averages about 13,000 cubic feet per second and the annual discharge decreases to 388,460,000,000 cubic feet. It takes four months for the flood peak to travel from Shakawe, through the swamp, to Maun, the administrative centre on the Thamalakane River. The average rate of outflow at Maun represents about 5 percent of the inflow at Shakawe.

Approximately 770 square miles of the swamp's total area of 6,500 square miles are permanently flooded, and between 3,800 and 5,400 square miles are inundated during the rainy season. The remainder of the delta is no longer affected by floodwaters.

The delta channel system is continually changing. The dense growth of papyrus reeds throughout the region is continually blocking channels, thus changing patterns of flow, while older blockages are occasionally removed by the movement of herds of hippopotamuses or other aquatic animals. The flow pattern is also changed by earth movements, or seismic shocks, apparently caused by the unstable nature of the bedrock. Because the gradient from north to south is insignificant, changes in levels of only a few inches can result in altered channels.

Vegetation and animal life. In its headwater course, the river flows through woodland country, known in the

vernacular as *myombo*, and containing mainly dominant species of bark cloth trees. On the Kalahari sand, to the south of Caiundo, the woodland is less dense and is characterized by the Rhodesian teak tree (*Baikiaea plurijuga*); the area is called the Baikeaea Woodlands or the Dry Forest. Little is known of the vegetation to the north of the river in this zone: the western area, called Chiculecandi Sandveld, and the eastern area, to the north of the delta, known as the Mbunda, are said to be occupied by dry savanna (grassland with scattered acacia trees).

In the delta the vegetation is generally considered to be of two main types—the riverine and flood plain vegetation, which is typical of the swamps, and the woodland or savanna, which occupies the slightly higher parts of the delta and the marginal areas. The riverine vegetation includes aquatic communities of such plants as dense papyrus, which grows to a maximum height of about 15 feet above the water level. Among the reeds and sedges are reeds which grow to between 10 and 15 feet above water level and smaller bulrushes of about five to 12 feet. On the seasonally flooded areas are many species of grasses. On the higher ground the mopane tree is generally found on clay soils, and camel thorns and palms are more common on the sandy soils. The Moremi Wildlife Reserve covers 700 square miles of the northeastern corner of the Okavango Swamp. Its teeming wildlife is representative of that found throughout the delta region. Game animals include the lions, cheetahs, buffalo, and wildebeests, and there are herds of hippopotamuses, zebras, and wild dogs. Crocodiles also are to be found. Birds include storks, ibis, herons, egrets, cranes, and weaver birds. There are also numbers of ducks, geese, and quail. Varieties of fish include bream, pike, barbels, and tiger fish.

Economic development. *Transportation.* The river is unnavigable except for small craft. Papyrus canoes are used for transport in the swamp area. At Jangada de Cahoco a ferry crosses the river between Angolan and South West African territory.

Plans for utilizing the river's waters

Agriculture. In South West Africa plans were made in the late 1960s to increase agricultural production in the river basin by irrigation. Seven separate schemes are proposed, but all are on a small scale; since the river gradient is small, water cannot be obtained by gravity but has to be pumped.

Industry. The discovery of diamonds, near Orapa, in Botswana, to the east of Lake Xau, has raised the possibility of using the waters of the delta for industrial purposes. If this project is approved by the Botswana government, it will require the clearance of papyrus and the maintenance of a regular flow of water into the Thamalakane and Boteti rivers. Water can then be stored in a reservoir near Lake Xau, and pumped some 30 miles to Orapa.

Tourism. Botswana is developing the Okavango Swamp and the Makgadikgadi Depression as a major wildlife area. Lodges have been built, and the government hopes to attract more tourists to the area.

Okhotsk, Sea of

The Sea of Okhotsk (Okhotskoye More in Russian; spelled Okhotskoje More in the transliteration system of the Akademiya Nauk), which borders the northwest Pacific Ocean, is enclosed by the east coast of Asia from Cape (Mys) Lazarev to the mouth of the Penzhina River, by the Kamchatka Peninsula and the Kuril Islands to the east, by Hokkaido (Japan) to the south, and by the island of Sakhalin to the southwest. Both Japan and the Soviet Union are washed by the Okhotsk, which covers 611,000 square miles (1,583,000 square kilometres), has an average depth of 2,549 feet, a maximum depth of 11,069 feet, and a volume of 294,500 cubic miles.

Physical characteristics. For the most part, the continental shore is high and rocky and interspersed with the mouths of large, regional rivers that flow into the sea—the Amur, Uda, Okhota, Gizhiga, and Penzhina. In the northern areas of the Sakhalin and Hokkaido islands, the shores are predominantly lower. The Gulfs of Aniva and Terpeniya are found on the southeastern coast of Sakhalin. Nearly all islands—Shantar, Zavyalov, Spafaryev, Yam, and others—are situated close to the shore; only the island of Ion is in the open sea.

Geologic history

The present formations of the Okhotsk Sea Basin were evolved in the Quaternary Period (2,500,000 to 10,000 years ago). The geological history of the sea shows that the forming of the present hollow was accompanied by repeated glacial transgressions and regressions. The sea bottom has a slope from north to south and southwest. The northern and northwestern parts constitute a continental shallow up to 650 feet in depth, while the remaining area (about 70 percent of the area) is a continental slope from 650 to 5,000 feet deep, on which isolated underwater heights, depressions, and troughs stand out. The deepest part of the sea, the southern part west of the Kuril Islands, is 8,200 feet and deeper. Bottom deposits in this deep basin are a clay–diatom silt, whereas approaching the shore there are fine, silt-covered sands, coarse sands, and pebbles mixed with mussel shells.

Climate. The northeastern, northern, and western regions of the Okhotsk experience severe weather during the winter, because of the influence of the Asiatic continent; from October through April these areas experience very cold air temperatures, are constantly covered with ice, and have very little precipitation. In short, a continental climate pervades these parts of the Okhotsk Sea. To the south and southeast, the proximity of the Pacific results in a softer marine climate. The coldest months in the Okhotsk Sea are January and February; the warmest are July and August. In the northeastern part the average monthly air temperature during February is −4° F (−20° C), while in August the average is 54° F (12° C). To the north and west of the sea, average monthly air temperature is −11° F (−24° C) in February and 57° F (14° C) in August. In the southern and southeastern parts, the average monthly air temperature is 19° F (−7° C) in February and 64° F (18° C) in August. The yearly precipitation averages in the north 16 inches, in the west, from 28 inches; and, in the south and southeast, about 41 inches.

Hydrology. The water of the Okhotsk Sea consists of continental drainage, precipitation, and waters flowing from the Pacific Ocean through the Kuril Straits and from the Sea of Japan through the La Perouse and Nevel straits. During the summer months the Okhotsk is warmed to a depth of 100–165 feet. The water temperature on the surface reaches 46° to 54° F (8° to 12° C) and the salinity 32.5 parts per thousand and lower. Deeper water has a temperature of 30° to 29° F (−1° to −1.8° C) and salinity of up to 33.75 parts per thousand. The thickness of the cold-water layer fluctuates from a few feet in the southeastern part of the sea to 245–525 feet in the northwest.

Water currents

The general movement of water in the Okhotsk is counterclockwise. Water flows from the Sea of Japan into the Okhotsk, accounting for the comparative warmth of its southwestern part. Warm water is also carried into the Okhotsk by Pacific currents. Because of their influence, the waters of the eastern half of the sea are warmer than those of the western part. For the most part, the currents flow clockwise around the Kuril Islands; in the northern half of the straits they flow into the Okhotsk but in the

southern half return into the Pacific. The Gulf of Shelikhov experiences the strongest tides (42.3 feet); the weakest tides occur at southeastern Sakhalin (2.6 feet). Ice cover appears at the end of October and reaches its greatest extent in March. In the coastal areas it welds to the shore, but in the open sea there is floating ice. The ice vanishes in June, with the exception of the Sakhalin Gulf and the Shantar Island region where ice floes are not uncommon in July and sometimes even in August.

Marine life. The river drainage, the intensive intermingling of waters by straits and wind, and the surge of deep ocean waters are all favourable to marine life. In months when it is warm enough, there occurs an extraordinarily rapid spread of life. The flora is represented by algae and seaweed and the fauna by crawfish, sea mussels, crabs, sea urchins, polyps, and various types of fish. Salmon, herring, pollack, flounder, cod, capelin, and smelts (or frostfish), as well as crab and shrimp, are all commercially important. The Okhotsk is also inhabited by mammals—whales, seals, sea lions, and fur seals. In 1965 record catches of fish in the Okhotsk totalled 1,500,000 tons.

Navigation. Regular navigation connecting the ports of the Soviet Far East is conducted through the Okhotsk. On the continental coast the most important ports are Nagayevo and Okhotsk. Korsakov on the island of Sakhalin and Severo-Kurilsk on the Kuril Islands are also important. During the winter, ice floes are an impediment to sea navigation, and dense fog is a hindrance during the summer. Strong currents and submerged rocks are other perils. The Okhotsk Sea region is playing an important role in the economic development of the Soviet Far East.

Oklahoma

In its land and its people, Oklahoma is a state of contrast and of the unexpected. The terrain varies from the rolling, timbered hills of the east, where it borders Missouri and Arkansas, to the treeless high plains that run on into Texas and New Mexico to the west. Its east central region is dominated by the lowlands of the Arkansas River, sweeping in from Colorado and Kansas on the north, and its tributaries and by the Red River, which forms nearly all of its southern border with Texas. Once basically agricultural—and the dust-bowl locale of John Steinbeck's famous novel *The Grapes of Wrath*—the state of Oklahoma now has hundreds of lakes and a diversified economy.

The word Oklahoma is derived from two Choctaw Indian words: *okla*, "people," and *humma*, "red." During the 19th century the future state was a symbol of one of the least glorious chapters in American history, becoming known as Indian Territory, the dumping ground for Indian tribes displaced by the white man's ever-increasing hunger for land. Since its admission in 1907 as the 46th state of the Union, however, Oklahoma has achieved an integration of its Indian citizens into modern economic and social life that probably is unmatched by any other state. There is no reservation in the usual sense for the Indian population. Though numbers of "blanket Indians" possess no more than their bedroll, others have risen to positions of distinction. Many share with their fellow Oklahomans the great wealth that oil resources have brought to the state.

In the census of 1970, Oklahoma's 69,919 square miles (181,089 square kilometres) held a population of 2,559,229, about 7 and 4 percent of whom were, respectively, black and Indian and about 70 percent of whom lived in urban areas. The state sent a considerably greater proportion of its high school graduates to college than the national average in the early 1970s, and the University of Oklahoma had become second only to Harvard in the number of Rhodes scholars among its graduates. The customs of the Deep South are reflected in the habits and attitudes of southern Oklahoma—"Little Dixie"—where cotton production, but not loyalty to the Democratic Party, has declined. The wheat growers in the north, however, show their largely Kansan origins by their dedication to Republican politics. (For further information about Oklahoma within larger geographic and political contexts, see UNITED STATES; UNITED STATES, HISTORY OF THE; NORTH AMERICA; and GREAT PLAINS.)

THE HISTORY OF OKLAHOMA

Early habitation and European exploration. Of the newer states, Oklahoma is one of the oldest in terms of human occupation. The abundant game of its plains attracted hunters of the Clovis and Folsom cultures 10,000 to 15,000 years ago. Others followed, producing between AD 500 and 1300 a golden age of exquisite pottery, textiles, sculpture, and metalware. Evidence indicates a widespread system of trade and communication. This high culture apparently fell before the onslaught of primitive people from the western plains, and until the expedition of Francisco Vásquez de Coronado in 1541 the region's population included representatives of at least three major Indian language groups.

Coronado claimed the area for Spain, but it became little more than a highway for wide-ranging Spanish explorers. In 1714 Juchereau de Saint Denis visited Oklahoma, and subsequent Frenchmen established a fur trade with the Indians. France and Spain struggled for control until 1763, leaving only the natives to contest Spanish authority until the return of the French flag in 1800. Three years later, through the Louisiana Purchase, Oklahoma was acquired by the United States.

American dominion. As one of the purchase's most attractive parts—because of trade opportunities—the area might well have become one of its first states; but it was, in fact, the last. Because of hostile Indians, Spanish intrigue, the mislabelling of its treeless plains as the American Desert, and the pressure for removal of the Indians from the settled East, Congress in 1828 reserved Oklahoma for red men and required all whites to withdraw. By 1880 more than 60 tribes had joined the local ones in Indian Territory. Some were sedentary, peaceful, agricultural, and semicivilized, others were migratory, belligerent, and barbaric. Indian sovereignty remained unchallenged until early in the Civil War when unhappiness with the federal government caused leaders of the Five Civilized Tribes—the Cherokee, Choctaw, Chickasaw, Creek, and Seminole—who had come from Southern states and some of whom owned plantations and held slaves, to sign treaties annexing Indian Territory to the Confederate States of America.

The Indian Territory

Not only did Indian land become a battleground during the war but defeat also brought other losses. The Reconstruction treaties required, among other things, land cessions to the former slaves, the resettlement of additional outside tribes, and railroad rights-of-way. Although a scheme to colonize black freedmen in Oklahoma never materialized, the weakness of the Indian governments encouraged both blacks and whites from adjoining states to trespass illegally. Thus, the territory again became a dumping ground for Indians and an even greater cultural hodgepodge of red, white, and black people.

White settlement and statehood. Railroads seeking revenue and land-hungry whites, both inside and outside the territory, coveted the Indian's land. By 1879 organized bands, the Boomers, were moving in despite federal law. Although most were ejected, pressure continued until Congress opened some 2,000,000 acres of western Indian Territory, bringing on the famous land run beginning at noon on April 22, 1889. Known as Oklahoma Territory, the new area came to include, through further land runs, about half of the former Indian domain. Then its settlers, many called Sooners for entering the area before official permission, sought union of the two territories in statehood. The remaining Indian Territory was dissolved by assignment of lands to the various tribes, and the Indians joined in approving the constitution of the proposed state in 1907.

The drought years of the 1930s blighted many rural areas of Oklahoma, driving thousands of farmers into long migrations in search of some form of livelihood. The economic boom of World War II allowed the economy to diversify. The major continuing event of the 20th century probably was the continuing exploitation of the state's vast petroleum reserves.

THE NATURAL AND HUMAN LANDSCAPE

Lying in a transitional zone in topography, climate, and other features, both east to west and north to south, Oklahoma comprises a jumble of environments.

Physical regions. Three of the nation's large physical regions extend into or across the state. The Interior Highlands is in the east; the Coastal Plain, extending through Texas to the Gulf of Mexico, is in the south; and the Interior Plains, including the Central Lowland and Great Plains, covers the remainder. Ten subregions lie within Oklahoma. Three are mountainous and in the south—the Ouachita, Arbuckle, and Wichita mountains—and are characterized by rough topography and thin soils. They have lumbering, grazing, some farming, and mining as their principal income. The northeastern Ozark Plateau, most of which lies in Missouri and Arkansas, has rough terrain and small fields devoted primarily to fruit and vegetables. Once important as a lead and zinc producer, it has a Cherokee heritage and beautiful rivers that make it a major recreation and tourist attraction.

The Sandstone Hills, a wide band stretching through the east central portion between the Red River and the Kansas border, is poor in agriculture and timber but important for oil, gas, and coal deposits. The region is sprinkled with deserted or dying oil-boom towns, with Tulsa a prosperous exception. The sparsely populated Gypsum Hills section of western Oklahoma is devoted largely to grazing and farming, with large wheat acreages in the north and smaller cotton farms in the south.

The remaining four areas are flat to rolling and agricultural. The Red River Plains, once the area of the best farmlands in the state, has been depleted by cotton. Its agriculture has been diversified by the addition of peanuts, melons, and vegetables grown on medium-sized plots. Its population is relatively dense, with many small towns serving as trade centres. The Prairie Plains region in the northeast is marked by grazing in its rougher portions and vegetable farms in the river valleys. Oil and gas fields are common, as is strip-mining for coal. It contains a number of middle-sized towns, some of which have small manufacturing plants. The Red Beds region is the largest, running through the middle of the state. The greatest population density is here, as are most of the larger towns. Oil provides much of the income. Although cotton rules in the south and wheat in the north, corn, watermelons, sorghum, alfalfa, vegetables, and livestock are common. The High Plains region of the northwest and the Panhandle offers a marked contrast. With the highest elevation and least moisture, wheat dominates the eastern portion and grazing the western.

Rivers and climate. Oklahoma's drainage pattern, consisting of the Arkansas and Red rivers and their tributaries, slopes from an elevation of 5,000 feet in the northwest to 500 feet in the southeast. Rainfall varies from more than 50 inches (1,270 millimetres) annually in the Ouachitas to less than 15 inches (380 millimetres) in the western Panhandle. Wheat and sorghum predominate in the drier western sections, whereas corn (maize), vegetables, and berries grow in the damper east. Virtually all of the ten regions have enough water for grass; hence, ranching is common.

Moisture and ecology

Oklahoma has a southern humid belt merging with a colder northern continental one and humid eastern and dry western zones that cut through the state. The result is normally pleasant weather and an average annual temperature of about 60° F (15.5° C), increasing from northwest to southeast. No region is free from wind; and, as the collision point for warm and cold air masses, with sudden rises and falls in temperature, the state has heavy thunderstorms, blizzards, and tornadoes.

Vegetation and animal life. Oklahoma is a transitional area for plant and animal life. More than 130 trees are native: the eastern forest of maple, sweet gum, hickory, oak, and pine phases into the cottonwood, elm, hackberry, and blackjack and post oaks of the grasslands. The arid zone plants are chiefly mesquite, sage, and cacti. There are deer, elk, antelope, rabbits, coyotes, wolves, foxes, prairie dogs, and the American bison. Native fish include bass, perch, catfish, and buffalo, and virtually every bird common to the land between the Mississippi and the Rockies is found. Horned toads, lizards, many varieties of nonpoisonous snakes, and the rattlesnake and the cottonmouth moccasin are native.

Human settlement. The outlines of roads and farms generally produce a pattern of unusual symmetry in the landscape, revealing the original survey divisions into townships, sections, and quarter sections. Small squares predominate where small-scale farming is common and very large ones where wheat and ranching prevail. As elsewhere in the nation, however, the trend has been toward urbanization. The Red Beds in the centre of the state grew most rapidly, and three of the state's four largest cities are found here, the exception being Tulsa.

Oklahoma City, the capital, is near the centre of the state and in area comprises one of the largest metropolitan areas in the nation. Banking, insurance, manufacturing, trade and transportation, state and federal installations, and educational facilities have made it the commercial and industrial heart of the state. Tinker Field, an Air Force base and the state's major employer, is located in nearby Midwest City. Tulsa, a former Creek Indian village in the Sandstone Hills region, grew slowly until the discovery of oil in the vicinity. Its refineries and facilities for manufacturing and distributing oil-field supplies make it the logical headquarters for numerous oil companies, and it has numerous other financial and industrial functions. Lawton is a centre for the Ft. Sill army reservation, the Wichita wildlife recreational centre, and the rural population of the area. Norman, the seat of the University of Oklahoma and the major state mental hospital, is also a "bedroom" city for commuters to Oklahoma City and Midwest City.

THE PEOPLE OF OKLAHOMA

Composition. During the 1960s, Oklahoma's Indians, most of whom live in the former Indian Territory in the eastern part of the state, increased in greater numbers than other races. The Plains tribes remain in western Oklahoma. Most of the blacks are descended from slaves of the Five Civilized Tribes, although some migrated from the South after 1865 and others came during the land runs. The majority live in urban centres or in the southern and eastern parts of the state, and several towns have entirely black populations.

Ethnic and religious groups

A wide variety of other racial and ethnic strains have contributed to Oklahoma's population. The original French claimants left their names and bloodlines, usually in conjunction with Indian families, and a mining boom in the 1870s brought an influx of Europeans into the Choctaw Nation. Descendants of these Italian, Slavic, Greek, Welsh, Polish, and Russian miners still live in Little Dixie. The land rushes brought homesteaders from China, Japan, Mexico, England, France, and Canada, and the spread of wheat farming attracted German Mennonites and Czechs to the northwest. German was the language of instruction in some public schools as late as World War I. By the 1970s, however, nearly all of Oklahoma's residents reflected a typically Midwestern American culture.

Religion. The state's religious sects bear out this trend toward uniformity. Of the Protestant majority, the Southern Baptists and the Methodists predominate, and the resultant conservatism has placed Oklahoma in the "Bible Belt." (This fundamentalism was a primary cause for Oklahoma's retention of the prohibition of liquor sales until 1959.) Other leading denominations include the Disciples of Christ, Presbyterians, Congregationalists, and Episcopalians. Roman Catholics and Greek Orthodox are represented throughout the state, but Jewish synagogues are limited to the cities. Most Indians have adopted some form of the white man's religion, although the Native American Church—in which use of the drug peyote is a part of the worship—is recognized by state charter. The Sun and Ghost dances of the western tribes reflect more primitive religious practices as well as reactions to the white man.

Demography. Though the average Oklahoman has kept his religious ties, he has changed his place of resi-

dence. In 1890, fewer than 4 percent of the population lived in towns, but by 1950 50 percent were urban, half of them living in the metropolitan areas of Oklahoma City, Tulsa, and Lawton. In the 1960s more counties lost population than gained, though the gains were far greater than the losses. Of the 26 cities of 10,000 or more in 1960, 21 continued to grow. Part of this willingness to move may be explained by the youthfulness of the people, one-third of whom are under 18 years of age.

It is predicted that Oklahoma's rate of growth below the national average will continue, with the growth continuing most heavily in the north central and northeastern areas, with Oklahoma City and Tulsa as focal points.

The state's vital statistics approximated the national averages, including birthrates and deathrates and causes of death. Infant mortality was higher among nonwhites by a ratio of 33 to 21 per 1,000 live births. The state has a below-average number of physicians per 100,000 but is above average in number of dentists and nurses.

THE STATE'S ECONOMY

At the start of the 1970s, Oklahoma had a per capita income comparable to that of the neighbouring states of Arkansas, Louisiana, and Texas as a group, but more than 15 percent below the nation as a whole; its unemployment rate, however, was lower.

Agriculture. Traditionally, agriculture has furnished an important part of Oklahoma's income, though Oklahoma's more than 90,000 farms and ranches are slightly larger than the nation's average in size but of slightly less value per acre. The United States Department of Agriculture forecasts that, in line with national trends, the averages will remain the same, but the number of units will continue to decline. In commercial agriculture, livestock ranked first, followed by grain, dairy products, cotton, and other field crops and general produce.

Major nonagricultural employment. Oklahoma remains somewhat of an economic satellite of the industrial North and East, furnishing food, raw materials, and fuels. Despite great efforts to diversify, the state still has far to go. In 1970 only 13 percent of its employed were in manufacturing, about half of the national average. Wholesale and retail trade employed the greatest number of persons, followed by government, services, transportation and public utilities, finance, insurance and real estate, construction, and mining. Union membership has not kept pace with the increases in nonagricultural employment. In 1968 nearly 30 percent of all such workers in the nation, were unionized, but Oklahoma's percentage was only about 17. Man-days lost by labour stoppages were about half of the national average.

Manufacturing and labour organization

Mining and forestry. In 1968, Oklahoma ranked fourth nationally in mineral production, with an income of more than $1,000,000,000 from petroleum, natural gas, natural-gas liquids, and stone, in that order. One year later its more than 81,000 oil wells, topped by about 10 percent of the nation's active drilling rigs, produced 224,000,000 barrels annually, with a proven reserve of 1,390,000,000. Timber is also important. In 1963 Oklahoma had about 5,300,000 acres of commercially exploitable timber divided almost equally between softwoods and hardwoods. In 1970, the first major commercial effort was made to establish a pulp and paper industry.

Transportation. Oklahoma's transportation facilities partially account for its favourable record in attracting new industry in recent years. Tulsa and Oklahoma City act as the major collection and distribution points. Railroads operate about 5,600 miles of track within the state. Though the inbound rail traffic exceeds the outbound by two to one, in 1968 well over 4,000,000 tons of agricultural produce alone were shipped by train. Seven airlines provide direct flights for passengers and freight to most cities, while interstate and auxiliary state and federal highways support an excellent trucking system that employs nearly 200,000 people. Intricate networks of pipelines move the petroleum products, with the newest addition to transportation a barge traffic linking Tulsa to the Gulf of Mexico by way of locks and dams on the Arkansas River.

ADMINISTRATION AND SOCIAL CONDITIONS

Territorial governments. Oklahoma's political identity began with the establishment of autonomous tribal governments in the 1820s. Indian Territory consisted of five republics, or nations, with fixed boundaries, written constitutions, courts, and other governmental apparatus similar to those of the Eastern states. The major difference was that in each all land was held jointly, or in severalty, by the individual tribes. The first major threat to these governments came when, as former allies of the South, they were placed under military rule during the Reconstruction period. The treaties of 1866 committed the tribes to eventual union under a single government, but this had not been accomplished when Congress, in its haste to open the unassigned lands, admitted whites in 1889 without making any provision for government.

In this interval Congress steadily encroached on Indian sovereignty by extension of federal law and the demand that landholding practices be brought into conformity with United States custom. Finally, on May 2, 1890, the Oklahoma Organic Act established a territorial government and provided that all reservations in the western Indian Territory, when opened for non-Indian settlement, would be annexed automatically to the new Oklahoma Territory. The last step came when the remaining tribal lands in eastern Oklahoma were distributed among the tribes, and it was agreed that tribal governments would cease in 1906.

Constitutional framework and politics. That same year the Oklahoma Enabling Act set the formula for statehood: the two territories—Oklahoma in the west, Indian in the east—would unite and draw up a single constitution. The resulting document reflected the influence of the progressives and reformers who dominated American politics. It became inordinately long in an effort to protect against corporations, bosses, and future redefinitions of intent by judicial interpretation. The general structure is common to other states, but Oklahomans strengthened the legislature by limiting the governor's appointive powers and ability to succeed himself, the latter prohibition removed in 1970, and making the judiciary elective. Also unusual was the right of initiating legislation by popular initiative and referendum. The governor is elected for four years, whereas the 48 senators serve similar but staggered terms, and the 99 house members serve two years. Each of the original 75 counties, later increased by two, has at least one representative. Constitutional provision was also made for township and city governments, though the former was abolished in 1913. This constitution, often amended, is still in force.

Eight of nine territorial governors were Republicans, but after statehood Oklahomans favoured the Democrats. Even when the state supports Republican presidential nominees, normally that party can hope for but one or two congressional seats, and it was not until 1962 that it won the governorship. Nevertheless, Oklahomans have a history of giving strong support to third parties; in 1914 the Socialists received 53,703 votes, and in 1968 the Southern states' rights candidate, George Wallace, received more than 20 percent of the total vote.

Judiciary and law enforcement. A major governmental change was revision of the state's court system in 1967, which abolished justices of the peace and established selection of major judgeships according to what has become known as the "Missouri Plan." Under this plan judges are nominated by a joint commission chosen by the governor and the state bar association rather than by the political parties. The state Supreme Court has exclusive appellate jurisdiction in civil cases, while the Court of Criminal Appeals has exclusive appellate jurisdiction in criminal cases. The Court of Appeal, with a judge elected from each congressional district, hears only cases assigned it by the Supreme Court, and there is no appeal from its decisions to other state courts. Lower courts include 24 district courts, with judges elected on nonpartisan ballots. In 1966 county attorneys were replaced by 27 district attorneys.

Social issues and state involvement. One of Oklahoma's major sociopolitical issues since statehood has

Education, health, and welfare

involved civil rights. Although its black population is small, as a border state Oklahoma was one of the first to feel the demand for equal education. All public education was segregated, and blacks who wanted advanced or professional degrees were furnished tuition for out-of-state institutions until 1948, when the United States Supreme Court ruled that a black must be admitted to the University of Oklahoma Law School. In 1949 all graduate work and in 1955 all higher education was opened to any qualified applicant. Economic, social, and public school integration moved forward with a minimum of violence.

Supervision of public schools is under elected state and county superintendents, and higher education is coordinated by the regents for higher education, appointed by the governor. The state university system is often regarded as overextended in relation to the state's needs and resources. Exceptions are the University of Oklahoma (founded, 1890) in Norman and Oklahoma State University (1890) in Stillwater. Both have an unusual number of graduate departments ranked above average in achievement. Private institutions enroll only about one-fifth of the college population.

The Commission of Charities and Correction has general charge of mental hospitals in Norman, Vinita, and Fort Supply, the state penitentiary in McAlester, and the reformatory in Granite. The majority of other similar institutions are under the Department of Institutions, Social and Rehabilitative Services. In spite of a generally conservative attitude toward federal intervention in local social questions, most federal welfare programs are represented. In addition, more than 100 recognized agencies or groups within the state have resulted from minority initiative, by Indians, blacks, and Mexican-Americans.

For financial support of its functions, Oklahoma relies basically on taxes on gasoline, income, and sales. The sales tax is earmarked for welfare, and property taxes are left largely for the support of county, municipal, and school needs. Though in 1970 the state was only 36th in per capita personal income, its appropriations for education, highways, and public welfare comprised the bulk of its expenditures, helping to rank it 21st nationally in per capita general expenditures. It was 29th per capita in outlay for all education, 18th for higher education, 16th for highways, and fourth for welfare. Voter rejection of increased state aid to education in the early 1960s led finally to swift moves by the state legislature to avoid nationwide boycotts of the public schools by the National Education Association. A major check on spending since 1939 has been Oklahoma's "budget balancing" amendment, by which the legislature is forbidden to appropriate more money than in the previous year plus estimated additional revenues.

CULTURAL LIFE AND INSTITUTIONS

Oklahoma is a blend of the old and new. Cowboys and Indians, who undergird a tourist attraction worth nearly $450,000,000 annually, may be seen at the national finals of the Rodeo Association or at the American Indian Exposition. As host of the annual exposition and the site of Indian City U.S.A., the National Indian Hall of Fame, and the Southern Plains Indian Museum, Anadarko is a major tourist attraction. Among the features are full-sized reproductions of the homes of various tribes, pictures and busts of their leaders, and extensive displays of their artifacts. The National Cowboy Hall of Fame is noted for its Western art and its exhibits of cowboy paraphernalia. The Will Rogers Memorial Museum at Claremore stresses exhibits depicting early Oklahoma and Rogers' career as a cowboy and entertainer.

The arts. Oklahoma's best known graphic artists are Indian, and Indian culture as well as works of European masters are represented in many of the museums. Oil as a symbol of Oklahoma has placed derricks on the capitol grounds and made it influential on the international petroleum landscape, but those that it has enriched have contributed much to the artistic scene. The Gilcrease, Philbrook, and Woolaroc museums originally reflected individual tastes, but they have joined other art museums (notably the Oklahoma City Art Center) to offer wide-ranging displays.

The performing arts

Symphony orchestras are supported in Oklahoma City, Tulsa, and Lawton. A public school music program culminates each spring in the Tri-State Music Festival. Several ballerinas of international fame are of Oklahoman Indian descent, the most noted of whom are Rosella Hightower and the sisters Maria and Marjorie Tallchief. Theatres have been sources of entertainment since frontier days. Universities and civic groups continue to provide a wide variety of dramatic experiences and professional training. Several towns feature annual folk plays or pageants, while Tulsa boasts an opera company with a regional reputation. The 7,000-member Tulsa Little Theater has given nearly 50 years of uninterrupted productions, and the Oklahoma City Mummers have constructed a $1,500,000 building and become a resident professional company. The state is unusually active in literature, with numerous writers' clubs, poetry societies, and folklore groups.

Publication and communications. Oklahoma's reputation in publication began with the founding in 1837 of Park Hill Press in the Cherokee Nation. The University of Oklahoma Press publishes both regional and international material. *Books Abroad*, established by the university in 1927, is a unique literary quarterly that also offers a major literary prize. Outstanding research opportunities exist in the holdings of the Oklahoma Historical Society, the Gilcrease Museum Library, and the University of Oklahoma's collections on the history of the West, of business, and of science. Popular sources of information and entertainment are the 52 daily newspapers and the 95 radio and nine television stations.

Prospects. Oklahoma of the 1970s is experiencing rapid change. Improved transportation and communication have eliminated rural isolation, and its population has an increasingly urban outlook. Politically, there is a growing basis for a two-party system, with Republicans making significant gains in recent years. The major economic need is for types of secondary manufacturing that will complement the state's primary mining and agricultural industries. Many persons hope that such additions might provide a broader tax base, making possible better solutions to inadequate financing for education and other social concerns.

Oklahoma's history is unique among American states and far shorter than most in its relation to the modern nation. Infusions of new blood and ideas and the cultural integration and interaction of many citizens in statewide social, economic, educational, and political activities have broken down many historical patterns of distinction and discrimination. In many areas, racial and cultural assimilation is moving more rapidly than in other parts of the nation. It may be soon nearing the time when the citizens of Oklahoma will have little but geography and history with which to distinguish themselves from other Americans.

BIBLIOGRAPHY. The best single volume covering the history, politics, economics, and social conditions is A.M. GIBSON, *Oklahoma: A History of Five Centuries* (1965). For biographical sketches as well as general history, see GASTON LITTON, *History of Oklahoma*, 4 vol. (1957). An updating of an older WPA guide that is strong in local descriptions is KENT RUTH (ed.), *Oklahoma: A Guide to the Sooner State* (1957). The best single source for geography is J.W. MORRIS and E.C. MCREYNOLDS, *Historical Atlas of Oklahoma* (1965). M.H. WRIGHT, *A Guide to the Indian Tribes of Oklahoma* (1951), is essential to understanding the Indian history of the state. IRVIN HURST, *The Forty-Sixth Star: A History of Oklahoma's Constitutional Convention and Early Statehood* (1957), is excellent for the descriptions of Oklahoma's founding fathers. A brief description of Oklahoma's judicial system is found in MARTINDALE-HUBBELL, "Oklahoma Court Calendar," *Law Directory, 1969* (1968). A brief description of the organization and history of higher education is found in the OKLAHOMA STATE REGENTS FOR HIGHER EDUCATION, *The Oklahoma State System of Higher Education* (1971). The best coverage of the oil industry and of ranching is found in C.C. RISTER, *Oil: Titan of the Southwest* (1949); and E.E. DALE, *The Range Cattle Industry* (1960).

(J.S.E.)

Old Age, Social Aspects of

Old age is both a stage in the life of an individual and a segment or stratum of the population of a society. Aging individuals (or cohorts of individuals born at the same time) change over their life course as their personality develops, their experience accumulates, or they make adjustments to new roles. Not all individuals age in the same way, and the aging of each new cohort is affected by the unique situation of its particular era in history as norms, mores, and attitudes change or as wars or economic depressions may occur. Within a society, successive cohorts fit together at any given time to form the age structure of young, middle-aged, and aged segments, and over time the particular individuals composing any particular segment are continually moving on and being replaced. Thus the meaning of old age varies from time to time and from place to place, as individual aging and social change interpenetrate and affect one another.

Even among Western societies today there are no consistent definitions of old age. Biologists are not agreed upon the existence of an inherent biological process, apart from the onslaughts of the social and physical environment, that produces a state of physical deterioration in old age. Epidemiologists describe old age in terms of current conditions of morbidity and mortality in a population. Administrative eligibility for retirement, pensions, or social security may be variously set from ages in the 70s down to ages in the 40s. The public considers as old people those who are anywhere from less than 50 to over 75, and substantial proportions of persons who are in their 60s or older do not look upon themselves as old. Social researchers, who often set the boundary of old age at 65, must reckon with the fact that there are large numbers of people who are themselves old enough to be the parents of other "old people" in the category aged 65 and over. (In the United States, for example, there are some 900,000 persons aged 85 and over.)

THE AGED IN MODERN SOCIETY

The position of older people in modern industrial society must be interpreted in light of the fact that many of them survive beyond the age at which they would perform or be rewarded in major social roles: worker, parent of dependent child, or spouse. By contrast, in most primitive and agrarian societies, old age (at least up to senility) has been associated with some special characteristic regarded as an asset in the respective culture, such as usefulness in the performance of chores, skill in dancing or storytelling, control of property rights, power in the family, seasoned experience, or (especially in preliterate societies) extensive knowledge.

Comparisons of the aged in traditional and industrial societies

The status of the aged in the economically advanced nations today derives from broad changes over the past century in the entire society and its culture. Demographic change has altered the age composition of the overall population, and for the individual, the expectation of life has been increasing as mortality rates decline. Economic development has been accompanied by decreasing proportions of older men in the labour force, posing problems of income maintenance for those no longer economically active. Levels of educational attainment have been rising. Urbanization has transformed the residential setting. The structure of the family has altered. Thus the social context of the aged today differs markedly from the earlier situation when today's older people were reared and almost certainly from the projected future when today's younger people will have grown old.

The demographic base. In Western nations generally, there has been a marked rise in the number of older people, paralleling the expansion of the population as a whole. Over the first half of the 20th century the annual rate of increase in the age category of 65 and over has ranged from about 1 percent in France or Sweden to nearly 3 percent in Canada or the United States. In the United States the number in this age category rose from 3,000,000 persons in 1900 to nearly 17,000,000 by 1960.

Numbers of older people have been increasing even faster than the total population. Thus, in Sweden and France the proportion of the total population aged 65 and over had already reached 8 percent by the turn of the century; in the United States between 1850 and 1960, this proportion rose from 3 percent to 9 percent. This long-term tendency for the older age groups not only to grow larger but to grow faster than the younger segments of the population is characteristic of industrialized societies generally; by contrast, in most of the less developed countries of Asia, Africa, and Latin America, the proportions of persons 65 and over still fall below 5 percent. These changing proportions of old people within the population have resulted primarily from declines in fertility rates, which have reduced the accretions to the younger age categories, and not, as commonly supposed, from the declines in mortality. The improvements in reducing mortality have, in the past, had their effect most directly on infants and small children (though any future benefits in Western countries are likely to accrue at the later ages). Although the increasing proportions of survivors may eventually swell the ranks of old people, they have in the meantime added to the numbers at the young ages, not only initially when they were young themselves but later on when they became parents.

Not only have the number and proportion of older people been changing in the West but among older people the proportion of females has been rising. Except in some underdeveloped areas, male mortality rates are generally higher at all ages than corresponding rates for females (even for some animal species). Hence there is typically an excess of females over males among the aged. In the category of people age 75 and over in the United States, there are only about 73 men for every 100 women, a discrepancy that has been widening.

Increases in females

For individuals within a society, the secular declines in mortality (and the consequent increase in the expectation of life) have greatly improved the chances of surviving into old age. The change is not in the *span* of human life (the ultimate length of life attainable by a member of the human species) but in the proportion of people enduring into the higher ages of this span. Thus the average lifetime in ancient Rome or medieval Europe is estimated at some 20 to 30 years. In several Western countries, a man born in the middle of the last century could look forward to four decades of life; today a man can look forward to living well into his 60s, a woman to living into her 70s. Such demographic changes characterizing Western civilization appear to be unparalleled in human history. They have profound societal implications—for example, for government involvement in programs for older people, for the increasing supply of mature individuals available for the labour force, or for the structure of the family because all the family members, but particularly the females, tend to live longer.

Economic status. The age structure of society is closely linked to the economy. In this realm older people tend, on the average, to be comparatively disadvantaged, although individual variations are great. Their low status is indexed by their comparatively low rates of participation in the labour force and by their low average incomes.

Decline in employment

There has been a steady decline (apart from short-term fluctuations attendant upon mobilization for war) over several decades in the proportion of men 65 and over who are in the labour force in most industrialized countries (in contrast to agricultural countries). In the United States this proportion has dropped to less than one-third from approximately two-thirds in 1900; and estimates suggest a possible reduction to one-fourth by 1975, if present trends continue.

No firm explanations for the long-term decline in the employment of older men have been satisfactorily demonstrated. Extensive research on past trends and on age patterns today point, however, to a variety of associated factors and facilitating mechanisms, such as the possibility that technology may have advanced to the point of a sufficiency of manpower to meet existing demands for goods and services without the participation of older workers; the decline of agriculture and of self-employment, in which the aged are free to continue work or to taper off from it gradually; the steady rise in the educational level of the labour force, which appears to favour

the better educated and the more recently trained younger workers; and the extension of public and private pension plans, which afford alternative sources of income to increasing proportions of older workers and which often specify the age for mandatory retirement.

The striking discrepancy in rates of labour-force participation between older and younger men (most younger men are in the labour force) has differential consequences for the age strata, affecting not only their respective involvement in the goal-directed activities of the society but also their financial status and the time available for their leisure pursuits.

Decline in income

In regard to financial status, people over 60 and even those in their 50s, have markedly lower median incomes than people in their middle years, even after various adjustments are made (for example, for family size). The substantial data available for the United States, for instance, show that, over time, there have been absolute increases in the income and the purchasing power of older people, with a declining share from earnings and a rising share from social security and other retirement benefits (often paid in fixed dollars); however, older people continue to lag behind the young.

To be sure, older people on the average, with their years of asset accumulation mainly behind them, own more and owe less than younger people. Among elderly married couples, substantial proportions (the majority in the United States) own their homes. But assets, which are very unequally distributed, tend to be correlated with income, so that those families with the lowest incomes are also the least likely to have any assets.

What kind of life does the older person's income support? Here again data available for the United States show that he tends to live closely within the limits of his income, spending less than younger age groups for most budgetary items, including leisure items, but spending a larger share for health expenditures when his government has no comprehensive program of medical insurance. His spending is restricted both by age-associated factors (such as reductions in family size after the children leave home) and by his comparatively low income; the income of many older people, when judged by arbitrary standards set by economists, is not adequate to meet their needs.

Education. The age strata of the society are distinguished from one another not only in labour-force participation and in income but also in educational background.

Lower levels of education

Older people have less formal education and less recent education than younger people. Among persons 75 and over in the United States, where the century-long spread of formal schooling accentuates the age differences, more than 70 percent have had only eight years of schooling or less, compared with less than 20 percent of those aged 25 to 29. Moreover, although the average educational attainment of older people is rising, the lag of old behind young persists.

These striking age differences in education have widespread ramifications throughout society. Since comparatively few older people are well educated, few of them possess those characteristics, typically valued in Western culture, that are associated with high education. Thus, the less educated majority of older people are less likely than the few who are well educated to remain active; they are more likely to retire. They are also less likely to belong to voluntary associations or to read or to want to learn more. They have lower incomes. They are often less happy and generally less optimistic about the future, but at the same time, they are less introspective and less ready to doubt their own adequacy as spouses or parents. They are more negative in their view of death and think about it more, although fewer of them are disposed to plan for it.

Age categories in the population differ not only in level but also in recency of education. Thus, the content of knowledge and attitudes acquired vary by cohort. The information imparted to doctors or engineers during their training, for instance, differentiates sharply between the backgrounds of old and young. Yet within each cohort, there is a certain age homogeneity in values and beliefs (about what is good, beautiful, or true) among individuals who were educated at the same point in history.

It is interesting to note that one reason education can make such enormous differences among the age strata in modern society is that formal schooling, rather than being spread over the life course, is almost completely concentrated in the early years of life. A person enters adulthood with a fixed educational background that functions sociologically in almost the same way as such inborn characteristics as skin colour or sex. Adult education (a channel that might close part of the age gap) is developing, but it still reaches only small proportions of people in their middle or later years.

Residential setting. Historic changes in population distribution, in community planning, and in the designing and marketing of houses affect the physical and social environment of the older person; influencing the range of his human contacts, his day-to-day activities, and the community services and facilities available to him. In the modernized nations persons who are now old have, to a great extent, been swept along in the massive movements of the population from agricultural to industrial areas, from farms to cities or suburbs. Many of the elderly, however, have been left behind, as age-mates die off and younger generations move away. Moreover, the houses in which most older people live were built in an earlier era. As their houses have aged, the inhabitants themselves have moved along the life course toward increased leisure in retirement, diminished families, and reduced incomes.

In general, however, most older people do not avail themselves of the freedom from occupational and family commitments to move away from their former homes, a fact that gives some indication of the meaning of the older person's home and the factors mediating his relation to his environment. Rates of moving are generally highest among people in the youngest age groups. Moreover, when older people do move they are more likely to move within the confines of their immediate locale than to change their community setting. It thus appears that, basically, the individual's ties to his place of residence become stronger as he grows older. And older people who own their homes, or those who have strong social connections with the neighbourhood, are the least willing to move.

Family status. The social position of the aged is importantly tied to the structure of the family, which has been gradually changing in Western society over the past century. Although this change is usually described as the isolation of the nuclear family (*i.e.*, parents and their children), perhaps it may be more accurately described as the subdivision into two or even three generations of distinct nuclear families: the young couple with their dependent children, the middle-aged parents, and the aged generation of grandparents.

Independence of the aged

As life expectancy has risen, husbands and wives have become increasingly likely to survive together into old age; and widowhood, even if not curtailed in length, has been postponed. Today, in such countries as the United States, Great Britain, or Denmark, in the 65-and-over age range, most men (about two-thirds), but a minority of women (about one-third), are living with their spouses. Moreover, most of those 65 and over, the married and even the widowed, maintain independent households. In the United States this way of living has been increasing, as decreasing proportions of older people live in the same household with their children. Even when households are shared today, the older person is, more often than not, himself the head of the house or the host, not a guest or subordinate in the home of his child. Living entirely alone is a frequent pattern among older people. This is especially true among women, over one-fourth of whom (mainly widows) live alone. Moreover, the norms appear to favour separate households for older people, except for those who are ill.

Thus a new type of nuclear family, the independent, older family (often a single-person "family") is developing, with little-explored consequences for the older person or for the society as a whole.

THE ORGANIC BASE

The social aspects of old age cannot be understood without reference to the physiological processes that distin-

guish old people from the young. The age structure of the society is fundamentally affected by biology, not only because there is the succession of births and deaths but also because individuals at different stages of life show important differences in both physical structure and function.

With age, there are declines in the number and quality of vital cells and a decreased ability of the organism to adapt to changes in the environment. Associated with such age-related differences is the fact that the health of older people is generally poorer than that of the young. While older people have fewer acute illnesses, they are more subject to chronic conditions: such impairments as failing vision or hearing or such ailments as rheumatism and arthritis, heart disease, and high blood pressure. In the United States, for example, some four out of five persons 65 and over have at least one chronic condition. Thus there are increases by age in physician visits, in the number and duration of hospital stays, and in the number of days spent in restricted activity or in bed. Nevertheless, only a small proportion of old people are so severely handicapped that they cannot carry on their major activity, whether it be a job outside the home or housework.

Behavioral changes

Physical changes associated with age are related not only to health but also to behaviour, though the causal linkages seem far from clear. When compared with younger people, older people are more likely to show deficits in sensory and perceptual skills; in muscular strength; in the ability to react quickly; in complex sensorimotor coordination (such as that required in driving a car); and, most important of all, in certain forms of memory, in learning and in various aspects of intellectual functioning. There are also age-related decrements for both men and women in sexual activity, though sexual capacity persists at least into the 70s or 80s.

Of course, not all the differences between old and young are necessarily reflective of a biological, or even a social, process of aging. It would be fallacious, for example, to attribute entirely to old age the comparatively poor performance of older people on intelligence tests. In cross-section studies (conducted among several age groups at a single time), intelligence appears to reach a peak among people in their late teens or early 20s and then to decline with age in the older strata. But to infer that intelligence falls off so early in the life course of particular individuals because of age-associated changes (as in general health) is open to serious question, as a few longitudinal studies (which trace individuals over the life course) have begun to suggest. In this instance, the interpretative difficulty seems associated with social change, with the long-term upward trend in education. Intelligence test performance is highly correlated with educational level, and education sets older cohorts sharply below younger cohorts.

Unfortunately, there is little information about trends over time in health, physical functioning, or the associated changes in behaviour. For the population as a whole, to be sure, the rising proportions of older people point to the likelihood of increasing prevalence of the chronic conditions associated with senescence; indeed, there have been increases over the past century in death rates resulting from such illnesses of later life as heart disease or cancer. But it is uncertain whether older individuals today are healthier than older individuals in the past. Medical advance may have improved their physical condition, or it may, by interfering with the principle of survival of the fittest, have yielded a larger but less hardy population.

Whatever the trends may be, the inferior physical state of the older segments of society, in contrast to the younger segments, has both societal antecedents and societal consequences. Health is conditioned by such social factors as standard of living, education, and advances in medicine and public health. In turn, the physical state of older people sets limits to their social adjustment and to the contributions that they can make to society.

THE AGED INDIVIDUAL

How, then, does the older individual respond to a life situation in which he tends to be comparatively disadvantaged both in health and physical fitness and as a member of society? Does he in fact conform to the tragic stereotype of the old person as destitute, ill, facing irreparable losses, no longer integrated into society, and no longer subject to society's controls and sanctions? Is it true, as often supposed, that his feelings are fully reflective of the relatively deprived status of the aged within the society and that he is characterized by a loss of self-esteem, a deprecatory view of his low education, a sense of dejection and despair over his losses, and anxiety about his health, finances, and death? A glance at the available clues shows a picture that is, at least in certain respects, at sharp variance with such a stereotype.

Personality. Old people resemble the rest of the population in many of their personality characteristics, despite certain distinctive types of emotional expressions and modes of adaptation. Thus the aged, in comparison with the young, appear to be more rigid, passive, and introverted, more restrained and cautious, and less oriented to achievement. Age differences in personality and the individual's disposition to organize his behaviour in particular ways cannot be separated, however, from his biological condition and the social roles that he plays. And there is little evidence to indicate how many of the unique aspects of the personality of the older individual are a result of accumulated experience, relative lack of education, inexperience with personality tests, weakened sensory and motor skills, or limited opportunities to test out his ideas on other people.

Degree of neurosis, psychosis, and deviance

Disturbances of thought, affect, or behaviour afflict, in varying degrees, somewhat fewer than 10 percent of the people 65 and over in several localities studied in Europe and the United States. The milder mental disorders (neuroses) do not appear to increase by age. But psychoses (and various psychiatric symptoms experienced as bodily illness) are apparently more prevalent among older than among younger people, both because in later life there are certain conditions connected with the degeneration of the central nervous system and because the older the individual is, the greater his chances are of having any chronic or irreversible disease that does not result in early mortality. Although the burden of mentally ill older people upon families and treatment facilities has undoubtedly been rising over time, the rise is due partly, perhaps entirely, to changes in longevity—to the increasing numbers of people who survive into old age.

There are differences by age in various types of deviant behaviour. For example, crime rates, as observed in disparate times and places, show a consistent decline as age advances beyond adolescence. Moreover, life-course analyses demonstrate a curtailment in criminal behaviour with age even among those who have previously engaged in such behaviour. Thus, in the comparatively rare instances when older people commit criminal acts, these are ordinarily relatively harmless offenses rather than aggressive outbursts against society or acts of violence against other persons. In contrast, suicide is most pronounced in the older age categories, a pattern observed in many countries in both the 19th and the 20th centuries.

Social roles. The older the individual is (beyond the middle years), the fewer social roles he plays on the average (as he retires from work, his children leave home, and his age peers die off) and the fewer and less varied are his contacts with other people and with the environment generally. Individuals are not all alike, however, and social activity is greatest among those aged who are in good health or who come from higher rather than lower socioeconomic backgrounds. Moreover, much depends upon the particular exigencies that permit some older individuals, but not others, to retain their major familial and occupational roles.

Work and retirement. The aging individual faces the culmination of his occupational role and a final period of retirement. For older men today, the modal role is retirement, not work. If they grew up in an era when retirement was not widely institutionalized, they now confront a world increasingly populated by age peers who are no longer full-time members of the labour force.

Those men and women who do remain in the labour

Productivity and commitment

force during their later years are not making generally inferior contributions, despite their frequently poorer performance under laboratory conditions. Studies under actual working conditions show older workers performing as well as younger workers, if not better, by most, though not all, measures. (Of course, such age patterns of actual performance are traceable in part to labour-market conditions and to selective processes that allow the retention of the more competent older workers in their jobs.) That there is no necessary decline in creative productivity with aging is evidenced through analyses of the published biographies of contributors to numerous scholarly, scientific, and artistic fields (though widely quoted earlier studies had propounded somewhat misleading contrary findings).

In addition to maintaining their productivity, many older people also take a generally positive view of their occupational role. As compared with the young, older people still in the labour force tend to be more strongly committed to the kind of work they do, to adapt better to the job, and to express greater satisfaction with it. Moreover, despite their inferior education and the lowered aspirations attendant upon age, older workers do not fall very far short of the young in their sense of occupational adequacy or in the emphasis they place on the intrinsic satisfactions of the work itself.

Once older people have retired, they seem on the whole to accept the new role of retired person, although many say that they regret losing their work associates, the feeling of usefulness, the work itself, and the associated earnings. Retirement per se does not appear to have a deleterious effect on health nor does it affect social participation in the other roles of the retired person. To be sure, adjustment to life is generally poorer among retired old people than among age peers who are still working, but this results in part from the selective process whereby the healthier and more advantaged oldsters tend to continue working.

Political roles. Older people, even those with little education, are significantly involved in the political system. They are, for example, at least as likely as younger people to vote. They are better represented among the political elite and in leadership positions in many types of decision making. They are more disposed to keep up with the news and with public affairs through the mass media.

In general, today's generation of older people are more conservative than younger people in their political attitudes. There are important exceptions, however, as on issues affecting their own economic self-interest. In the United States, for example, the old have often tended to support extensions of social security or government health insurance but have frequently voted against school bonds. Yet there is little indication whether future generations of old people, subjected to shifting political climates and to rising levels of education, will perhaps adopt a less conservative stance and a generally greater flexibility of attitude.

Religious roles. Religion assumes greater importance among older than younger segments of the society, although research (which is less complete than research on the polity) does not show whether religious values become intensified with aging or whether the older cohorts reflect a stronger religious emphasis in their early training. The aged are more caught up than the young in such personal observances as prayer and reading scriptures, and elderly members of religious organizations benefit from a variety of special programs, such as home visits and nursing homes. Church attendance, however, declines in the oldest years.

Voluntary associations. In addition to religious and political affiliations, modern pluralistic societies offer a variety of voluntary associations as potential links between older people and the larger community—associations such as clubs, lodges, auxiliaries, and the many other formal organizations to which people belong part-time and without pay. To be sure, membership in such associations is less widespread among older people generally than membership in a church or voting in a national election; and average membership rates show a drop in later life after a rise in the middle years, though individuals vary greatly around this average—depending upon their education and income. The special clubs (such as Golden Age Clubs or Senior Centres) established in many Western countries to provide older people with recreational, educational, health, or welfare services seem to attract comparatively few participants.

Family roles. Old people play a variety of family roles, and they seem no less likely than younger people to feel satisfied and adequate both as spouse and as parent. For those older people who have a living spouse, the marital relationship is of central importance, and older couples share many joint activities; but many of the aged, especially women, must adjust to widowhood.

Ties with children and relatives

Most old people play the enduring role of parent. While their children in turn form families of their own, new linkages develop with children-in-law; and grandchildren, even great-grandchildren, proliferate. Living separately from children does not mean complete isolation from them. Over 80 percent of older people who have living children live less than an hour away from the nearest child, and a similar proportion see one of their children at least every week. Bonds with siblings or other relatives are often maintained, and a few old people continue in the role of offspring to parents who have survived into very old age.

The ties of the elderly to their relatives and to their children in particular are by no means limited to visiting. There are also widespread exchanges of material support of various amounts and kinds, ranging from financial contributions and care in illness to baby-sitting and help with housework and home repairs. Contrary to the often-held theory of a one-way flow of contributions to older people, the flow of support between aged parents and their adult offspring appears to be two-directional, from parent to child or from child to parent as need and opportunity dictate.

Although close parent–child ties seem important to both older people and their offspring, the offspring feel closer to their new family of procreation than to their family of orientation. Thus the norms of intergenerational independence seem to operate to reduce the emotional dependence of the elderly upon their adult children.

Friends and neighbours. Friends and neighbours play an important part in the lives of many older people, often providing help and services as well as informal contact with the world outside the home. They are, however, generally less important to the aged individual than children and other relatives, serving more as a complement than as a substitute for kinship association. Friendships and neighbourly relations, which tend to be maintained well into later life, are most widespread among older people of comparatively high socioeconomic status and among those who have resided for a long time in the same neighbourhood. Older people tend, though by no means exclusively, to have friends who are similar to themselves in status characteristics (notably age) that reflect common experiences or values.

Leisure. Maturity yields new increments of leisure time, as commitments relax to parental and later to occupational roles. Many and varied pursuits fill these hours of leisure. Visiting with friends and relatives is an important activity. Much time is devoted, for purposes of information as well as entertainment, to watching television and reading the newspaper. Only small minorities, however, spend their leisure in crafts, hobbies, or intellectual and artistic activities; and vacations and outings beyond the home, particularly foreign travel, are restricted to the few. Indeed, some older people, especially the very old and the disadvantaged, often have difficulty finding anything at all to do.

When the leisure of old and young is compared, varied age patterns emerge for different sets of activities. In the United States, for example, certain types of activities (gardening or walking) seem characteristic of older people. Other kinds of activities (swimming, museum attendance, or playing a musical instrument) are widespread among the young but largely unfamiliar to today's older generation—a possible portent of social changes to come. Thus a "mass" culture may exist at the younger age levels that will permeate society only as these cohorts (generations) reach maturity.

Attitudes and satisfactions. Age is related not only to psychological characteristics and to performance in roles but also to the individual's estimate of himself, his attitudes toward the environment, and his feelings of gratification or deprivation.

The self. Underlying the several dimensions of his personality, a clear sense of his own identity is experienced by the typical older person. Although conceptions of old age are often assumed to be largely pejorative, the modal older person appears to evaluate quite positively such aspects of the self as his moral virtues or the adequacy of his role performances. At the same time, he minimizes in his self-image many of those aspects that are negative, such as his failing health, his personal appearance, his relative lack of education, or the fact that he is old.

Relatively positive self-evaluations

If many older people, even though objectively disadvantaged, fail to take deprecatory views of themselves, the reasons are not entirely clear. By virtue of their long years of life, these people have acquired experience, possible wisdom, and the opportunity to come to terms with themselves. Perhaps they judge themselves less with reference to younger people or to themselves at an earlier age than with reference to others who are at least as old as they.

Views of life. Older people differ sharply from the young in many of their opinions, feelings, and dispositions toward such central aspects of life as health, personal problems, or death. To a greater degree than younger people, they take aches and pains for granted, put relatively little faith in medical science, and feel they understand their own health best—though the frequency of thinking about health, visiting doctors, and taking medicines rises with age. Certain elements in their conception of physical illness appear also in their outlook on mental illness: the sense of inevitability and incurability and the stricture that the individual should look after himself. They are likely to define their personal problems generally as unchangeable and to stress the individual's responsibility, although they seem ready enough to seek assistance in those instances when assistance is deemed appropriate. Death is typically confronted openly as an inexorable fact. Most older people report that they think about death, are willing to discuss it, and have made preparation for it. Few stress otherworldly aspects, either hope of heaven or fear of a last judgment. Indeed, few show marked fear of any sort, expressing the view rather that death is more tragic for the survivor.

Fatalism combined with stress on individual responsibility

Certain recurrent themes are discernible beneath the myriad specific differences, as old and young define and assess their life situations differently and hence are inclined toward differing courses of action. First, older people tend to have less "sense of mastery" over the conditions of their lives than do younger people, considering the world potentially less changeable. Second, older people tend (paradoxically) to stress the "responsibility of the individual" for his own destiny; whereas younger people are more likely to stress environmental influences. Third, in line with such differences in definitions of the situation, old and young tend to favour different "types of approaches" to life situations. Thus older people, defining many of life's ills as inevitable, may be more disposed to seek palliative rather than corrective or preventive treatment. Or again, if older people attribute to the individual the responsibility for cause and cure of his problems, they may be more disposed to lay exhortation or blame upon him than to attack his social or his somatic conditions. Fourth, when older people do become committed to a particular approach, they may be typically as willing and able as the young to *implement* it. Thus much of the often noted lower activity levels of the aged may perhaps be explained through their differing definitions and evaluations of the situation rather than through any age-related tendency toward generalized passivity.

Such differences in the life attitudes of old and young are probably traceable in part to the differences in educational level and to the impact of the aging process itself. In addition, the differences are undoubtedly reflective of the long-term social and cultural change in which each new cohort (generation) has been socialized to new understandings, norms, and habit patterns.

Life satisfaction. In some general sense, satisfaction with life (happiness, morale, adjustment) seems to diminish with age. This decline, already apparent in early adulthood, is not peculiar to senescence; but it becomes intensified (as both longitudinal and cross-section studies suggest) with age-related deterioration in health, loss of key roles, or reduction of activity. Thus age appears to be associated with a general diminution of the opportunities for happiness.

Nevertheless, when research is focussed, not upon overall satisfaction but upon more specific reactions to particular areas of life, older people appear to differ from younger people in the kinds of gratifications and anxieties experienced and regarded as salient. The typical older person is as likely as the younger person to seem content with his occupational and familial roles and to encounter no greater problems in them. And despite the objective difficulties confronting him, he appears even less likely to worry about his health, for example, or his finances. Thus, the older a person is, the more nearly he seems to have come to terms with many of the specific conditions of his life.

Many studies of life satisfaction have challenged the provocative notion of "disengagement," conceived by some researchers as a mutually satisfying process of withdrawal between the individual and society in preparation for the incapacitating diseases of old age and eventual death. In the main, the evidence lends little support to the theory, although continuing activity is clearly not a *necessary* condition of satisfaction for all older people. For the majority, however, the sense of well-being is associated with high rates of interaction and contact with the environment—just as adjustment is associated also with good health, with favourable occupational and familial circumstances, and with a high sense of self-esteem.

PROGRAMS AND POLICIES

The modern stereotypical view of old age as a situation of utter and inevitable disadvantage has often overemphasized the problems and weaknesses of the elderly without paying proper attention to their strengths and their potential contributions to society. In fact, there are many areas of independence and an absence of serious physical disability among the majority of today's aged. Moreover, the relative deprivations of the older population as a whole are offset by numerous exceptions, since there are segments of this population who enjoy adequate education or income or who exhibit high levels of adjustment and interaction with their fellows. Such exceptions serve both to deny the intractability of the current problems of the elderly and to suggest areas in which ameliorative effort is likely to produce needed solutions.

Nevertheless, the deprivations remain. The central fact is that a great many older people nowadays are not filling socially valued roles in the economically developed countries. This fact can be punishing to the individual, and for the society it can be a costly waste of human resources. Concern for this fact—a concern that has become intensified with the multiplying proportions of old people in the population and with the recently emerging power of the medical profession to prolong the lives of many dying patients—has led to the formulation of various policies and programs.

Types of programs. The problems of the aged, like those of the poor or the disabled, have been handled through a wide variety of institutions and arrangements at different times and in different places. In most agrarian societies, the aged have found security in a familistic social organization in which food is shared, oldsters often marry younger mates, or progenitors hold sway over descendants. The family has been bulwarked by such other structures as the church or the guilds in medieval Europe, by private philanthropy and the giving of alms as broadly established in many cultures, or by the building of institutions to house the aged (which existed in Europe as early as the 3rd and 4th centuries).

Comparisons between agrarian and industrial societies

Modern industrial societies, with their complex structures and their large proportions of older people, have developed many special forms of adaptation.

The family is still of central importance to the older person's security (statutory responsibility of adult children for their needy parents continues to exist in a number of countries); today's aged couple, however, with their increased years of joint survival and their tendency to live apart from their children, are likely to depend primarily upon each other, turning to children or relatives only under conditions of special need.

Following the breakup of medieval institutions in Europe, the aged are variously assisted by state intervention, private and corporate philanthropy, religious and fraternal organizations, or labour unions; and private enterprise is often engaged in building housing and residential communities for the aged or in arranging for the delivery of health care or other services to older people. In the United States, for instance, many older people have secured financial protection above the government-supported minimum through private pensions, voluntary health insurance, or life insurance benefits to the bereaved spouse. Only small fractions of those 65 and over (less than 5 percent in the United States and less than 4 percent in England and Wales) are residents of old age homes and other institutions.

Public programs and governmental acts to meet the needs of the aged, from the bread and circuses of ancient Rome to the modern welfare state, have had varying histories in different countries throughout the world—depending upon particular social philosophies; upon the crises created by war, plague, or famine; or upon the maladjustments and dislocations created by basic changes in economic, religious, military, and other social institutions. In England, for example, a series of 16th-century enactments, culminating in the Poor Law of 1601, recognized a degree of public responsibility for the aged, along with the sick and the poor, although the administration was left to the local parish. In subsequent years, various legislative and administrative modifications were made in the law, including the reversion (under the Poor Law Amendment Act of 1834) to an austere system of workhouses in which a uniform, stringent discipline was imposed upon the aged, the sick, and the able-bodied poor. Not until 1925 did England introduce social insurance for the aged (followed in the 1940s by the legislation underpinning the full welfare state system), in which contributions are regulated by law and benefits disbursed without a means test. Meanwhile in Germany Bismarck instituted as early as the 1880s a full program of social legislation, including old-age pensions. Austria, the Scandinavian countries, the Low Countries, France, and Italy followed the German model; and by the mid-1960s, well over 100 countries had social security programs. The United States, slow to yield its philosophy of individualism, long clung to vestiges of Elizabethan-type poor laws, not enacting an old-age pension program until 1935, when, as a consequence of the Depression, the Social Security Act was signed. The basic plan has been supplemented by other federal, state, and municipal programs, including Medicare, Medicaid, the Older Americans Act, income-tax exemptions, subsidized housing and liberal financing of mortgages, and old-age assistance as the last line of income defense. These and many other aids and services to older people have alleviated some of the difficulties and set a floor to older people's income, but they have not brought this income up to the level of younger people.

Poor laws and social insurance

Development of the professions. The extension of programs to ameliorate the condition of older people has enlarged the demands upon the practicing professions. The long-term intrusion of old age and its concomitants into the established professions, though often unnoticed, has increased the likelihood that the physician or nurse must treat the chronic ailments and disabilities associated with senescence, that the architect must provide housing for older couples or widows living alone, that the social worker or minister must deal with persons no longer absorbed in occupations or parenthood, and that the lawyer must advise on the estates of persons who can expect to live well beyond the age of retirement.

Professional aid to the aged

In addition to increasing in numbers within the clientele of the professions, older people have created demands that often require new kinds of services or shifts in professional emphasis. Thus educators may be expected to provide continued education or retraining to adults, mass communicators to forge links between old people and society, or public-health experts to expand the delivery of health care to this segment of the community. Architects and city planners must arrange for nearby facilities (such as stores, buses, medical services, churches, or recreational activities) on which older people in failing health and vigour are especially dependent; and, since the elderly seem loath to move away from familiar surroundings, homes may be designed to allow expansion and contraction, for example, or ranges of housing suitable for all stages of the life course may be planned within a single neighborhood.

Furthermore, certain developing needs of older individuals, notably their need for help in planning for retirement and for income maintenance, point to gaps in the structures of existing professions. To be sure, advice is proffered by a number of specialists on selected aspects of the older worker's participation in the labour force or on financial management, and thousands of recreation workers offer leisure-time programs for the aged. Yet there is typically no single source of unified advice for the person who is considering retirement, who is seeking to optimize his use of leisure in retirement, or who is attempting to understand the intricacies of social security, pension benefits, insurance annuities, real property, and other assets. This gap becomes increasingly apparent as the mass of today's workers confront the necessity of planning for retirement, suggesting possible future changes in the structure of existing professions to meet developing needs.

The basis in research. The planning of programs and policies and the training of professionals to implement them rests increasingly upon research on old age and on the related processes of individual aging and social change. Early forerunners of research leading to social policy include the monographs of Frédéric Le Play (*Les Ouvriers européens*, 1855), which were used in propaganda for state reform in France entailing patriarchal control in the family; or the detailed house-to-house surveys of Charles Booth (*Labour and Life of the People*, 1889), which led eventually to the Old Age Pensions Act of 1908 in Britain. More general studies of age as an explanatory factor in social behaviour were conducted as early as the mid-19th century, when Adolphe Quételet made quantitative analyses by age categories of crime rates and suicide rates (*Du système social et des lois qui le régissent*, 1848).

Recent social research on old age has benefitted from the advances of the social sciences generally, from the compilation of basic demographic data for many countries, and from the proliferation of empirical studies in the Western world, particularly in the United States. Research has been stimulated by interdisciplinary groups formed to develop gerontology as a special field (in particular, the International Association of Gerontology and its branches in many countries). The focus of such groups, initially centred on biology and clinical medicine, was extended in the 1950s to include psychology and the social sciences as well. The accumulation of knowledge has been fostered in various ways by universities, by foundations, and by governmental and international agencies and has begun to yield not only more rational solutions to practical problems but also a more complete understanding of old age in terms of the dynamic processes of aging and the flow of cohorts through a changing society.

FUTURE STATUS OF THE AGED

Because the state of being old is influenced by the dual processes of aging and cohort succession, the prospects for the people who will become old in the next decades depend upon the social changes, including interventions by policy makers and professional groups, to which each new cohort will respond.

The process of becoming old does not always occur in the same way but is subject to change as when, for example, certain of the current ills of older people are prevented through individual treatment or through manipulation

of the relevant environment. Little is known about the extent of the individual's capacity to adapt or about the conditions for fulfillment of this potential. Yet intervention at earlier stages of the life course might well result eventually in continuing education and development over the lifetime, in anticipatory learning of postretirement skills or of new careers, in lifelong accumulation of savings and estate planning, in preparation for changing housing needs, and even in prevention of certain of the apparent "chronic" ailments of later life.

Prevention of future deprivations of persons not yet arrived at old age is still not only possible because of changes in the way people grow old but also because of differences in the kinds of people who compose the successive cohorts and in the kinds of early training and life attitudes to which they are exposed. It is already clear, for example, that future old people, as compared with the old people of today, will have higher education and higher levels of lifetime earnings and that, since far fewer of them will have been born on a farm, they will be more readily at home in an urbanized society. And if there is a continuation in industrial countries of the long-term trend toward declining labour-force participation and earlier retirement of the older population, this trend can alter drastically the organization of work and leisure, the supporting values, and the total role complexes of individuals at all ages.

Of course, not all the long-term effects of social change will be beneficial. It is by no means clear that future cohorts of old people will have fewer problems or be better off in every respect. For example, the income or the education of tomorrow's aged, *relative* to other age groups, may not improve or may even deteriorate. The social and personal costs may be immeasurably high if the lives of large numbers of helpless and hopeless older people are medically prolonged. And the level of public health, though advancing on many fronts, is subject to possible deleterious effects from such aspects of the urban environment as air or water pollution.

However imprecisely the implications can be foreseen, the forces of social change, whether through deliberate action or as an indirect consequence of existing trends, are not only constantly intervening in the aging process but are also bringing new influences to bear on the situation and on the characteristics of persons who are old.

BIBLIOGRAPHY. Extensive empirical and theoretical work has been collected in the following three handbooks, comprising essays on varied aspects of gerontology: J.E. BIRREN (ed.), *Handbook of Aging and the Individual: Psychological and Biological Aspects* (1959); C. TIBBITTS (ed.), *Handbook of Social Gerontology: Societal Aspects of Aging* (1960); and E.W. BURGESS (ed.), *Aging in Western Societies* (1960). More recent information on several of these topics may be found in a special issue of the *International Social Science Journal*, entitled "Old Age," vol. 15, no. 3 (1963). Findings from some 3,000 social science studies concerning people in their middle and later years have been condensed and organized for ready reference in M.W. RILEY and A. FONER *et al.*, *Aging and Society*, vol. 1, *An Inventory of Research Findings* (1968). The findings from this inventory are interpreted for use in those professions concerned with older people in M.W. RILEY, J.W. RILEY, JR., and M.E. JOHNSON (eds.), *Aging and Society*, vol. 2, *Aging and the Professions* (1969). Systematic research findings for selected times and places appear in the analysis of ethnographic reports in L.W. SIMMONS, *The Role of the Aged in Primitive Society* (1945); H.D. SHELDON, *Older Population of the United States* (1958); and in the parallel surveys reported for Great Britain, Denmark, and the U.S. in E. SHANAS *et al.*, *Old People in Three Industrial Societies* (1968).

(M.W.R./A.F.)

Old Catholic Churches

Churches correctly described as Old Catholic include a number of well-organized local churches that claim to have maintained all the essentials of Christian doctrine and to have kept the historic succession of the episcopate but are not in communion with the see of Rome. The term is used less correctly of certain churches that have come into existence as the result of nationalist movements and in some cases stand outside the main stream of Christianity. It is also used incorrectly of a number of small bodies brought into existence by the enterprise of private individuals, who have in one way or another secured for themselves episcopal consecration and in certain cases have conferred the title Old Catholic on the church bodies that they themselves have brought into being.

NATURE AND SIGNIFICANCE

Different views are held as to the origin of the local episcopate in Christianity. It is clear, however, that from the middle of the 2nd century onward the term *episkopos* ("bishop") was used exclusively of ministers of the church who had been chosen to be chief pastors of cities and of the regions surrounding them, consecrated by their fellow provincial bishops and recognized as being in communion with the entire Christian episcopate throughout the world. But from an early date there were *episcopi vagantes*, or wandering bishops—men who had been deprived of their sees but still claimed the right to minister, bishops expelled from their sees by Muslim occupation (from the 7th century onward) or Protestant occupation (from the 16th century onward), bishops of sees that had ceased to exist, or men who had secured episcopal consecration otherwise than through the regular process of public election and consecration. One of the best known bishops of this type in the Reformation period was Pietro Paolo Vergerio (1497/98–1565), who accepted the principles of the Reformation and served for a time as a pastor in the Grisons (Switzerland) but does not seem to have exercised any further episcopal functions.

Importance of episcopal consecrations

Since the consecration of Jules Ferrette at Homs (Syria) in 1866 by bishop Mar Bedros of the Syrian Jacobite Church, the number of *episcopi vagantes* has enormously increased. It is to be noted that only one such consecration, that of Arnold Harris Mathew (1852–1919)—who was successively an Anglican, Roman Catholic, Old Catholic, and leader of his own series of churches—has been carried out by Old Catholic (Jansenist, or those who followed the mystical and quietist teachings of Bishop Cornelius Otto Jansen, 1585–1638) bishops, and that within three years of the consecration these bishops had withdrawn their recognition of Mathew as a bishop.

Various views have been held as to the validity of such consecrations and of the consecrations and ordinations carried out by bishops of this type. The Eastern Orthodox churches have almost universally condemned them, on the ground that in no case did the consecrators have the *kyriotes* ("authority") from the church to act. Roman Catholic authorities have inclined to the view that such consecrations are valid but irregular. The Anglican Communion, on the ground that a bishop must be consecrated in, by, and for a church, has consistently refused any kind of recognition to such bishops and to the bodies founded by them.

HISTORY

Old Catholic churches. *Origins.* A schism, small in numbers but of great historical importance, was precipitated by the definition and promulgation of the doctrine of the infallibility of the pope at the first Roman Catholic Vatican Council in 1870. That doctrine declared that in matters of faith and morals the pope was infallible. In the 19th century many of the most learned Roman Catholics rejected the doctrine, on the ground that Christ had granted the blessing of infallibility to the church at large and not to any one member of it, however eminent. Others, such as Cardinal J.H. Newman (1801–90, a former Anglican), believed that the declaration of any new dogma would be inopportune. Yet a third group, which Newman described as an "insolent and aggressive faction," but which included the English archbishop, later cardinal, H.E. Manning (1808–92), eagerly desired the declaration. Among the dogma's strongest opponents was the German church historian Ignaz von Döllinger (1799–1890), one of the most learned men of his time. In a long series of works Döllinger had elucidated the history of the church; now his voice was raised in earnest protest against a doctrine that he regard-

Importance of I. von Döllinger

ed as having been unknown in the great ages of the church. After the dogma had been promulgated and the council prorogued, almost all the bishops of the minority group made their submission to Rome. Those who could not repudiate their deeply held convictions turned to Döllinger, who never submitted and died unreconciled in 1890. He never formally joined the Old Catholic movement, as the group of dissidents came to be called, but remained in close touch with the leaders of the movement and was willing to advise. In view of their need for a valid episcopal succession, which they regarded as essential to the being of a church, he recommended them to turn to the Jansenist Church of Holland. Thus, the Old Catholic churches of the continent of Europe came into being.

The Jansenist Church of Holland. On September 8, 1713, Pope Clement XI (1649–1721) in his constitution *Unigenitus* ("Only begotten") condemned what were supposed to be the tenets of Jansenism, which emphasized the doctrine of God's grace. In Holland, the teachings of Cornelius Otto Jansen, bishop of Ypres, were still widely revered, and the condemnation of Jansenist doctrine was not accepted. In 1723 the chapter of the ancient see of Utrecht (founded by St. Willibrord, 658–739) elected as its bishop Cornelius Steenhoven, who secured episcopal consecration at the hands of the missionary bishop of Babylon, Dominique-Marie Varlet, in 1732; this consecration has never been condemned by Rome and is generally accepted as having been valid though irregular. This small but highly cultured and wealthy church has managed to maintain itself in existence over two and a half centuries and can boast of an unbroken episcopal succession. Thus, much sympathy was expressed in Holland for the groups that after 1870 had considered it necessary to separate themselves from Rome in protest against what they believed to be new and unacceptable claims to authority. It was from the Old Catholic bishop of Deventer, Holland (Hermann Heykamp), that Germany in 1873 received its first Old Catholic bishop (J.H. Reinkens), to be followed by Switzerland in 1876 (E. Herzog) and Austria in 1925 (A. Schindelaar)—the Austrian Church had been organized in the 1880s but had not been able to secure the consecration of a bishop.

The Old Catholic churches today. Since 1889 the Old Catholic churches of the world—including the Polish National Catholic churches in Poland and in the United States, but not including the schismatic Mariavite Church in Poland, which in 1924 was disowned by the other Old Catholic churches on the grounds of alleged unorthodoxy in doctrine—have been united in the Union of Utrecht, of which the archbishop of Utrecht is ex officio president. Following the lead given by Döllinger, these churches have always maintained that they have no new doctrine to preach; they exist in order to call the churches back to what they believe to be an older and sounder tradition of Catholicism, and to serve as an instrument in the hand of God for the promotion of the unity of all Christians. With this special sense of vocation to work for Christian unity, the Old Catholic movement has from the start been deeply interested in relationships with other Christian bodies. The Old Catholic conferences of 1874 and 1875, presided over by Döllinger, were attended by Anglicans, Orthodox, Lutherans, and representatives of other Christian traditions. The Anglican Lambeth Conference of 1878 pronounced favourably on the Old Catholic churches, recognizing the group as a genuine reforming movement and not as schismatic.

The Union of Utrecht

National church movements. In the formation of the Old Catholic churches, national feelings played some part—especially in Switzerland—but were not dominant. In a number of other similar movements, national feelings and a striving after national independence played a much stronger role. Such feelings could not but be strengthened by the increasing centralization that the Roman Catholic Church has practiced since the Council of Trent (1545–63).

In Czechoslovakia, at the end of World War I (1918), the Los von Rom ("Away from Rome") movement attracted much interest and support and within a brief period claimed 800,000 members for the newly formed Czech National Church. Within a short time, however, this church adopted Unitarian (*i.e.*, non-Trinitarian) principles, rapidly declined in numbers, and ceased to exercise any powerful influence on church life in Czechoslovakia.

In the United States, Polish Roman Catholics became increasingly dissatisfied with the manner by which the Roman Catholic hierarchy, which was predominantly Irish or German, administered the affairs of the church; and, in the opinion of the Poles, that hierarchy neglected the interests of groups other than those of their Irish or German supporters. Some of their leaders entered into correspondence with Old Catholics in Europe; and in November 1897 Antonius Stanislas Kozlowski was consecrated in Berne (Switzerland) by three Old Catholic bishops. He thus became the first bishop of what has come to be known as the Polish National Catholic Church of America. This has grown to be the largest of all the Old Catholic churches, having (in 1970) a reputed membership of about 350,000.

Philippine Independent Church

In the Philippines, the Spaniards had done little to encourage Filipinos in the ways of independence in either church or state. At the time of the political revolution at the end of the 19th century, an ecclesiastical movement similar to the Polish National Catholic Church came into being, and in a short time (by 1902) the Philippine Independent Church was established under the leadership of Gregorio Aglipay y Labayán and Isabelo de los Reyes y Florentino. Since there was no way of securing regular episcopal consecration, 12 priests followed the custom of the laying on of hands, which is known to have been the practice of the early church of Alexandria, and thus consecrated Aglipay as their bishop. At one time the Philippine Independent Church claimed about 3,000,000 members. It was ill organized, however, and, as it had adopted Unitarian ideas, was not in communion with any other church of the Christian world. A change began when Isabelo de los Reyes, Jr., was consecrated as supreme bishop of the church, a post to which he was elected in 1946. Under his influence the church recovered its orthodox Christian faith and entered into relations with the Protestant Episcopal (Anglican) Church in the United States of America, which in 1948 conferred regular episcopal orders on three bishops of the Philippine Independent Church. Through them the succession was passed on to all other bishops, and in 1961 the Philippine Independent Church was admitted to full communion with the Church of England and with the Old Catholic churches.

Movements headed by episcopi vagantes. Since the second half of the 19th century there has been a considerable number of movements (more than 150) of dissent from the main-line Christian churches, many of them under the lead of virtuous but ill-advised clergymen, who have aspired to become bishops and have believed themselves to have received a special vocation to unite all the now separate sections of the Christian Church. Historically, the first of these new leaders was Jules Ferrette, who had received Roman Catholic orders in 1855 and in 1866 was consecrated with the title Mar Julius I, bishop of Iona, by the Jacobite bishop (who is not recognized by the patriarch of Constantinople) of Homs (Emesa) in Syria. It is affirmed, and also denied, that this consecration had the approval of the Jacobite patriarch. The arrival of Mar Julius in England aroused some interest among Anglicans who hoped for the reunion of Christendom through the Eastern rather than through the Roman Church. Mar Julius seems to have consecrated one successor, Richard Williams Morgan (1874), to whom he gave the title Mar Pelagius I, first patriarch of a restored Ancient British Church, supposedly founded in AD 63 by Joseph of Arimathea. Ferrette later spent some years in the United States but returned to Europe and died in Geneva in 1903. A large number of *episcopi vagantes* claim descent from Ferrette.

The work of Joseph René Vilatte

The second notable figure among the *episcopi vagantes* is Joseph René Vilatte (1854–1929), a French Roman Catholic, who had for a period worked in association with the Protestant Episcopal Church in Wisconsin but

on the recommendation of the bishop of Fond du Lac was ordained deacon and priest by Bishop Herzog of the Swiss Christian Catholic Church in 1885. Having vainly sought episcopal consecration in various directions, in the end Vilatte obtained what he desired from Antonio Alvarez (Mar Julius I), a Goan in South India who was metropolitan of the Independent Catholic Church of Ceylon, Goa, and India, and who had received rather doubtful episcopal orders from prelates in Kerala (India). The consecration took place in Colombo in May 1892. Although Vilatte referred to himself as metropolitan of the Old Catholic Church of America, he was formally repudiated by the Old Catholic bishops of Europe, who did not accept his consecration as valid. Vilatte's high hopes of extensive work among French-speaking Roman Catholics in the United States came to nothing, and toward the end of his life he returned to France. He died on July 8, 1929, having consecrated a number of bishops who in their turn have become the progenitors of a number of espiscopal successions.

Arnold Harris Mathew (1852–1919), after education as an Anglican, joined the Roman Catholic Church in 1875 and was ordained priest in 1877. Having become convinced that there was a great future for an Old Catholic movement in England, he approached the Old Catholic bishops with a view to episcopal consecration. In spite of the fact that Mathew was married—whereas the Dutch Church had not abolished the rule of celibacy for the clergy—he was consecrated at Utrecht in April 1908. Shortly after his return to England, Mathew took the title of "Old Catholic archbishop of London." But before long he gravely offended the Old Catholic bishops by raising to the episcopate two dissident Roman Catholic priests, without consultation with any other bishop. From this time on these bishops made it clear that they had disowned Mathew and that they would have nothing more to do with him. Mathew made various approaches to the Church of England, but these were not enthusiastically welcomed. He had been hopelessly mistaken in his estimation that there were possibilities of creating a large Old Catholic movement in England; his following was never other than very small, and no such movement ever came into being.

Succession of the *episcopi vagantes*

Almost all of the *episcopi vagantes* trace their succession to one or other of the above three bishops. The majority of these bishops were and are good and simple men, in part inspired by personal ambition but in many cases driven on by a genuine desire to be of service to the cause of Christian unity. Few of them have had any deep theological training. A notable exception is F. Heiler (1892–1967). Professor of the University of Marburg and author of many distinguished theological works (*Das Gebet*, 1918), he secured consecration in the Vilatte succession in 1932 with the title of bishop of the Communio Evangelica Eucharistica (Evangelical Eucharistic Communion).

Almost all of these bishops have an intense and one-sided belief in the power of the laying on of hands by anyone who stands in any line of allegedly valid episcopal succession. One of the strangest features of their belief is the desire to collect in one person as many lines of episcopal succession as possible, as a kind of extra guarantee for the validity of their claims. Thus, in April 1944 Hugh George de Willmott Newman (1905–) was raised to the episcopate by Mar Basilius Abdullah III (W.B. Crow) of the Ferrette line and given the name Mar Georgius and the title "Archbishop and Metropolitan of the Holy Metropolis of Glastonbury, the Occidental Jerusalem, and Catholicos of the West." Mar Georgius is understood to have undergone in the course of the next ten years a number of reconsecrations, as a result of which no fewer than 23 lines of succession have come to be united in his person. At the recent consecration of a Lutheran pastor in Germany, it was affirmed that 15 distinct lines of succession were represented.

In spite of the multiplication of successions, not one of these churches has received recognition from any one of the historic Old Catholic churches or from any one of the major churches of Christendom. Thus, their contribution to the cause of Christian unity has been minimal. The communities over which such bishops rule are very small and have exercised no major influence on the developments that have taken place in the Christian world in the last century.

DOCTRINE, PRACTICE, AND ORGANIZATION

Claim to the true tradition of the Western Church

Doctrine and practice. The Old Catholic churches of the continent of Europe claim to maintain the true tradition of the Western Church, without the new Roman Catholic doctrines of the Immaculate Conception (*i.e.*, that Mary, the Mother of Jesus, was conceived without sin; 1854), the corporal Assumption of Mary (*i.e.*, that Mary was physically taken up into heaven; 1950), and the infallibility of the pope (1870). True to the commission laid upon them by Döllinger, these churches have avoided doctrinal innovation. Yet all seem to have been influenced to some extent by the doctrinal ferment around them and to have given some attention to Protestant theological thought.

The churches founded by the *episcopi vagantes* have made little contribution to theological thought. Most of them may be classed as orthodox in theology, and this is an indispensable condition for the fulfillment of their self-imposed mission of working for the unity of all the great Christian traditions. The one notable exception is the Liberal Catholic Church, which from the beginning held theosophical (Oriental-Western mystical) views, and, since it denies the uniqueness of Jesus Christ, stands only on the very fringe of the Christian tradition.

Liturgical practice. In worship, the one radical change made by the Old Catholic churches was the introduction of the vernaculars in church services. In Holland, however, Latin was used until 1909 (a new liturgy was promulgated in 1960). The Swiss liturgy was issued both in French and German in 1880, and that for Germany in 1888. The giving of communion to the laity in both kinds (bread and wine) seems to have been practiced for the first time at Berne in 1879. All these liturgies are conservative, following closely the traditions of the Western Church but omitting or modifying everything that is considered to be inconsistent with true Catholic theology. The unrecognized churches have brought forth a multiplicity of liturgies. These are almost without exception eclectic in character, taking characteristic features from all the known liturgies of Christendom but themselves without clear character as the expression of any particular form of Christian theology.

Ecumenical relationships. True to the charge laid upon them by Döllinger, the Old Catholics have always been in the forefront of the modern ecumenical movement. They have been present at all the great ecumenical conferences and at the present time are represented on the Central Committee of the World Council of Churches. Perhaps their greatest contribution has been in the field of ecumenical journalism. The periodical known today as the *Internationale kirchliche Zeitschrift* ("International Church Journal"), founded in 1893 as the *Internationale theologische Zeitschrift* and from 1895 to 1911 as the *Revue internationale de théologie*, and edited for many years by the Swiss Bishop A. Küry, is indispensable to the student of church history for that period; in particular, the quarterly survey of events in the Eastern churches is unique in the variety and reliability of the information provided.

Relationships with other communions

The Old Catholic churches have always been especially interested in the Orthodox churches and in closer relations with them. Efforts continue to be made in this direction, but so far no formal step has been taken. They likewise have not remained unaffected by the new currents in the Roman Catholic Church. Relations, which naturally had been strained for a century, are probably better today than they have been at any time since 1870. Since 1931 the Old Catholic churches have had a steadily increasing measure of communion with the churches of the Anglican Communion. According to the Declaration of Bonn (Germany) of 1931, accepted first by the Church of England but subsequently by most of the other Anglican churches, each of the negotiating groups of

churches recognized the catholicity and independence of the other, though without being committed to being identical in regard to all doctrinal opinions or liturgical practices. Since that date interconsecration of bishops has been frequently practiced; it is probable that today 80 percent of Anglican bishops and clergy have the Old Catholic as well as the Anglican succession of the episcopate and the ministry. In 1946 the Polish National Catholic Church of America entered into similar relations of communion with the Protestant Episcopal Church in the U.S.A. This has gradually been extended to most of the other churches of the Anglican Communion. Similarly, the Philippine Independent Church, which first entered into relationship with the Protestant Episcopal Church, now has relations with a wide range of churches, including the Old Catholic churches.

Being small in numbers and preoccupied with maintaining their own existence, the Old Catholic churches have never had missionary work of their own. With ecumenical contacts, a new interest in missions in the non-Christian world has grown up, and some support has been given to Anglican missions, especially in South Africa.

Organization. The Old Catholic churches hold firmly to episcopacy as an essential element in the life of the church. Each bishop has considerable liberty in his own diocese, and national churches are self-determining also in the fields of liturgy and of the organization of parochial life. The centre of unity for the scattered churches is the Union of Utrecht, to which all the Old Catholic churches in Europe have adhered since 1889, and in which the conference of Old Catholic bishops is accepted as the highest authority in the church. As such, the conference determined the terms of intercommunion with the Church of England in 1931, affirmed the adherence of the Old Catholic churches to the World Council of Churches in 1948, and defined the attitude of these churches to the dogma of the Assumption of the Blessed Virgin in 1950.

The churches brought into existence by the *episcopi vagantes* depend very much on the charismatic qualities of the founder and can hardly be said to have any recognized organization.

Official statistics for the Old Catholic churches were given in 1970 as follows: Holland 12,000; Switzerland, 30,000; Germany 30,000; Austria 38,000; Czechoslovakia 4,000; Polish National Catholic Church of America 350,000, in Poland 90,000; smaller groups 25,000. The Philippine Independent Church claims 3,500,000 adherents under 56 bishops and 640 priests; it seems likely, however, that this is a considerable overestimate and that there are not more than 1,000,000 members closely in touch with the church.

BIBLIOGRAPHY. For the main-line Old Catholic movement the standard work in English is C.B. MOSS, *The Old Catholic Movement: Its Origin and History*, 2nd ed. (1964). In German, U. KURY, *Die Altkatholische Kirche: ihre Geschichte, ihre Lehre, ihr Anliegen* (1966), is valuable as a comprehensive survey. The Philippine Independent Church, still a highly controversial subject, is treated at great length in P.S. DE ACHUTEGUI and M.A. BERNARD, *Religious Revolution in the Philippines: The Life and Church of Gregorio Aglipay, 1860–1960*, 2 vol. (1960–66). Another point of view is presented in L.B. WHITTEMORE, *Struggle for Freedom: History of the Philippine Independent Church* (1961). The most recent and very full study of the *episcopi vagantes* is P. ANSON, *Bishops at Large* (1964), including a splendid bibliography; however, Anson does not entirely supersede the pioneer work on the subject: H.R.T. BRANDRETH, *Episcopi Vagantes and the Anglican Church*, 2nd rev. ed. (1961). The affair of Bishop A.H. Mathew has been dealt with from the Anglican side by G.K.A. BELL in *Randall Davidson: Archbishop of Canterbury*, 3rd. ed., pp. 1016–1023 (1952).

Oldenbarnevelt, Johan van

Johan van Oldenbarnevelt was a Dutch statesman and (after William I the Silent, prince of Orange) the second founding father of Dutch independence.

Born at Amersfoort (province of Utrecht) on September 14, 1547, Oldenbarnevelt studied law at Louvain, Bourges, and Heidelberg (where his ultimate conversion to Protestantism first germinated) and, probably, Padua. After his return to the Netherlands he settled down as an *advocaat* ("counsel") at the Hof van Holland, roughly speaking, the court of appeal for the province of that name, established at The Hague.

Role in Dutch independence

When, in 1572, two of the Netherlands provinces, Holland and Zeeland, succeeded in shaking off the Spanish rule from Brussels, Oldenbarnevelt did not follow the Court of Appeal, which fled to Utrecht, but decided to throw in his lot with the movement of national liberation. He even took part in an attempt to relieve the besieged towns of Haarlem and Leiden. In 1576 he was appointed "pensionary" (strictly, legal adviser, but as a full-time job) of Rotterdam, an office that automatically implied membership of the provincial states (assemblies), and, when the national revolt had spread to the other provinces, frequent attendance at the States-General in Brussels or Antwerp. In 1578, when a total reconquest by the Spanish armies under the leadership of Alessandro Farnese, duke of Parma, threatened, Oldenbarnevelt was one of the negotiators of the so-called closer Union of Utrecht (concluded January 1579), which was to serve as a kind of makeshift constitution for the United Provinces until 1795. During the negotiations, it became apparent that Oldenbarnevelt was aiming at securing for Holland the politically unassailable position to which the strategically all but unassailable province considered itself entitled after having borne the brunt of the revolt alone with Zeeland for nearly seven years. These activities also brought him into fairly close contact with William the Silent.

In 1586, two years after the Prince's assassination, Oldenbarnevelt accepted the appointment by the States of Holland as the province's *landsadvocaat—i.e.*, the office that, after his downfall, was renamed *raadpensionaris* ("great pensionary"); in this office he became the real trustee of William the Silent's political inheritance. While the latter's son, Maurice of Nassau, a brilliant military commander, was in charge of the actual warfare in the field, it was Oldenbarnevelt who, at first in close collaboration with him, mobilized and coordinated the country's available energy and resources, thus making warfare possible. As one of these activities, he took an active part in the founding of the Dutch East India Company.

Although theoretically a servant of only one out of seven sovereign provinces, Oldenbarnevelt, who himself undertook several diplomatic missions to France and England, was virtually the union's foreign secretary. In this capacity, too, it was he who continued the work of William the Silent and succeeded in integrating the somewhat suspicious, politically unorthodox new commonwealth of rebels against their lawful overlord. In this respect, his greatest triumph was the conclusion of a full-fledged triple alliance with France and England in 1596.

Oldenbarnevelt's main achievement in the field of foreign policy was, however, the so-called Twelve Years' Truce, concluded in 1609 after long-protracted negotiations, by which the original national program of ousting the Spaniards from the whole of the Netherlands was virtually abandoned and the northern commonwealth of the seven provinces established as such.

On the other hand, it was also in this achievement that the all-pervading flaw in Oldenbarnevelt's position as the union's leading statesman became apparent—*i.e.*, the very circumstance that he was pledged by oath to only one out of those seven provinces of the ancient Netherlands that, as the saying was, "remained with the union," the province of Holland. Filling a vacuum created by the fact that the formerly predominant provinces, Brabant and Flanders, had been reconquered by the Spanish arms, Holland, a hitherto peripheral county, had become preeminent; it contributed close to 59 percent of the federal budget. Under those conditions, a large degree of "Hollandocentrism" or even of "Hollandism" appeared more or less inevitable, and the landsadvocaat, or "great pensionary," was its chief exponent and advocate within the union setup.

In the same way, the princes of Orange found themselves almost automatically cast in the role of prime exponents of the union conception, and it is in the light of this that the ensuing conflict between Oldenbarnevelt and Maurice becomes fundamentally understandable, even without a detailed examination of its multiple origins. In this context it is utterly irrelevant that, after his father's death, Maurice had been made stadholder of Holland by Oldenbarnevelt and his political friends, with the express purpose of safeguarding the province's individuality and special position in the days (1586) when Robert Dudley, earl of Leicester, as governor general, tried to impose his conception of centralized government on the various provinces.

Religious conflicts during the Twelve Years' Truce

During the Twelve Years' Truce, the latent conflict crystallized around its religious facets. The astonishing success of the Netherlands' independence movement was indissolubly connected with the fact that, sooner or later, all the provinces "remaining with the union" came to be ruled by Calvinist minorities for whom, short of renouncing their faith, there existed no possibility of reconciliation with the abjured ruler, Philip II of Spain. As for Oldenbarnevelt, like William the Silent, he too had accepted membership of the Reformed Church, but he and his fellow "regents" in Holland cherished the ideal of a church that was, though based on the Reformation in its Calvinist shape, sufficiently latitudinarian in its dogma to attract and satisfy all those who were willing to relinquish the Roman obedience. According to these rulers of Holland, the nation had rebelled against the centralizing and tyrannical tendencies of its Hispanicized overlord for the sake of freedom, including the freedom from inquisitorial practices, of which they were equally unwilling to accept the Calvinist Genevan as well as the Roman or Spanish brand. As seen by many theologians and preachers, on the other hand, the revolt had taken place for the sake of the Reformed religion in its most uncompromisingly strict dogmatic variety. When, on the perilous issue of predestination, the antithesis became polarized in a conflict between two professors of theology at Leiden—the strict Gomarus and the more moderate Arminius—Oldenbarnevelt and the majority of the voting towns in Holland, though not Amsterdam, favoured the Arminians against the bulk of the Calvinized masses, who were staunchly Gomarist or, as they were commonly called, Counter-Remonstrant. Paradoxically, Oldenbarnevelt and his adherents even had to safeguard the principle of tolerance by somewhat intolerant measures; those preachers who, in spite of various decrees to the purpose, remained stubbornly unwilling to refrain from preaching controversial sermons were dismissed and occasionally sent into exile.

The religious controversy was, moreover, inextricably interwoven with the antithesis of province versus union, the Counter-Remonstrant preachers consistently referring to their religion as the God-given "cement" that kept the union together. Translated into terms of actual politics, this meant that they wanted to convoke a "national"—*i.e.*, an interprovincial—synod trusting (as it turned out, wrongly) that it would establish a church triumphant on the Genevan model, completely independent from all civil authorities whose worthiness and consequently whose right to govern would be judged by the churchmen. For obvious reasons, the States of Holland, led by Oldenbarnevelt, considered a synod of this kind far too risky and withheld their consent to its meeting.

Disputes with Prince Maurice

Seen in retrospect, the climax announced itself when in July 1617 Prince Maurice sided openly, not to say defiantly, with the Counter-Remonstrants. This veiled declaration of war on Oldenbarnevelt and the Holland regents' party was answered by a so-called sharp resolution voted by the States of Holland on August 4, 1617, which, among other things, encouraged the various towns in the province to recruit armed units of their own, not integrated in the federal army and not even subject to Maurice's command as the province's captain general. The states remained within their rights in taking such measures. It is understandable that a man like Maurice considered such measures as an intolerable violation of the union statute. Slow-moving tactician that he was, the Prince spent no less than a whole year in reinforcing his position throughout the union, until suddenly, on August 29, 1618, he took Oldenbarnevelt prisoner, together with some of his closest collaborators, chief among whom was his informal "crown prince," the famous Hugo Grotius, then pensionary of Rotterdam.

Never in the course of Dutch history was the problem of union versus province more crudely manifest than when it materialized in the vexing question of how and by whom Oldenbarnevelt was to be tried for his life. His own thesis, unassailable at least in theory, was that, having exclusively acted as a civil servant of the sovereign province of Holland, he was responsible only to the judiciary of the province of Holland; his enemies, on the other hand, wanted to have him tried for felony against the union. As, however, no federal judiciary existed, the only possible expedient was to summon an extraordinary tribunal ad hoc; it consisted of 24 judges, by no means all of whom were qualified lawyers, and not a few of whom, besides being political opponents, were also personally antagonistic to Oldenbarnevelt. Even so, after more than half a year's imprisonment and interrogation, he was condemned to death not for high treason, for which public opinion had been carefully propagandized, but for the "subversion" of the country's religion and policy. On May 13, 1619, he was beheaded on the Binnenhof, at The Hague. More than any other event in the country's history, his execution has continued to haunt Dutch historiography and even Dutch politics, almost until the present day.

BIBLIOGRAPHY. In spite of its enduring literary merits, J.L. MOTLEY, *Life and Death of John of Barneveld, Advocate of Holland*, 2 vol. (1874), is utterly untrustworthy as far as the subject matter is concerned, although, to a lesser extent, its extreme partiality justifies the same verdict on the book written against Motley by the Dutch historian and politician, GROEN VAN PRINSTERER, *Maurice et Barnevelt* (1875). The authoritative biography is the Dutch work by JAN DEN TEX, *Oldenbarnevelt*, 3 vol. (1960–71).

(J.J.P.)

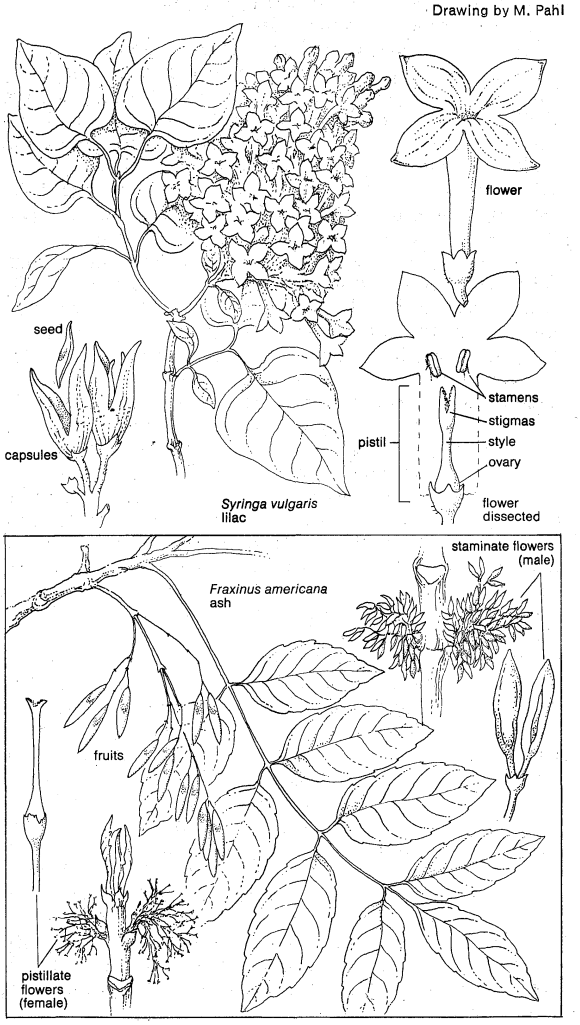
Oleales

The olive order (Oleales) is a small order of flowering plants containing a single family, the Oleaceae. The woody plants comprising this group are distributed throughout the world, except in the Arctic. Although they are found in many different habitats, only rarely are they the most dominant plants.

General features. *Diversity and distribution.* A number of plants in this order are of economic or aesthetic importance—for example, the olive (*Olea europaea*) is the source of olives and olive oil; the ashes (genus *Fraxinus*) are noted for their hardwood timber; and many genera are famous for their horticultural merit—*e.g.*, *Syringa* (lilacs), *Jasminum* (jasmines), *Ligustrum* (priv-

ets), *Forsythia*, and *Osmanthus*. Most members are trees or shrubs, but a number, such as most jasmines, are woody climbers. The tropical and warm-temperate species are evergreen; those from the colder North Temperate Zone are deciduous. Certain genera are found in both Eurasia and North America (*e.g.*, *Fraxinus*), others are scattered throughout the tropics (*e.g.*, *Linociera*). The largest genus, *Jasminum*, is confined to the Old World; any species growing wild in the Americas today have escaped from cultivation. The genus *Menodora* has an unusual disjunct distribution (found in widely separated regions without apparent connections) and is found in North America, South America, and South Africa. This distribution is also remarkable in that one species, *M. heterophylla*, is native to both South America and South Africa.

Drawing by M. Pahl



Representative plants of two genera in the order Oleales.

Origin of the cultivated olive

Economic importance. The most important economic product is the olive, the fruit of *Olea europaea*. This tree, particularly characteristic of the Mediterranean region and of very ancient origin, appears to have no truly wild progenitors, and, although the cultivated olive can seed itself, the offspring fail to produce the same large fruits. The olive probably arose at the dawn of agriculture, perhaps in the area of the Fertile Crescent in the Middle East. Very closely related plants with small, generally inedible fruits are found over a large part of the Old World—in southwest Asia; in eastern Africa as far south as South Africa, including the highest mountains of the Sahara; on Madeira Island in the North Atlantic; and in the drier areas of the Sino-Himalayan region. Today the olive is widely grown as a commercial crop in every country with a Mediterranean-like climate.

Although several members of the order Oleales are well-known in horticulture, the most famous is the lilac, with its colourful, sweetly scented blossoms. Over 400 cultivars of the European lilac, *Syringa vulgaris*, with colours ranging from lilac, purple, red, and pink to white and with single or double flowers, have been developed. Lilacs have been grown in gardens for centuries. The Persian lilac, *S. persica*, was one of the first plants introduced to Europe from the East; other Asiatic species have been introduced more recently.

Natural history. Members of this order are generally characteristic of woodlands, woodland margins, and forests of various types. Their ecological amplitude is not particularly great, and no members are especially adapted to desert conditions, salty soils, or the Arctic climate. Some species of *Fraxinus*, the ashes; of *Olea*, the olives; and of *Menodora* grow in dry climates, but not in true desert.

Pollination and diversity of flowers. Pollination is usually carried out by insects; many types are involved, and no particular specialization exists between the flowers and their pollinators. Nectar is usually produced within and at the base of the petals, and where these form a tube, it is more or less concealed. This ensures that in obtaining nectar the insect pushes down beyond the stamens (male pollen-producing structures) and stigma (the female pollen-receiving structure), touching both. A wide variety of insects visit flowers within this order, including bees, beetles of various kinds, and several different flies.

The most common flower colour in the order is white, although lilacs occur in a range of colours, and in *Forsythia*, *Menodora*, and a few species of *Jasminum* the flowers are yellow. In many genera, where the individual flowers are not very large, their conspicuousness to pollinating insects is increased by aggregation into fairly compact inflorescences (flower clusters) and by the production of a strong scent. In fact, the family Oleaceae, especially lilacs, jasmines, and *Osmanthus*, is noted for its sweetly fragrant flowers. The name *Osmanthus* means "fragrance flower," and this genus is particularly prized in China and Japan, where the dried flowers are used to scent certain Oriental teas, as are those of a few species of *Jasminum*. *J. sambac*, whose native provenance is uncertain but is probably India or Southeast Asia, is cultivated throughout the tropics and has been for many centuries. Its flowers are often used in making necklaces, or leis; and in Hawaii, where it is not native, it is especially grown for this purpose. *J. grandiflorum*, commonly called Spanish or Catalonian jasmine, has long been prized for its scent and cultivated in Spain and in southern France, where it is grown commercially for the extraction of oil of jasmine.

Scent and colour

Other genera in the order are also noted for their fragrance, and even the privets (species of *Ligustrum*) have a strong, sweet odour. It is probable that some of the heavily scented, white-flowered members are pollinated at night. The pollinating insects of *Jasminum*, the fused petals of which form a longish tube, probably are night-flying moths with a long proboscis, a tubular sucking organ with the mouth at the tip.

In a few species of *Fraxinus*, such as the manna or flowering ash, *F. ornus*, which is native to the Mediterranean region, the flowers have small, white, strap-shaped petals and produce nectar. (The name manna ash refers to an edible sugary material exuded from the cut stem of the tree and at one time used in medicine.) Most species of *Fraxinus*, however, like the majority of forest trees in temperate regions, are wind-pollinated. The flowers of the white ash (*F. americana*), many other American species, and the common European ash (*F. excelsior*) possess no petals; quantities of pollen are blown by the wind, and the sexes of flowers on individual trees are often separate.

The chance of cross-pollination is increased by the development of unisexual flowers in several genera. The American genus *Forestiera*, like many ashes, has unisexual flowers without petals. In other genera, such as *Osmanthus*, the flowers of individual trees are often functionally unisexual because either the small ovary or the stamens are nonfunctional. In *Forsythia*, *Abeliophyllum*, and *Jasminum* the flowers of individual plants have either

short styles (the narrow upper end of the ovary, with the stigma at its top), with the stigma below the level of the stamens, or long ones, with the stamens borne below the stigma. Seed normally develops only if pollen is transferred from a long-styled to a short-styled flower or vice versa. The plants in fact are self-sterile, and cross-pollination is essential.

Seed dispersal. Seed dispersal in a number of genera is aided by wind. The whole fruit is winged in *Fontanesia*, *Abeliophyllum*, and the ashes, in which the fruit is traditionally known as a "key." Individual seeds are somewhat flattened in *Forsythia*, *Syringa*, and the tropical genus *Schrebera* so that, after being shed from the capsule, each has a greater chance of being blown away from the immediate vicinity of the parent plant. In most members of the family (*e.g.*, olive, most privets, and jasmines), however, the fruit is fleshy, generally dark purple or black, and has a hard, stony seed. In the natural state these fruits are consumed by birds, which helps to disperse the plant species.

Form and function. *Vegetative features.* A vegetative feature common to almost every member of the order is that of opposite leaves; a few species of *Jasminum* are the only exceptions. In many genera the leaves are pinnately compound—*i.e.*, with numerous small leaflets arranged on both sides of a central axis, the whole constituting a single leaf. Examples include most species of *Fraxinus*, many jasmines, two lilacs (*S. laciniata* and *S. pinnatifolia*), and some species of *Schrebera*. In *Forsythia suspensa* the leaves are trifoliolate (three leaflets) on some shoots, especially those growing rapidly, or single-bladed, as in the other forsythias. The groups of genera closely related to the olive have simple leaves, often thick and leathery, and in some species of *Osmanthus* the leaves are holly-like and prickly.

Characteristic wood of the Oleales

Anatomically the family is fairly uniform in its characteristics. Typically the vessels (*i.e.*, the water-conducting cells) of the wood are small, and accordingly, the wood of the olive, with its fine and close grain, is prized for carving and turnery. The timbers of most species of *Olea* and their close relatives are very durable—even when used out-of-doors—and their hardness is often reflected in their native names; *e.g.*, black ironwood, for *Olea capensis* of South Africa, and devilwood, for *Osmanthus americanus* of southeastern United States. Ash timber, from species of *Fraxinus*, has a worldwide reputation for toughness and resilience and is used for purposes where these characteristics are required—*e.g.*, in tool handles, hockey sticks, and frames for tennis rackets.

Floral features. Generally speaking, flower structure throughout the family is very uniform with four sepals, four petals, two stamens, and two fused carpels forming a single superior (*i.e.*, positioned above the other flower parts) ovary. The four petals (in *Jasminum* there may be seven, eight, or nine) are generally joined at the base to a greater or lesser extent to form a tube. Most species of *Fraxinus*, however, have no petals; nor do the four native olives of New Zealand (*Nestegis* species), the American genus *Forestiera*, and one of two Asiatic species of *Olea*. In *Chionanthus*, the fringe-tree, the long, strap-shaped petals form a very short tube at the base. Superficially similar flowers are found in the relatives of *Fraxinus ornus*; in *Linociera* the petals, split to the base, are held together in pairs by the base of stalks of the two stamens.

Although two is the characteristic stamen number, there are a few exceptions. *Nestegis* species, four of which are from New Zealand and one, *N. sandwicensis*, from Hawaii, often bear four stamens (occasionally up to six), as does the Malesian *Osmanthus scortechinii*. The ovary is much more constant in its characters, producing only one, or at most two, mature seeds in a fleshy olive-like fruit, in a winged "key" as in *Fraxinus*, or in a dehiscing (splitting-open) capsule as in the lilacs. In *Forsythia* the capsule may contain several seeds.

The pollen produced by members of the order is more or less similar in structure and of a rather nonspecialized type. The grains are ellipsoid with three (or four) longitudinal furrows and a finely reticulate surface. The minor differences in pollen structure among the various genera help confirm that the members form a natural group. Pollen grains somewhat similar in appearance are found, however, in several other families, including, for example, certain members of the family Celastraceae (order Celastrales).

Evolution. *Fossil record.* The order Oleales is relatively poorly known from fossils. The oldest one recognized as belonging to the order is a leaf impression identified as *Fraxinus* from the early Cretaceous beds of Greenland (of about 80,000,000 years ago). Similarly, a leaf identified as *Fraxinus* is recorded from the Upper Cretaceous in the United States (about 65,000,000 years ago). Numerous fruits and leaf impressions, many bearing a very close resemblance to present-day species, have been found in later beds throughout North Temperate regions, through to the Pliocene (7,000,000 years ago), and in even more recent deposits.

Oldest known members of the order

Other fossil members of the Oleales are first known from a fruit named *Olea headonensis* from the early Paleocene to Oligocene deposits in Britain (65,000,000 to 38,000,000 years ago) and one called *Oleaecarpium germanicum* from the upper Oligocene of Europe (about 30,000,000 years ago). Good leaf impressions of *Olea* dating from 20,000,000 to 12,000,000 years ago have been found in south and central Europe and North America. Leaves said to represent *Notelaea*, a present-day Australian genus, have also been found in the same regions, but in this case the generic identification is not so certain. A fruit identified with the tropical genus *Nathusia* (now known as *Schrebera*)—several living species occur in Africa, one in South America, and one in Asia—and called *N. rugosa* has been found in European deposits from the middle to upper Oligocene (30,000,000 to 26,000,000 years ago). Another tropical genus, *Jasminum*, has been recorded from fruits found in the Netherlands dating from 7,000,000 years ago in the lower Pliocene.

Phylogenetic-evolutionary relationships. The order Oleales contains the single, somewhat isolated family Oleaceae. A relationship has been suggested to certain families in the order Celastrales, such as the holly family, Aquifoliaceae, the Salvadoraceae, and the Icacinaceae, and it has also been suggested that these groups probably share a common ancestor in the order Saxifragales. There is little unanimity among botanists, however, as to how the family Oleaceae should be classified. It has been variously given ordinal status, sometimes alone or with the small family Salvadoraceae; classed within the order Gentianales; and sometimes placed in a restricted part of the Gentianales that is separated and called the order Loganiales. Most recently it has been placed within a modified order Scrophulariales. Because in most genera the petals are joined into a tube and the ovary is always two-parted, the family Oleaceae has usually been included in orders in which there is always a corolla (the collection of petals) of united petals and often in that group of families that have in the past been loosely called the "Bicarpellatae." It seems most probable, however, that the order Celastrales or its progenitors were the group from which the family Oleaceae arose.

Various classification schemes

The family Oleaceae seems to consist of two main groups of genera: those placed in the subfamily Jasminoideae and those in the subfamily Oleoideae. A study of the chromosome numbers of different genera confirms the affinity of various genera otherwise grouped on morphological characters. *Forsythia* and *Abeliophyllum* (which has been called white forsythia) are unique in that both possess 28 chromosomes in their vegetative cells; in a recent classification the two genera have been placed in the subfamily Jasminoideae along with *Jasminum* and *Menodora*, which have 26 and 22 chromosomes respectively. They are perhaps best treated separately, however, as the two pairs of genera bear little resemblance to each other.

Within the subfamily Oleoideae the genus *Fraxinus*, which, because the best known species lack petals, has traditionally been classified alone or with *Fontanesia* (because of the latter's winged fruits), is probably quite closely related to the many genera that produce olive-like fruits. The genus *Syringa* (lilacs) and the genus *Ligus-*

trum (privets) also belong in this subfamily and are closely related, despite their dissimilar fruits.

The small genus *Nyctanthes* (best known from *N. arbor-tristis*, a tree sacred to the Hindus), native to India, together with the related monotypic (having a single species) *Dimetra* of Thailand, has been variously classified in the family Oleaceae or in the family Verbenaceae (order Lamiales). Traditionally it belongs to the former and is possibly, if distantly, related to *Jasminum* or *Schrebera*; various anatomical and morphological characteristics suggest, however, that they should be treated as a subfamily within the family Verbenaceae.

Classification. *Distinguishing taxonomic features.* The family Oleaceae is most easily recognized by a combination of characters: it has a woody habit with opposite leaves; flowers consisting of four sepals and petals (usually united), two stamens, and a united ovary of two chambers. There are exceptions, however, to most of these individual features.

The characters used to classify the genera within the family are the presence or absence of the petals and whether they are united to form a tube, however short, or free, and whether the petals overlap in the bud (imbricate) or are arranged with their edges touching (valvate). The type of fruit has also been important, whether it is a fleshy olive-like drupe (a stony-seeded fruit), a capsule that splits open to release dry seeds, or a winged samara (or key) as in the ashes. The fruit type, however, is no sure guide to relationships, nor is the absence of petals; *Nestegis*, for example, generally has no petals but is related to the petaloid genera *Olea, Osmanthus*, and *Notelaea*. The wild olive of Hawaii (*Nestegis sandwicensis*), however, has petals in its flowers. Similarly, although most species of *Fraxinus* have no petals, those related to *F. ornus* have well-developed ones. Most ashes, such as the common European ash, *F. excelsior*, have flowers reduced to complete simplicity, for there are no sepals either, and because the sexes are often separated in different inflorescences or on different individual trees, the flowers consist only of a single, naked ovary or a pair of stamens. Many of these, however, are crowded together in branching inflorescences. There seems no doubt that this simplicity results from reduction and does not reflect primitiveness.

Structural variation among close relatives

Annotated classification.

ORDER OLEALES

Woody plants, trees, shrubs, or climbers. Leaves opposite, rarely alternate, simple or pinnately compound, and lacking stipules (small, leaflike appendages at the base of the leafstalk). Inflorescence basically cymose (determinate; *i.e.*, the flowers mature in sequence from the tip, or central flower, downward) but paniculate, decussate, fasciculate (various modes of branching), or single-flowered. Flowers regular (radially symmetrical); bisexual, or rarely unisexual, sometimes by abortion. Calyx (sepals) of 4 lobes (rarely more, or lacking). Corolla (petals) of 4 (rarely to 12) united lobes, rarely almost free or lacking, aestivation (condition of the petals in the bud) imbricate or valvate (rarely contorted). Disc absent. Stamens 2 (rarely 3, 4, or 6), borne on the corolla and alternate with the lobes; anthers usually with a slight extension to the connective, dehiscing (opening) longitudinally. Ovary superior, of 2 fused carpels, each locule with two (rarely 1 to 4) axile, pendulous or ascending, ovules, style 1 or lacking, usually with a 2-lobed stigma. Fruit usually 1-seeded, a drupe, berry, capsule, or samara, seed with cellular endosperm (nutrient tissue for the developing embryo) or none. About 28 genera and between 500 and 600 species in temperate and tropical regions throughout the world, but especially the Old World, eastern Asia, and the tropics.

Family Oleaceae

The only family in the order, it has the characters of the order. It is divided into 2 subfamilies, Jasminoideae and Oleoideae.

Critical appraisal. The Oleaceae comprise a natural family, despite the number of individual exceptions to characteristic features, such as the lack of petals in some members and the occasional occurrence of alternately arranged leaves. Moreover, its classification in an isolated position is probably correct, for relationships with other families and orders are not clear. New information from the traditional study of morphology or anatomy that might help to elucidate these relationships is unlikely, but the rapidly developing fields of palynology (the study of pollen grains) and chemotaxonomy (the study of biochemical characters in relation to taxonomy) may well provide valuable new evidence.

Within the family the relationships of certain genera are uncertain. The subfamily Jasminoideae, as at present constituted, appears to be a rather heterogeneous assemblage containing the genera *Jasminum, Forsythia, Fontanesia, Schrebera*, and *Myxopyrum*. It is doubtful whether these genera are really more closely related to one another than to others now placed in the second subfamily, the Oleoideae. Here, however, the correct delineation of the genera themselves is often the problem. Should *Olea* be split into two or three separate genera (*e.g.*, into *Steganthus* and *Tetrapilus*) as has been proposed, and within the genus *Osmanthus*, should the sections *Leiolea* and *Siphosmanthus* be raised to generic rank? As with problems at interordinal and interfamilial levels, new and significant morphological data are unlikely to be forthcoming. Chromosomal information seems of no assistance in this subfamily, but modern developments in biochemistry may eventually be of value.

Taxonomic problems

Perhaps the outstanding problem at the species level concerns the relationships and origin of the cultivated olive. *Olea europaea* is not known in the wild, and, although closely related plants exist in many tropical and warm temperate parts of the Old World, it is uncertain whether the domesticated olive was developed from them and, if so, how it was done. Chemotaxonomic studies together with breeding and cultural experiments—growing species and plants from different provenances side by side and crossing them—might provide decisive information, but because the olive is a relatively slow growing tree such investigation could be undertaken only on a long-term basis.

Olivares, Conde-Duque de

Prime minister and court favourite of King Philip IV, the Conde-Duque de Olivares governed Spain for over 20 years during a period that saw the climax of an epoch of literary and artistic splendour as well as the most chronic political decadence.

Olivares was born Don Gaspar de Guzmán y Pimental, in Rome on January 16, 1587. His father, Don Enrique de Guzmán, was the Spanish ambassador to that city. His mother, Doña María Pimental Fonseca, was a member of the Castilian nobility.

As second-born son of an aristocratic family, Don Gaspar studied for the priesthood, obtaining a degree from the University of Salamanca in law, theology, and the arts (1601–04). With the death of his older brother, however, he renounced his position as canon in Seville (to which he had been appointed by Pope Clement VIII) and joined his father in Valladolid, then the location of the Spanish royal court. In 1607, orphaned and heir not only to a noble title but also to one of the largest fortunes of the kingdom, Don Gaspar married his cousin and niece (they were related through both sides of the family), Doña Inés de Zúñiga y Velasco, lady-in-waiting to Queen Margaret. Their only child was a girl, María, who died shortly after her marriage. Don Gaspar also had an ille-

Archivo Mas, Barcelona

gitimate son, Julianillo Valcárcel, whom he later recognized and named Enrique Felipez de Guzmán, marquis of Mairena.

In 1615 Olivares became one of Prince Philip's six personal attendants. When Philip was crowned king in April of 1621, he had just reached 16 years of age, and Olivares was approaching the age of 34. By this time Olivares, a man of unpleasing appearance and changing moods, had become the young king's irreplaceable companion. As Philip's favourite he was given the rank of grandee, the title most coveted by Castilian nobility. Reluctant to drop any part of his title, he styled himself "conde-duque" (count-duke).

Domestic policies

From 1623 until January 24, 1643, Olivares served as prime minister of Spain. He was unswervingly loyal to the King and was vehemently patriotic. He was also avid for power—both for himself and for Spain. The main objective of his domestic policy was to engender national unity among the separate kingdoms of the peninsula, kingdoms that he described as "anachronistic as crossbows." He attempted many economic reforms aimed at relieving the difficult situation that had arisen as a result of long reliance on the influx of precious metals from the New World. Among these programs were restrictions on granting favours (except for honorary titles); recoining of the old copper alloy moneys; introduction of paper money; promotion, with the aid of the Castilian Cortes (council), of various royal decrees to stop the industrial and commercial decline of the kingdom; and a project whereby the shipping companies would be able to compete more advantageously with the Dutch, English, and French commercial fleets. But his attempts to promote trade and industry met with failure, due largely to the fact that aristocratic Castilians, slaves to the idea of a rigid class structure, looked down upon all mercantile professions. His moves toward centralizing power in the hands of the king and his ministers were partly responsible for the revolts of the Catalans and the Portuguese, which began in 1640, and for an abortive conspiracy to form a separate Andalusian kingdom (1641).

In foreign policy Olivares was guided by the dream of *austracismo,* a joint European hegemony of the Austrian and Spanish Habsburg kingdoms. This policy meant continued Spanish involvement in the Thirty Years' War and ended with the eclipse of Spanish power by France. Yet in the period of the Counter-Reformation, it is difficult to conceive of Spain following a different course: in this sense it was almost inevitable, and Olivares can hardly be judged in terms of its ultimate failure.

Olivares' character

One biographer has painted a picture of Olivares as the typical *picnico,* a man who was strong and slightly heavy, a man subject to wide and sudden ranges of mood—from a maniacal, irrational exultation and optimism to complete despair and depression. He thus presented a sharp contrast to his main rival, Cardinal Richelieu of France, a cold, irritable, reserved man, known for using few words and taking swift action. In 1632 Olivares envisioned the inevitable destruction of the Spanish monarchy; in 1635 he was convinced that, if all his war plans were executed, there would be no enemy capable of opposing or defeating Spain. Scarcely two months later, in another mercurial change of mind, he again gave up any hope of Spain's retention of power. From that time onward, his moods tended more toward deep depression, with occasional euphoric interludes, such as that caused by the success of Spanish armed forces threatening Paris in December 1636.

As a result of a court intrigue headed by the Queen (Elizabeth of France), Philip removed his ailing favourite from office in January 1643. Although the King would undoubtedly have liked to recall him later, other grandees, long jealous of his power, continued to discredit him. Eventually Olivares was exiled, along with his wife, to the city of Toro. In December 1644 the Inquisition began to investigate his conduct. He died at Toro on July 22, 1645.

ZUDAIRE HUARTE, *El conde-duque y Cataluña* (1964), a valuable study of the fight between Olivares' modern concept of the State and Catalonia's separatist policy; J.H. ELLIOTT, *The Revolt of the Catalans: A Study in the Decline of Spain, 1598–1640* (1963), an analysis of the political relations between Castille and Catalonia during the reign of Olivares, and *Imperial Spain, 1469–1716* (1963), an excellent history of Spain dealing with the tensions that resulted from Castille's unitarian policies and Catalonia's federalist policies.

(E.Z.H.)

Olivines

The olivines comprise a group of common rock-forming silicate minerals that are closely related on chemical and structural grounds. The name olivine alludes to the quasi-olive green colour of the most abundant varieties, forsterite and fayalite, which are silicates of magnesium and ferrous iron, respectively. Other members of the group may contain manganese or calcium in addition to, or substituting for, iron or magnesium; among these, the more important named varieties are tephroite (containing manganese), monticellite (calcium and magnesium), kirschsteinite (calcium and iron), and glaucochroite (calcium and manganese). These varieties and some of their physical properties are listed in the accompanying Table.

Some Physical Properties of the Olivines

end members	composition	specific gravity	hardness on Mohs scale	unit cell dimensions*		
				a	b	c
Forsterite	Mg_2SiO_4	3.22	7	4.756	10.195	5.918
Fayalite	Fe_2SiO_4	4.39	6½	4.817	10.477	6.105
Tephroite	Mn_2SiO_4	3.78	6	4.90	10.60	6.25
Monticellite	$CaMgSiO_4$	3.08	5½	4.815	11.08	6.37
Kirschsteinite	$CaFeSiO_4$	—	—	—	—	—
Glaucochroite	$CaMnSiO_4$	3.41	—	4.92	11.19	6.51

*The unit cell is the smallest volume of a mineral containing a complete sample of the atomic or molecular groups that comprise it. Unit cell dimensions along the three crystallographic axes (*a, b, c*) are given in angstrom units (one angstrom equals 10^{-8} centimetres).

The olivine minerals that contain magnesium and iron are generally believed to be among the most important minerals in the Earth's upper mantle (the region directly beneath the Earth's crust). They are particularly characteristic of basic and ultrabasic igneous rocks; that is, rocks that are relatively poor in silica and rich in iron and magnesium that crystallize from molten material within the Earth (Figure 1). They also occur in metamorphic

Figure 1: Phenocryst of olivine (centre) in a fine-grained groundmass; olivine basalt from Ookala, Mauna Kea, Hawaii (magnified 28 ×).

(altered) rocks and in some meteorites. When clear and of good colour, magnesium-rich olivine is used as a gemstone and has the names peridot (for dark-coloured varieties) and chrysolite (light-coloured). Because of its high melting point and resistance to chemical reagents, magnesium olivine is an important refractory material—*i.e.*, it can be used in furnace linings and in kilns when other materials are subjected to heat and chemical processes.

This article treats the crystal structure and chemical composition of the olivines and their physical properties, occurrence in nature, and synthesis. For further information on crystal structures see CRYSTALLOGRAPHY, and for the general relations of olivines to other mineral groups, see MINERALS and SILICATE MINERALS. Ornamental varieties are covered in the article GEMSTONES.

FORSTERITE–FAYALITE SERIES

Chemical composition. The most abundant olivines are intimate mixtures of forsterite, pure magnesium silicate (Mg_2SiO_4), and fayalite, pure ferrous silicate (Fe_2SiO_4); most of the naturally occurring specimens are intermediate in composition to these two pure compounds, called end-members, and have the general chemical formula $(Mg,Fe)_2SiO_4$ (Figure 2). The members of this mixture, the forsterite–fayalite solid-solution series (a single crystalline phase that varies in composition between finite limits—*i.e.*, the end-members), are given the general mineral name olivine. The name forsterite is restricted to those species with no more than 10 percent iron substituting for magnesium; fayalite (from Fayal Island in the Azores, where it was believed to occur in a local volcanic rock but probably was obtained from slag brought to the island as ship's ballast) is restricted to species with no more than 10 percent magnesium substituting for iron. Species intermediate in composition to forsterite and fayalite are also named; from most magnesium-rich to most iron-rich they are: chrysolite (90–70 percent Mg), hyalosiderite (70–50 percent Mg), hortonolite (50–70 percent Fe), and ferrohortonite (70–90 percent Fe).

Solid-solution series

The continuity in the forsterite–fayalite series has been verified experimentally. At the magnesium-rich end of the solid solution series, natural crystals may contain very small amounts of calcium, nickel, and chromium; the iron-rich members near the other end of the series may incorporate small amounts of manganese and calcium. Apart from ferrous iron, the crystalline structure of the olivines is also capable of accommodating relatively small amounts of ferric iron; dendrites (small branching crystals) of magnetite or chromite found oriented with respect to some crystallographic direction within such olivines may be attributed to exsolution (that is, to precipitation while cooling in the crystalline state). But the presence of relatively large amounts of ferric oxide in the analyses of olivines clearly indicates either an advanced state of oxidation or the mechanical inclusion of co-precipitating magnetite upon crystallization from the magma.

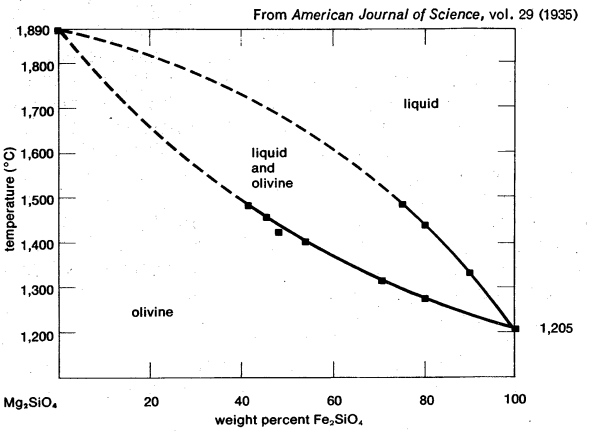

Figure 2: Equilibrium diagram of the system Mg_2SiO_4-Fe_2SiO_4.

X-ray diffraction data for powders of synthetic forsterite and fayalite permit estimation of the composition of any solid solution between these two end-members to an accuracy of better than 4 percent.

In addition to the forsterite–fayalite series, other complete solid-solution series exist among the various olivine minerals. Fayalite is soluble in all proportions with ashgray tephroite (from Greek *tephros*, "ashen"), pure manganese silicate (Mn_2SiO_4); the intermediate in the series is knebelite ($FeMnSiO_4$). Tephroite and knebelite are known only from manganese and iron-ore deposits, from metamorphosed manganese-rich sedimentary rocks, and from slags.

Crystal structure. The olivines are classified as nesosilicates because their crystalline structure (Figure 3) consists of silicate tetrahedra (structures in which four oxygen atoms surround and are bonded to a central silicon atom) that are completely separated from each other by the various metal cations (positively charged ions)—*i.e.*, Mg^{+2}; Fe^{+2}. These positive cations are in octahedral coordination; that is, they are immediately surrounded by six oxygen atoms at the corners of an octahedron, with each oxygen atom belonging to a different silicate tetrahedron. The symmetry of the structure is orthorhombic (referable to three mutually perpendicular crys-

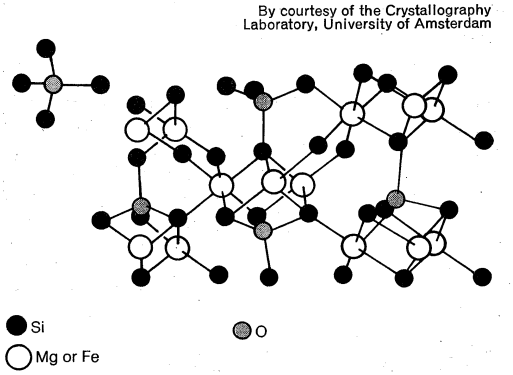

Figure 3: Model of the structure of olivine.

tallographic axes of unequal length), and the unit cell (the smallest volume containing a complete sample of the atomic or molecular groups present) contains four molecules. The oxygen atoms form parallel sheets so stacked that their arrangement approximates the intimate configuration known as hexagonal close packing, wherein the position of every second sheet approximates the position of the initial sheet.

Monticellite, calcium and magnesium silicate ($CaMgSiO_4$), and kirschsteinite, calcium and iron silicate ($CaFeSiO_4$), have essentially the same structure as the forsterite–fayalite minerals, but the calcium atoms are so placed that the magnesium and iron atoms are restricted to certain positions.

PROPERTIES OF OLIVINES

Banded structures

Physical properties. The specific gravity and hardness of the olivines are listed in the Table. There are at least two cleavages—*i.e.*, the tendency to split along preferred crystallographic directions (perpendicular to the *a* and *b* axes in this case)—both of which are better developed in the iron-rich varieties. Forsterite contained in certain ultrabasic rocks may show a banded structure when observed in thin sections with a polarizing microscope; in some dunites (a rock consisting nearly entirely of olivine), for example, olivine is preferentially oriented so that the cleavage plane perpendicular to the *b* axis is parallel to the microscopic laminated structure of the rock. Individual grains of olivine within such rocks typically appear as oriented bands with angles of up to 10 degrees between them. Such banding, which is undoubtedly the product of incipient mechanical deformation, also can be observed within the olivine nodules of some basalts.

To the unaided eye pure forsterite appears colourless, but as the content of ferrous oxide increases, specimens show yellow-green, dark-green, and, eventually, brown to black tints. In thin sections under the microscope, however, even pure fayalite appears pale yellow. Pure tephroite is gray, and monticellite also appears gray or colourless.

Some variations of optical properties observed in natural olivine crystals probably result from small but varying replacements of magnesium and iron by calcium and manganese and of silicon by titanium, chromium, and ferric iron.

Crystal habit and form. The magnesium-iron olivines occur most commonly as compact or granular masses. Except for the well-shaped phenocrysts (single crystals) of such olivines found embedded in the fine-grained matrices (groundmass) of basalts (see Figure 1), distinctly developed crystals are relatively rare. The phenocrysts in basalts are characterized by prominent pinacoid (*i.e.*, having a pair of parallel faces) and prism faces, so that their cross sections often appear six- or eight-sided. With fayalite the morphology is often simple. Monticellite and tephroite commonly show prominent pyramidal faces. Twinning, the intergrowth of two or more grains of the same mineral according to some crystallographic pattern, is not very frequently observed. When twinning does occur, trillings (the intergrowth of three grains) may be produced and, in monticellite, six-pointed star shapes, as reported from the Highwood Mountains in Montana.

OCCURRENCE IN NATURE

In igneous and metamorphic rocks. The magnesium-iron olivines are essential minerals in basic and ultrabasic rocks. Their composition in these rocks ranges from Fo_{92} (92 percent forsterite by molecular weight) in dunites and about Fo_{88} in peridotites through the interval Fo_{88}–Fo_{50} in basalts, gabbros, and dolerites. The minerals associated with olivine in basalts and in gabbros are indicated in the expanded basalt tetrahedron (see Figure 4). This tetrahedron represents the chemical relationships between the minerals larnite (La), nepheline (Ne), forsterite (Fo), and the various phases of silica (Qz). These minerals are shown at the corners of the tetrahedron, which represent the pure compounds. Moving along the edges and faces of the tetrahedron from one corner increases the content of the other mineral phases. Thus, along the edges and faces of this tetrahedron are located the intermediate phases enstatite (En), albite (Ab), wollastonite (Wo), monticellite (Mo), diopside (Di), akermanite (Ak), and sodamelilite (Sm). On the tetrahedron, the four points representing the minerals nepheline, forsterite, quartz, and diopside form the corners of another tetrahedron, the simple basalt tetrahedron: Ne - Fo - Qz - Di. The three points Di, Ne, and Fo define a critical plane (shaded) of undersaturation with respect to silica. This plane separates the basic mineral assemblages of the simple basalt tetrahedron, which contain plagioclase (Ab) and olivine (represented below the plane) from the olivine-bearing ultrabasic mineral assemblages that are devoid of plagioclase but contain monticellite (Mo) and melilite (Ak) (represented above the plane).

The basalt tetrahedron

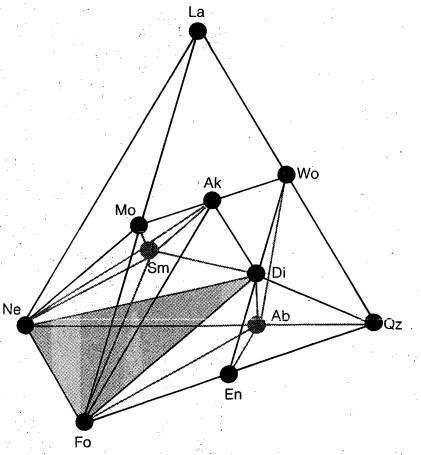

Figure 4: Expanded basalt tetrahedron showing mineral associates of magnesium-iron olivine (see text for explanation of symbols).

From J.F. Schairer and H.S. Yoder, Jr., "Crystal and Liquid Trends in Simplified Alkali Basalts," *Carnegie Institution of Washington Year Book 63*, p. 65, 1964

Olivines richer in iron than Fa_{50} are less common; they do occur in the iron-enriched layers of some intrusive rocks, however. Fayalite itself occurs in small amounts in some silicic volcanic rocks, both as a primary mineral and in the lithophysae and vugs (bubble-like hollows) of rhyolites and obsidians (volcanic glass). It also occurs in acidic plutonic rocks such as granites, in association with iron-enriched amphiboles and pyroxenes (*qq.v.*).

Olivines also occur in metamorphic environments. Both forsterite and monticellite typically develop in the zones in which igneous intrusions make contact with dolomites. Forsterite tends to develop at lower temperatures than monticellite as the process of decarbonation in the contact zone progresses. Fayalitic olivines develop within metamorphosed iron-rich sediments. In the quaternary (*i.e.*, four-component) system Fe_2O_3 - FeO - SiO_2 - H_2O, fayalite is associated with the minerals greenalite (iron-serpentine), minnesotaite (iron-talc), and grunerite (iron-amphibole) in various metamorphic stages. In chemically more complex environments, which, in addition to the above components, also involve lime (CaO) and alumina (Al_2O_3), fayalite may be associated with hedenbergite, eulite (iron-rich orthopyroxene), grunerite, and almandine (iron-garnet).

In meteorites and in the Earth's mantle. In meteorites, the olivine is usually a forsteritic variety containing only Fa_{15} to Fa_{30}. In the Nakhla (Egypt) meteorite, an achondrite, the olivine is more ferrous, however, containing as much as Fa_{65}. In the chondrites (stony meteorites), the olivine commonly is incorporated in the distinctive spheroidal bodies referred to as chondrules, which range up to one millimetre in diameter.

Because the rocks of the upper mantle directly below the Mohorovičić discontinuity (the zone separating the crust from the mantle, in which the velocity of transmission of seismic waves changes) are believed to consist of peridotite and garnetiferous peridotite that contain oliv-

ines as their most abundant minerals, it is of crucial importance to establish experimentally the behaviour of these minerals when subjected to high pressures (see also EARTH, STRUCTURE AND COMPOSITION OF). Study of the olivine-like compound magnesium germanate, Mg_2GeO_4, showed that it has polymorphs (same chemical composition but different crystal structures) that have both the olivine structure and spinel structure. In the spinel structure, the oxygen atoms are arranged in cubic close packing (in which the position of every third layer repeats that of the initial layer) instead of hexagonal close packing (in which the position of every second layer repeats that of the initial layer) of the olivine structure. The spinel form of Mg_2GeO_4 was found to have a density exceeding that of the olivine form by 9 percent. In 1936 it was suggested that at high pressures Mg_2SiO_4 might also transform to a spinel structure; this suggestion was adopted in 1937 as a basis for explaining the so-called 20°-discontinuity, an observed seismic discontinuity in the mantle at a depth of about 400 kilometres (250 miles).

Relation to the spinel structure

In 1966 it was shown that each of the three synthetic olivines, Fe_2SiO_4, Ni_2SiO_4, and Co_2SiO_4, could be transformed directly to a spinel structure at a temperature of 700° C (1,300° F) and at pressures below 70 kilobars (the bar is a unit of pressure equal to atmospheric pressure about 100 metres above sea level). These spinel structures were denser by approximately 10 percent than the corresponding olivine structures. In 1968 a series of synthetic magnesium and iron olivines was subjected to a range of pressures between 50 kilobars and 200 kilobars (700,000 pounds per square inch and 3,000,000 pounds per square inch) at a temperature of 1,000° C (1,800° F). In the composition range Fe_2SiO_4 to $(Mg_{0.8}Fe_{0.2})_2SiO_4$, these olivines were transformed completely to their spinel polymorphs, which are isometric crystals (referable to three mutually perpendicular crystallographic axes of equal length), with an accompanying increase in density of 10 percent. In the composition range $(Mg_{0.8}Fe_{0.2})_2SiO_4$ to Mg_2SiO_4, however, the olivines were transformed to another orthorhombic structure (called β-orthosilicate) at a pressure of about 130 kilobars (1,900,000 pounds per square inch) and a temperature of 1,000° C (1,800° F). This β-phase polymorph, with a density only 8 percent greater than that of the corresponding olivine structure, is believed to be the stable phase in the field of its synthesis. The change in the crystalline structure of olivine to its spinel polymorph, accompanied by a change in the structure of magnesium-iron pyroxenes to a new garnet-like structure at depths of 350 kilometres (220 miles) to 450 kilometres (280 miles) in the mantle, is believed to be responsible for the observed abrupt change in the velocity of seismic waves at these depths (see also EARTHQUAKES).

The spinel polymorph of olivine has been recorded in the Tenham (Queensland) chondrite as pseudomorphs after olivine. Portions of some large grains of olivine immediately adjacent to black, shock-generated veins are recognized as transforms to the spinel phase; the associated plagioclase feldspar was converted to maskelynite. The composition of the spinel phase in the meteorite has been analyzed by means of an electron probe and found to be $(Mg_{0.75}Fe_{0.25})_2SiO_4$; in thin sections it appears blue-gray to violet-blue. It has been named ringwoodite after A.E. Ringwood, an Australian earth scientist who synthesized spinel phases with compositions and properties close to those of the mineral found in the meteorite. More recently, ringwoodite also has been found in the Coorara (Western Australia) meteorite in association with a garnet phase. The β-phase polymorph has not yet been observed in shocked meteorites—*i.e.*, those that have undergone impact shock—but it is highly probable that it, too, exists in relative abundance within the Earth's mantle.

Other occurrences. Knebelite olivines are restricted to iron-manganese ore deposits, to their associated skarn (lime-bearing silicate rocks) zones, and to metamorphosed manganiferous sediments. At Franklin, New Jersey, tephroite and glaucochroite occur in the same deposit as roepperite, a knebelite containing 10.7 weight percent zinc oxide (ZnO).

Monticellite occurs in some alkali peridotites and within limestones near their contact with peridotites. Pure kirschsteinite is known only from slags and has not yet been observed as part of a natural mineral assemblage. The most plausible natural environments for kirschsteinite should be altered limestones, and it is possible that the mineral has remained unrecognized in such rocks because its optical properties (the chief means of identification) are similar to those of the much more common magnesium-iron olivines. A kirschsteinite containing 31 percent by weight of other olivines, particularly monticellite, has been reported from a nepheline-melilite in north Kivu Province, Zaire.

Sources of monticellite

Glaucochroite, pure calcium and manganese silicate ($CaMnSiO_4$), is rare; it has only been reported from an ore deposit in Franklin, New Jersey, where it occurs with tephroite. It is thought that the limited availability of manganese in parent magmas accounts for the rarity of minerals intermediate in the solid solution series between the calcium-rich olivines monticellite, glaucochroite, and kirschsteinite.

Alteration products and weathering. Olivines gelatinize in even weak acids and offer little resistance to attack by weathering agents and hot mineralizing (hydrothermal) solutions. The forsteritic olivines are altered principally through leaching, which results in the removal of magnesium and the addition of water and some iron. The chemical reactions are usually complex and involve hydration, oxidation, and carbonation. The fayalitic olivines are altered principally through oxidation and the removal of silica. The usual products of alteration are the minerals serpentine, iddingsite, and bowlingite, all of which may occur as pseudomorphs (forms with the outward appearance of the original mineral but which have been completely replaced by another mineral). Serpentine, which is the most common alteration product of olivine in ultrabasic rocks, often is accompanied by magnesite. Iddingsite and bowlingite are variable in composition and, even though they appear optically homogeneous, each actually consists of an intimate mixture of several distinct minerals. X-ray diffraction analyses of iddingsite show that the mineral goethite ($FeO{\cdot}OH$) is a frequent component. Also included with the mixture may be hematite (Fe_2O_3), as well as a silicate phase whose structure, even though very irregular and disordered, appears to be related to that of the clay minerals vermiculite or montmorillonite. Iddingsite develops almost exclusively from the olivines of extrusive and hypabyssal (minor intrusive, such as sill and dike) rocks and practically never from the olivines of plutonic and metamorphic rocks. The process of "iddingsitation" of olivine may set in even before the complete consolidation of the lava or the hypabyssal magma. This is evident from the observation of rock textures in which shells of iddingsite surrounding a core of olivine are, in turn, surrounded by more unaltered olivine.

The mechanical weathering of olivine-rich rocks leads to the release of olivine particles that, in the absence of much chemical weathering, may accumulate to produce green or greenish-black sands. Conspicuous examples of such sands occur on the beaches of the islands of Oahu and Hawaii, particularly at Diamond Head (Oahu) and South Point (Hawaii). Alluvial sands rich in olivine are also known from the Navajo County of Arizona and from New Mexico; these sands provide clear olivine used in jewelry.

Olivine in beach sands

EXPERIMENTAL STUDIES

The general stability fields of the olivines are shown in Figure 5, on which the olivines, pyroxenes, and silica phases present are plotted. With regard to olivine end-members, forsterite is readily prepared by heating its component oxides (2MgO and SiO_2) to temperatures of at least 500° C (900° F) at water-vapour pressures of from 140 to 2,800 atmospheres (2,000 to 4,000 pounds per square inch; one atmosphere is equal to the atmospheric pressure at sea level). Although forsterite remains stable

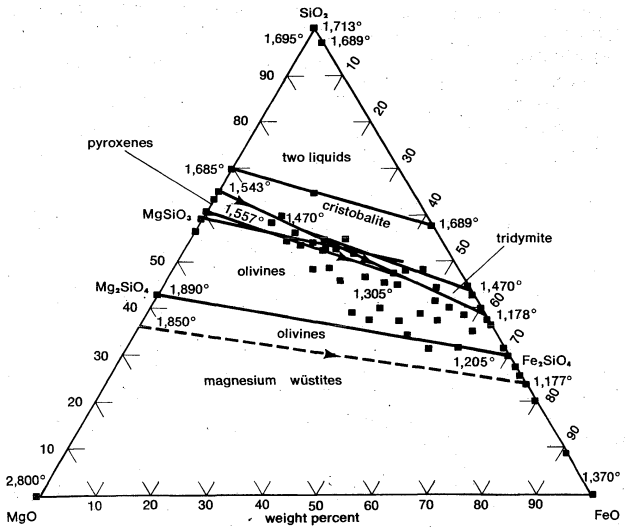

Figure 5: Equilibrium diagram of the system MgO-FeO-SiO_2. Temperatures are given in degrees Celsius.
From *American Journal of Science*, vol. 29 (1935)

in contact with water vapour at all temperatures above 400° C (750° F), below this temperature it is attacked by water, yielding serpentine and brucite:

$$\underset{\text{forsterite}}{2Mg_2SiO_4} + \underset{\text{water}}{3H_2O} \rightleftharpoons \underset{\text{serpentine}}{H_4Mg_3Si_2O_9} + \underset{\text{brucite}}{Mg(OH)_2}.$$

Fayalite also can be prepared hydrothermally from iron oxide and silica ($2FeO + SiO_2 \rightleftharpoons Fe_2SiO_4$) at low partial pressures of oxygen and at temperatures above 250° C. Below this temperature, fayalite is unstable in contact with water, and hydrous phases such as greenalite, accompanied by magnetite, appear instead.

Many of the experimental studies are of great importance for the interpretation of the role of olivine in rocks. In synthetic systems fayalite is found to be quite stable even in the presence of free silica, but forsterite is unstable unless the system is undersaturated with respect to silica. In the binary system MgO - SiO_2 the stability field of the pyroxene-like metasilicate called protoenstatite separates the stability field of forsterite from that of cristobalite. Upon heating to nearly 1,560° C (2,840° F), the pyroxene melts according to the reaction: $2MgSiO_3 \rightleftharpoons MgSiO_4 + SiO_2$. This melting relationship, called incongruent melting because the solid and the melt are not identical, is carried over into the ternary system CaO - MgO - SiO_2, involving diopside, forsterite, and silica, and into the quaternary system Al_2O_3 - CaO - MgO - SiO_2, involving anorthite, diopside, forsterite, and silica. The reverse reaction occurs when forsterite, in contact with the liquid, cools to the incongruent melting temperature. It is recorded in basic and ultrabasic rocks in which partially resorbed crystals of olivine are observed to be encased in a shell of pyroxene, the product of the incongruent melting reaction.

From *American Journal of Science*, vol. 29 (1935)

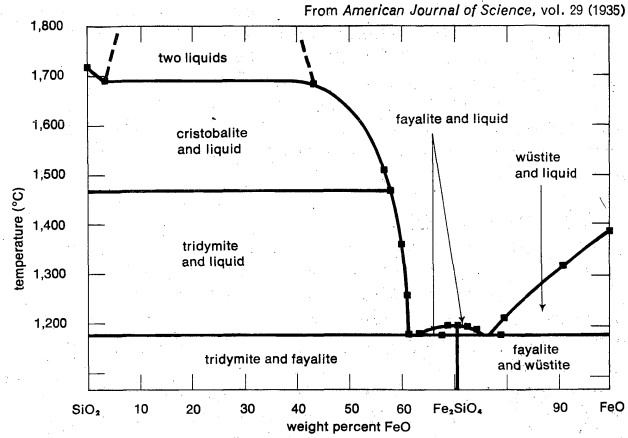

Figure 6: Equilibrium diagram of the system FeO-SiO_2.

Unlike the MgO - SiO_2 system, the binary system FeO - SiO_2 (Figure 6) has no metasilicate phase ($FeSiO_3$) intervening at liquidus temperatures, and there is no obstacle to the coexistence of fayalite (Fe_2SiO_4) with tridymite (SiO_2). But at 1,205° C (2,201° F), fayalite undergoes incongruent melting, with the separation of metallic iron and the simultaneous enrichment of the liquid in Fe_2O_3. This incongruent melting is characteristic of all phase assemblages in the system FeO - SiO_2.

Olympia

Olympia, a place in Greece in the western Peloponnese, was an ancient religious sanctuary and the scene of the Olympic Games. It lies on the northern bank of the Alpheius (Alfios) River about 10 miles (16 kilometres) from its mouth. A tributary stream, the Cladeus (Kladios), joins the Alpheius just below Olympia, to the south. The country is rich and well watered, consisting of low, wooded hills alternating with farmland.

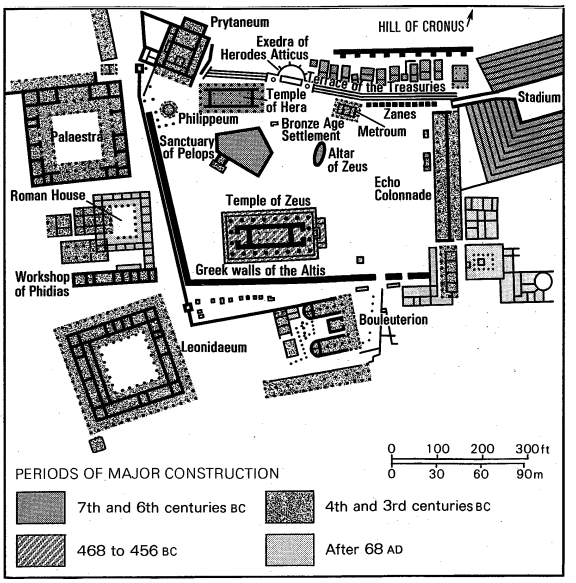
History and excavations. The earliest remains date from 2000–1600 BC, the sanctuary itself from around 1000. First controlled by the town of Pisa, after 570 Olympia came under the jurisdiction of Elis and Sparta. The religious festival, of which the Games were a part, was held there every four years from the 8th century BC until the end of the 4th century AD.

The first excavations were conducted on the site of the Temple of Zeus in 1829 by the French Expédition Scientifique de Morée (A. Blouet). The temple was sufficiently cleared to reveal its general plan, and fragments of three sculptured metopes (panels) were found, which were later placed in the Louvre, in Paris. The great German excavations of 1875–81 cleared the whole of the sacred precinct and some buildings that lay outside it; the position of the stadium was located by exploratory trenches. Thus the plan of a great Greek sanctuary was revealed for the first time. In the early 20th century some small-scale exploratory digging was done in the deeper layers in the sanctuary. Large-scale work was resumed by the Germans in 1936, one of the chief aims being the excavation and restoration of the stadium. Interrupted by World War II in 1942, work was resumed in 1952, and in 1960 the excavation of the stadium was completed, with its restoration in 1961. Other structures were explored in this period, the most important of which was the workshop of the sculptor Phidias.

The remains. The sacred precinct, the Altis, or "sacred grove of Zeus," was an irregular quadrangle over 200 yards (182.9 metres) on a side, bounded on the north by the hill of Cronus and enclosed by a wall on the other three sides. In it were the temples of Zeus and Hera, the principal altars and votive offerings, the treasuries, and administration buildings. Outside were the athletic installations and the hostels, baths, and other accommodations for visitors.

The Temple of Zeus was the largest and most important building at Olympia and one of the largest Doric temples in Greece. Built about 460 BC by the architect Libon of

The Temple of Zeus



Plan of the sanctuary at Olympia.
Adapted from *Westermann Grosser Atlas zur Weltgeschichte;* Georg Westermann Verlag, Braunschweig, West Germany

Elis, the temple was made of a coarse local shell conglomerate, the exposed surfaces being covered with a coat of fine white stucco. The temple had six columns across the front and 13 on the sides. There was a *pronaos* (porch) and an *opisthodomos* (rear porch), and the *naos* (cella; part enclosed by the walls) was divided into three aisles by two rows of slender columns arranged in two stories. The roof tiles were of marble.

The temple was richly decorated with sculpture, much of which has survived and is to be seen in the Olympia Museum. In the front gable the chariot race between Pelops and Oenomaus was represented, and both parties were shown preparing for the race. In the back gable was the battle of the Lapiths and Centaurs at the wedding of Perithous. These sculptures are masterpieces of the early classical style, but the name of the artist is not known. Pausanias' attribution of them to Paeonius and Alcamenes is generally rejected because these sculptors are known to have worked in the later 5th century. The frieze that ran above the front and back porches had sculptured metopes with the 12 labours of Heracles, six at each end. At the peak of the gable was a gilded figure of Victory, and at each corner a gilded caldron, but these have not survived.

Within the temple was the great gold and ivory statue of Zeus, the work of the Athenian sculptor Phidias, the most famous of all ancient statues and counted one of the seven wonders of the world. It made a profound impression on all who saw it, and people generally agreed that Phidias had succeeded in creating the image of Homer's Zeus. The god was represented seated on an elaborately wrought throne. He held a figure of the goddess of victory (Nike) in his right hand and a sceptre in his left.

"The workshop of Phidias"

This statue was made piece by piece by Phidias and his collaborators in a building just outside the Altis to the west of the temple. Subsequently converted into a church, the building was still known in the time of Pausanias as the "workshop of Phidias." The excavations of 1954–58 brought dramatic confirmation of the identification. In the deep layers in and around the building, particularly toward the south, a great mass of material, evidently waste from an artist's atelier, was found. This material included tools, slivers and worked fragments of ivory and bone, glass ornaments, and molds. The clay molds, of a very heavy fabric, like roof tiles, with the larger ones sometimes reinforced with iron rods, are of an unusual open form and were evidently used for hammering into shape the thin plates of gold that formed the statue's drapery. Pottery found with this debris indicates that the workshop was active in the years around 430 BC, an important fact because it settles an old controversy as to whether Phidias made the Zeus before or after his other great chryselephantine statue, the Athena Parthenos, which was completed in 438 BC. The new evidence is decisively in favour of the later date. One of the pieces of pottery, a ribbed mug, has inscribed on its bottom in neat clear letters the words "I am [the property] of Phidias."

The great altar of Olympian Zeus was not in front of the temple, as might have been expected, but to one side and nearer the Temple of Hera. It was elliptical in shape and consisted of an elevated base approached by steps. From the base rose a large mound made of the ashes of the thighs of victims sacrificed to Zeus. The whole height of the altar was 22 feet (6.7 metres).

Temple of Hera

The oldest temple at Olympia and one of the most venerable in all Greece was that of Hera, originally a joint temple of Hera and Zeus until a separate temple was built for him. It has sometimes been thought that the Temple of Hera was built in the 10th or 11th century BC, but this view is now rejected. The existing temple was probably built about 600 BC, and an earlier phase, without peristyle (colonnade), may go back to the 8th century. The temple is long and narrow, having six columns across the ends and 16 along the sides. The columns are Doric, showing a great variety of styles because they were originally of wood and were gradually replaced in stone. In the 2nd century AD there was still one wooden column in the *opisthodomos*. The entablature was of wood, and the upper parts of the walls were of mud brick. The cella had two interior rows of columns, alternate columns being attached by spurs to the cella walls and thus forming bays. Pausanias says that in the temple was an image of Hera seated on a throne with an image of Zeus standing beside her. An archaic limestone head thought to be that of the Hera has been found. Pausanias also reports a stone statue of Hermes carrying the young Dionysus, a work of Praxiteles that was found in the cella of the temple in 1877 and is one of the most prized possessions of the Olympia Museum.

A row of 12 treasuries overlooked the Altis from the lowest slopes of the hill of Cronus. These small structures in the form of Doric temples, date from the 6th century BC. All were erected by Dorian states ranging from Byzantium to Gela in Sicily and Cyrene in north Africa. In the case of only three, Sicyon, Megara, and Gela, is enough material available to allow a reconstruction on paper. These treasuries were erected by the several states either as thank offerings for Olympic victories gained by its citizens or as a general mark of homage to Olympian Zeus and to contain the dedicated gifts in which the wealth of the sanctuary consisted.

Between the temples of Zeus and Hera, the Elean hero Pelops had a sanctuary in the Altis that was open to the sky and surrounded by a wall, with trees and statues within.

The Metroum, or Temple of the Great Mother of the Gods, was a small Doric temple of the 4th century BC just below the treasuries. Because the cult no longer existed in Roman times, the excavated temple contained statues of Roman emperors.

A round building of the Ionic order, with Corinthian half columns on the inside, was erected by Philip of Macedon to commemorate his victory over the Greeks at Chaeronea in 338 BC. The building contained gold and ivory statues of Philip, Alexander, and other members of the family.

The Prytaneum, in the northwest corner of the Altis, was a building that contained a hearth on which burned a perpetual fire and a banquet room in which the Olympic victors were feasted. A large, lavishly decorated fountain, on an apsidal (semicircular) plan, was erected by Herodes Atticus in the name of his wife Regilla. On it were displayed some 20 statues of Herodes and his family and of the Roman emperors Hadrian and Antoninus Pius.

This building was officially called the Stoa Poikile, or "painted colonnade," from the paintings that used to be on its walls, but it was popularly called the Echo Colonnade because an echo repeated a word seven times or more. The colonnade closed the east side of the Altis and was separated from the east Altis wall, which supported

the stadium embankment, by a narrow passage. The colonnade was built soon after the middle of the 4th century BC. Deep down beneath its floor, the starting line of the early classical stadium has been found.

Zanes were bronze statues of Zeus erected with money from fines imposed on those who wantonly violated the rules of the Games. The bases of 16 of these have been found just outside the covered entrance to the stadium, the entrance by which the athletes entered.

The Bouleuterion, or council house, lies just outside the Altis to the south. It comprised two Doric buildings of different date but of identical oblong form with apsidal ends toward the west. In the space between was a rectangular court at the centre of which stood the statue of Zeus Horkios ("Zeus Who Presides over Oaths"). Beside this statue the athletes took the oath not to indulge in foul play during the contests.

Outside the Altis to the southwest stood the Leonidaeum, a large hostel for the reception of distinguished visitors, which was built in the 4th century BC and remodelled in Roman times. To the northwest were the Palaestra, where wrestlers and boxers trained, and the gymnasium, which included an elaborate entrance gateway and a covered running track.

The stadium

The stadium lay to the east of the Altis. In early classical times it was not cut off from the sanctuary, and one end of the track was in the area directly in front of the temple and the great ash altar of Zeus (beneath the later Echo Colonnade). About the middle of the 4th century BC the stadium was shifted about 90 yards (about 82 metres) eastward and a little to the north. The track was surrounded by massive sloping embankments of earth for the accommodation of the spectators, except to the north where the natural slope of the hill sufficed. The western embankment, parallel to which the Echo Colonnade was built, effectively cut the stadium off from the Altis. Connection between the two was maintained by what was called the Krypte, or "covered entrance," which pierced the embankment and, in Roman times, was covered with a stone vault. This entrance was used by the athletes and the umpires. There were no stone seats in the stadium except for a box on the south side about one-third of the way from the starting line nearest the Altis; here the *hellanodikai*, or chief judges of the Games, sat. Directly opposite the box was the altar of Demeter Chamyne, from which the priestess of that cult was privileged to watch the Games (married women were excluded from the Olympic festival, but unmarried girls were permitted). The track was about 230 yards (210 metres) long and 35 yards (32 metres) wide and separated from the sloping embankments by a low stone parapet beside which ran an open stone water channel with basins at intervals. The actual course was marked by stone starting lines at either end. These were about 210 yards apart (192.28 metres = 600 Olympic feet). There was space for 20 runners at a time. The classic race was the stade—*i.e.*, one length of the course. There was also a *diaulos*, two lengths, and a *dolichos*, or long-distance race, the length of which varied and might be as much as 24 stades or nearly three miles. Other athletic contests were also held in the stadium. This 4th-century stadium has been fully excavated and its track and embankments restored so that it may be seen as it was in late classical times.

When the stadium embankments were excavated many votive offerings were discovered. Some of these were works of art of various kinds, including bronze statuettes and reliefs and several terra-cotta statues, of which the most noteworthy was a group of Zeus and Ganymede, about half-life-size and dating from around 470 BC. Others were arms or armour that had been dedicated in the sanctuary; the Olympia Museum houses the largest collection of ancient Greek weapons in the world, some of which have identifying inscriptions on them that are interesting historical documents, such as a Persian helmet with the inscription "The Athenians [dedicated the helmet] to Zeus, having taken it from the Medes."

The hippodrome where the horse races were held lay south of the stadium in the open valley of the Alpheius. No trace of this has been found. Pausanias gives a long description of the hippodrome and of the elaborate starting machinery.

BIBLIOGRAPHY. J.G. FRAZER, *Pausanias's Description of Greece*, trans. with commentary (1913), is the story of the Greek traveller Pausanias, who visited Olympia in the 2nd century AD and wrote a long description of the place in his books v and vi. Frazer's commentary is thorough and makes full use of modern knowledge of Olympia gained from the original German excavations. E. NORMAN GARDINER, *Olympia: Its History and Remains* (1925), is a good general account; and LUDWIG DREES, *Olympia: Götter, Künstler und Athleten* (1967; Eng. trans., *Olympia: Gods, Artists and Athletes*, 1968), an up-to-date account, richly illustrated, with sections on the religious festival, the Games, and the buildings. See also BERNARD ASHMOLE and NICHOLAS YALOURIS, *Olympia: The Sculptures of the Temple of Zeus*, with new photographs by ALISON FRANTZ (1967).

(E.V.)

Oman

Oman—until 1970, Muscat and Oman—is an independent sultanate that occupies the southeastern coast of the Arabian Peninsula. It is bounded on the southwest by the People's Democratic Republic of Yemen, on the south and east by the Arabian Sea, on the north by the Gulf of Oman, on the northwest by the United Arab Emirates, and on the west by Saudi Arabia. In addition, Ru'ūs al-Jibāl (the Mountaintops), a small territory occupying the northern tip of the Musandam Peninsula between the Gulf of Oman and the Persian Gulf, forms a part of Oman; it is separated from the rest of the country by the United Arab Emirates. The United Kingdom assigned three of the nine villages in the oasis of al-Buraymī (Buraimi), south of the United Arab Emirates, to Oman in 1955, but the oasis is still claimed by Saudi Arabia, which also claims the eastern part of the sand desert of the Rub'al-Khali (the Empty Quarter). Because the boundaries with Saudi Arabia are not fixed, the area of Oman cannot be determined; the maximum estimate is about 82,000 square miles (212,400 square kilometres). Since 1967 the Kuria Muria Islands, 25 miles off the south coast of Oman, have also been under Omani sovereignty. The population of the country is about 750,000. Muscat (Masqaṭ), a port on the Gulf of Oman, is the capital.

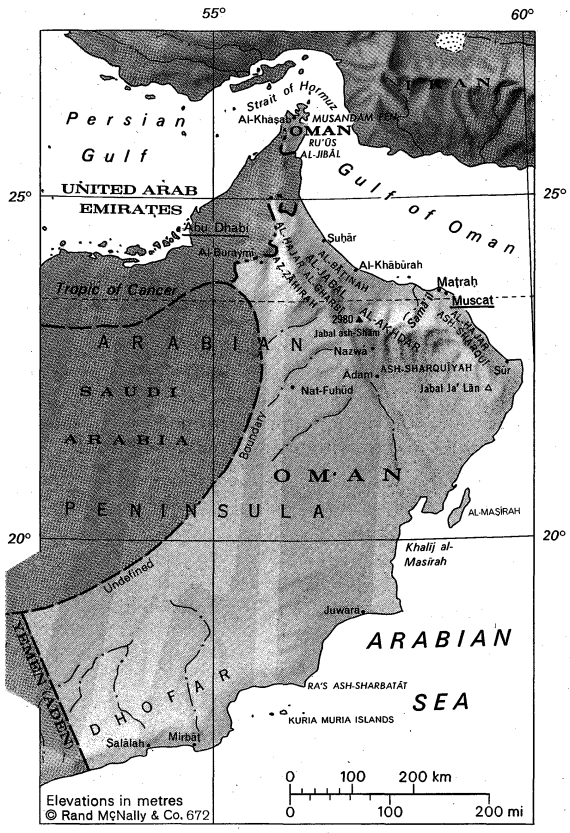
Sultan Sa'īd ibn Taymūr, who acceded to the then British-protected sultanate in 1932, kept Oman isolated from most of the world—maintaining diplomatic relations only with the United Kingdom, the United States, and India—and did little to develop the country. Sultan Qābūs ibn Sa'īd, since overthrowing his father, Sa'īd, in 1970, has taken steps to liberalize the government. Trying to reverse his father's record in external and internal affairs, Qābūs has been handicapped by the fact that many Arabs still regard Oman as too closely linked with the United Kingdom. (For an associated physical feature, see ARABIAN DESERT.)

The landscape. *Relief features and drainage.* The outstanding relief feature in northern Oman is the mountain chain of al-Ḥajar (the Stone), which parallels the coast of the Gulf of Oman from Ru'ūs al-Jibāl to Ra's al-Ḥadd, the eastern extremity of the Arabian Peninsula. These bleak mountains reach a height of 10,194 feet (3,107 metres); their steeper slopes are on the seaward side. Rainfall from the mountains is brought to the oases by ancient underground conduits of a type common in Iran. Mountains also line the Arabian Sea coast of Dhofar (Ẓufār), Oman's southernmost province, reaching their greatest elevation in the hinterland of Ṣalālah, the capital of Dhofar province.

The al-Ḥajar mountains

The Kuria Muria Islands are a group of five; from east to west they are al-Ḥāskīyah, as-Sawdā', al-Ḥallānīyah, Qarzawīt, and al-Qiblīyah. Only al-Ḥallānīyah—the largest, with a population of less than 100 people—is inhabited.

Climate, vegetation, and animal life. Oman is a hot and arid country with high humidity along the coasts. Annual rainfall is between three and four inches. Vast plantations of date palms cover the plain of al-Bāṭinah, and oases dot the mountains and the interior plains. Fruits and some



OMAN

grains are grown, but the staple food, rice, must be imported. The camels of Oman are recognized as the best breeds in the Arabian Peninsula, the mountain donkeys compare with mules in strength and endurance, and a variety of game is found at the higher elevations.

Human settlement. Al-Bāṭinah, the Gulf of Oman coastal plain lying east of al-Ḥajar and reaching south almost to Muscat, is sometimes 20 miles broad and is intersected by many *wādī*s (seasonal watercourses). Ṣuḥār, in the north, is the principal town of al-Bāṭinah. East of Muscat the mountains crowd close to the sea, leaving little room for farming or travel. Al-Ḥajar al-Gharbī ends west of Muscat in al-Jabal al-Akhḍar (the Green Mountain), distinguished from the rest of the range by its larger population and comparatively rich cultivation.

The more gently inclining landward side of western al-Ḥajar is called aẓ-Ẓāhirah (the Upland). The region just below al-Jabal al-Akhḍar is Oman Proper (ʿUmān al-Wusṭā), with Nazwā (Nizwa) as its most important town. Landward of al-Ḥajar ash-Sharqī lies ash-Sharqīyah (the Eastern Region) and Jaʿlan, the latter region extending to the coast of the Arabian Sea, off which lies the island of Maṣīrah, used by the United Kingdom as an air base. Farther south is the region of Dhofar, with the port of Ṣalālah, from which Sultan Saʿīd governed the country.

The harbour city of Muscat, with a population of about 10,000, is ringed by steep, gaunt hills. Access to the interior is easier from its twin port of Maṭraḥ (population 16,000) through the pass of Wādī Samāʾil, which divides al-Ḥajar into its western and eastern halves.

Omani towns are usually dominated by old forts, often now crumbling. Houses are commonly built of stone or palm thatch. Many settlements on the landward side of al-Ḥajar consist of a cluster of villages on an open plain or along a *wādī* bed.

People and population. Of Oman's total population of about 750,000, about 200,000 are settled, the rest being nomadic. Only 5 percent of the population are urban, with 95 percent rural. Arabs constitute the great majority of the people. There are considerable non-Arab elements in the ports—Persians, Baluchis (people of Baluchistan, Pakistan), Pakistanis, Indians, and blacks from East Africa. In aẓ-Ẓāhirah, a thriving community of Baluchi villagers has become thoroughly Arabized.

Most of the Arabs are affiliated with tribes that long kept alive the ancient rivalry between Southern Arabs (descendants of Qaḥṭān) and Northern Arabs (descendants of Nizār). In Oman the tribesmen claiming descent from Qaḥṭān are called Hināwīs, and those claiming descent from Nizār are called Ghāfirīs. This factionalism, once one of the most important features of the society of Oman, appeared to be on the wane in the early 1970s.

Rivalry between the Southern and Northern Arabs

Oman harbours the largest group of Ibāḍīs in the Islāmic world; the Ibāḍīs are a branch of the Khārijites, the first sect to break away from the main body of Islām. Since the 8th century the Ibāḍīs have elected *imāms* in Oman, the last of whom—because of his opposition to Saʿīd—was driven into exile by the British in 1958. Sultan Qābūs, though an Ibāḍī, is not recognized as the religious head of the sect. The Ibāḍīs are concentrated on the landward side of al-Ḥajar, with Nazwā as the old capital of the *imāms*. Sunnites (members of one of the two main religious divisions of Islām, who regard the first four caliphs as legitimate successors of Muḥammad), however, are also fairly numerous in northern aẓ-Ẓāhirah and Jaʿlan, where the influence of Wahhābism (a fundamentalist, puritanical doctrine that opposes all practices not sanctioned by the Qurʾān and the *sunnah*) spread in the 19th century. A sprinkling of Shīʿites (members of the second of the two main religious divisions of Islām, who regard ʿAlī, the son-in-law of Muḥammad, as his legitimate successor) and Ismāʿīlī Muslims (a Shīʿite sect with an esoteric philosophy) and followers of other religions is found among the foreign elements.

The oil industry and development of the country have brought a number of Westerners into Oman, with the government showing a strong preference for hiring British experts. Oman is also attracting Arabs from other countries.

The national economy. *Economic activity.* The discovery of oil in commercial quantities was announced in 1964. A pipeline was constructed from the Nati-Fuhūd area on the edge of the Rubʿ al-Khali down to the Gulf of Oman, and export of oil began in 1967. Production, however, is modest, averaging 300,000 barrels a day in 1971, and reserves are regarded as relatively small. Petroleum is the country's only commercial mineral resource, accounting for more than 90 percent of the total revenue, the remainder of which came from customs duties and a religious tax.

Oil production

Trade is the chief industry of Muscat and Maṭraḥ. Elsewhere the economy is agricultural, the principal crops being dates, limes, coconuts, papayas, bananas, wheat, sugarcane, oranges, and grapes. Agriculture is limited by the shortage of water for irrigation. Camel breeding is practical in the interior and fishing on the coast. Dried fish, dates, and limes are shipped abroad, but, apart from oil, imports greatly exceed exports. The government, which dominates the economy, is heavily burdened with military expenditures.

Transport. In 1971 Oman had two main roads—the paved road from Muscat to the military base of Bayt al-Falaj, next to Maṭraḥ (three miles), and the dirt road from the oil-shipping terminal west of Maṭraḥ across al-Ḥajar to the oil fields. A new road is being constructed from Muscat to Ṣuḥār. Country tracks are often difficult or impassable in al-Bāṭinah and al-Ḥajar but are usually easier on the landward side of the mountains. Improved and unimproved roads total about 600 miles. In 1971 a modern port was being built at Maṭraḥ and an international airport at Muscat. Small steamers call at some of the principal ports, all of which are much frequented by ancient types of sailing craft. Dates are exported from Ṣuḥar, and dried fish and fish meal from Ṣūr and Mirbāt. There is also some shipping at Ṣalālah. Even with the improvements being introduced, development of the country continues to be greatly hampered by inadequate communications.

Administration and social conditions. Sultan Saʿīd had kept personal control of even trivial affairs of state. In the early 1970s, Sultan Qābūs began building up a more elaborate apparatus of government, with ministries and departments, but foreign advisers remained essential as few citizens were qualified for administrative and technical positions. The relatively well-equipped armed forces are trained and led by British officers.

Health and education

Oman faces serious health problems, with many diseases being widespread and the infant mortality rate very high. The government is spending large sums for new hospitals, clinics, doctors, and nurses.

Under Sultan Saʿīd, Oman had three elementary schools, with 900 boys enrolled. In 1970 the number of schools rose to 15, including one for girls; the number of students increased to 7,000. Secondary and higher education still had to be obtained abroad.

Cultural life and institutions. The cultural life of Oman has been confined by the strict form of Islāmic belief prevailing there, particularly among the Ibāḍīs. While representational art has been forbidden, Oman has developed a picturesque style of architecture, seen at its best in the old forts. The cultivation of literature has been impeded by the lack of a printing press, but manuscripts on religious subjects and history have been produced. Until the departure of Sultan Saʿīd, music, the cinema, fraternal associations, and other diversions and activities were forbidden. In the early 1970s cultural life was beginning to expand under the new regime. Oman's first weekly newspaper is printed in Beirut.

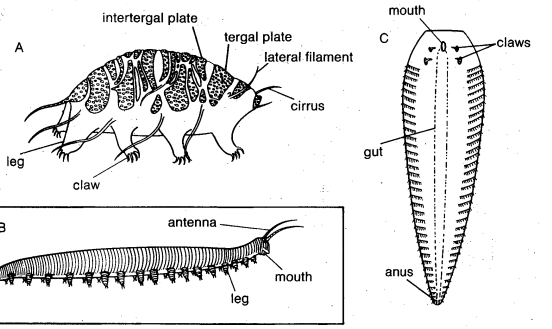
Prospects for the future. The viability of the sultanate depends primarily on the success of its development program and of its campaign against revolutionary Arab leftists and militant tribesmen in Dhofar and the interior. Domestic progress is calculated to weaken popular support for the dissidents, and military successes, to strengthen the government's control throughout the country. Acceptance of Oman in the Arab world requires a demonstration of decreasing reliance on Great Britain.

ZWEMER, *Arabia: The Cradle of Islam* (1900), by an American missionary who worked in Muscat and travelled in the interior.

(G.Re.)

Oncopod

The term oncopod (sometimes Pararthropoda) is the collective name for three groups of animals usually considered classes: Onychophora and Tardigrada, which are free-living forms, and Pentastomida, which are parasitic (*i.e.*, deriving nourishment from the body of another living animal). The groups are of interest chiefly because they bear strong resemblances to primitive annelidan forms as well as to the phylum Arthropoda (*e.g.*, insects, crustaceans)—the most highly evolved invertebrates.



Body plans of (A) tardigrade, *Echiniscus scrofa;* (B) peripatus, *Peripatopsis capensis;* (C) pentastomid, *Linguatula taenoides.*

The Onychophora (meaning "claw bearers") were once thought to be intermediate between the annelid worms and the arthropods. They comprise fewer than 100 species and exhibit little diversity of form. Onychophores, which vary in length from about 14 to 150 millimetres (about ½ to six inches), are elongated, terrestrial animals covered by a soft, furrowed skin. They occur widely in tropical and subtropical regions of the world and, because they are unable to control water loss, must live in a moist habitat. *Peripatus,* a typical genus, is the best known of the group.

The Tardigrada, the so-called bear animalcules, or water bears, comprise about 350 species, which are distributed worldwide, mostly in damp or aquatic habitats. Their length ranges from about 0.05 to 1.2 millimetres (0.002 to 0.05 inch).

Pentastomids, comprising some 70 species, are wormlike parasites up to nine centimetres (about four inches) in length that live in the respiratory systems of vertebrate hosts. Although they are mostly tropical or subtropical, those with homoiothermic, or warm-blooded, hosts may also be found in cold regions. A few species are of medical interest because man occasionally serves as the host.

Natural history. *Reproduction and life cycle.* The sexes are separate; *i.e.*, male and female sex organs do not occur in one animal. Except in many tardigrades, in which the sexes are similar in appearance, males are smaller than females. The sex organs (gonads) are always on the back side and may be paired or single. The gonad cavity is a remnant of the coelom, the general body cavity. The genital pore, from which the eggs or sperm are discharged, is located either ventrally (*i.e.*, on the lower side) in front of the anus (onychophores, some tardigrades, females of a few pentastomids) or in the anterior, or front, part of the trunk (pentastomids); in some tardigrades the genital ducts open into the rectum.

Transfer of sperm

Copulation, with internal fertilization of the egg, is the general rule, though modifications occur. In many onychophores the male deposits a spermatophore, or sperm case, on the skin of the female; the skin then dissolves,

allowing the sperm to reach the ovaries via the hemocoel (*i.e.*, a network of spaces between the internal organs). In some tardigrades fertilization is external. Oncopods are oviparous (*i.e.*, the young hatch from eggs that have been laid), with the exception of most onychophores. In most viviparous (*i.e.*, giving birth to live young) onychophores, the embryos receive nourishment from the mother. Development is direct—*i.e.*, there is no radical change in form except in size—in tardigrades and onychophores, but larval stages occur in pentastomids. Many pentastomids must parasitize an intermediate host—usually a vertebrate prey of the adult pentastomid's host—in order to complete their life cycles; others are thought to have a single host. Molting, or shedding of the skin, occurs throughout the lives of all oncopods.

Ecology and behaviour. Because onychophores, which are terrestrial, cannot control water loss, they cannot tolerate dry habitats. They live among litter in forests, under stones or fallen logs, inside galleries of fallen logs, inside nests of termites, or in crevices and galleries in the soil, sometimes to depths of more than one metre (about three feet). Onychophores have a remarkable ability to squeeze themselves through narrow passages, an adaptation that permits them to find shelters of satisfactory humidity and safety. Onychophores are carnivorous (*i.e.*, flesh eaters); they use their jaws to open captured prey and suck out the juices. A quick-hardening slime squirted from the oral papillae, fingerlike projections near the mouth, is used for defense or to subdue prey. Onychophores avoid light and are usually well concealed from casual observation. Touch is important, and onychophores are provided with tactile spines that are sensitive to air currents.

A few tardigrades are marine; others are found in freshwaters, and many occur in terrestrial habitats in which droplets or a film of water are available. Thus, terrestrial species occur in mosses, lichens, or other cushiony plants; they are also regular inhabitants of the soil and may be locally abundant in a given area. Most are herbivorous (*i.e.*, plant eaters), piercing individual cells with their stylets (spearlike structures near the mouth) and sucking out the cell contents. A few tardigrades are predacious carnivores. Species normally living in habitats subject to sudden drying or freezing are able to enter into a resistant state. Some species may encyst within the molted skin. In such states tardigrades are easily distributed by wind, water, and other means.

Modes of locomotion

Onychophores and tardigrades move by using their legs, the body remaining straight. In walking, the onychophore foot usually remains lifted, the weight of the body resting on the creeping pads; the claws are used only on slippery surfaces. Many tardigrades use only the three anterior pairs of legs in walking; the fourth trails behind.

Form and function. *General features.* A common feature of oncopods is the presence, in some stage of the life history, of oncopodia—*i.e.*, locomotory lobopodia, which are nonjointed, usually hollow, paired appendages with claws at the tips. The onychophoran oncopodium has a conical basal portion with a furrowed, papillose (*i.e.*, with many short protuberances) skin; a specialized distal, or end, portion comprises a broad spiny pad and a foot bearing the pair of terminal claws. Ventrally, at the base of the leg, is an excretory pore. Onychophores have two pairs of modified oncopodia: the oral papillae, at the tip of which open the ducts of large slime glands, and the jaws.

Tardigrade oncopodia are simpler and conical or cylindrical in shape; they are often divided into a thinner basal portion that may telescope into a broader basal portion, ending in two, four, or more claws. In pentastomids, typical oncopodia bearing two claws and similar to those of tardigrades occur only in embryos and some larvae.

Organ systems. Of the three oncopod groups, only the Onychophora have well-developed organ systems. Both the Tardigrada and Pentastomida have undergone reductions in, or even loss of, some organ systems, a consequence of small size in the former and of parasitism in the latter. Thus, neither group has respiratory or circulatory organs; excretory organs, in addition, are found neither in pentastomids nor in many tardigrades.

A cuticle, or skin, secreted by epidermis, or surface cells, and molted periodically, is present in all oncopods. It is generally soft, sometimes with local thickenings, and is heavily sclerotized, or hardened, only in structures such as the claws of oncopodia. Chitin, a tough, resistant material, is a component of the cuticle in onychophores and pentastomids; in tardigrades the cuticle consists of albumin, a protein. In onychophores the epidermis forms numerous papillae over the body, many of which are tipped by a sensory spine; under the epidermis is a strong fibrous layer.

The muscle fibres of onychophores and tardigrades are smooth (*i.e.*, nonstriated), while those of pentastomids are striated. Beneath the skin of onychophores are circular, diagonal, and longitudinal muscle layers as occur in annelids (segmented worms); in addition, transverse muscles also occur. Pentastomids have a similar muscle organization but do not have a diagonal layer of muscle. Tardigrades have discrete muscle fibres segmentally arranged.

Structure of the nervous system

The nervous system consists of a brain dorsal to the pharynx and connected by a pair of nerves encircling the pharynx to the ventral nerve cords. These usually form a ventral chain of ganglia, or nerve centres. Tardigrades have a brain, often containing a pair of eyespots, and a ventral chain of five ganglia. In pentastomids there may be a short ventral chain, or a single ventral ganglion; the brain halves shift ventrally, leaving a band of connecting nerve fibres. Onychophores have a well-developed brain and two widely separated, nonganglionated ventral nerve cords that unite caudally (*i.e.*, toward the tail) above the rectum, a very primitive condition. The eyes of Onychophora are similar in structure to those of some annelids.

In oncopods the gut is usually a straight tube. The foregut and hindgut are lined with cuticle. The mouth is usually ventral, but at the anterior tip in most tardigrades. In onychophores the mouth is bordered by a row of oral lobes (lips). The salivary glands are modified segmental organs of the oral papillae segment. In the mouth cavity are two pairs of jaw blades, which are the modified claws of a pair of reduced oncopodia. In tardigrades the mouth is small and round; a pair of stylets may protrude through it. A sucking pharynx and salivary glands are also present in tardigrades. The anus is terminal.

The body cavity is a hemocoel. In onychophores the dorsal portion, separated as a pericardium, contains the long tubular heart provided with segmental pairs of ostia, or openings.

The respiratory system of onychophores consists of numerous, irregularly distributed pits, from which many thin tracheae, or breathing tubes, originate. The tracheae may penetrate deep into the body and may branch.

Onychophores have a pair of excretory segmental organs on each leg-bearing segment. A ciliated (*i.e.*, with hairlike structures) funnel leads to the outside at the excretory pore. Each segmental organ eliminates water and other substances, but nitrogenous excretion, in the form of uric acid, takes place into the midgut. Many tardigrades have three excretory rectal glands.

Early fossil forms

Evolution. *Paleontology.* Two fossils, probably both marine, are directly relevant to the oncopods. The first, *Xenusion auerswaldae,* possibly from the Precambrian (more than 570,000,000 years ago), may well represent a lobopod stage (*i.e.*, with fingerlike body extensions) in the evolution of oncopods and arthropods. The clearly segmented body is provided with relatively large, annulate (ringed) lobopodia; the presence of claws could not be ascertained, and the cephalic (head) end was not preserved. The second fossil, *Aysheaia pedunculata,* from the Middle Cambrian (about 535,000,000 years ago), is generally considered to be an onychophore. The body has ten or 11 postcephalic segments, each with four rings bearing skin papillae, and a pair of ringed oncopodia provided with six apical (*i.e.*, at the apex, or tip) claws. The head may have had antennae and, probably, oral papillae; jaws were not detectable.

Historical development. The evolution of oncopods, as of other very old groups with few or no fossils, is a speculative subject, on which no consensus has yet been reached. Oncopods, as well as arthropods, originated in Precambrian times from marine, bottom-dwelling forms that may also have been ancestral to modern annelids. The adaptation that resulted in the evolution of oncopods and arthropods was the acquisition of lobopodia, locomotory appendages that could work independently of the waves of contraction of the body. The acquisition of lobopodia led to the dissolution of separate coelomic compartments and to the formation of a hemocoel; it also permitted the development of a firmer cuticle, which made molting necessary. The development of the cuticle also led to the loss of external cilia.

Tardigrades evolved toward small size, with a consequent simplification of body organization. Some of their primitive characteristics—*e.g.*, the cuticle of protein, brain, and absence of specialized legs on the head—suggest that their ancestors diverged very early from the oncopod–arthropod stem. Tardigrades show interesting similarities to some aschelminths (roundworms).

The evolution of pentastomids has been greatly influenced by their endoparasitic (internal parasitic) mode of life; it also entailed simplifications. Their chitinous cuticle, striated muscles, and brain form indicate that they had ancestors more active and advanced than those of tardigrades; it is possible that they shared a common ancestor with the arthropods. Pentastomids could have evolved from free-living forms, first as parasites of fishes, then becoming parasites of terrestrial vertebrates as they appeared in the Devonian Period (345,000,000 to 395,000,000 years ago).

The formation of a strong "skeleton" under a soft epidermis is a characteristic of onychophore evolution and permits the body to be deformed. Among oncopods, onychophores have the most extensive combinations of primitive features—*e.g.*, structure of nerve cords, persistence of cilia, smooth muscles—with oncopodan characters or basic arthropodan characters (*e.g.*, chitin and molting, hemocoel, gonads, embryonic development) or both. They also developed specializations of their own (*e.g.*, dermis, tracheae, viviparity). Both onychophores and arthropods could have arisen in Precambrian seas from a *Xenusion*-like ancestor, arthropods acquiring sclerites (*i.e.*, hard body plates) and joints and onychophores developing a strong dermis while keeping a thin cuticle. According to some authorities, the myriapod–insect line originated from onychophore ancestors, independently from the other arthropods.

Classification. *Distinguishing taxonomic features.* The various groups considered together as oncopods have several common features: similar paired locomotory appendages called oncopodia at some stage in the life cycle; a body cavity (hemocoel); a cuticle (skin) secreted by surface cells and shed periodically (molting); a gut that is usually a straight tube; and separate sexes and gonads. The groups also differ: only the onychophores have well-developed organ systems; those of pentastomids and tardigrades are reduced or lacking. The pentastomids are parasites; the other two groups are free-living.

Annotated classification.

ONCOPOD

General term commonly used to refer to three arthropod-like animal groups; tardigrades, pentastomids, and onychophores.

Class Onychophora

Length about 14–150 mm; predatory on other small organisms; cuticle containing chitin, a tough, complex nitrogen-containing carbohydrate; genera include *Peripatus, Peripatopsis;* fewer than 100 species in tropics and subtropics.

Class Pentastomida (or Linguatulida)

Parasites of vertebrates; length up to 9 cm; cuticle containing chitin; about 70 species; mostly tropical or subtropical.

Order Cephalobaenida

Genera include *Cephalobaena, Raillietiella, Reighardia.*

Order Porocephalida

Genera include *Porocephalus, Linguatula.*

Class Tardigrada (water bears)

Size 1 mm or less; found in marine waters and freshwaters and in various terrestrial habitats (*e.g.*, soil); mostly plant eaters; cuticle composed of protein; worldwide distribution; about 350 species.

Order Heterotardigrada

Genera include *Echiniscus, Batillipes.*

Order Eutardigrada

Genera include *Macrobiotus, Hypsibius, Milnesium.*

Critical appraisal. The name oncopod is used for convenience to refer to these three groups of invertebrates of uncertain relationship to the phylum Arthropoda. Some authorities have elevated the Onychophora to the rank of phylum and regard the Tardigrada and Pentastomida either as Proarthropoda or as orders of the arthropod class Arachnida (*e.g.*, spiders). Other authorities regard the three groups as distinct phyla.

(C.G.F.)

Onega, Lake

Lake Onega (Onezhskoye Ozero in Russian; spelled Onezhskoje Ozero in the transliteration system of the Akademija Nauk) lies in the northwest part of the European portion of the Soviet Union. It is situated mainly in the Karelian Autonomous Soviet Socialist Republic (Karelskaya Avtonomnaya Sovetskaya Sotsialisticheskaya Respublika), but its southern shores are in the Leningrad and Vologda *oblasti* (regions) of the Russian Soviet Federated Socialist Republic. It covers an area of 3,753 square miles (9,720 square kilometres), being the second largest lake in Europe after Lake Ladoga.

Geological structure

The hollow of the lake was formed by movements of the Earth's crust, but Quaternary glaciers (10,000 to 2,500,000 years ago) elongated it from northwest to southeast. It is 154 miles long; its greatest width is 50 miles; and its greatest depth is about 380 feet, the average being about 100 feet. The shores to the north and northwest are high and rocky, built of layered granite and covered with forest. There are deep bays at Petrozavodsk, Kondopoga, and Povenots. The southern shores are narrow, sandy, and often marshy or flooded. The floor of the lake in the north and northwestern part is broken and has deep depressions, the deepest one being more than 300 feet in places and extending out 380 feet to the west of Bolshoy Lelikov Island. The centre of the lake is deepest toward the west, while the floor of the southern part is flat, reaching depths of 150 feet only in its western part. The depth in the northeast is similar, though Povents Bay reaches 300 feet in places. The floor is rocky and sandy at the shores and, in the open part, covered with silt. Onega has about 1,650 islands covering a total of about 100 square miles, mostly in the northern and northwestern bays.

Fifty rivers enter Onega, the largest being the Shuya and Suna in the northwest and the Vodla in the east, together accounting for 60 percent of the water inflow. In the southeast and east are the Andoma, Vytegra, and Megra rivers. Lake Onega itself empties into the River Svir. The

rivers supply 75 percent of the lake's water, and the rest comes from the atmosphere. It loses 84 percent of its water output through evaporation. The water level reaches its highest point in the summer, and its lowest in March–April, varying about 24 inches annually. Water levels at the northern end of the lake may differ by 20 to 26 inches from those at the southern end. The water circulates in a twisting pattern within the lake because of differences of temperature between the coastal and the open regions. The rate of flow at the surface is eight to ten inches per second. During autumn gales, waves sometimes reach 14 or 15 feet.

The region has a cold climate. Air temperatures in February average 10° F (−12° C) in the north and 14° F (−10° C) in the south, while July temperatures average 61° F (16° C). The absolute minimum air temperature is −54° F (−48° C), and the absolute maximum is 93° F (34° C). The highest temperature of the water at the surface in the open part of the lake is 64° or 68° F (18° or 20° C) and 75° or 81° F (24° or 27° C) in the bays. The bottom layers of the water are much colder, varying from about 36° F (2° C) in the winter to 39° or 43° F (4° or 6° C) in the summer. The coastal parts and the small bays begin to freeze at the end of November, and the deeper central parts in the middle of January, although in some years the central parts do not freeze. Thawing begins at the end of April.

The colour of Onega's water is dark yellowish brown in the open part and grayish brown along the shores. Its average transparency in the open lake and deep bays is 16 to 28 feet, and three to 12 feet near the shore. The lake contains 47 species of fish, including ryapushka (a small member of the salmon family), smelt, burbot (a freshwater variant of the cod), bream, pike, perch, roach, and salmon. The fish are of considerable economic value.

Onega as a transport route

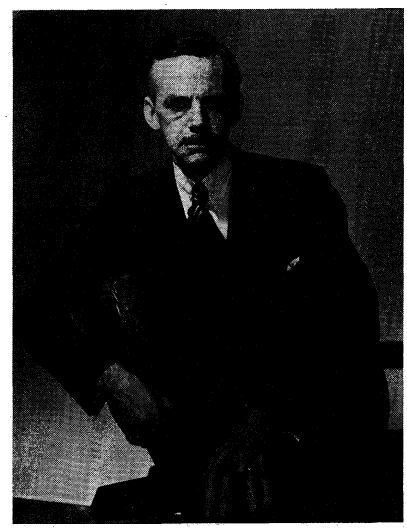
Lake Onega is connected with the Baltic and White seas by the White Sea–Baltic Canal and with the basin of the Volga River by the Volga–Baltic Waterway, which enable it to play an important part in both internal and international transportation. Goods are shipped over this route from Finland, Sweden, Denmark, and East Germany to points in the east and north. For protection against storms, a bypass canal has been dug along the south and southeastern shores from the mouth of the River Vytegra to the source of the Svir. The cities of Petrozavodsk, Kondopoga, and Medvezhyegorsk are on Lake Onega. The island of Kizhi houses the internationally known architectural organization of that name.

(B.B.Bo.)

O'Neill, Eugene

Eugene O'Neill was the first American dramatist to regard the stage as a literary medium and the only American playwright ever to receive the Nobel Prize for Literature. Through his efforts, the American theatre grew up during the 1920s, developing into a cultural medium that could take its place with the best in American fiction, painting, and music. Until his *Beyond the Horizon* was produced, in 1920, Broadway theatrical fare, apart from musicals and an occasional European import of quality, had consisted largely of contrived melodrama and farce. O'Neill saw the theatre as a valid forum for the presentation of serious ideas. Imbued with the tragic sense of life, he aimed for a contemporary drama that had its roots in the most powerful of ancient Greek tragedy—a drama that could rise to the emotional heights of Shakespeare. For more than 20 years, both with such masterpieces as *Desire Under the Elms, Mourning Becomes Electra,* and *The Iceman Cometh* and by his inspiration to other serious dramatists, O'Neill set the pace for the blossoming of the Broadway theatre.

Early life. O'Neill was born into the theatre. His father, James O'Neill, was a successful touring actor in the last quarter of the 19th century whose most famous role was that of the Count of Monte Cristo in a stage adaptation of the Alexandre Dumas *père* novel. His mother, Ella, accompanied her husband back and forth across the country, settling down only briefly for the birth of her first son, James, Jr., and of Eugene.



O'Neill.

Shattering experiences of family life

Eugene, who was born in a hotel in New York City, on October 16, 1888, spent his early childhood in hotel rooms, on trains, and backstage. Although he later deplored the nightmare insecurity of his early years and blamed his father for the difficult, rough-and-tumble life the family led—a life that resulted in his mother's drug addiction—Eugene had the theatre in his blood. He was also, as a child, steeped in the peasant Irish Catholicism of his father and the more genteel, mystical piety of his mother, two influences, often in dramatic conflict, which account for the high sense of drama and the struggle with God and religion that distinguish O'Neill's plays.

O'Neill was educated at boarding schools—Mt. St. Vincent in the Bronx and Betts Academy in Stamford, Connecticut. His summers were spent at the family's only permanent home, a modest house overlooking the Thames River in New London, Connecticut. He attended Princeton University for one year (1906–07), after which he left school to begin what he later regarded as his real education in "life experience." The next six years very nearly ended his life. He shipped to sea; lived a derelict's existence on the waterfronts of Buenos Aires, Liverpool, and New York; submerged himself in alcohol; and attempted suicide. Recovering briefly at the age of 24, he held a job for a few months as a reporter and contributor to the poetry column of the *New London Telegraph* but soon came down with tuberculosis. Confined to the Gaylord Farm Sanitarium in Wallingford, Connecticut, for six months (1912–13), he confronted himself soberly and nakedly for the first time and seized the chance for what he later called his "rebirth." He began to write plays.

Entry into theatre. O'Neill's first efforts were awkward melodramas, but they were about people and subjects that had, up to that time, been in the province of serious novels and not considered fit subjects—prostitutes, derelicts, lonely sailors, God's injustice to man—for presentation on the American stage. A theatre critic persuaded his father to send him to Harvard to study with George Pierce Baker in his famous playwriting course. Although what O'Neill produced during that year (1914–15) owed little to Baker's academic instruction, the chance to work steadily at writing set him firmly on his chosen path.

O'Neill's first appearance as a playwright came in the summer of 1916, in the quiet fishing village of Provincetown, Massachusetts, where a group of young writers and painters had launched an experimental theatre. In their tiny, ramshackle playhouse on a wharf, they produced his one-act sea play *Bound East for Cardiff.* The talent inherent in the play was immediately evident to the group, which that fall formed the Playwrights' Theater in Greenwich Village. Their first bill, on November 3, 1916, included *Bound East for Cardiff*—O'Neill's New York debut. Although he was only one of several writers whose

plays were produced by the Playwrights' Theater, his contribution within the next few years made the group's reputation. Between 1916 and 1920, the group produced all of O'Neill's one-act sea plays, along with a number of his lesser efforts. By the time his first full-length play, *Beyond the Horizon*, was produced on Broadway, February 2, 1920, at the Morosco Theater, the young playwright already had a small reputation.

Beyond the Horizon impressed the critics with its tragic realism, won for O'Neill the first of four Pulitzer prizes in drama—others were for *Anna Christie* (1922), *Strange Interlude* (1928), and *Long Day's Journey into Night* (posthumously, 1957)—and brought him to the attention of a wider theatre public. For the next 20 years his reputation grew steadily, both in the United States and abroad; after Shakespeare and Shaw, O'Neill became the most widely translated and produced dramatist.

Period of the major works. O'Neill's capacity for and commitment to work were staggering. Between 1920 and 1943, he completed 20 long plays—several of them double and triple length—and a number of shorter ones. He wrote and rewrote many of his manuscripts half a dozen times before he was satisfied, and he filled shelves of notebooks with research notes, outlines, play ideas, and other memoranda. His most distinguished short plays include the four early sea plays, *Bound East for Cardiff*, *In the Zone*, *The Long Voyage Home*, and *The Moon of the Caribbees*, which were written between 1913 and 1917 and produced in 1924 under the overall title *S.S. Glencairn; The Emperor Jones* (about the disintegration of a Negro Pullman porter turned tropical-island dictator); and *The Hairy Ape* (about the disintegration of a displaced steamship coal stoker).

Evolving themes of tragedy and conflict

O'Neill's plays were written from an intensely personal point of view, deriving directly from the scarring effects of his family's tragic relationships—his mother and father, who loved and tormented each other; his older brother, who loved and corrupted him and died of alcoholism in middle age; and O'Neill himself, caught and torn between love for, and rage at, all three.

Among his most celebrated long plays is *Anna Christie*, perhaps the classic American example of the ancient "harlot with a heart of gold" theme; it became an instant popular success. O'Neill's serious, almost solemn treatment of the struggle of a poor Swedish-American girl to live down her early, enforced life of prostitution and to find happiness with a likable but unimaginative young sailor is his least complicated tragedy. He himself disliked it from the moment he finished it, for, in his words, it had been "too easy."

The first full-length play in which O'Neill successfully evoked the starkness and inevitability of Greek tragedy that he felt in his own life was *Desire Under the Elms*. Drawing on Greek themes of incest, infanticide, and fateful retribution, he framed his story in the context of his own family's conflicts. This story of a lustful father, a weak son, and an adulterous wife who murders her infant son was told with a fine disregard for the conventions of the contemporary Broadway theatre. Because of the sparseness of its style, its avoidance of melodrama, and its total honesty of emotion, the play was acclaimed immediately as a powerful tragedy and has continued to rank among the great American plays of the 20th century.

Innovative playwriting and staging techniques

In *The Great God Brown* O'Neill dealt with a major theme that he expressed more effectively in later plays—the conflict between idealism and materialism. Although the play was too metaphysically intricate to be staged successfully in 1926, it was significant for its symbolic use of masks and for the experimentation with expressionistic dialogue and action—devices that since have become commonly accepted both on the stage and in motion pictures. In spite of its confusing structure, the play is rich in symbolism and poetry, as well as in daring technique, and it became a forerunner of avant-garde movements in American theatre.

O'Neill's innovative writing continued with *Strange Interlude*. It was revolutionary in style and length: when first produced, it opened in late afternoon, broke for a dinner intermission, and ended at the conventional hour. Techniques new to the modern theatre included spoken asides, or soliloquies, to express the characters' hidden thoughts. The play is the saga of Everywoman, who ritualistically acts out her roles as daughter, wife, mistress, mother, and platonic friend. Although it was innovative and startling in 1928, its obvious Freudian overtones have rapidly dated it.

One of O'Neill's enduring masterpieces, *Mourning Becomes Electra*, represents the playwright's most complete use of Greek forms, themes, and characters. Based on the *Oresteia* trilogy by Aeschylus, it was itself three plays in one. To give the story contemporary credibility, O'Neill set the play in the New England of the Civil War period, yet he retained the forms and the conflicts of the Greek characters: the heroic leader returning from war; his adulterous wife, who murders him; his jealous, repressed daughter who avenges him through the murder of her mother; and his weak, incestuous son who is goaded by his sister first to matricide and then to suicide.

His one comic vision

Following a long succession of tragic visions, O'Neill's only comedy, *Ah, Wilderness!* appeared on Broadway in 1933. Written in a lighthearted, nostalgic mood, the work was inspired in part by the playwright's mischievous desire to demonstrate that he could portray the comic as well as the tragic side of life. Significantly, the play is set in the same place and period, a small New England town in the early 1900s, as his later tragic masterpiece, *Long Day's Journey into Night*. Dealing with the growing pains of a sensitive, adolescent boy, *Ah, Wilderness!* was characterized by O'Neill as "the other side of the coin," meaning that it represented his fantasy of what his own youth might have been, rather than what he believed it to have been (as dramatized later in *Long Day's Journey into Night*).

The Iceman Cometh, the most complex and perhaps the finest of the O'Neill tragedies, followed in 1939, although it did not appear on Broadway until 1946. Laced with subtle religious symbolism, the play is a study of man's need to cling to his hope for a better life, even if he must delude himself to do so.

Even in his last writings, O'Neill's youth continued to absorb his attention. The posthumous production of *Long Day's Journey Into Night* brought to light an agonizingly autobiographical play, one of O'Neill's greatest. It is straightforward in style but shattering in its depiction of the agonized relations between father, mother, and two sons. Spanning one day in the life of a family, the play strips away layer after layer from each of the four central figures, revealing the mother as a defeated drug addict, the father as a man frustrated in his career and failed as a husband and father, the older son as a bitter alcoholic, and the younger son as a tubercular, disillusioned youth with only the slenderest chance for physical and spiritual survival.

O'Neill's tragic view of life was perpetuated in his relationship with the three women he married—two of whom he divorced—and with his three children. His elder son, Eugene O'Neill, Jr. (by his first wife, Kathleen Jenkins), committed suicide at 40, while his younger son, Shane (by his second wife, Agnes Boulton), drifted into a life of emotional instability. His daughter, Oona (also by Agnes Boulton), was cut out of his life when, at 18, she infuriated him by marrying Charlie Chaplin, who was O'Neill's age.

Until some years after his death in 1953, O'Neill, although respected in the U.S., was more highly regarded abroad. Sweden, in particular, always held him in high esteem, partly because of his publicly acknowledged debt to the influence of the Swedish playwright August Strindberg, whose tragic themes often echo in O'Neill's plays. In 1936 the Swedish Academy gave O'Neill the Nobel Prize for Literature, the first time the award had been conferred on a U.S. playwright.

Unfinished plays and unwritten cycles

O'Neill's most ambitious project for the theatre was one that he never completed. In the late 1930s he conceived of a cycle of 11 plays, to be performed on 11 consecutive nights, tracing the lives of an American family from the early 1800s to modern times. He wrote scenarios and

outlines for several of the plays and drafts of others but completed only one play in the cycle—*A Touch of the Poet*—before a crippling illness ended his ability to hold a pencil. An unfinished rough draft of another of the cycle plays, *More Stately Mansions*, was published in 1964 and produced three years later on Broadway, in spite of written instructions left by O'Neill that the incomplete manuscript be destroyed after his death.

O'Neill's final years were spent in grim frustration. Unable to work, he longed for his death and sat waiting for it in a Boston hotel, seeing no one except his doctor, a nurse, and his third wife, Carlotta Monterey. As broken and tragic a figure as any he had created for the stage, O'Neill died on November 27, 1953.

MAJOR WORKS

ONE ACT PLAYS OF THE SEA: *Bound East for Cardiff* (performed 1916); *The Long Voyage Home* (performed 1917), later used as the title of a film version of O'Neill's plays of the sea; *Ile* (performed 1917); *In the Zone* (performed 1917); *The Moon of the Caribbees* (performed 1918), published in a collection, *The Moon of the Caribees, and Six Other Plays of the Sea* (1919), which included the first book publication of the above plays plus *The Rope* (performed 1918), and *Where the Cross Is Made* (performed 1918). This same collection was published in 1940 as *The Long Voyage Home: Seven Plays of the Sea.*

LONGER PLAYS: *Beyond the Horizon* (performed and published 1920); *The Emperor Jones* (performed 1920, published 1921); *Anna Christie* (performed 1921, published 1922); *The Hairy Ape* (1922); *All God's Chillun Got Wings* (1924); *Desire Under the Elms* (performed 1924, published 1925); *The Great God Brown* (1926); *Marco Millions* (performed 1928, published 1927); *Strange Interlude* (1928), a two-part play in 9 acts; *Mourning Becomes Electra* (1931), a trilogy comprising *Homecoming, The Hunted,* and *The Haunted; Ah, Wilderness!* (1933), O'Neill's only comedy; *The Iceman Cometh* (written 1939, performed and published 1946); *A Touch of the Poet* (written 1935–42; performed and published posthumously, 1957), third of a projected cycle of 11 plays to be collectively entitled *A Tale of the Possessors, Self-Dispossessed; Long Day's Journey Into Night* (written 1939–41; performed and published posthumously, 1956); *A Moon for the Misbegotten* (written 1943; performed 1957, published 1952); *Hughie* (written 1941; first performed 1964; published 1959, one of a projected cycle of one-act plays, to have been collectively entitled *By Way of Orbit*); *More Stately Mansions* (written 1935–41; performed 1962; published 1964).

The handiest source for all the plays listed from the beginning of this Major Works section through *Mourning Becomes Electra* is *The Plays of Eugene O'Neill,* 3 vol. (1951). Some of the other plays have been published as separate volumes.

BIBLIOGRAPHY. ARTHUR and BARBARA GELB, *O'Neill* (1962), is the definitive critical biography; see also DORIS ALEXANDER, *The Tempering of Eugene O'Neill* (1962); AGNES BOULTON, *Part of a Long Story* (1958), a memoir of their married life, by O'Neill's second wife; HELEN DEUTSCH and STELLA HANAU, *The Provincetown* (1931), a history of the Provincetown Players, who produced O'Neill's early works in New York; BARRETT H. CLARK, *Eugene O'Neill: The Man and His Plays,* rev. ed. (1936, reprinted 1967), a brief biography and critical analysis of the plays by a contemporary of O'Neill; and RALPH SANBORN and BARRETT H. CLARK (comps.), *A Bibliography of the Works of Eugene O'Neill* (1931, reprinted 1965).

(B.Ge./A.Ge.)

Ontario

Ontario, the second largest province of Canada, occupies the strip of the Canadian mainland lying between Hudson and James bays, on the north, and the St. Lawrence Rivers an area of 412,582 square miles (1,068,582 square by Quebec Province and to the west by Manitoba, it covers an area of 412,582 square miles (1,068,582 square kilometres). It is the most populous Canadian province, with more than 7,700,000 inhabitants representing more than one-third of the country's total by the early 1970s.

Ontario is also the nation's wealthiest province, having a substantial share of the country's natural resources and its most mature and diversified industrial economy. It is at once Canada's economic pacemaker and a major force in national politics. Some Ontarians call it the "Empire Province," while to those Canadians living outside its boundaries, its pre-eminent position and the influence of Toronto, the provincial capital, have constituted a not infrequent source of regional resentment. (For associated physical features see GREAT LAKES; SAINT LAWRENCE RIVER; HUDSON BAY; for related city articles see TORONTO; OTTAWA; and DETROIT; and for a detailed discussion of history see CANADA, HISTORY OF.)

HISTORY

The earliest known Indian inhabitants of the Ontario region included the agricultural Huron, Tobacco, and Erie tribes of the south and the hunting groups of the Algonquin, Ojibwa, and Cree of the north. The French explorer Étienne Brûlé was the first known white man to travel among them, doing so on an expedition to the Ottawa River in 1610–11. He was shortly followed by Samuel de Champlain and other French explorers, fur traders, and missionaries. In 1648–49 the southern tribes were dispersed when the Iroquois destroyed the Jesuit mission at Ft. Ste.-Marie, and France established Ft. Frontenac (present-day Kingston) in 1673 to begin the military protection of its westward-spreading fur empire. When Canada was ceded to Great Britain in 1763, however, no French colonization had taken place, except for a small farming settlement in the Detroit area.

Early European settlement

The Quebec Act of 1774 established Ontario as part of an extended colony ruled from Quebec. During the American Revolution, the region was a base for Loyalist and Indian attacks upon the American frontier, and in 1784 it was settled by approximately 10,000 Loyalists and those of the Iroquois Indians who had fought for the British. The Constitutional Act of 1791 divided Quebec colony into Lower Canada, with a French majority, and the new Loyalist province of Upper Canada. Upper Canada received representative government; provision was made for the support of the colonial administration and an established church by substantial land endowments called the Crown and Clergy Reserves.

John Graves Simcoe, the vigorous first lieutenant governor of Upper Canada, supervised the introduction of English legal and local government practices, laid out the land-granting pattern, supported the construction of trunk roads, and fixed the capital at York (now Toronto). His policy of welcoming massive American immigration was a source of tension between the newcomers and the established anti-American Loyalists, a rift that deepened during the War of 1812.

From 1815 to 1841 the province was dominated by a conservative coalition that was known as the "Family Compact" because it was alleged to be a self-perpetuating elite, tied together by family relationships and intermarriage. It favoured the Anglican Church and the Crown and Clergy Reserve system. Reformers demanded responsible government, and in 1837 a radical minority led by William Lyon Mackenzie attempted an unsuccessful revolt. In 1841 the provinces of Upper and Lower Canada were united, and Upper Canada became known as Canada West. Responsible cabinet government was achieved with the formation of the Robert Baldwin–Louis Hippolyte Lafontaine ministry in 1848, and the present system of municipal government and the province's educational system were created. The 1850s brought the railways, the beginnings of industrialization, and the emergence of Toronto as a commercial rival for Montreal.

Achievement of provincial status

Political deadlock and the impetus of the new Ontario economy contributed to the movement for Canadian political union. Canadian federation—achieved in 1867—was brought about in large part by such Ontario politicians as the Conservative John A. Macdonald and the Liberal George Brown. Canada West became the province of Ontario, and the capital was located at Toronto. For a generation Ontario's government was headed by Oliver Mowat, the Liberal premier who won a boundary dispute with Manitoba that doubled the size of Ontario and confirmed the supremacy of provincial governments within their constitutionally-assigned powers.

In the 20th century, the chief concern of Ontario's governments has been the fostering of economic growth. The

province has been transformed into a multicultural society engaged in a highly industrialized economy. With the harnessing of Niagara Falls in 1882, Ontario entered into an energy revolution that also encompasses the power potential of the north, the St. Lawrence River, and uranium-generated thermal power. Since 1914, there have been major discoveries of gold, silver, iron, nickel, copper, and other minerals, as well as the expansion of the forest products industry, particularly in the development of pulp and paper. Tied to the swift emergence of the northern natural resources, the rise of manufacturing in southern Ontario was spurred by the two world wars to the production of a surplus for export. The provincial government has also been concerned with the growth of services, especially education, for its burgeoning population and ever-expanding cities.

THE LANDSCAPE

Northern Ontario. Ontario is composed of two regions of widely different character. Northern Ontario, as usually defined, lies north of a line drawn from the confluence of the Mattawa and Ottawa rivers southwest to the mouth of the French River on Georgian Bay. Most of the region's 350,000 square miles is part of the ancient Canadian Shield, characteristically marked with a profusion of lakes and rivers, muskeg (bogs), and densely forested, rocky, and rugged terrain. A low plateau, it is generally no more than 1,500 feet (450 metres) above sea level, although it contains the highest point in the province, Ogidaki Mountain, which rises to 2,183 feet (665 metres) on the eastern shore of Lake Superior. Although the region has always been an obstacle to transportation and communication, its rich mineral deposits, huge forest reserves, and the hydroelectric power potential of its swift rivers have made it a major source of the province's contemporary wealth.

The forests of the north

The vegetation is that of the boreal (northern, mountain) forest, and includes the black and white spruce, jack pine, tamarack, poplar, white birch, and balsam. The soils of the region, apart from peat, consist largely of brown podzolic (mineral-covered, leached) soils unsuitable for agriculture, except for two clay belts in the Timiskaming and Cochrane farming areas. The region contains parts of two major drainage basins—that of the Great Lakes to the south and of Hudson Bay to the north—separated by a band of higher land running from Lake of the Woods to Kirkland Lake. Major rivers of the northern system are the Severn, the Winisk, and the Albany, while the major rivers in the southern system are the Ottawa and French. Both Hudson Bay and James Bay are bordered by sparsely forested lowlands less than 500 feet above sea level, and, at the northern limit of the province, there is a band of tundra along Hudson Bay.

The climate varies from that of the districts close to the Great Lakes, which are frost free on more than 100 days a year, to the harsh climate of the Hudson Bay area, where the period free from frost may be as low as 40 days. At Thunder Bay on Lake Superior the mean temperature in January is 7° F (−14° C), and in July 64° F (18° C), the annual precipitation is 29 inches (737 millimetres), and the annual snowfall 85 inches (216 centimetres).

Southern Ontario. Though covering less than 10 percent of the area of the province, southern Ontario contains 90 percent of its population and is, in addition, the major urban-industrial region of Canada. It is a land of gentle relief; its lowest area on the Ottawa River is only 150 feet above sea level, and its highest point—on Blue Mountain south of Georgian Bay—is just over 1,700 feet. The east is divided from the rest of the region by an extension of the Canadian Shield, known as the Frontenac Axis. This crosses the St. Lawrence River east of Kingston and forms the Thousand Islands region. Along the southern edge of the shield lies a series of beautiful lake districts—including the Muskoka Lakes, the lakes of the Haliburton Highlands, and the Rideau chain—which are the province's best known resort areas. The most dramatic feature of the landscape is the Niagara Escarpment, running from Niagara Falls to the Bruce Peninsula; roads and rail lines pass through its notched valleys, and a nature trail runs along its length. The landforms of southern Ontario were shaped by glacial action, and most of the region consists of gently rolling plains. Both the Ottawa–St. Lawrence lowlands of eastern Ontario and the lands at the western tip of the Ontario Peninsula are, however, quite flat. The retreating glaciers left over most of the region a thick overburden of gray-brown podzolic soil, fertile in character, although sand plains are also found north of Lake Erie and along the eastern Lake Ontario shore. Rivers of the region are short, draining into the Great Lakes from the Western Ontario Upland and from the Oak Ridges Moraine north of Lake Ontario. Eastern Ontario, however, is drained chiefly by tributaries of the Ottawa River.

The Niagara Escarpment

The original natural vegetation of the area consisted of hardwood forests with great stands of white and red pines on the lighter soils, but during the 19th century land clearing and lumbering removed most of the original forest cover. Since the 1880s, the provincial government has engaged in farm woodlot and reforestation programs; it has also encouraged the formation of watershed-conservation authorities concerned with problems of soil erosion, drainage, forestry, and pollution.

The climate of the whole region is generally favourable to agriculture, although considerable local variation exists. The eastern section, away from the moderating influence of the lakes, tends to be cooler and more humid than the southern and southwestern zones. Ottawa receives 34 inches of rain and 86 inches of snow yearly, as compared to Toronto's 31 inches of rain and 54 inches of snow. The mean temperature in January for most of the southern region is about 25° F (−4° C), and for July, about 72° F (22° C). The Ottawa Valley, however, has means of 13° F (−11° C) and 69° F (21° C).

Pollution. In both regions of the province, industrialization and urbanization have created problems of pollution, the most acute of which are the death of Lake Erie and the polluted air of the Toronto urban complex. Air and water pollution associated with the mining and pulp and paper industries of the north has also emerged and increasing concern has been expressed about the presence of mercury in some northern lakes and rivers. The resort region is also endangered because of the high concentration of cottagers.

Settlement patterns. In northern Ontario, settlement has little agricultural base and is largely connected with major industries and transportation routes. Thunder Bay (formerly the twin cities of Port Arthur and Fort William) is located at the head of the Great Lakes navigation system and is the transshipment point for western wheat. Its population exceeded 110,000 by the early 1970s. Sudbury (pop. 155,000) is the centre of a major mining area, as are such communities as Timmins, Kirkland Lake, and Geraldton. Sault Ste. Marie is both an important lake-navigation port and a centre of large steel and paper industries.

Urban growth

Agricultural settlement is more frequent in southern Ontario, and about 80 percent of the region's farms are family-owned. The standard farm lot, determined in the 1790s, was an oblong of 100 or 200 acres, and despite a recent increase in the number of large farms, the average farm size was about 160 acres in 1966. Fields and townships were laid out in a square grid pattern, with roads one mile apart. In areas of French settlement, however, the long, narrow fields typical of French-Canadian strip farming may be seen. Villages grew up at water-power sites, convenient distribution points, and around early garrison centres. Kingston, the first important town, combined all three of these advantages.

Urbanization and industrialization are rapidly transforming the contemporary Ontario countryside; although the population density of southern Ontario as a whole grew from 39 persons per square mile in 1861 to 152 per square mile in 1961, the farming population dropped from 31 percent of the labour force in 1911 to 7 percent in 1961, with the absolute total also falling toward the end of the period, dropping below the half-million mark during the 1960s. Total farm acreage has also diminished,

due to the disappearance of farms on marginal lands, the conversion of land to recreational use, the great expansion of urban areas, and the growth of commercial farming operations. Urban growth has been confined almost entirely to the south-central and southwestern parts of the province, except in Ottawa, the national capital, in the east whose population approached the half-million mark by the 1970s. The Toronto metropolitan complex—the so-called "Golden Horseshoe"—sprawls along the Lake Ontario shore from Oshawa (population 100,000) to St. Catharines (population 110,000), and includes the major port and industrial city of Hamilton (population 499,000). Metropolitan Toronto, whose total population exceeds the 2,600,000 mark, is Canada's second largest city, with a hinterland that embraces not only much of the province but a good part of the country. It has a phenomenal rate of growth. Other important urban concentrations in western Ontario include Windsor, London, and Kitchener–Waterloo, all with populations above the 200,000 mark.

THE PEOPLE

Until the end of the War of 1812, Ontario was peopled chiefly from the United States, by Loyalists, frontier farmers, and Quakers and Mennonites from Pennsylvania—the latter forming a nucleus for German settlement in Waterloo County. For the remainder of the 19th century most of the immigrants were Protestants from the British Isles, although both Irish and Scottish Catholics came in large numbers. The first wave of British immigration, between 1815 and 1850, altered the original American character of the province. The second phase of European immigration, from 1896 to 1914, included sizable numbers from Germany, Scandinavia, Russia, Poland, the Ukraine, and Italy. Their arrival coincided with the first great mining discoveries in northern Ontario, and, as a result, the composition of that region's population became much less British in character than the remainder of the province. After World War II, Ontario's immigrants were mainly attracted to the industrial areas of the province, being drawn by the demands of a rapidly expanding economy. Although people from the British Isles still formed the largest single group (about 44 percent), they were no longer in the majority, and the cities of Ontario became more cosmopolitan.

Immigration from Europe

The change in urban populations has been quickened by the growth of suburbs. In the case of Toronto, the city proper has grown little since 1921 because of the stability of its boundaries. Metropolitan Toronto, however, has grown from about 1,000,000 people in 1951 to over 2,600,000 in 1971. Since the movement to the suburbs was largely by citizens of British origin, there has been an extraordinary change in the ethnic composition of the population. Whereas the city was 80 percent British in 1931, the proportion dropped to 52 percent by 1961 and to 43 percent by 1966. The largest single increase was in Toronto's Italian community, which now numbers well over 200,000, and the German, Polish, and Ukrainian communities also grew substantially. Most Ontario cities have mirrored these changes to some degree. Political disruption in Hungary in the 1950s, and in Czechoslovakia in the 1960s, brought thousands of immigrants to the province, and there has been a marked increase in Portuguese and Greek immigration. The general result has been to alter the cultural pattern of life considerably and to enliven it decidedly. Also, Roman Catholics have become, at 30 percent, the largest single religious denomination; they are followed by members of the United Church at 26 percent and Anglicans at 18 percent.

There are no Eskimos indigenous to Ontario, and the small Indian population is almost exclusively rural. Blacks first arrived as slaves to Loyalist immigrants and, in the 19th century, as escaped slaves from the southern United States. Immigration continued during the 20th century, especially from Detroit, Michigan. The black population is also small and is concentrated largely in Toronto, where most are probably of West Indian origin.

As well as immigration from abroad, Ontario has benefitted from population movements within Canada. Approximately a quarter of the net migration into Ontario came from other parts of the country. After Newfoundland joined the confederation in 1949, Newfoundlanders began to move to Ontario in increasing numbers, and there has been a continuing movement from Nova Scotia and New Brunswick. There are about 500,000 French-speaking Canadians living in Ontario, who were drawn from Quebec since the 19th century by the lumber industry and railroads of the north, the farms of the east, and the Cornwall industrial area. Ottawa contains the largest concentration of French-Canadians, and there are sizable communities in Windsor, Toronto, and the Niagara Peninsula.

Emigration

Balanced against large-scale immigration is the fact that, as with Canada as a whole, there has long been substantial emigration from the province. As early as the 1850s, Ontarians were attracted by the westward movement in the United States, and outflow to the south has been important ever since. In the 20th century, much concern has been caused by what appears to be a disproportionate loss of professionally and technically skilled people to the United States. Similarly, many thousands of Ontarians have migrated to the Canadian West—to Manitoba in the 1870s and to Alberta and Saskatchewan after the turn of the century.

The result of the relationship between immigration and emigration is that natural increase has been the more important cause of population growth. The population more than doubled between 1901 and 1951 and reached 7,703,106 in 1971. Despite this growth, Ontario's proportion of the total Canadian population dropped from 41 percent in 1901 to 33 percent in 1951. This reflected not only the opening up of the Canadian and American, West and British Columbia, but also the fact that Ontario's birthrate declined to a 1937 low of 16.9. The birthrate later rose to a high of 26.8 in 1957, but it has since declined to 17.5 in 1969. The combination of birthrate trends and immigration meant that in the 1950s the province absorbed almost 39 percent of Canada's total increase in population, and by the mid-1960s it represented more than a third of the country's total population.

The province is overwhelmingly urban, with 80 percent of its citizens living in metropolitan areas. The population is relatively young, with only 8 percent of the total being over age 65 and 38 percent under age 20. This has meant an enormous expansion of educational facilities and has accentuated the need for continuing economic growth. Although the Ontario death rate of 7.5 per 1,000 is slightly above the national average of 7.3, it is well below death rates for comparable Western countries.

THE ECONOMY

Ontario's strategic central location with respect to the Canadian provinces, its proximity to U.S. markets and coal supplies, its cheap power, its large and skilled labour force, its abundant natural resources and diversified transportation system, and its general attractiveness to both domestic and foreign investment, have made its economy the most productive in Canada. As with all mature economies, the bulk of employment and output is concentrated in the manufacturing and service industries.

Agriculture. With the annual value of agricultural production exceeding $1,000,000,000 during the 1960s, Ontario is second only to the three Prairie Provinces as a Canadian farming region. The most important cash crop is tobacco, but most farms are concerned with dairying or livestock. As a result of this specialization, corn (maize) acreage has more than doubled since 1951. Nevertheless, it is still necessary to import corn from the United States for livestock feed. The Niagara Peninsula is the chief fruit-producing region, while Kent and Essex counties in western Ontario and the Holland Marsh north of Toronto are the major areas of vegetable production.

Mining and forestry. Ontario is Canada's leading mining province; the value of its mineral production rose from under $200,000,000 in 1946 to over $1,000,000,000 20 years later. The province mines 51 percent of the world's nickel; this metal alone accounts for more than a third of the total value of mineral production. Copper

production, whose annual value approaches $300,000,000, is the second most important metal, followed by iron, zinc, gold, uranium, and silver. The iron reserves alone are estimated at 3,000,000,000 tons.

Although the forest products industry does not rank with agriculture and mining in terms of value of production, it is still one of the most important branches of the industry in Canada. Over 600,000,000 cubic feet of lumber were produced annually by the early 1970s, nearly 80 percent of which was for pulpwood; pulp and paper manufacture dominate the industry in Ontario.

Manufacturing. Ontario is the leading manufacturing province in Canada, employing half of the country's workers and generating the same proportion of the total value of production. Historically, this pre-eminence derived from the milling, farm implement, furniture, and textile industries of the 19th century. The Canadian protective tariff of 1878 encouraged a domestic steel industry at Hamilton and the location of many American branch plants in the province. Since the United States-Canada automobile agreement of 1965, Canadian automobile production—almost all of which is in Ontario—has jumped by 270 percent, and the impact on related industries also approaches the phenomenal. Other leading industries include textiles, food processing, and the manufacture of industrial machinery, electrical goods, farm implements, rubber and synthetics, aircraft, and furniture.

The automotive industry

Labour. In 1973 the total labour force was estimated at over 3,250,000 persons, almost 75% higher than 1961. There has been a noticeable trend to the service industries that now employ over three-fifths of the working force, only 5% of which remains in agriculture and the extractive industries. Since World War II, the most remarkable change, however, has been the increasing participation of women. In 1951, 26% of women over 15 years of age were in the labour force, in 1961, 33%, and by 1969, 38% were working. Trends in the distribution of labour are shown in the Table.

Trends in Distribution of Labour Force in Ontario
(percentage)

	1961*	1973†
Agriculture	7.1	3.5
Forestry	0.7	1.5
Fisheries	0.1	
Mining	1.8	
Total primary industries	9.7	5.0
Manufacturing	26.9	28.9
Construction	6.4	4.9
Total secondary industries	33.3	33.8
Transportation, communications, utilities	8.2	7.8
Trade	15.5	16.3
Finance, insurance, real estate	4.1	5.1
Services (includes public administration)	27.1	31.9
Total tertiary (service) industries	54.9	61.2

*Excludes 2.16% whose occupations were unspecified or undefined at the 1961 census. †Employed, rather than labour force, in March, 1973; *i.e.*, excludes unemployed and certain others classified in 1961 figures.

Management of the economy. Federal economic policy remains the chief agent of control acting upon the private sector, but the provincial government has played an increasingly important role. Since 1962 the province has been divided into ten economic regions for planning purposes, and planning advice is given to the Cabinet by the Ontario Economic Council. The provincial government has stimulated industrial research and development with the Sheridan Park Project near Toronto, where the research facilities of more than 30 industries are now located. Industrial disputes are regulated by the Ontario Labour Relations Board; minimum-wage laws have set wage levels throughout the province, and government-sponsored marketing boards have influenced agricultural production.

TRANSPORTATION

Bulk cargoes, chiefly consisting of mining and forestry products and prairie grains, are moved to the United States or overseas by the Great Lakes–St. Lawrence waterway system. Seagoing carriers bring imports from abroad by the same route: roughly two tons move out of this sytem for every incoming ton.

Road system

The 80,000 miles of provincial roads carry Ontario's 3,000,000 or so motor vehicles, plus the heavy annual influx of tourist traffic. The basic road pattern, laid out in the 1790s, is an east–west highway from the Quebec border to Windsor and a north–south expressway from Toronto. The Ontario section of the Trans-Canada Highway runs for 1,400 miles from Montreal through Ottawa to the Manitoba border. Capital and maintenance costs are high because the region's heavy snowfall and extreme temperature range make constant repairs necessary.

Ontario has over 10,000 miles of standard-gauge railroad track, about 40 percent of which is in the north. It is crossed by two transcontinental lines and is bisected by one provincially owned railroad with its northern terminus at Moosonee on James Bay. Although there has been a recent reduction in passenger mileage in southern Ontario due to lack of revenue, this region's rail network—centred around Toronto—is Canada's most elaborate.

Toronto is also the focus for the province's air traffic. Its International Airport is now the country's largest and is a main centre of operations for both domestic and international flights. Other important airports are located at Ottawa, London, Sault Ste. Marie, and Thunder Bay.

ADMINISTRATION AND SOCIAL CONDITIONS

The provincial government consists of the lieutenant governor, appointed by the governor general in council, whose functions are purely formal; the Executive Council, or Cabinet; and the elected Legislative Assembly of 117 members. The province is represented in the federal government by 24 senators and 85 elected members of the House of Commons. Manhood suffrage, except for Indians living on reservations, has obtained since 1888. Women were given the vote in 1917, and in 1954 Indians were enfranchised.

Rural political domination

Since 1963, urban constituencies elect the majority in the legislature, but rural areas are still over-represented. The Cabinet, headed by the premier (frequently called prime minister in Ontario), contains about 20 ministers, and it, too, tends to be dominated by rural interests. Northern Ontario is habitually under-represented, as is the province's Catholic population.

Ontario has three political parties—the Conservatives, the Liberals, and the New Democratic Party. The latter, founded in 1961, represents an amalgamation of the Socialist Co-operative Commonwealth Federation and sections of the trade-union movement. Stability and one-party dominance, however, has long been the mark of Ontario politics, and there were only six changes of government in the hundred years following the establishment of federation in 1867. The Liberals were in power from 1872 to 1905, the Conservatives from 1905 to 1919, and —after the fall of a United Farmers government in 1923 —the Conservatives returned until 1934. Although the Liberals held sway from 1934 to 1943, the Conservatives have held office since. It is conceivable that the changing character of Ontario society might alter the tradition of one-party rule, but the existence of three parties competing for votes has so far prevented that possibility. In 1963 and 1967, the Conservatives won the elections, although they received less than half of the vote, because the majority was split between the other two parties.

Municipal government in Ontario consists of elected township and county councils in rural areas and of elected councils in cities and towns. Urban growth, the demand for enhanced services, and the movement of taxpayers to the suburbs promoted the federation of the city of Toronto and its 12 suburbs in 1954. The 13 components retained their existence as political entities, but certain general powers and responsibilities were transferred to a second tier of government. In 1965 the federation was adjusted, subsequently being composed of the city proper and five boroughs with roughly equal populations. These changes have brought an efficient centralization of public services, have enhanced the borrowing capacity of the

Municipal federation

municipality, and have created a uniform tax system. Similar regional governments were instituted for Ottawa–Carleton in 1969 and for Niagara in 1970.

The province is constitutionally responsible for the administration of justice. Although the federal government appoints the Supreme Court and district and county court judges, the province appoints magistrates and juvenile and family court judges. A legal-aid system provides free counsel based on assessment of means, and compensation is given to innocent victims of criminal acts and to those injured attempting to prevent a crime. The Ontario Provincial Police, with a strength of 4,500, is the third largest deployed force in North America.

Government expenditure per capita is about Can$160. From 1955 to 1962, Ontario expenditures increased by 105 percent, and in 1962 the province had its first Can$1,000,000,000 budget. By the early 1970s, total expenditure was more than Can$3,000,000,000.

Education costs have risen sharply to over 40 percent of the provincial budget because of increased enrollment in elementary and secondary schools and increased assistance to higher education. Undergraduate and graduate schools are rapidly expanding, and 14 universities, though legally autonomous, receive both operating and capital grants from the Department of University Affairs, which has a measure of control over university planning, intake, and curricula. The province has also established 18 colleges of applied arts and technology to provide postsecondary technical education.

In the field of social legislation, the province has entered into important shared-cost arrangements with the federal government. An Ontario Health Services Insurance Plan, for example, provides comprehensive medical insurance to all residents, and is free for those with no taxable income. Ontario receives 50 percent of the cost of its welfare services from federal sources under the Canada Assistance Plan of 1966.

Health and welfare

Poverty among Indians, marginal farmers, and city dwellers is of continuing concern, but the proportion of the population on welfare has remained fairly constant at a relatively low level. Real wages have risen steadily and exceed the national average for manufacturing and other industrial personnel. The cost of living, however, is high compared to most of the other provinces, and substantial discrepancies exist between male and female wages, although legislation is now in force against some forms of such wage and job discrimination.

CULTURAL LIFE AND INSTITUTIONS

Toronto tends to dominate the province's cultural activities, although its pre-eminence is by no means exclusive. The first notable school of Canadian painting—that of the Group of Seven—was founded there in the 1920s. The capital city is the centre of Canada's English-language theatre, as well as the headquarters of national radio and television broadcasting. The city supports two symphony orchestras, two choirs, national opera and ballet companies, and many art galleries and museums.

Cultural institutions are also growing in other urban centres. Ottawa boasts the National Arts Centre, a symphony orchestra, museums, and art galleries. London is developing an artists' colony, while Stratford is already established as a fine dramatic arts centre and site of the annual Shakespearean Festival. The latter, first launched in 1952 in this pleasant but previously culturally undistinguished western Ontario town, has had a substantial impact upon the cultural life of the province. There is also an annual George Bernard Shaw Festival at Niagara-on-the-Lake. Upper Canada Village near Morrisburg is a re-creation of a 19th-century Ontario community, and Ft. Henry at Kingston and Ft. George at Niagara Falls have been preserved.

THE FUTURE

Ontario's remarkable growth in wealth and population has brought not only greater educational, cultural, and recreational opportunities for its people but also many of the difficulties of other highly urbanized areas of North America. In 1970 the provincial government disclosed its "Design for Development: the Toronto-Centred Region." This plan contained an estimate that, by the year 2000, at least 8,000,000 of a total provincial population of 13,000,000 would live in the area of the Toronto conurbation. Since Ontario is already experiencing serious pollution, traffic congestion, and the complex social dislocations incidental to rapid urbanization, it is likely that public concern will increasingly be directed to the environmental and social consequences of further growth. It seems probable that the planning function of the provincial government will be enlarged and that efforts will be made to locate both industry and population in eastern and northern Ontario to a greater degree than has yet been the case. With a large and self-conscious French-speaking minority, Ontario has committed itself to the task of reaching agreement with Quebec and the other provinces on a satisfactory restructuring of the Canadian union. In 1967 Premier John Robarts took the initiative by calling the Confederation of Tomorrow Conference of provincial premiers in Toronto, and his successors will continue to bear a heavy responsibility for the provision of leadership in the quest for national unity.

BIBLIOGRAPHY

History: No complete history of Ontario has yet been written. E.G. FIRTH (ed.), *Profiles of a Province: Studies in the History of Ontario* (1967), is the most useful single source.

Landscape: L.J. CHAPMAN and D.F. PUTNAM, *The Physiography of Southern Ontario*, 2nd ed. (1966), is excellent. The Canadian Shield region is described in JOHN WARKENTIN (ed.), *Canada: A Geographical Interpretation* (1968). For settlement patterns, see JACOB SPELT, *The Urban Development in South-Central Ontario* (1955).

People: The peopling of Ontario may be followed in two volumes ed. by J.M.S. CARELESS, *Colonists and Canadiens, 1763–1867* (1971), and *The Canadians, 1867–1967* (1967).

Economy: The best statistical source for the economy, as well as for other aspects of Ontario, is the *Canada Year Book;* W.T. EASTERBROOK and H.G.J. AITKEN, *Canadian Economic History* (1956), is a useful introduction. W.G. DEAN, *Economic Atlas of Ontario* (1969), is a magnificent compilation in graphic form.

Transportation: G.P. DE T. GLAZEBROOK, *A History of Transportation in Canada*, 2 vol. (1964), is a standard source. P. CAMU *et al.*, *Economic Geography of Canada* (1964), gives a good functional treatment.

Administration and social conditions: F.F. SCHINDELER, *Responsible Government in Ontario* (1969), is the only good treatment of the structure of government. Local government is treated by T.J. PLUNKETT, *Urban Canada and Its Government: A Study of Municipal Organization* (1968); education by ROBIN HARRIS, *Quiet Evolution: A Study of the Educational System of Ontario* (1967). JOHN PORTER, *Vertical Mosaic: An Analysis of Social Class and Power in Canada* (1965), is a major work of scholarship.

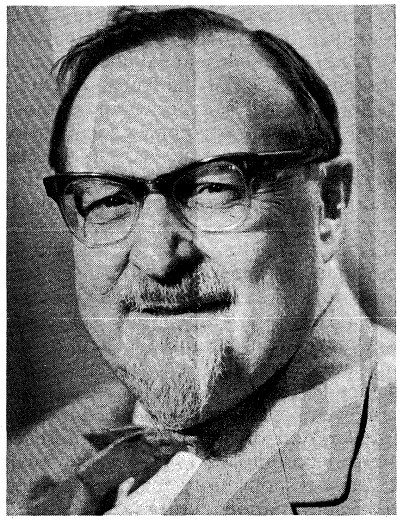
Oparin, Aleksandr Ivanovich

The 20th-century idea that there can be a natural explanation of the origin of life pervaded the scientific career of Aleksandr Ivanovich Oparin. By drawing on the insights of chemistry, he extended the Darwinian theory of evolution backward in time to explain how simple organic and inorganic materials might have combined into complex organic compounds, and how the latter might have formed the primordial organism.

Oparin, the youngest of three children, was born in 1894 in a small village near the Volga River, north of Moscow. When he was nine, his family moved to Moscow because there was no secondary school in their village. While majoring in plant physiology at Moscow State University, Oparin was influenced by K.A. Timiryazev, a Russian plant physiologist, who had known Darwin. The indirect effect of Darwin upon Oparin's thinking can be found in many of the latter's writings.

In his postdoctoral days Oparin was influenced also by A.N. Bakh, a botanist. Bakh left Russia at the time of the Revolution but later returned. Despite the financial difficulties of the times, the Russian government established a biochemical institute in his honour in 1935 in Moscow; Oparin helped to found it and has been its director since 1946.



Oparin, 1970.
Tass—Sovfoto

Concept of primordial organism

At a meeting of the Russian Botanical Society in the spring of 1922, Oparin first introduced his concept of a primordial organism arising in a brew of already formed organic compounds. He stated a number of premises that were not popular at the time. For example, according to his hypothesis, the earliest organisms were heterotrophic —*i.e.*, they obtained their nutrition ready-made from compounds that had already been formed in variety and profusion by what are in the laboratory quite ordinary means. Thus, at that early stage, these first organisms did not need to synthesize their own food materials in the way that present-day plants do. Oparin also emphasized that a high degree of structural and functional organization is characteristic of the living state, a point of view that is in opposition to the idea that "life" is essentially molecular. He was also farsighted in his observation that living organisms, as open systems, must receive energy and materials from outside themselves; they cannot, therefore, be limited by the second law of thermodynamics, which is applicable to closed systems in which energy is not replenished.

When Oparin first proposed his hypothesis, the prevailing view was that the first organisms could make all of their own organic compounds, and so the negative reaction to his proposal was almost universal. With continued retesting, however, his concept has come to be accepted in its main outlines. Although the possibility of a natural origin of life had been promulgated for at least 2,500 years, a specific formulation had to compete with vitalistic points of view in modern times. Also, organic chemistry, necessary for Oparin's hypothesis, had not been sufficiently developed by the time of Pasteur.

Oparin's various novel premises can be shown to be closely related to one another. What had been missing was an explanation of (1) how populations of large, complex molecules of largely predetermined structure could have arisen in contrast with the widely held view that the first proteins would have been random in structure and (2) an adequate explanation of how a first cell-like system might reproduce. When experimental answers to these questions arose from another laboratory, Oparin acknowledged them in a forthright manner. These answers consisted essentially of (1) ordered coupling of amino acids due to their differing shapes and distribution of electric charge and (2) the formation of buds on microscopic droplets followed by growth of separated buds and cyclical repetition of the process. In attempting to test his basic hypothesis, Oparin dealt with coacervate droplets, which are microscopic units assembled typically from gelatin and gum arabic, as models of early cells. His experiments showed that enzymes (biological catalysts) could function more efficiently within the boundaries of these artificial cells than they could in ordinary aqueous solution. This helped emphasize the fact that complete cells are important for the action of enzymes and metabolism.

The heterotroph hypothesis

The heterotrophic hypothesis for the origin of life has gained wide attention through Oparin's efforts. He organized the first international meeting of the origin of life in Moscow in 1957 at which representatives from 16 countries participated. A second conference was held in 1963, and at a third in Pont-à-Mousson, France, in 1970, Oparin was acclaimed president of the newly formed International Society for the Study of the Origin of Life.

Although he is best known for his contributions to studies of the origin of life, Oparin also devoted considerable effort to enzymology and to the closely related subject of industrial biochemistry. His wide interests are reflected in the title of the volume prepared in honour of his 70th birthday, *Problems in Evolutionary and Industrial Biochemistry*. But at the start of the 1970s, the centre of his interest remained at the A.N. Bakh Institute, where, under his direction, a number of research workers were concerned with the problems of the origin of life. Oparin's decorations include the Order of Lenin, Hero of Socialist Labour, the Bakh Prize, and the Mechnikov Gold Medal.

BIBLIOGRAPHY. Oparin's definitive work is *The Origin of Life on Earth*, 3rd rev. ed. (1957). His other books (in English translation) include: *Enzyme Action in the Living Cell* (1934); *Life: Its Nature, Origin, and Development* (1961); *The Chemical Origin of Life* (1964); and *Genesis and Evolutionary Development of Life* (1968). S.W. FOX (ed.), *The Origins of Prebiological Systems and Their Molecular Matrices* (1965), treats technical and historical aspects; and J.D. BERNAL, *The Origin of Life* (1967), discusses related sciences and some aspects of the main problem.

(S.W.F.)

Opera

The English word opera is an abbreviation of the Italian phrase *opera in musica* ("work in music"). It names a theatrical form consisting of a dramatic text (libretto, or "little book") combined with music, usually singing with instrumental accompaniment. Besides solo, ensemble, and choral singers and a group of instrumentalists, the forces performing opera since its inception have often included dancers. A complex, often costly variety of musicodramatic entertainment, opera has attracted audiences for nearly five centuries. Although its supporters have greatly outnumbered its detractors, it has been the target of intense adverse criticism.

Charles de Saint-Évremond, a French man of letters in the 17th century, called it "a bizarre thing consisting of poetry in music, in which the poet and the composer, equally standing in each other's way, go to endless trouble to produce a wretched result." The 18th-century English statesman and writer Lord Chesterfield wrote to his son: "As for operas, they are essentially too absurd and extravagant to mention. I look upon them as a magic scene contrived to please the eyes and the ears at the expense of the understanding." At the opposite extreme of reaction to opera, it has been said that the mere existence of such a masterpiece as Mozart's *Le nozze di Figaro* (*The Marriage of Figaro*) suffices to justify Western civilization.

The unique characteristics of opera

Although the characteristic of opera that most clearly separates it from other theatrical forms is that its principals sing rather than speak their lines, to approach it or criticize it as simply one variety of the musical art is to misjudge it. Its multiple creators almost always have intended an opera to be a lofty and eloquent form of theatrical performance. What commonly differentiates it from other varieties of musicodramatic theatre such as operetta (literally "small opera") and musical comedy is sobriety of workmanship, density of texture, and (even in operas with comic and farcical librettos) accompanying seriousness of musical tone. On the other hand, some lighter works—by Jacques Offenbach, Johann Strauss the Younger, Gilbert and Sullivan, Kurt Weill, George Gershwin, and a few others—make neat categorization impossible.

In the preparation of an opera performance, many individual artists and artisans, sometimes spread out across a

century and more, necessarily are or have been involved. The first, unintentional recruit is likely to have been the writer of the original story. Then comes the librettist, who puts the story or play into a form suitable for musical setting and singing, and the composer, who sets that libretto to music. Architects and acousticians have built an opera house suited or adaptable to performances that demand a sizable stage, a pit to house an ensemble of instrumentalists, and a reasonably large audience. A producer-director has to specify the work of designers, scene painters, costumers, and lighting experts. The producer, conductor, and musical staff have to work for long periods with chorus, dancers, orchestra, and extras as well as the principal singers to prepare the performance—work that may last anywhere from a few days to many months. All this does not even take into account the part played by the administrative staff.

Once the complete operatic score—the final libretto and music—is available, what must rule all of those involved is dedication to fulfilling the wishes of the librettist and the composer. Overemphasis or underemphasis of any larger component of an operatic performance can be as damaging to it as off-pitch singing or false entries by instrumentalists. More than one desirable balance among the constituents of performance is often possible. What is certain is that one or another of them must be decided upon, worked toward, and achieved.

The article is divided into the following sections:

I. The early centuries

ITALIAN ORIGINS

Works in antiquity had combined poetic drama and music. The plays of the ancient Greek dramatists Aeschylus, Sophocles, and Euripides employed choral music in a manner that certainly reflected related usages in earlier times. During the Middle Ages, biblical dramas were commonly accompanied by some music, being known under various labels, including mystery and miracle plays. These and other related musicodramatic forms may or may not have become collateral ancestors of opera: their descent seems most certain in some 17th-century operas on religious subjects performed in Rome and at several places in Germany. Musical historians and musicologists continue to debate opera's ancestry. The earliest universally accepted direct ancestors of opera appeared in 16th-century Italy. Purely nonreligious works of edifying drama with music, they included intermezzos and *intermedii* played between the acts of spoken dramas, with which their purported subject matter often claimed a tenuous connection, and staged ballet. The latter, Italian by birth, achieved a complex, quasi-operatic state in the court ballet (*ballet de cour*) danced in France late in the 16th century and throughout the 17th: it approached ever closer to opera in the *comédie-ballet* evolved by Molière and Jean-Baptiste Lully in the 1660s, beginning with *Le Mariage forcé* (*The Enforced Marriage*, first performed 1664).

16th century. Musicians, singers, poets, playwrights, and enthusiasts of the literary, musical, and theatrical arts had long cherished a desire for some more formally constituted and more stable form of drama with music, especially in Italy. One response to that expressed desire was the 16th-century "madrigal comedy," the singing of dramatic or semidramatic lines (often farcical, and most often with story and characters borrowed from the traditional commedia dell'arte as it had become formalized during the 16th century) in a linked series of more or less discrete madrigals and other varieties of polyphonic song.

16th-century "madrigal comedy"

But polyphony—the musical texture created by simultaneous, largely unaccompanied singing of interwoven melodies—was by nature alien to theatrical drama: it made extremely difficult, when not impossible, the delineation of individual characters through clearly understandable text words. This is noticeable even in the most celebrated of the madrigal comedies, Orazio Vecchi's paean to the "double Parnassus" of poetry and music, *L'Amfiparnaso* (Modena, 1594).

The gestation of opera required the simultaneous availability of a dramatic literary style and a musical texture suitable for incorporation into a new theatrical unity. The essential literary materials had begun to appear in Italy in such chivalresque epics as Lodovico Ariosto's *Orlando furioso* (published complete in 1532) and Torquato Tasso's *Gerusalemme liberata* (1575), both of which were to be mined for subjects by innumerable opera librettists. More immediately decisive in setting the first direction of opera was one sort of poetic drama: the shorter pastoral writings of 16th-century Italian poets, notably Tasso's *Aminta* (1573) and Giovanni Battista Guarini's *Pastor fido* (*The Faithful Shepherd*, completed in 1590). Idylls or eclogues that had sprung up in the 15th century, like the *Orfeo* of the Italian poet Poliziano (Politian) with music by Germi (one of the earliest examples, which was staged at Mantua in 1472, with solo song, chorus, and spoken dialogue), were seized on, adapted, and imitated by the men who had begun to evolve the musical texture essential to the birth of opera and who found apt subjects in the loves, joys, and sorrows of Arcadian shepherds and shepherdesses, often with the intervention of gods, demigods, and heroes.

Until the 1950s it was generally accepted that opera originated with a *camerata* (a sort of humanistic discussion group) that met in the late 1570s and early 1580s in the Florentine palace of Giovanni Bardi, count of Vernio. In 1953, however, the Roman musicologist Nino Pirrotta showed that the Bardi Camerata, far from having furthered innovation or interested itself in musical drama, was predominantly conservative, often acted in defense of the polyphonic madrigal, and showed no sympathy with the new combinations that would shortly produce opera. In fact, that literary–musical texture was evolved at Florence, but largely among a group of intellectuals, artists, and dilettantes who met informally in the palace of the theatrical theoretician Jacopo Corsi during the 1590s. This latter group also included Emilio de' Cavalieri, the composer, impresario, and choreographer who was to write what is often called the first oratorio, *Rappresentatione di anima et di corpo* (*The Representation of Soul and Body*, an acted form unlike later oratorios); the singer-composer Jacopo Peri; and—although they attended infrequently—both the poet Tasso and the composer Claudio Monteverdi. Still active at the time, though a little out of favour, was the singer-composer Giulio Caccini. Corsi and his friends were by no means the first creators of solo vocal lines with instrumental accompaniment, and they shaped their musicotheatrical creations partly in the mistaken belief that their performances were reviving ancient Greek procedures. What, in fact, they did was to take hints from the French court ballet and simultaneously discard polyphony in favour of monody (or homophony)—accompanied singing or recitation on musical tones (recitativo) of one melody at a time. Thus, they insured both the relative comprehensibility of the words (which to them seemed much more important than the accompanying music) and the use of at least some instrumental support.

Florentines who "created" opera

An important "manifesto" of the monodic innovators was a collection of short vocal pieces with thorough-bass

accompaniment (instrumental chords in sequence as accompaniment to melody) by Caccini, published in 1602: *Le nuove musiche*, a title that often has been extended to cover the novel musical texture itself. The interaction of these and other Italians with the texture of monody was what finally led, after some false starts, to the emergence not only of opera more or less as it is known today but also of the cantata and the oratorio.

The honour of being deemed "the first opera" usually is given to a setting by Peri of *Dafne* by the Renaissance pastoral poet Ottavio Rinuccini. It was staged at the Palazzo Corsi in Florence during the pre-Lenten Carnival of 1597–98. The text, divided into a prologue and six scenes, was published in 1600 and therefore survives, but neither Peri's music (the prologue and one aria excepted) nor that of an almost contemporary setting of the same text by Caccini can now be recovered. The earliest surviving opera is also Peri's: a setting of Rinuccini's pastoral *Euridice*, likewise in a prologue and six scenes, which was performed at the Palazzo Pitti in Florence on October 6, 1600. More unusual, the musical score also was issued in 1601 and reprinted several times thereafter.

17th and 18th centuries. However significant historically, the pioneering operas of Peri and Caccini were tentative in both style and structure; further, neither of the founding fathers of opera seems to have possessed notable dramatic talent.

Monteverdi. Within ten years of the premiere of Peri's *Dafne* at Florence, Mantua heard an opera that is a masterpiece and still is staged frequently. This was *La favola d'Orfeo* (*The Fable of Orpheus*), a setting by Monteverdi of a poetic text by Alessandro Striggio the Younger. Presented during the Carnival of 1607 (the libretto was published then, the score in 1609), it soon was presented elsewhere in Italy. In *Orfeo*, the accompanying instruments come into their own as a dramatic element: the score contains more than two dozen pieces for increased (though not precisely determinable) numbers of instruments. It not only introduces, as a preluding toccata, the idea of the operatic overture but also achieves some sectional unity by repeating brief instrumental numbers (ritornellos). More important, Monteverdi uses recitative expressively and gives it an organizational function by repetitions and developments in predetermined patterns.

Monteverdi's *Orfeo*

Monteverdi continued to compose operas for more than 35 years; meanwhile, the new manner of musicodramatic entertainment spread to other Italian cities. Rome probably first heard an opera as early as 1606, Bologna before 1610. Continuing to employ librettos based on Italian interpretations of Greek and Roman myth, legend, and pseudo-history, literary men and composers rapidly swelled the number of operas heard. At Venice in 1642, the 75-year-old Monteverdi created his masterpiece *L'incoronazione di Poppea* (*The Coronation of Poppea*). Gian Francesco Busenello's superior libretto carried a new note of realism into opera, particularly in the development of human character; it was to have a prolonged, important line of descent, and Monteverdi translated it blazingly into music. Throughout that first period of operatic history, the importance given by composers to emotional drama, to instrumental music, and to structural stability increased along with the capabilities (and pretensions) of singers and the magnificence and complexity of stage settings, stage machinery, and costuming.

The first opera house

Venice. The inauguration early in 1637 of the first opera house open to the general public, the Tron family's Teatro di San Cassiano at Venice, was another decisive factor in establishing opera. That action removed opera from the exclusive hands of royalty and nobility and placed it within reach of all but the poorest sectors of the Italian urban population.

A pupil of Monteverdi, Pier Francesco Caletti-Bruni, known as Francesco Cavalli (1602–76), became the most popular opera composer of his era by furnishing the opera houses of Venice with some 40 operas between 1639 and 1669. A highly talented but not always fastidious composer, Cavalli reacted to the librettos he used with dramatic force and directness. The most renowned of his operas was *Giasone* (*Jason*, 1649), whose libretto by Giacinto Andrea Cicognini included farcical episodes. His chief Venetian rival and successor was Pietro Antonio (often called Marc' Antonio) Cesti (1623–69), about a dozen of whose nearly 100 operas have survived. Some notion of the extravagance to which imitation of Louis XIV's spectacles at Versailles had driven the production of opera elsewhere can be gained from descriptions of the Cesti opera *Il pomo d'oro* (*The Golden Apple*, 1667), composed for the wedding of Emperor Leopold I and Margarita Teresa of Spain in Vienna. Constructed in a prologue and five acts (the third and fifth of which have been lost), with 48 characters, it contained 66 scenes requiring 24 stage settings making use of complex stage machinery. Ballets occurred in every act, and a grand triple ballet brought the opera to its conclusion. *Il pomo d'oro* provided numerous purely instrumental introductions and interludes, gave relatively little importance to the chorus, skipped rapidly over the essential storytelling recitative, and concentrated on arias and duets that often were most sensuous and almost feminine in allure.

Opera in Venice and Rome

Venetian opera continued to flourish in the works of such greatly talented theatrical composers as Cavalli, Cesti, and Giovanni Legrenzi (1626–90). In some details, these Venetian operas reflected the pressures exerted by the tastes and wishes of the paying audiences for which they were designed. Not so lavish with choral interpolations as their Roman contemporaries, the Venetians demanded and received complex, strong librettos calling for large casts and special lavishness in staging. They also began to develop the sensuous melodic profiles that have come to be thought of as particularly "Italian." Furthermore, they all but separated the solo aria from the surrounding recitative. They also frequently prefaced and followed solos with purely instrumental music, so continuing the orchestra's elevation from a purely accompanying role. After the middle of the 17th century, the Venetian operatic style began to decline. Among the later Venetian operatic composers of talent and fame were Antonio Lotti (*c.* 1667–1740), Carlo Francesco Pollaroli (1653–1722), Antonio Vivaldi (*c.* 1678–1741), and Baldassare Galuppi (1706–85), who is often referred to somewhat loosely as "the father of opera buffa."

Rome. Several Italian cities soon developed recognizably indigenous operatic styles. At Rome, for example, a group of composers tended toward unified structure, gave ensemble and choral song expanded roles, and increased the difference between the solo (aria) and the Florentine type of continuous recitative by allowing arias to interrupt dramatic progress in order to express or comment upon emotional moods. Less emphatic about stage magnificence than their Venetian counterparts, such Roman composers as Stefano Landi (*c.* 1590–*c.* 1655), Domenico Mazzocchi (1592–1655), Luigi Rossi (1597–1653), and Michelangelo Rossi (1600?–70) also permitted comic episodes to lighten prevailingly tragic stories. They concentrated attention productively on instrumental overtures and on overture-like pieces preceding acts or sections of acts. Two Roman composers—Domenico Mazzocchi's brother Virgilio (1597–1646) and Marco Marazzoli (1619–62)—often are cited as having created the first completely comic opera, *Chi soffe speri* (*He Who Suffers, Hopes*, 1639). Its libretto was written by Cardinal Giulio Rospigliosi, who was to be elevated to the papacy in 1667 as Clement IX. The invited guests at its first performance, in the Palazzo Barberini, included the English poet John Milton and Giulio Mazarini, the future Cardinal Mazarin, statesman to Louis XIV.

Naples. With the 18th century the centre of Italian opera shifted to Naples, where so great a variety of styles evolved that the term Neapolitan opera eventually covered operas that dominated most of Italy and many foreign centres of operatic activity. With some exceptions, the earliest unmistakably Neapolitan operas changed their focus back from the music to the words. Two of its instigators were dramatic poets: Apostolo Zeno (1668–1750), born a Venetian, and the Roman Pietro Trapassi, known as Metastasio (1698–1782)—perhaps the greatest of the 18th-century librettists. Continu-

Contributions of Zeno and Metastasio

ing the custom of basing librettos on Greco-Roman legend and pseudo-history (but dispensing almost entirely with classical mythology), Zeno and Metastasio wrote texts of formal beauty and linguistic clarity, preferring solemn, usually tragic subjects (opera seria) in three acts to comic episodes and characters. The aria came to dominate, and the use of chorus declined.

The term Neapolitan opera also came to indicate harmonically naïve, melodious lighter operas in the gallant tone of the Rococo style; the rich development of the bel canto styles (where beautiful singing *per se* was predominant), signifying supreme vocal agility and smoothness that was supplied first by castratos, men who had been castrated before puberty in order to preserve the high ranges of their boyish voices; and the appearance of the *centone* or pasticcio, a libretto set to a score made up of music borrowed either from scores (then uncopyrighted or otherwise legally protected) of several composers or from several operas by a single composer. The use of the orchestra also became limited. But perhaps the most discussed, and often senselessly maligned, feature that particularly designated Neapolitan opera was the aria da capo, an aria in three sections, the third part repeating the first. It had appeared in northern Italy early in the 17th century but was employed with comparative infrequency there. Some Neapolitan operas, however, consisted of up to 20 da capo arias separated by a minimum of story-advancing recitativo secco (narrative passages in which voice is accompanied only by a thorough bass).

Domination of the aria da capo

A masterly operatic composer of the transitional style who bridged the era between the Baroque and the preclassical Neapolitan style was Alessandro Scarlatti (1660–1725). In his many operas Scarlatti triumphed, by the strength of musical imagination, over librettos intended to provide vehicles for phenomenally trained singers in the prevailing pattern and the consequent reduction of dramatic interest to a narrow minimum. Talented and influential among Scarlatti's contemporaries were such composers as Nicola Antonio Porpora (1686–1768), Leonardo Vinci (1690–1730), and Leonardo Leo (1694–1744).

Attempts at reform. In 1720 the Venetian composer-poet-statesman Benedetto Marcello (1686–1739) published a mordant satire on the increasingly rigid and undramatic conventions that had taken hold of opera seria: *Il teatro alla moda, o sia metodo sicuro e facile per ben comporre ed eseguire opere italiane in musica* ("The Theater à la Mode, or The Secure and Easy Method of Composing and Performing Italian Operas"). The distress that it and other criticisms brought resulted in an improved genre, still in effect opera seria but showing attempts at reform of its mannerisms. The principal operas against which that reform later evolved were the often melodically seductive works of Gaetano Latilla (1711–88), Giuseppe Sarti (1729–1802), Antonio Sacchini (1730–86), Johann Christian Bach (1735–82), Antonio Salieri (1750–1825), and Mozart's *Idomeneo, rè di Creta* (1781) and *La clemenza di Tito* (*The Clemency of Titus,* 1791). Representative composers within the short "reform" movement itself were Niccolò Jommelli (1714–74) and Tommaso Traetta (1727–79). A more intellectually rigorous reformation was undertaken consciously by Christoph Willibald Gluck (see below *The "reform"*) in collaboration with the librettist Ranieri de' Calzabigi, beginning with *Orfeo ed Euridice* (1762).

Comic opera. Comic opera meanwhile had expanded from its shadowy existence within and between the acts of opera seria. From the early, tentative efforts of several 17th-century Roman and Florentine composers, it had moved into a bustling, rude, independent vitality of its own, often in the form of satirical opera buffa (Italian: "comic opera"), generally shaped in two acts rather than the usual three of opera seria. Expelled from the precincts of opera seria by the librettos of Zeno and Metastasio, the comic spirit had taken refuge in such an expanded intermezzo as *La serva padrona* (*The Maid Mistress,* 1733), by Giovanni Battista Pergolesi. When it matured, the style borrowed back some of the more serious emotional qualities of opera seria, often including "serious" roles among those of the comedians. This led to a hybrid nature in many operas, including two works using librettos derived from the plays of Pierre de Beaumarchais—*Il barbiere di Siviglia* (*The Barber of Seville,* 1782), by Giovanni Paisiello, and Mozart's *Le nozze di Figaro* (1786)—as well as *Il matrimonio segreto* (*The Secret Marriage,* 1792), by Domenico Cimarosa.

One of the determining characteristics of this mixed style was the elaboration of ensemble numbers concluding acts. These operas dispensed almost entirely with the magnificent display and grandeur of staging increasingly required of opera seria. Another of the drawbacks of the mixed style was well summed up by the 20th-century Italian musicologist Andrea Della Corte:

> With few exceptions among the great composers dedicated to instrumental music or to teaching, almost all the serious composers also collaborated in the comic theatre. Not so the literary men. The best dramatists were not equally tempted by this tendency.

The natural result was that the large majority of opera buffa librettos remained inferior to the serious texts by Metastasio and his imitators and successors, though not necessarily less workable in their own way.

EARLY OPERA IN FRANCE

Opera was imported into France from Italy before 1650, but it long failed to take firm hold there with royal and other audiences, at first having to compete on unequal terms with the spoken drama (often with musical interludes) and the ballet. The *Pomone* (1671) of Robert Cambert, to a pastoral libretto by Pierre Perrin, is commonly called the first French opera. Its premiere almost certainly inaugurated the Académie Royale de Musique (now the Paris Académie de Musique or Paris Opéra) on March 3, 1671. Only fragments of the music of *Pomone* still exist.

Lully's important role

Opera really did not become a French art until the time of Jean-Baptiste Lully (1632–87). This highly talented, very shrewd, and dictatorial man borrowed freely from both the spoken French drama and the court ballet. Though himself an Italian, he played down the extended, formalized Italian aria in favour of shorter, more instantly captivating "airs." He formed recitative after the declamatory manner of the Comédie-Française theatre company and also evolved the "French overture" (one movement with a slow and a fast section) as distinct from the "Italian overture" (one movement with a fast, slow, and another fast section). His operas and those of his imitators and followers assigned great importance to dancing, choruses, instrumental interludes, and a dazzlingly complex stage setting. Lully became the virtual dictator of music in France partly because of the strengths of his literary collaborators: first the dramatist Molière (1662–73) in *comédie-ballet,* then the exceedingly able librettist Philippe Quinault (1635–88).

The pervasive Lullyan style, altered surprisingly little except in the direction of still more imposing grandeur, attained its culmination in the magnificent operas of Jean-Philippe Rameau (1683–1764), especially in his *Hippolyte et Aricie* (1733; libretto by Simon-Joseph de Pellegrin), *Les Indes galantes* (*The Courtly Indies,* 1735; libretto by Louis Fuzelier), and particularly *Castor et Pollux* (1737; libretto by Pierre-Joseph-Justin Bernard), which was performed at the Paris Opéra 254 times in 48 years. Except for the special instance of *Les Indes galantes,* which was billed as a *ballet héroique,* Rameau's chief operas were each divided into a prologue and five acts, a pattern that many later French composers favoured. Rameau confirmed the still-enduring insistence of French operatic composers on setting their language to music with such probity and clarity that it can be understood properly when sung. His operatic works are regarded widely as the apogee of 18th-century French opera.

EARLY OPERA IN GERMANY AND AUSTRIA

Although Heinrich Schütz composed *Dafne,* the first known opera with a German text, and heard it played at Torgau on April 23, 1627, the active history of opera in Germany began with the Italian composers residing

there. A remarkable Venetian composer-diplomatist-ecclesiastic, the Abbé Agostino Steffani, carried much of his native city's early operatic manner to Munich, Hanover, and other German centres, beginning his operatic production with *Marco Aurelio* (Munich, 1681), and continued thereafter to compose operas for 28 years. In his use of both Italian and French procedures, particularly in handling overture and recitative, Steffani evolved a sort of international Italian style that clearly influenced other "transplanted" composers.

For the next 100 years the influence of Italian opera was so pervasive that even native German composers adopted the Italian operatic style and used texts in Italian.

Singspiel. The German word *Singspiel* was originally used for all sorts of opera. The earliest known entertainments so designated were composed by a pupil of Heinrich Schütz, Johann Theile (1646–1724). One of them, *Adam und Eva*, eminently "serious" as to story, inaugurated the Hamburg Opera in 1678. During the mid-18th century the term singspiel came to be reserved for what the English called "ballad opera," the French *opéra-comique*: light, usually comic operas including spoken dialogue. The comic singspiel of the 18th century was born with *The Devil to Pay* (London, 1731) and its sequel, *The Merry Cobbler* (London, 1735), English ballad operas with texts by Charles Coffey. These had pasticcio scores capitalizing, not very successfully, on the great popularity of *The Beggar's Opera* (1728), which had a text by John Gay and an assembled (pasticcio) score brought together by John Christopher Pepusch. The Coffey texts having been translated into German, scores were composed to them by J.C. Standfuss (died 1759?) as *Der Teufel ist los* (Leipzig, 1752) and *Der lustige Schuster* (Lübeck, 1759); they later were restaged as arranged by Johann Adam Hiller (1728–1804), who also composed several other singspiels and brought to culmination the so-called Leipzig School. Both Berlin and Vienna inevitably took up the singspiel, examples of which, composed in those cities and elsewhere, included *Der neue krumme Teufel* (Vienna, 1752, music lost), by Joseph Haydn; Mozart's *Die Entführung aus dem Serail* (*The Abduction from the Seraglio*, Vienna, 1782) and *Die Zauberflöte* (*The Magic Flute*, Vienna, 1791); *Doktor und Apotheker* (Vienna, 1786), by Karl Ditters von Dittersdorf; Beethoven's *Fidelio* (Vienna, 1805), which, like *Die Zauberflöte*, immeasurably transcends the common artistic scope of the singspiel; and *Die Zwillingsbrüder* (*The Twin Brothers*, Vienna, 1820), by Schubert.

Popularity of *The Beggar's Opera*

Opera seria. The most important opere serie composed in Germany during the early 18th century were created for the Hamburg Opera, at which both Reinhard Keiser (1674–1739) and, for a brief interval, the young George Frideric Handel worked. Keiser composed more than 125 operas, mostly to German texts. Of Handel's large operatic output, only two works with Italian texts—*Almira* and *Nero* (both 1705, the second now lost)—were staged during his Hamburg stay. Keiser doggedly tried to attract the widest possible public. His operas often succeeded in charming audiences, but most of them have vanished, and those that survive appear to possess only superficial allure, although they are historically of interest for their skillful exploitation of the orchestra and of solo instruments tellingly used during arias.

Handel went from Italy to England in 1710. In London, with the opera *Rinaldo* (1711), he began 30 years of stubborn dedication to the by then moribund (but still dominant) traditions of Neapolitan opera seria. He created, however, a dozen or more of the most inspired operas of the first half of the century, including *Giulio Cesare* (*Julius Caesar*, 1724), *Tamerlano* (1724), *Rodelinda* (1725), *Sosarme* (1732), *Orlando* (1733), *Ariodante* (1735), and *Alcina* (1735). Handel transcended the formal style of opera seria by his melodic inspiration and harmonic daring. He even managed an immense variety of characterization within the cramped style with which he had to comply.

Handel's operatic style

German by births, but almost wholly Italianate by disposition, Johann Adolph Hasse (1699–1783) successfully carried on the Metastasian traditions of opera seria in a plethora of operas to Italian texts. The intensely Italian sensuousness of his best melodies, supported by some attractive adventurousness in harmonic placement and in instrumentation, did almost as much as Handel's operas to prolong past its true prime the glory of the Neapolitan style.

II. From the "reform" to grand opera

THE "REFORM"

Christoph Willibald Gluck (1714–87) has become an ambivalent figure in the evolution of opera: he has been loosely and often incorrectly categorized, and both praised and condemned, for mistaken reasons. His operas to Italian texts that he composed up to about 1756 were conventional settings of Metastasian librettos. After settling in Vienna in 1750, though not abandoning the composition of traditional opere serie in Italian, Gluck began to react to the French operatic styles popular there. At first he merely added a few new numbers to trivial one-act opéras-comiques brought to Vienna from Paris, which he arranged and conducted for the court at Schönbrunn and Laxenburg. Then he began to compose similar operas in French.

Thanks to the enthusiasm of the superintendent of the imperial Vienna theatres, Conte Giacomo Durazzo, Gluck had been absorbing the example of the outstanding French dancer-choreographer Jean-Georges Noverre (1727–1810). Seminal in Noverre's call for reform was the insistence that a ballet should not be left as a simple collection of unconnected episodes but should be shaped into a mimed dance drama. Gluck then composed the ballet *Don Juan* (1761), the earliest of his scores to place him among the great composers. In the same year a very talented poet-librettist-adventurer, Ranieri de' Calzabigi, reached Vienna from Paris. Falling in with the anti-Metastasian intellectuals spearheaded by Durazzo, Calzabigi thereafter brought his acquaintance with Rameau's stately operas to the writing of three librettos for Gluck, for whose signature he also drew up the renowned preface to the publication of the Calzabigi–Gluck *Alceste* in 1769. That dedication is the central document of "operatic reform," summing up one side of the unending debate between supporters of the primacy of the opera libretto and supporters of the primacy of the music. It emphasized that superfluous, florid da capo arias were to be dispensed with: simplicity of expression and emotional truth were to take their place.

The influence of *Alceste*

Although some of the most accomplished composers of opera certainly would not have agreed that, as Calzabigi–Gluck stated, the "true office" of music is "serving poetry," and though a strict obedience to all the precepts of the *Alceste* dedication would have impoverished much of the richest operatic music (Gluck himself did not follow them with iron strictness), the pronouncement unquestionably summoned opera back temporarily to its best condition: as musicotheatrical drama. The most obvious, as well as the greatest, results of the attitudes it expressed were the magnificent Calzabigi–Gluck operas first staged in Vienna: *Orfeo ed Euridice* (1762), *Alceste* (1767), and *Paride ed Elena* (*Paris and Helen*, 1770). The two earliest of these became even more stately and Rameau-like when Gluck reconstituted them to French librettos for Parisian audiences.

A little below *Orphée* and the French *Alceste* in austere dramatic force stands the somewhat mixed, only partially "reformed" *Armide* (Paris, 1777). But Gluck was to produce his best results in *Iphigénie en Aulide* (*Iphigenia in Aulis*, 1774; libretto adapted from Racine's tragedy by Bailli du Roullet) and in his masterpiece, *Iphigénie en Tauride* (*Iphigenia in Tauris*, 1779; libretto adapted from Euripides by Nicholas-François Guillard).

Gluck's extraordinary power at his best derives from a reasonable, pliable adherence to the precepts of the *Alceste* dedication; a lean sparseness of means, particularly of harmonic density, with the result that the smallest shifts arrive with great power; and the ability to make the most of the dramatic strengths of the often excellent librettos he used. Yet Gluck did not really "reform" opera, for opera is an incorrigible art form. Its mood and

manners shift with changes in society, dramaturgy, techniques of composition, and taste.

Followers and imitators of the Gluck reform

Gluck had some immediate followers and imitators, notably Antonio Salieri, who gave lessons to Beethoven, Schubert, and Liszt, was friendly with both Haydn and Rossini, and was ridiculously accused of having poisoned Mozart. Another, belated, Gluckian was Gluck's onetime "rival" in a Parisian polemic "war," Niccolò Piccinni (1728–1800), whose masterpiece, *Didon* (*Dido*, 1783; libretto by Jean-François Marmontel, Fontainbleau), joined a peculiarly Italianate melodiousness to Rameau-like solemnity and the massive simplicities of Gluck's style. Finally, there was Antonio Sacchini, remembered chiefly for his *Oedipe à Colone* (*Oedipus at Colonus*, 1786; libretto by Nicolas-François Guillard). On the highest level, however, the Gluckian "reform" produced only his own masterpieces, although it led indirectly to certain of the "international," though very French, operas of Gasparo Spontini (1774–1851), particularly *La Vestale* (*The Vestal Virgin;* Paris, 1807), and Luigi Cherubini, particularly *Médée* (1797). In part, Gluck also influenced the vast masterwork of Hector Berlioz, *Les Troyens* (*The Trojans*, composed 1856–58).

OPERA IN ENGLAND

Just as immediate acceptance of opera had been made difficult in France by the entrenched ballet and the 17th-century drama of Jean Racine and Pierre Corneille, so it was delayed in England by the court masque, an aristocratic 16th- and 17th-century entertainment derived largely from ballet. Most often dealing with allegorical and mythical subjects, the masque mixed poetic text, instrumental and vocal music, dancing, and acting. The most familiar masque is *Comus* (text by John Milton and music by Henry Lawes), which was staged at Ludlow Castle in 1634. Many other embryonic operas were produced in the middle decades of the 17th century, often being more like plays with incidental music. The first (and, in the view of many, still the finest) English opera, *Dido and Aeneas*, by Henry Purcell (*c.* 1659–95), was originally sung about 1689 by the pupils at a girls' school in London. This musical masterpiece, with libretto by a future poet laureate, Nahum Tate, contains the earliest operatic aria (apart from "Lasciatemi morire" from Monteverdi's *Arianna*) still frequently heard: Dido's lament "When I am laid in earth." In this opera, Purcell succeeded in writing a real, albeit brief, music drama, breaking down the formal barriers between recitative and song.

The first English opera

England, however, was not ready for opera. Although later Purcell works, including *The Fairy Queen* (1692), *The Indian Queen*, and *King Arthur* (1691), have been called operas, they were actually suites of incidental music for plays. No other composer in England of Purcell's genius turned his attention to opera, and before many decades had passed after the scarcely noticed performance of *Dido and Aeneas*, the rage for Italian opera (particularly when the singers included a good castrato) barred that road to English composers. The arrival of Handel from Italy in 1710 decided the direction of opera in London for many decades. Beginning in 1711 with *Rinaldo* (libretto by Giacomo Rossi, indirectly derived from Tasso's epic *Gerusalemme liberata*) and continuing intermittently until *Deidamia* (libretto by Paolo Rolli) in 1741, Handel provided English audiences with his own remarkable variant of Neapolitan opera seria, acting as both composer and, most often, impresario. The greatest composer of opera in his age, Handel eventually outlasted his popularity in London's opera houses and turned to the creation of a magnificent series of oratorios set to English texts. His operatic reign was challenged at its height only by a faction that set up the very gifted Modenese composer Giovanni Bononcini in an unequal battle against him. Handel's operas all but vanished from the repertory in the 19th century, but after a burst of German interest in them in the 1920s, they began to be increasingly revived by some major opera houses, smaller opera companies, students, musicologists, and recording companies.

An event that contributed to the defeat of Handel as an opera impresario was the London production in 1728 of *The Beggar's Opera*. That bawdy, rollicking satire in English became phenomenally popular and spawned a family of imitations that finally accustomed audiences in London and elsewhere in the British Isles to hearing a staged play sung in the vernacular.

VIENNESE MASTERS

Italian opera buffa strongly attracted Viennese audiences, and Austrian composers were naturally influenced by it. Perhaps the most interesting of the Vienna-born composers of 18th-century comic opera was Karl Ditters von Dittersdorf, whose Italianate *Doktor und Apotheker* (1786; libretto by Gottlieb Stephanie), though successful and lively, was overshadowed by the contemporary works of Mozart.

Haydn, who lacked a strong theatrical bent, nonetheless composed about 20 musicodramatic scores: a singspiel, five short operas for marionettes, and several very Italianate opere buffe and opere serie for private performance in the Eisenstadt palace theatre of his employer-patrons, the Esterhazy princes. Several of Haydn's dramatically undistinguished operas have had modern revivals, including *Il mondo della luna* (*The World on the Moon*, 1777; libretto by Carlo Goldoni), *L'isola disabitata* (*The Deserted Island*, 1779; libretto by Metastasio), and *La fedeltà premiata* (*Faithfulness Rewarded*, 1780; libretto by Giovanni Battista Lorenzi).

Mozart. Vienna, however, was to be one of the centres of the operatic career of Mozart, one of the greatest masters of opera. Mozart began to write theatrical music when only ten years old and brought out the first of his important operas at Munich in 1781, when only 25. This was *Idomeneo*. Its libretto, by Giambattista Varesco, is an imitation of Metastasio's style. But Mozart rose above the conventional operatic patterns and filled them with richly expressive music so that the result is scarcely recognizable as an opera seria. As a work of musical (though not of dramatic) art, *Idomeneo* is as fine as Gluck's *Iphigénie en Tauride* and ranks as the supreme Italian opera seria of the late 18th century.

One year after *Idomeneo*, Mozart, with the versatility of his unique genius, wrote a masterly, charming singspiel to a German text: *Die Entführung aus dem Serail* (libretto by Christoph Friedrich Bretzner as edited by Gottlieb Stephanie). A sentimental farce full of immediately attractive music and graced with a fine part for a comic bass (Osmin), *Die Entführung* also contains in "Martern aller Arten," a soprano aria so extensive in plan and difficult to sing that it has challenged the foremost sopranos down to the present. The opera has been called the greatest of all truly comic singspiele, and it is notable for the seriousness with which it treats the relationship between its two principal characters and for the human nobility of its "moral."

Mozart's next completed opera—except for *Der Schauspieldirektor* (*The Impresario*, 1786), a trifling one-act comedy—is one of the treasures of Western civilization, the greatest of all seriocomic operas, *Le nozze di Figaro* (libretto by Lorenzo da Ponte, after Pierre de Beaumarchais's *Le Mariage de Figaro*, 1786), produced at Vienna. In addition to its purely musical beauty, this work shows Mozart to be a creator of individual characters of almost Shakespearean calibre; he goes far beyond the opportunities offered by his able librettist and creates, by musical means, believable, rounded human beings, often employed in ensembles as well as in solos and in elaborately constructed finales.

Production of *Figaro* at Vienna

In 1787 Mozart's next opera, written for Prague, was *Don Giovanni* (libretto by da Ponte, based on earlier Don Juan librettos and other writings related to plays by Tirso de Molina, Thomas Corneille, and others). The 19th century tended to regard *Don Giovanni* as the greatest opera ever composed, in part because musical elements in it foretold operatic romanticism. Aspects of da Ponte's libretto disturb some 20th-century critics—particularly the grim, morally justifiable ending of what up to then has been a comedy, followed by the "vaudeville" postlude, during which the singers step out of character to

underline the "moral," in line with a then long-established convention. Musically, *Don Giovanni* shares many of the supreme virtues of *Le nozze di Figaro*, in beauty, in characterization, and in dramatic power.

In his last collaboration with Da Ponte, Mozart created another opera buffa, *Così fan tutte* (1790). Most musical opinion today considers it to be an opera of flawless workmanship reconciled with the dramatic claims of a seemingly artificial and cynical libretto, which in fact exposes the foibles of mankind. Farcical productions too often destroy its knife-edge balance between artificiality and reality. Too richly scored, too erotic, and too intense for Viennese taste of the time, it was not a success with the easy-going Viennese, but it now ranks as one of Mozart's greatest stage works.

In 1791, returning to the singspiel in German, Mozart composed *Die Zauberflöte* (libretto by Emanuel Schikaneder), an allegorical and Masonic opera with a seemingly nonsensical but in fact elaborately significant libretto in strong contrast with *Così fan tutte*'s cynicism about women. Here, Mozart created some of the most radiantly beautiful music ever composed, assigning it lavishly to both the serious and the comic, both the admirable and the vicious characters. George Bernard Shaw once said that the two arias given to the benevolent Sarastro in *Die Zauberflöte* were the only music he knew that would not sound out of place in the mouth of God—and they are but two of many numbers in this opera that have helped to place Mozart's theatrical works, together with his concertos, at the very apex of his astonishing and endlessly varied output.

Also in 1791 Mozart composed, to a Metastasio libretto slightly revised, another outdated opera seria, *La clemenza di Tito*. Created in 18 days for festivities surrounding the coronation of Emperor Leopold II as king of Bohemia in Prague, *La clemenza* provides numerous examples of Mozart's musical mastery, none of his mastery of dramatic creation through music.

Beethoven. Like *Die Zauberflöte*, Beethoven's *Fidelio* (1805, revised 1806 and 1814) rose above the limitations of the singspiel pattern, becoming something bigger and grander. In most of this, his only opera, Beethoven is musically at nearly his greatest. The libretto has never satisfied anyone entirely; also, some of the writing for the voices is instrumental rather than truly vocal. Beethoven lacked Mozart's theatrical sensibility and his ability to mix the comic–frivolous with the solemn and near tragic, as the text required. Yet the grandeur of much of the *Fidelio* music and the noble humanity of the central character (a wife, Leonore, who disguises herself as a young man, Fidelio, in order to rescue her husband, at terrible risk, from political incarceration in a dungeon) irradiates the opera from the moment of Leonore's first appearance. Its theme of the triumph of the human spirit over oppression has helped to place *Fidelio* among the world's most popular operas.

FRANCE, 1752–1825

The *Guerre des Bouffons*

Political changes and that intensity of intellectual discussion that has always played a role in determining the nature of artistic production in Paris led, in the early 1750s, to one of those polemic "wars"—this one called the *Guerre* (or *Querelle*) *des Bouffons* (War of the Buffoons)—that delight the French. This was a mainly literary confrontation of the solemn past of opera seria and *tragédie lyrique* with the farce and sentiment of opera buffa, though many of the writers saw it in nationalistic terms. It had a happy outcome: the subsequent composition by both French composers and resident foreigners of excellent examples of opéra comique, which became a French amalgam of the English ballad opera, the German singspiel, and the Italian opera buffa.

In 1752, the year of the first battles of the *Guerre des Bouffons*, Jean-Jacques Rousseau staged at Fontainebleau his one-act comic opera *Le Devin du village* (*The Village Soothsayer*). The libretto was his own. In the score he had brought together, in the pasticcio manner, melodies reflecting the very popular romances and vaudevilles being heard at the Paris fairs. It pleased battlers on both sides of the operatic war, being very French in manner and sentiment but Italian in being through-composed (continuously set) and employing recitative. Rousseau hoped to establish this combination as a standard for French comic opera, but his plan was not immediately successful. In 1755, however, a Naples-trained Italian, Egidio Duni, settled in Paris and began to compose (or perhaps, at first, merely to assemble) recognizably Rousseauesque opéras comiques. French and Belgian composers gladly adapted the new variety of opéra comique (not always with comic subject matter) and soon established its reign in the Paris and provincial theatres (nearly all of them simultaneously composed other sorts of musicodramatic works as well). Among them, several names stand out, together with the finest or most renowned of their operas. One of the most interesting of these opéra comique composers was François-André Danican (1726–95), called Philidor, also a famous chess player, who wrote about 20 works in the evolving manner.

More sentimental—in fact, tending toward the tenderly tearful—was Pierre-Alexandre Monsigny (1729–1817), never thoroughly trained in music but endowed with the ability to create winning melodies and to exploit for dramatic purpose the timbres of individual instruments. Probably the finest of the 18th-century composers of opéra comique was a Belgian, André Grétry (1741–1813), who most happily balanced the French and Italian styles. He was a very original and extremely productive composer over a 30-year period spanning the French Revolution.

Étienne-Nicolas Méhul (1763–1817), who used opéra comique conventions including the retention of spoken dialogue, also had a career spanning the Revolution. A devoted Gluckian, Méhul had composed numerous works in many genres when, in 1807, he produced his masterpiece, *Joseph*, which is a rarity among operas in several ways: its libretto by Alexandre Duval is derived from the Bible, a source of drama usually reserved for the oratorio; it has no female characters; and it mixes the most solemn classicism with the sentiment of the popular romances.

Boieldieu's immense success

Early in the 19th century, French opéra comique achieved a new equilibrium of classical tint in the best works of François-Adrien Boieldieu (1775–1834). He won truly astonishing and, to several composers (Berlioz included), maddening popularity with *La Dame blanche* (*The White Lady*, 1825; libretto by Eugène Scribe, based upon Sir Walter Scott's novels *Guy Mannering* and *The Monastery*). There were 1,669 performances of this work at the Opéra-Comique, Paris, between 1825 and 1926.

Le Pré aux clercs (*The Field of Honour*, 1832; libretto by François de Planard), the most accomplished opera of Louis-Joseph-Ferdinand Hérold (1791–1833), all but equalled the popularity of *La Dame blanche*; it had received 1,600 performances at the Paris Opéra-Comique by 1939. Hérold's other outstanding success was *Zampa* (1831; libretto by Anne-Honeré Mélesville), so much like the work of Carl Maria von Weber that it became vastly popular in Germany. An extraordinarily prolix composer, Hérold never succeeded in working out a dependable, unified manner of his own, with the result that his French operas are structurally weak. Opéra comique after Boieldieu became more Italianized, reflecting very largely Rossini's influence.

ITALY IN THE FIRST HALF OF THE 19TH CENTURY

The splendid musical achievements of the classicial Viennese style during the late 18th century and early 19th threatened to leave Italy, opera's native home, to one side of the operatic highroad. Two accidents—one the voluntary expatriation to northern Italy of a German, Johann Simon Mayr, the other the unpredictable eruption of a genius, Gioacchino Rossini—saved the day for Italian opera in Italy and outside it.

Mayr, known in Italy as Giovanni Simone Mayr, composed nearly 70 operas in Italian between his first (1794) and his last (1815). He appears to have been influenced deeply by Mozart, and his intensely keen dramatic sense, together with the extraordinary pliability with which he employed the conventions of opera seria and his varied

use of the orchestra (particularly of solo woodwinds and horns within it), would have made him a major composer of opera had he not lacked major gifts as a melodist. Many of his operas were for a long time extremely popular throughout Italy, and his immediate influence was beneficial, particularly on the practice of his most famous pupil, Gaetano Donizetti, and on another, less talented, but still admirable operatic composer, Saverio Mercadante.

The operas of Nicola Zingarelli (1752–1837) and of Ferdinando Paer (1771–1839) were transitional, between Classical and grand opera in mode and manner. Zingarelli's conventional opere buffe displayed a genuine humour and some liveliness of musical imagination; his most enduringly performed work, however, was an opera seria, *Giulietta e Romeo* (1796; libretto by Giuseppe Maria Foppa). He is now remembered chiefly as a teacher of Vincenzo Bellini. Paer, who composed more than 40 operas, worked mostly in Vienna, Dresden, and Paris; his musical style changed with his surroundings.

Rossini. The production at Venice in 1810 of the first performed opera of Rossini, *La cambiale di matrimonio* (*The Bill of Marriage;* libretto by Gaetano Rossi), announced a new operatic genius. Into the genteel, often charming atmosphere of lingering 18th-century operatic manners, Rossini brought genuine originality marked by rude wit and humour and an entire willingness to sacrifice all "rules" of musical and operatic decorum. Both his opere buffe and his now sadly neglected opere serie soon became so popular throughout Italy and then throughout the Western world that they all but blotted out his unfortunate contemporaries—Donizetti and Bellini excepted.

Rossini's originality and wit

Rossini's dazzling career marked the zenith of the bel canto style, a singer-dominated manner of composition (and at times improvisation) that played to audiences' delight in vocal agility, smoothness of voice, and long, florid phrasing. From the period of Rossini's greatest Italian triumphs (he had a second career in Paris) and of Donizetti and Bellini come the names of now legendary voices such as Isabella Colbran (Rossini's first wife), Giuditta Pasta, Maria Malibran, Giovanni David, Giovanni Battista Rubini, Domenico Donzelli, Antonio Tamburini, and Luigi Lablache. For appearances by these singers, composers altered their scores; when they sang, they interpolated extraneous arias that displayed their prowess. Rossini tried to insist that his operas be sung as he himself composed or revised them, but it was a losing battle. The polished artistry and extreme technical training and technique of such singers, as well as their extraordinarily wide ranges, have left performance of the bel canto operas bristling with nearly insoluble problems for latter-day singers.

Rossini's most famous opera is *Il barbiere di Siviglia* (*The Barber of Seville,* 1816; based on the libretto by Cesare Sterbini after the 18th-century play by Beaumarchais), the most nearly flawless of all opere buffe. Several others among his comedies rank only a little lower in musical invention, genuine comic brio, and opportunities for trained singers of vocal display and for farcical characterization: *L'Italiana in Algeri* (*The Italian Girl in Algiers,* 1813; libretto by Angelo Anelli), *Il Turco in Italia* (*The Turk in Italy,* 1814; libretto by Felice Romani); *La cenerentola* (*Cinderella,* 1817; libretto by Jacopo Ferretti), and the half Italian opera buffa and half French opéra comique *Le Comte Ory* (*Count Ory,* 1828; libretto by Scribe and Charles-Gaspard Delestre-Poirson). Rossini prefaced several of these operas with swift, witty overtures that have held a place in the repertory of symphony orchestras.

Perfection of Rossini's comic operas

His style began to have a more serious bent with *Otello* (*Othello,* 1816; libretto by Francesco di Salsa), the opera semiseria (a serious opera with a happy ending), *La gazza ladra* (*The Thieving Magpie,* 1817; libretto by Giovanni Gherardini), and *Armida* (1817; libretto by Giovanni Schmidt), all of which show the composer adapting his florid style to more dramatic, and often eloquent, purposes. But it was only in his Parisian pieces, such as *Semiramide* (1823; libretto by Gaetano Rossi), *Le Siège de Corinthe* (*The Siege of Corinth,* 1826; a revision of the earlier opera, *Maometto II* [1820]; libretto by Alexandre Soumet and Luigi Balocchi), and *Guillaume Tell* (*William Tell,* 1829; libretto by Étienne de Jouy and Hippolyte Bis), his last opera, that his talent for works on a bigger scale, presaging Parisian grand opera, found its full flowering. Some of these later operas owe their revival in the middle of the 20th century to the appearance of a few singers able to project meaningfully their difficult vocal lines.

Donizetti. Gaetano Donizetti first composed a series of very Rossinian, well-made, and largely undistinguished operas but gradually developed dramatic strength, a latent gift for memorable melody, and a forceful deployment of the orchestra for theatrical drama. In 1830, the year after Rossini's farewell to operatic composition, Donizetti produced at Milan the first of his forward-tending, less Rossinian, dramatically remarkable operas: *Anna Bolena* (*Anne Boleyn*), with a libretto by Felice Romani, who worked with so many opera composers of the time. It immediately placed him with Bellini as an inevitable successor to Rossini. What became clear only in retrospect was that it also showed him to be the most important immediate predecessor—in some sense, teacher—of Giuseppe Verdi. Donizetti clung to the long, legato (smoothly flowing) melodies and the ornamented vocal lines of bel canto, but he also unmistakably foreshadowed Verdi's dramatic vigour and many of the younger man's compositional methods. Several unconscious borrowings from Donizetti have been noted by students of Verdi's operas.

Like Rossini, but unlike Bellini, Donizetti moved freely back and forth between serious and comic subjects. He composed about 70 stage works in 25 years. After the success of *Anna Bolena,* with speed and facility that remain astonishing, he composed numerous operas of enduring quality. They include the sentimental comedy *L'elisir d'amore* (*The Elixir of Love,* 1832; libretto by Felice Romani); *Lucrezia Borgia* (1833; libretto by Romani) and *Maria Stuarda* (*Mary Stuart,* 1834; libretto by Giuseppe Bardari); the popular *Lucia di Lammermoor* (1835; libretto by Salvatore Cammarano was derived from Sir Walter Scott's *The Bride of Lammermoor*)—an opera that reflects Donizetti's acquaintance with the music of Bellini; *Roberto d'Evereux* (1837; libretto by Cammarano); the delightful opéra comique *La Fille du régiment* (*The Daughter of the Regiment,* 1840; libretto by Jules-Henri Vernoy de Saint-Georges and Jean-François-Alfred Bayard); the grand opera *La Favorite* (1840; libretto by Alphonse Royer, Gustave Vaëz, and perhaps Scribe); the opera semiseria *Linda di Chamounix* (1842; libretto by Gaetano Rossi); and—judged by many to be Donizetti's masterwork—the ever fresh and vivid opera buffa, *Don Pasquale* (1843; libretto by Giacomo Ruffini and Donizetti).

Bellini. Altogether different from either Rossini or Donizetti was Vincenzo Bellini. His operas have come to seem the natural habitat of bel canto, of the unchallenged supremacy of vocal melody in amazingly long-breathed and highly decorated lines. Only his first student opera contains even a trace of humour. He and his librettists filled their collaborations with intensely amorous and other subjective emotion, ethical confrontations, and usually tragic involvements (of the seven finest among his ten operas, only two—*La sonnambula* and *I puritani*—conclude happily for the principal characters). Bellini cultivated with meticulous care his unrivalled, native gift for convincingly melancholy melody, especially in arias and duets; he gave much less attention to ensembles, choruses, and the expressive potentialities of the orchestra. His orchestra, in fact, might have been what it was had Haydn, Mozart, Mayr, and Rossini never existed.

Bellini's innate gift of melody

Beginning in 1827 with *Il pirata* (*The Pirate,* libretto by Felice Romani, who thereafter supplied all of Bellini's librettos except that for *I puritani*), Bellini made his presence felt throughout Italy and then gradually throughout Europe and the Americas. In 1831 two of Bellini's enduring masterworks were produced: the pastoral opera semiseria *La Sonnambula* (*The Sleepwalker*) and the heroic tragedy *Norma.* Bellini's previously faith-

ful public temporarily deserted him when, in 1833, he gave it *Beatrice di Tenda.* In the year of his death after his final removal to Paris, he won another triumph with an opera very loosely connected with Cromwellian times in England, *I puritani* (*The Puritans;* libretto by conte Carlo Pepoli).

Unlike Rossini and Donizetti, Bellini exercised little or no influence upon the style of his successors: the most noticeable of his compositional means, his exclusively personal sort of melody, could only be debased in imitation by others. With these three men, both the late period of bel canto and the second period of opera buffa drew to a close. After the onset of Donizetti's crippling illness in 1847, the Italian opera houses in Italy, Paris, London, and elsewhere could look to Giuseppe Verdi.

III. Grand opera and beyond

FRENCH GRAND OPERA

Nineteenth-century Paris was to foster and witness the birth of "grand opera," an international style of large-scale operatic spectacle employing historical or pseudo-historical librettos and filling the stage with elaborate scenery and costumes, ballets, and phalanxes of supernumeraries. Dispensing almost entirely with the delicacies of bel canto, it vastly enlarged both the orchestra itself and its role in the dramatic happenings. Grand opera naturally had roots in the past, particularly in the Venetian "machine operas" of the 17th century, such as Cesti's *Il pomo d'oro,* as well as in the stately scores of Rameau and Gluck. But the immediate drive toward this new style of opera was instituted in Paris by Italian expatriates: Luigi Cherubini, who spent the last 54 years of his life in France, and Gasparo Spontini, whose most impressive operas were designed for Paris.

Cherubini was a greatly learned composer in almost all musical forms who won the admiration of Beethoven. His two most imposing operas were the embryonic grand opera *Médée* (1797; libretto by François-Benôit Hoffman) and a *comédie lyrique, Les Deux Journées* (*The Two Days,* 1800; libretto by Jean-Nicolas Bouilly). *Les Deux Journées* became something like a national German opera under its German title, *Der Wasserträger* (*The Water Carrier*). Spontini, in his French operas, ranged far beyond Cherubini and his other contemporaries in his demands for complex staging, finally reaching a sort of splendid megalomania. Daniel-François-Esprit Auber brought out a nearly total grand opera; *La Muette de Portici* (*The Mute Girl of Portici,* also known as *Masaniello,* 1828; libretto by Scribe). The popularity of *La Muette* became phenomenal in both France and Germany. This opera remains unique on several counts. Its title character neither sings nor speaks, the role being performed by a mime. A performance of it at Brussels on August 25, 1830, set off disorders that led to the separation of Belgium from The Netherlands. Eighteen months after the premiere of Auber's opera, the appearance of Rossini's *Guillaume Tell* showed that master of opera buffa and bel canto responding to the new genre. Auber's later operas include several charming comedies, among them *Fra Diavolo* (1830; libretto by Scribe).

Meyerbeer. The final, official birth of grand opera occurred in 1831, with the first French opera of another Parisian expatriate, the German Giacomo Meyerbeer: *Robert le Diable* (libretto by Scribe and Germain Delavigne). The popularity of this work became a sort of frenzy (by August 1893 it had been sung 751 times at the Paris Opéra). Although Meyerbeer's operas are rarely performed in the later 20th century, he remains a controversial figure. Using an expanded, powerful orchestra, with much emphasis placed on individual instrumental colours, requiring almost every kind of singing, filling huge stages with dazzling pageantry, employing characters who pretend to be actual figures from history, four of his operas held their leading positions even through the Wagnerian revolution and into the early 20th century. Besides *Robert le Diable,* they were *Les Huguenots* (1836; libretto by Scribe with the collaboration of Émile Deschamps), *Le Prophète* (1849; libretto by Scribe), and the posthumously staged *L'Africaine* (libretto by Scribe). The author of all of these, Eugène Scribe, was the most phenomenally productive librettist of his time, writing (with the help of various collaborators) a huge number of librettos for many composers, including Auber, Boieldieu, Cherubini, Donizetti, Gounod, Halévy, Meyerbeer, Rossini, and Verdi. He was, in fact, a major force in the evolution of French grand opera.

Imitators of Meyerbeer's successes naturally sprang up immediately. Later, numerous men totally unlike him stylistically—including Berlioz, Wagner, and Verdi—were influenced unwittingly by his practices. The first of the imitators was Fromental Halévy, whose works included at least one grand opera that could almost be mistaken for Meyerbeer's: *La Juive* (*The Jewess,* 1835; libretto by Scribe). After the times of Meyerbeer and Halévy, grand opera began to respond to new musical and intellectual currents, evolving into a variety of mixed forms.

Berlioz. Like most of Hector Berlioz's other compositions, his three operas stand apart from the mainstream of historical evolution. When first staged at the Paris Opéra in the shadow of *Robert le Diable* and *La Dame blanche,* his first opera, *Benvenuto Cellini* (1838; libretto by Léon de Wailly and Auguste Barbier), was a complete failure. The second, the lighthearted *Béatrice et Bénédict* (his own libretto, based upon Shakespeare's *Much Ado About Nothing*), finally was given its premiere at Baden-Baden in 1862 by Franz Liszt. And Berlioz's masterpiece, *Les Troyens* (his own libretto), is based on Virgil's *Aeneid* and divided into *La Prise de Troie* (*The Capture of Troy*), two acts, and *Les Troyens à Carthage* (*The Trojans at Carthage*), three acts. It was not performed complete during his lifetime: he heard only the second part as staged in Paris in 1863. Mid-20th-century complete (or very nearly complete) performances of *Les Troyens,* notably in London, showed it to be a great, noble, idiosyncratic work not without traces of grand opera, but in seriousness and scope much closer to the Wagner of *Der Ring des Nibelungen.* Berlioz's operas, like his other music, are distinguished by the individual arch of his melody, his revolutionary orchestration, and the dramatic thrust of the whole.

Modern revival of *Les Troyens*

Offenbach. Even more popular than Auber as a purveyer of light operatic comedy was Jacques Offenbach, a German émigré to Paris who supplied the Second Empire and the early years of the Third Republic with a long series of very tuneful, witty, and satiric operettas of deliberate frivolity. Remembered among them are *Orphée aux enfers* (*Orpheus in the Underworld,* 1858; libretto by Hector Crémieux and Ludovic Halévy), *La Belle Hélène* (*Beautiful Helen,* 1864; libretto by Henri Meilhac and Halévy), *Barbe-Bleue* (*Bluebeard,* 1866; libretto by Meilhac and Halévy), *La Vie Parisienne* (*Parisian Life,* 1866; libretto by Meilhac and Halévy), *La Grande-Duchesse de Gérolstein* (1867; libretto by Meilhac and Halévy), and *La Périchole* (1868; libretto by Meilhac and Halévy). Left incomplete at Offenbach's death was his major serious opera, *Les Contes d'Hoffmann* (*The Tales of Hoffmann;* libretto by Jules Barbier and Michel Carré, after their play of the same name based on tales by the German Romantic writer E.T.A. Hoffmann). Recitatives replacing the original dialogue were provided by Ernst Guiraud, and the opera was staged posthumously in 1881. This fantasy involving supernatural interventions rapidly became a worldwide favourite.

GERMAN ROMANTIC OPERA

Weber. Romanticism, part philosophical, part literary, part aesthetic, made one of its first appearances, and certainly its earliest overt appearance, in opera, in three works composed between 1821 and 1826 by Carl Maria von Weber. Beginning with his masterpiece, *Der Freischütz* (*The Freeshooter,* 1821; libretto by Friedrich Kind), Weber successfully challenged the outdated dictatorship of Spontini at Berlin. For the Italian's stiff grandeurs he substituted, in singspiel form, tender sentiment, grisly horrors, manly choruses, moral nicety, and music of extraordinary instrumental and vocal allure. *Der Freischutz* illustrates the German Romantic writers' love

Elements of German Romanticism

for dark forests, the echoes of hunters' horns, the threatening supernatural, the frustrations of pure young love. Its popularity in Germany and elsewhere was enormous.

Weber smarted under the anti-Romantic criticism of *Der Freischütz* as a mere singspiel (a work with spoken dialogue) rather than a musically continuous opera. His next major composition, *Euryanthe* (1823; libretto by Helmina von Chézy), was something like a proto-grand opera and therefore contained no spoken dialogue. Almost since its premiere, writers have attacked the remarkable silliness (on paper) of its libretto, but most of them have never witnessed the work in performance and therefore cannot judge how the libretto works on stage with Weber's fine score. His last opera, *Oberon*, or *The Elf King's Oath* (1826; libretto, in English, by James Robinson Planché), returns to the singspiel form. Like *Euryanthe*, it has not held the stage, and again the libretto has been blamed. The overtures to all three of these operas are still played frequently, and whatever future opinion of the operas themselves may be, *Der Freischütz* opened the floodgates of musical Romanticism in Germany.

Spohr, Lortzing, and others. Louis Spohr (1784–1859), a violinist, conductor, and composer of instrumental music, sounds pallidly Romantic if compared with Weber, but certain of his harmonic innovations taught something to Wagner, of whose early operas he was a defender. Heinrich August Marschner (1795–1861), more Romantic by nature than Spohr, borrowed sufficiently from Weber's style to serve as one bridge to Wagner. He displayed talent as orchestrator and melodist, and he applied his gifts to intensely Romantic and equally Teutonic librettos. The finest of his now unheard operas is *Hans Heiling* (1833; libretto by Eduard Devrient).

The other German-language composers of opera active during the Weber–Spohr–Marschner period were less important. Albert Lortzing composed several operas that have been likened to genre painting. He travelled in the direction of operetta in his popular sentimental comedies, such as *Zar und Zimmermann* (*Tsar and Carpenter*, 1837; his own libretto) and *Der Waffenschmied* (*The Armourer*, 1846; his own libretto). The same direction was taken by Friedrich, Freiherr von Flotow, whose operetta-like *Martha* (1847; libretto by Friedrich Wilhelm Reise) continues to be performed frequently. This trend toward operetta as a less intense variety of Romanticism continued in *Die lustigen Weiber von Windsor* (1849; libretto by Salomon Hermann Mosenthal, based on Shakespeare's *Merry Wives of Windsor*), the major success of Otto Nicolai, and in the extremely popular works of Franz von Suppé, a Dalmatian of Belgian ancestry. It culminated in operetta on the highest level of musical accomplishment in the masterworks of Johann Strauss the Younger. Many of Strauss's operettas are known now only by their overtures and waltzes, but one of them, *Die Fledermaus* (1874; libretto by Carl Haffner and Richard Genée), has never left the stage for long. Only the finest opéras comiques and opéras bouffes of Auber and Jacques Offenbach match Strauss's elegance, wit, humour, musical invention, and scrupulous workmanship.

Strauss's operettas

VERDI

When, in 1839, an opera called *Oberto, conte di San Bonifacio* (libretto by Antonio Piazza, revised by Bartolomeo Merelli and Temistocle Solera) was staged at the leading Italian opera house, the Teatro alla Scala (La Scala) at Milan, its first audiences received it reasonably well. Rossini had not offered a new opera for ten years, Bellini was dead, and Donizetti was composing for Paris, so the debut of a new talent was welcome. Those early audiences, however, could not know that *Oberto* had opened the active career of the greatest of all later Italian composers of opera, Giuseppe Verdi. Verdi's second opera, *Un giorno di regno* (*King for a Day*, 1840; libretto by Felice Romani), was a failure and was to remain his only comedy for 53 years. It was followed by *Nabucodonosor*, known as *Nabucco* (1842; libretto by Solera), which displayed the emergence of a musical dramatist of enormous vigour and rich melodic invention.

Verdi long suffered from his inability to obtain librettos worthy of his special talents, but each of the six operas that he wrote between *Nabucco* (1842) and *Macbeth* (1847) includes scenes and numbers of great power and immediately winning, memorable melody. Even *Macbeth* (libretto by Francesco Maria Piave, revised in 1865 by Verdi to a libretto in French), although it is marked both dramatically and musically by passages of astonishing vitality, has structural weaknesses.

Another period of lesser achievement by Verdi stretched from 1847 to 1851, the best of his five operas of those years having been *Luisa Miller* (1849; libretto by Salvatore Cammarano). Meanwhile, Verdi was on the way to becoming a public symbol of the risorgimento, the Italian movement of rebellion against foreign domination and toward political unification, both because of the patriotic emphasis in several of his librettos and because of his staunchly liberal public character (he was eventually to become a true national hero).

Beginning in 1851, Verdi produced three masterpieces, having found three librettos that fired aspects of his genius. The first of them was *Rigoletto* (libretto by Piave), in which his abundant creation of melody was at the service of his gift for musical characterization. *Rigoletto* was followed, less than two years later, by *Il trovatore* (*The Troubadour*, 1853; libretto by Cammarano), perhaps unmatched among his operas for its profusion of strong and memorable melodies.

Less than two months after the premiere of *Il trovatore* came *La traviata* (1853; libretto by Piave, after Alexandre Dumas *fils*'s *La Dame aux camélias*). At first a failure, it later came to be accepted as a masterpiece. It also established a composer's right to set librettos dealing with contemporary life and with characters not of exalted station. By comparison with the thunderous melodrama of *Il trovatore*, *La traviata* seems an intimate, quiet, almost chamber-music opera. The musical portrait of Violetta, the tubercular courtesan heroine, remains extraordinary for its depiction of the effects of love and sorrow on her character.

Production of *La traviata*

After *La traviata* came a comparative failure, a grand opera composed in French for Paris, *Les Vêpres siciliennes* (*The Sicilian Vespers*, 1855; libretto by Scribe and Charles Duveyrier). It was succeeded only two years later by *Simon Boccanegra* (1857; revised 1881), a gloomy opera of great power. Then came *Un ballo in maschera* (*A Masked Ball*, 1859; libretto by Antonio Somma, after Scribe's libretto for Auber's 1833 opera *Gustave III, ou Le Bal Masqué*), no less gloomy and powerful but including, in the page Oscar (sung by a soprano), a ray of light and youthful humour, and *La forza del destino* (*The Force of Destiny*, 1862; libretto by Piave), a kaleidoscopic mixture of the tragic and the farcical, with touches of matter not far from operetta and opera buffa.

For Paris, and again to a libretto in French, Verdi next composed *Don Carlos* (1867; libretto by François-Joseph Méry and Camille du Locle, revised by Verdi in 1884 to an Italian translation and again in 1887). This long opera, and particularly its fourth act, is majestic and subtle, its various musical confrontations—many of them duets—displaying a depth of characterization hitherto unknown in Italian or French opera, in spite of faults in the libretto.

By 1869 Verdi's fame had become so international that the Khedive of Egypt invited him to compose an opera for Cairo to mark the opening of the new Cairo Opera House (and possibly the opening of the Suez Canal). In fact, the canal began to operate in 1869, but the opera received its premiere at Cairo only in 1871. This was *Aida* (libretto by Antonio Ghislanzoni, based on a scenario by Auguste Mariette, the French Egyptologist, and Camille du Locle, with the collaboration of Verdi). The masterly libretto and its four well-delineated principal characters evoked from Verdi a Meyerbeerian opera of such unfailing melodic, orchestral, and dramatic richness that many have called *Aida* his masterpiece. For pageantry, combined as it is with harmonic, melodic, and instrumental skills and convincing, if generalized, characterization, it remains

unrivalled—and probably has been sung more often than any other opera.

Verdi's Shakespearean operas

In 1869 the public and the writers on opera assumed that Verdi would continue to produce a new opera every few years. But 16 elapsed before the premiere of his next opera, *Otello* (1887; libretto by Arrigo Boito). Verdi's varied, intensely dynamic, compressed, and tragic score was the result not only of his ripened genius but also of nearly 50 years of operatic practice. Many critics consider it the finest tragic opera ever composed.

In the following six years, rumours grew that the aged Verdi not only was composing still another opera but that it was to be a comedy. The comic masterpiece *Falstaff* (libretto by Boito, derived largely from Shakespeare's *Merry Wives of Windsor* and *Henry IV*) was performed in 1893 at La Scala, where Verdi's first opera had been staged more than 53 years before. An opera buffa with serious overtones, *Falstaff* always has been praised by critics and enthusiasts, but it has never become a true popular favourite.

Arrigo Boito not only wrote the librettos of Verdi's last two operas but was also himself a composer, as well as a poet, polemicist, and man of letters. He completed only one opera, *Mefistofele* (1868; his own libretto, derived from Goethe's *Faust*). It was at first a failure and then became more popular. His command of technical musical resources was vast. Unfortunately, he placed them at the service of lofty but diffuse philosophical concepts and ideals mostly beyond his range of expressiveness. *Mefistofele*, for instance, is more impressive and admirable than theatrically convincing.

WAGNER AND HIS SUCCESSORS

Richard Wagner (1813–83) is a unique figure in the history of both opera and music. A concentrated egoist gifted with a powerful, tenacious, and at times stubbornly confused intellect, he wrote both the music and librettos of his operas. He began his career, except for a youthful attempt, *Die Feen* (*The Fairies*, completed, 1834; first performed, 1888), with two grand operas mixing the influences of Meyerbeer, Marschner, and Weber: *Das Liebesverbot* (*The Ban on Love*, 1836) and *Rienzi* (1842). In 1843, with *Der fliegende Holländer* (*The Flying Dutchman*), he began to develop what was to become an extremely personal, powerful manner of operatic construction. Turning to mythic legend for his subjects and making unacknowledged bows to the operas of Weber and Marschner, while dispensing with the trappings of grand opera, he composed an intensely German, Romantic opera. In it he instituted the use of brief melodic and other motifs as materials for evolving a more-or-less continuous web of music in which the separate numbers of earlier opera appeared only when the libretto demanded them. Already, at the age of 30, he was giving harmony, in very unclassical guise, a central constructive role in the creation of both drama and characterization.

Wagner's personal operatic style

Patiently and challengingly elaborating a vast, interlocked system of theories in many published books and essays, Wagner continued the ripening of his style in two large, transitional operas, *Tannhäuser* (1845) and *Lohengrin* (1850). *Tannhäuser* again displays some grand-opera characteristics (particularly in the revision of it that Wagner prepared for the 1861 Paris performance); *Lohengrin*, the last of Wagner's serious operas peopled by human beings of recognizable dimensions, has been called the Romantic opera par excellence.

The earliest example of what Wagner called "music drama" (a term he preferred to "opera") was the monumental *Tristan und Isolde* (1865), the libretto of which illustrates his obsession with the idea of man's redemption through woman's love. *Tristan und Isolde* advances harmonic language. The score is woven in a harmonic idiom so advanced chromatically that it speeded the destruction of orthodox concepts of harmony. *Tristan* requires singers possessed of powerful voices capable of penetrating a vastly enlarged orchestra. It came to be regarded as the greatest German opera of the late 19th century, and its influence upon compositional methods and techniques continued into the 20th century.

In *Die Meistersinger von Nürnberg* (*The Mastersingers of Nürnberg*, 1868) he partly deserted his most "advanced" style because central episodes in the libretto required self-contained numbers. Warmhearted, overflowing with young love and the bitter wisdom of age, *Die Meistersinger* ranks with Verdi's *Falstaff* among late-19th-century comic operas. From 1853 until 1874 Wagner worked intermittently on the four poems and the scores of *Der Ring des Nibelungen*. It is an epic, based on Teutonic myths, of such proportions and implications that it cannot be summarized. Musically, Wagner uses leitmotiv—constantly recurring fragments—and weaves them into a large, elaborate pattern. Performed in its entirety, and without intermissions, the *Ring* would last about 12 hours; many listeners, almost bewitched, would have been and now would be willing to attend such a continuous performance, so compelling is the musical power of this unique, all but inhuman, masterpiece.

The last of Wagner's operas, *Parsifal* (1882), introduced few structural elements not used in *Tristan und Isolde* and *Der Ring des Nibelungen*. Wagner called it *Ein Bühnenweihfestspiel*—a sacred festival drama—and it is heavy with religious and ethical messages. It perfectly illustrated both his musicodramatic theories and the unsmiling solemnity with which he approached operatic composition and demanded, successfully, that his audience absorb the results. *Parsifal* closed a career unparalleled in its aggressive demands on society and on opera goers, a career that would have seemed a form of madness if it had not produced some of the most lastingly impressive of all operatic creations and many pages of music of the greatest beauty.

Operatic composers influenced by Wagner

Curiously, Wagner's influence has been felt more in the evolution of post-Romantic harmony than in the constructive practices of later operatic composers. An adaptation of his leitmotiv usage marked the delightful fairy-tale opera *Hänsel und Gretel* (1893; based upon the tale by the Brothers Grimm), by Engelbert Humperdinck. Wagner's early theories about both libretto and music played a constructive part in the excellent comic opera *Der Barbier von Bagdad* (*The Barber of Bagdad*, 1858), by Peter Cornelius, and his mature style was wholly adopted in *Guntram* (1894), the first opera of Richard Strauss. Otherwise, the Wagnerian revolutions (in contrast with his at times unrevolutionary practice) are clearly seen in the operas of some ardent French Wagnerians such as Ernest Reyer and Vincent d'Indy.

LATER OPERA IN FRANCE

Gounod. The history of French opera contemporary with and later than Berlioz includes many talented composers and stageworthy works, but it degenerates quickly into a catalog of pieces of considerable charm and some originality seldom made arresting by the appearance of operas unmistakably of the first rank. Charles Gounod, who composed many operas, had a unique gift for sentimental melody but an uncertain sense of what is theatrically viable. In his ever-popular *Faust* (1859; libretto by Jules Barbier and Michel Carré), his talents were most creatively gathered together, but *Faust* took no place in the steady evolution of operatic styles. Among Gounod's other operas, the best, mixing in different proportions the virtues and flaws of *Faust*, are probably *Mireille* (1864; libretto by Carré, derived from Frédéric Mistral's Provençal poem *Mirèio*) and *Roméo et Juliette* (1867; libretto by Barbier and Carré).

Bizet. The works of Georges Bizet are on a higher level in both their vigour and variety. He began to display his considerable ability with *Les Pêcheurs de perles* (*The Pearl Fishers*, 1863; libretto by Eugène and Carré) and *La Jolie Fille de Perth*, (1867; libretto by Jules-Henry Vernoy de Saint-Georges and Jules Adenis, based on Sir Walter Scott's *Fair Maid of Perth*). In 1875 Bizet produced his masterpiece, *Carmen* (libretto by Henri Meilhac and Ludovic Halévy, after a tale by Prosper Mérimée). Its then savage realism, broad but convincing characterization, and dazzling pseudo-Spanish ambience shocked its first audiences and strongly influenced Italian *verismo* (see below *Later opera in Italy: Verismo*). A

Production of *Carmen*

lonely masterpiece, *Carmen* remains one of the steady props of operatic repertory everywhere.

Thomas and others. Ambroise Thomas, as prolific as Gounod but not as gifted in emotional or musical persuasion, had composed many operas when Paris first welcomed his *Mignon* (1866; libretto by Barbier and Carré), probably his best opera. Two years later he composed *Hamlet* (1868; libretto by Barbier and Carré). Thomas, like Gounod, interlarded his operas with florid, often essentially undramatic and "showy" arias for a new type of lyric-coloratura soprano. One of the most frequently heard of such vacuous arias is the "Bell Song" from Léo Delibes' *Lakmé* (1883; libretto by Edmond Gondinet and Philippe Gille). Although Camille Saint-Saëns composed numerous operas, the only work by him to remain in the repertory is *Samson et Dalila* (libretto by Ferdinand Lemaire), originally sung under Franz Liszt's aegis in 1877 in German. It is lusciously melodic but so lacking in drama as to seem half oratorio.

Massenet. Phenomenally popular when first composed were many of the operas of Jules Massenet, who had a surer sense of the stageworthy than Saint-Saëns but often made saccharine what to many had seemed too sweet in the earlier French opera of the 19th century. At his best however, Massenet was something better than "the daughter of Gounod": in *Manon* (1884) he produced not only one of the most enduringly popular of operas but also a stylistically unflawed reflection of the tragico-sentimental 18th-century novel by the Abbé Prévost on which Henri Meilhac and Philippe Gille had based the libretto. Much the same qualities have kept alive Massenet's *Werther* (1892; libretto by Édouard Blau, Paul Milliet, and Georges Hartmann, derived from Goethe's *Leiden des jungen Werthers*), first performed at Vienna in a German translation. Some other operas by Massenet, particularly *Thaïs* (1894; libretto by Louis Gallet, after the novel by Anatole France), are important for their sensuous portrayals of seductive female characters.

Gustave Charpentier's *Louise* (1900; libretto by the composer) has remained in opera house repertories because of its loving, romanticized portrait of "Bohemian" Paris, the sentiment and surface allure, and the popularity of Louise's hymn to love, "Depuis le jour."

Debussy. Claude Debussy, the greatest French composer after Berlioz and a decisive influence upon 20th-century music, completed only one opera: *Pelléas et Mélisande* (1902), an almost verbatim setting of Maurice Maeterlinck's play. Like *Tristan und Isolde*—which, having helped to shape Maeterlinck's drama, inevitably and against Debussy's will also shaped some of his compositional procedures—*Pelléas* remains unique. Listeners immune to the attraction of its aristocratic sensuality often find it monotonous. Nonetheless, it is a masterwork in its wholly apt amalgamation of text and score, the inescapable rightness for its quiet dramatic purposes of Debussy's individual harmonies, the marvelous manner with which he made the sounds of Maeterlinck's French an integral element in a shimmering orchestral web. In *Pelléas*, the Wagnerian ideal of continuous music without separate numbers was attained. Although *Pelléas* remains one of the handful of important operas composed in the 20th century, it has had few descendants. One of those few is Paul Dukas' *Ariane et Barbe-Bleue* (*Ariadne and Bluebeard*, 1907)—like *Pelléas*, an almost verbatim setting of a Maeterlinck play. It, however, is notably noisy where *Pelléas* is quiet, and it lacks Debussy's thematic invention.

The achievement of *Pelléas*

Ravel. Maurice Ravel wrote one opera, *L'Heure espagnole* (*The Spanish Hour*, 1911; libretto by Maurice Legrand), and a *fantaisie lyrique* (really a ballet-pantomime-opera), *L'Enfant et les sortilèges* (*The Child and the Enchantments*, 1925; text by Colette). The former is opéra bouffe in Spanish dance rhythms overlaid with vocal lines that seem indebted to the works of Richard Strauss. The latter reverses the orchestra's domination over the voices in *L'Heure espagnole*. It is an edifying and hilarious fantasy about a child being punished for his mistreatment of his toys and other objects. Perhaps only its uncomfortable mixture of genres has kept it from widespread performance.

Les Six. Of the professedly anti-Debussyan, anti-Impressionist group known as Les Six, three have places in the history of opera: Arthur Honegger, Darius Milhaud, and Francis Poulenc. Honegger, a Swiss, employed a somewhat Teutonic "neoclassical modern" idiom in thickly dissonant, heavily percussive operas that have failed to hold the stage. Milhaud's once sensational *opéras-minutes* (1927–28), three brief one-act compositions, were first staged in German translation in Germany. They parody Greek myths and have music composed in a jazz manner that inevitably has lost effectiveness with the passing decades. Milhaud also composed large modern versions of grand opera, but his persistently undramatic and often busily indecisive musical style have kept them from popularity. Poulenc composed one comic monodrama and one serious opera that seem likely to endure. The first, *Les Mamelles de Tirésias* (1947), is a wildly nonsensical opéra bouffe, the sardonic music of which is humorously appropriate to the text by the French poet Guillaume Apollinaire. The second, *La Voix humaine* (*The Human Voice*, 1959; text by Jean Cocteau), has as its only visible character a distraught young woman conversing by telephone with her lover. Poulenc's only large serious opera, *Dialogues des Carmélites* (*Dialogues of the Carmelites*, 1957; libretto by Georges Bernanos), appears to be the most impressive French opera since *Pelléas et Mélisande*. It makes telling operatic use of Poulenc's instantly identifiable style of melody, harmony (only very gently dissonant), and rhythm to tell a moving and tragic story of nuns martyred during the French Revolution.

Tragic and sardonic themes

LATER OPERA IN ITALY

Viewed broadly, the story of Italian opera contemporary with and following Verdi parallels that of French opera after Berlioz, in the appearance of talented composers and stageworthy operas as well as in quickly becoming a tally of pieces of considerable charm and some degree of originality responding to shifting musical techniques and manners. It includes only two or three composers of the first rank.

Verismo. Amilcare Ponchielli, shining clearly in light reflected from Verdi, composed one opera that remains in the international "standard" repertory—*La Gioconda* (1876; libretto by Arrigo Boito). The general turn toward realism began on a Roman stage in 1890 with Pietro Mascagni's dazzlingly successful one-act opera *Cavalleria rusticana* (*Rustic Chivalry;* libretto by Guido Menasci and Giovanni Targioni-Tozzetti). It soon evoked the descriptive term *verismo* (realism) and set a vogue for raw, violent, melodramatic librettos matched to music clearly descended from the middle-period operas of Verdi. Mascagni went on composing operas for 50 years after *Cavalleria*, but none won a permanent place on the stage. The best of them is *L'Amico Fritz* (*Friend Fritz*, 1891; libretto by Nicolo Despure). And two years after the premiere of *Cavalleria rusticana*, an equally successful product of *verismo* was staged in Milan: *I Pagliacci* (*Clowns*, 1892; libretto by the composer), by Ruggero Leoncavallo, who had no more staying power than Mascagni, though he produced operas for the remainder of his life.

Puccini. The Italian counterpart of Massenet in France made his first important contribution to the operatic stage the year after *I Pagliacci*. He was Giacomo Puccini, whose work is characterized by emotional directness of appeal and colourful, rich orchestration; the opera was *Manon Lescaut* (1893), based on the novel by the Abbé Prévost from which the libretto of Massenet's *Manon* had been derived. Puccini established himself unmistakably as the most important post-Verdian Italian operatic composer with *La Bohème* (1896; libretto by Giuseppe Giacosa and Luigi Illica, after Henri Murger's *Scènes de la vie de bohème*). It, too, remains "standard," as do *Tosca* (1900; libretto by Giacosa and Illica) and *Madama Butterfly* (1904; libretto by Giacosa and Illica), which again capitalized upon Puccini's attraction to, and ability to characterize in music, sorrowing, attractive young women. Returning closer to violent

Establishment of Puccini's reputation with *La Bohème*

verismo, Puccini (who always had to struggle to find librettos germane to his purposes) next composed an opera of the American "Wild West," *La fanciulla del west* (*The Girl of the Golden West*, 1910; libretto by Guelfo Civinini and Carlo Zangarini).

Fumbling for apposite literary materials, Puccini next proposed to write an operetta for Vienna; the outcome was a mixed, uncertain operetta-like piece, *La Rondine* (1917; libretto by Giuseppe Adami), produced by Monte Carlo, instead of Vienna, because of World War I. It was followed by a trio of one-act operas given its premiere at the Metropolitan, in 1918. *Il trittico* (*The Triptych*) consisted of the veristic and powerful *Il tabarro* (*The Cloak*; libretto by Adami), the sweetly sad, all-female *Suor Angelica* (*Sister Angelica*; libretto by Giovacchino Forzano) and the opera buffa of medieval Florence, *Gianni Schicchi* (libretto by Forzano). *Gianni Schicchi*, in its sarcastic humour and musical vitality, is the finest Italian operatic comedy after *Falstaff*.

Puccini died before finishing *Turandot* (libretto by Adami and Renato Simoni based on the Italian writer Carlo Gozzi's fable of the same name). It was produced posthumously in 1926. *Turandot* shows Puccini taking note of the then-recent developments in harmony, while giving them an Eastern flavour. The bloodthirsty story with a happy ending (for the two characters who least deserve it) alienates some opera goers, but many of those who accept *Turandot* as the brilliant, extremely melodious, highly pictorial representation of a legend consider it the finest of Puccini's operas. The music of *Turandot* was completed after the composer's death by the Italian composer Franco Alfano.

Puccini's contemporaries. The other Italian operatic composers of the late 19th century and early 20th displayed neither the brash originality of the young Mascagni and Leoncavallo nor the varied theatrical genius of Puccini. They included Alfredo Catalani, whose best known opera, shaped with extreme melodic refinement and mildly interesting orchestral commentary, is *La Wally* (1892; libretto by Luigi Illica). Another of these minor men was Umberto Giordano (1867–1948), whose bombastic *Andrea Chenier* (1896; libretto by Illica) and *Fedora* (1898; libretto by Arturo Colautti) are still staged. Francesco Cilea overtly copied the more sentimental aspects of Puccini in his biggest success, *Adriana Lecouvreur* (1902; libretto by Colautti). The 20th-century music critic Donald Jay Grout made an accurate description of nearly all of the post-Verdian Italian operas except *Cavalleria rusticana*, *I Pagliacci*, and the best of Puccini when he wrote of *Adriana Lecouvreur* as "expertly contrived music of a lyrical-tragic sort . . . unadventurous harmonically or rhythmically, but good theatre and grateful for the singers."

Busoni and Wolf-Ferrari. Of much greater interest (though not of equal popularity) were two contrasted half-Italian, half-German composers active early in this century: Ferruccio Busoni and Ermanno Wolf-Ferrari. Busoni, a learned musician, wrote, in a then-advanced harmonic idiom and using his own librettos, four operas that have had scattered enthusiasts but no large public: *Die Brautwahl* (*Choice of a Bride*, 1912); two commedia dell'arte parodies—*Turandot* (1917; libretto after Gozzi) and the equally short *Arlecchino* (*Harlequin*, 1917)—and his major work, *Doktor Faust*, left incomplete at his death and completed by Philipp Jarnach (1925). Busoni's operas, and *Doktor Faust* in particular, are notable for their intellectual mastery, spiritual elevation, and other operatically peripheral virtues, but their almost total lack of dramatic cogency and musical allure have probably kept them from frequent performance.

At the other end of the operatic spectrum, Wolf-Ferrari possessed a fine talent for opera buffa of an especially light, airy sort, and also composed one of the rawest later examples of *verismo*. There is enormous charm in his comedies *Le donne curiose* (*The Curious Women*, 1903; libretto by Luigi Sugana), *I quattro rusteghi* (*The Four Ruffians*, 1906; libretto by Giuseppe Pizzolato), and *Il segreto di Susanna* (*The Secret of Susanna*, 1909; libretto by Enrico Golisciani). All three were first given in German translation. The melodrama *I gioielli della Madonna* (*The Jewels of the Madonna*, 1911; by Golisciani and Zangarini) has been well described as Donizetti plus *verismo*.

The "big three" Italian composers of the 1920s and 1930s—Ottorino Respighi, Gian Francesco Malipiero, and Alfredo Casella—all composed operas and opera-like works of considerable musical interest but little theatrical vitality. What historical influence they have had has operated largely outside the opera house.

RUSSIAN OPERA

After long subjection to imported Italian, French, and German composers, opera in Russia by Russians asserted itself in two well-known works by Mikhail Ivanovich Glinka (1804–57): *Zhizn za tsarya* (*A Life for the Tsar*), also known as *Ivan Susanin* (1836; libretto by Baron Georgy Fyodorovich Rosen), and *Ruslan i Lyudmila* (*Ruslan and Lyudmila*, 1842; libretto by Valeryan Fyodorovich Shirkov and others). Basically old-fashioned Italianate operas, they—*Ruslan* in particular—determined the nature of much future Russian music because of Glinka's approximations of Slavic folk music, his pre-Wagnerian use of a tentative leitmotiv technique, and the clarity and shifting colours of his orchestration. Glinka's operas, weakened by evidence of his lifelong dilettantism, remain in the repertory only in the Soviet Union, but their stylistic importance was decisive.

Glinka as father of Russian nationalism

Almost as influential as Glinka in shaping future Russian opera was his much less successful disciple Aleksandr Sergeyevich Dargomyzhsky. His *Rusalka* (1856; his libretto, after a fairy tale by Pushkin) illustrated his strong emphasis on a declamation midway between recitative and aria, as well as his musical amateurism. Even more influential, although left incomplete at Dargomyzhsky's death, was *Kamenny gost* (*The Stone Guest*, an integral setting of Pushkin's short Don Juan play; completed by César Antonovich Cui and Nikolay Rimsky-Korsakov and staged posthumously in 1872). It is couched in what were then advanced harmonic terms, powerful in characterization, but musically all but sterile. Dargomyzhsky remains more interesting to historians than to opera goers.

The operas of Aleksandr Borodin, Rimsky-Korsakov, and Modest Mussorgsky are still performed. Borodin's incomplete *Knyaz Igor* (*Prince Igor*, his own libretto; completed and edited by Rimsky-Korsakov and Aleksandr Glazunov) was staged posthumously in 1890. It is dramatically shapeless but is splashed with Slavic and Oriental colours. Most of Rimsky-Korsakov's numerous fairy-tale operas have the nature of brilliantly illustrated books, but what may be his finest work is "the Russian *Parsifal*," *Skazaniye o nevidimom grade Kitezhe i deve Fevroni* (*The Legend of the Invisible City of Kitezh*, 1907; libretto by Vladimir Ivanovich), a work of marked emotional strength. Of his lighter works, the best known are *Snegurochka* (*The Snow Maiden*, 1882; his own libretto), *Sadko* (1898; libretto by the composer and Byelsky), and the fantastic opera buffa, *Zolotoy petushok* (*Le Coq d'or*, or *The Golden Cockerel*, 1909; libretto by Byelsky, after Pushkin). Like *Prince Igor*, Rimsky-Korsakov's operas contributed largely to what many music lovers came to consider typically "Russian" music, though the splashily coloured world they create was in reality Rimsky-Korsakov's own invention.

Mussorgsky. Mussorgsky composed all or part of several operas. Among them, *Khovanshchina* (to his own libretto; the score completed and orchestrated by Rimsky-Korsakov; posthumous premiere in 1886) bears a family resemblance to *Prince Igor*, particularly in its employment of real and simulated Orientalism, but is more serious and much more confident in tone. Mussorgsky's greatest achievement, and the most worthwhile Russian opera, is *Boris Godunov* (1874; his own libretto, based upon Pushkin's drama and a history of Russia by Nikolay Mikhailovich Karamzin). Boris, the guilty usurper of the throne, dominates this glittering but dour pageant in which the Russian people are present in remarkably forceful choral writing. Mussorgsky's ability to transmit

Greatness of *Boris Godunov*

textual points in very condensed music has possibly never been matched. Except at a few weak moments, he made a virtue out of amateurishness and naïveté, fearlessly extracting intense power and theatrical effectiveness from his newly developed techniques. The influence of *Boris Godunov* has been strong on numerous composers of opera both in Russia and elsewhere.

Tchaikovsky. The operatic practice of Peter Ilich Tchaikovsky was very different. For dramatic vigour he substituted clear characterization expressed lyrically, creating, among others, two highly idiosyncratic operas: *Eugene Onegin* (1879; libretto by the composer and Konstantin S. Shilovsky, after Pushkin) and the stronger melodrama *Pikovaya dama* (*The Queen of Spades*, 1890; libretto by Modest Ilich Tchaikovsky, after Pushkin). The personal emotion and the characterization of hero and heroine in *Eugene Onegin* are vivid. In all of Tchaikovsky's operas the highly subjective emotion that long made him the most often performed of orchestral composers is tellingly present. Many consider his other operas, containing much fine music, all unjustly neglected.

Stravinsky. Igor Stravinsky turned to opera three times during his long composing career, to near-opera more often. First came *Solovey* (*The Nightingale*, 1914; libretto by the composer and Stepan Nikolayevich Mitusov, after Hans Christian Andersen), which clearly reveals the influence of Rimsky-Korsakov, who had been Stravinsky's teacher. Next among his true operas came *Mavra* (1922; libretto by Boris Kochno, derived from Pushkin), an opera buffa in the unmistakable musical style that made Stravinsky the foremost composer of his era. Then a long period, marked by several near-operas (among them the urgent opera-oratorio *Oedipus Rex*, 1927) elapsed before the appearance of Stravinsky's full-length opera in English, *The Rake's Progress* (libretto by the poets W.H. Auden and Chester Kallman, after Hogarth's engravings, 1951), a neoclassical, austere, but compassionate work.

Prokofiev. Sergey Prokofiev composed numerous operas both in his "modern" musical manner and in a harmonically less advanced "socialist realist" style after his return to the Soviet Union in 1934. Among the former, the best and most often staged are the opera buffa, *L'Amour des trois oranges* (*The Love for Three Oranges*, Chicago, 1921; his own libretto), in a musical style that might be called Rimsky-Korsakov updated, and the lurid opera of hallucination, *Angel of Fire* or *The Fiery Angel* (radio premiere 1954; his own libretto after a story by Valery Yakovlevich Bryusov). Of Prokofiev's Soviet operas, the most winning is the gay *Betrothal in a Monastery*, also known as *The Duenna* (1946; libretto by Mira Mendelson based on a play of that name by the 18th-century Irish-born dramatist Richard Brinsley Sheridan). The most ambitious is the massive *War and Peace* (1946; revised, condensed version, 1955; libretto by the composer and Mira Mendelson).

Prokofiev's Soviet operas

The best known Soviet opera outside its homeland, however, is a grim tale of sexual repression and violence by Dmitry Shostakovich originally called *Ledi Makbet Mtsenskogo Uyezda* (*Lady Macbeth of the Mzensk District*, 1934; libretto by the composer and Y. Priess, after a story by Leskov), later revised, after a long period of eclipse caused by government disapproval, as *Katerina Ismaylova* (1963). Numerous other Soviet operas have not been staged outside the Soviet Union or have proved substantially unexportable when so staged.

LATER OPERA IN GERMANY AND AUSTRIA

Strauss. Richard Strauss was greeted as the obvious "heir to Wagner" (and Liszt). His worldwide reputation was being established by his orchestral music and lieder (songs) before he turned to opera for the first time. But his pre-eminence among non-Italian composers of opera was established by two "shocking" one-act operas: *Salome* (1905; libretto taken from Oscar Wilde's drama, translated into German by Hedwig Lachmann) and *Elektra* (1909). With the latter work Strauss began a long and fruitful association with the poet and dramatist Hugo von Hofmannsthal as his librettist. Couched in a violent harmonic idiom, requiring huge orchestral forces and leading singers of great vocal power and stamina, *Salome* and *Elektra* seemed to many critics to be Straussian tone poems with added voices, but they soon became, and have remained, part of the standard repertory. They were followed by an altogether different sort of opera, *Der Rosenkavalier* (1911), again with a libretto by Hofmannsthal, a bittersweet comedy notable for the superb musical creation of the central character (the Marschallin) and for three-quarter rhythms that placed this Strauss alongside Johann the Younger as a composer of Viennese waltzes. It marks Strauss's invention of a subtle *parlando* (conversational) style all his own, which he also used to great effect in his later opera.

Strauss's collaboration with Hofmannsthal

Strauss composed ten operas after *Der Rosenkavalier*. All but one or two of them won wide popularity; none of them displays any constructive or musical characteristics not present in his earlier works. The most successful have been the "chamber opera" *Ariadne auf Naxos* (*Ariadne on Naxos*, 1912; revised 1916); the giant allegory *Die Frau ohne Schatten* (*The Woman Without a Shadow*, 1919), which some writers have called Strauss's masterpiece, whereas others denounce it as confused, even megalomaniac; and *Arabella* (1933), which closely resembles *Der Rosenkavalier* in many details. *Capriccio* (1942), his last opera, is an absorbing characterization of the old argument as to whether words or music should take precedence in opera.

Pfitzner and Hindemith. Several harmonically conservative German composers active during and just after Strauss's long career were much less gifted and also less successful. Probably the most notable of them were Hans Pfitzner and Paul Hindemith. The antimodern Pfitzner, partly a belated Wagnerian, composed several operas of melodically long-lined, subjective, at times mystical content which have not reached beyond the German-speaking countries. The best-known is *Palestrina* (1917; his own libretto), dealing with the great Italian composer, in which the austerities of 16th-century counterpoint are oddly mixed with Pfitzner's often abrupt dissonances.

Hindemith damagingly lacked theatrical insight, but was admired for his technical wizardry and lofty aims. He composed some satirical comedies, but came to be heard in opera houses only with the serious *Cardillac* (1926, revised 1952; libretto by Ferdinand Lion, after a tale by E.T.A. Hoffmann) and *Mathis der Maler* (*Mathias the Painter*, 1938; his own libretto on the life of Matthias Grünewald).

Schoenberg. If "modernism" seems to be struggling toward birth in the operas of Strauss, Pfitzner, Hindemith, and some others, it sprang fully armed from the music of three Viennese composers: Arnold Schoenberg, Alban Berg, and Anton von Webern, propagators and chief practitioners of what came to be called atonality and 12-tone composition. Webern composed no operas. Schoenberg's first theatrical works—the one-act *Erwartung* (*Expectation*, composed in 1909, performed in 1924; single-character libretto by Marie Pappenheim) and the one-act *"Drama mit Musik" Die glückliche Hand* (*The Hand of Fate*, 1924; his own libretto)—are extremely discordant, thickly and earnestly romantic, even expressionistic, and occasionally use *Sprechstimme*, a variety of vocal emission between speech and song that Schoenberg himself described as "the voice rising and falling relative to the indicated intervals, and everything being bound together with the time and rhythm of the music except where a pause is indicated." Their harmony is unremittingly chromatic.

Schoenberg's first theatrical works

Schoenberg's only comedy, the one-act *Von Heute auf Morgen* (*From Today to Tomorrow*, 1930; libretto by Max Blonda), is in strictly construed 12-tone texture; following the theories attending that technique, it therefore returned to separate-number construction. Schoenberg's largest opera, left incomplete at his death, was the powerful, oratorio-like *Moses und Aron* (1957; his own libretto).

Berg and others. The two operas of Alban Berg—*Wozzeck* (1925; libretto by the composer, after Georg Büchner's play *Woyzeck*) and the unfinished *Lulu* (1937;

his own libretto)—are among the most powerful, effective music dramas of the 20th century. Well described as "expressionistic, morbid, neurotic, hysterical" as to story, *Wozzeck* seamlessly joins an intensely learned and appropriate score to a melodrama of a poor soldier's helplessness at the hands of his fate. *Wozzeck* is such an intense work that audiences who might be expected to be alienated by its extreme dissonance and "tunelessness" have accepted it as the great opera it is. The unfinished *Lulu*, a part-tragic, part-comic drama of the hectic life and final murder of a nymphomaniac, adds film clips and spoken dialogue to the means employed in *Wozzeck*. Although Berg's score was elaborated from a single "tone-row" (arrangement of the 12 tones of a chromatic scale) and though the resultant tonal clashing is not bilked, many passages in *Lulu* appear to show Berg tending toward less dissonance.

Intensity of *Wozzeck*

The most appreciable Germanic musicodramatic composer outside the Viennese orbit has appeared to be Carl Orff (1895–), who has juggled many varieties of almost-operatic forms. Best known for his absorption of bawdy medieval student songs into a "scenic oratorio," *Carmina Burana* (1937), Orff worked that singular exploitation of repetitive rhythms, bare harmonies, *ostinati*, and crying vocal colours into a trilogy called *Trionfi* by adding to it *Catulli Carmina* (1943) and *Il Trionfo d'Afrodite* (1953). More conventionally operatic is his one-act comedy *Die Kluge* (*The Clever Girl*, 1943; his own libretto, after a tale by the Brothers Grimm). Probably his major effort in musical drama is another trilogy, consisting of *Antigonae* (1949), *Oedipus der Tyrann* (1959), and *Prometheus* (1968). In it a texture of spoken and declaimed texts is spaced out with incidental music of almost brutal force. Bernd Alois Zimmermann's opera *Die Soldaten* (*The Soldiers*, 1969) is the most successful of the multi-media operas.

Hans Werner Henze (1926–) is the most recent major operatic composer to come out of Germany. The works of his most likely to be encountered in the opera house are *Elegy for Young Lovers*, his first collaboration with the poets W.H. Auden and Chester Kallman, and *Der junge Lord* (*The Young Lord*), which satirizes German provincial life. In the 1970s he turned from opera to forms of musicodramatic experiment.

NATIONALIST OPERA

Czechoslovakia. The specifically Russian operas of Glinka, Dargomyzhsky, and the Five, as well as the non-operatic music they influenced, have parallels in other countries. In what is now Czechoslovakia, the national school effectively began with Bedřich Smetana, known, operatically speaking, outside his homeland almost exclusively for the vigorous, highly coloured folk comedy *Prodaná nevěsta* (*The Bartered Bride*, 1866; libretto by Karel Sabina), which determined many aspects of future Czech musical usage as clearly as Borodin and Mussorgsky had set Russian styles. Several of Smetana's other operas, both comic and tragic, remain on Czech stages—most notably the overtly patriotic *Dalibor* (1868) and *Libuše* (1881), both to librettos in Czech translation of originally German texts by Joseph Wenzig, and his comedy *Hubička* (*The Kiss*, 1876). The other leading Czech composer of Smetana's period, Antonín Dvořák, wrote nine operas but remained preponderantly an instrumental composer, never matching the older composer's stage success. Of Dvořák's mature operas, the best known outside Czechoslovakia is the melancholy fairy tale *Rusalka* (libretto by Jaroslav Kvapil), made attractive by his considerable melodic and harmonic gifts.

Production of *The Bartered Bride*

Leoš Janáček was specifically Moravian in musical background, far more harmonically advanced than Smetana and Dvořák, though less adroit technically. He was clearly a 20th-century composer, whose highly individual music, typified by a short-phrased melodic idiom used to catch the speech-rhythm of his native language, was rediscovered after World War II. A follower of Mussorgsky, whose much-discussed "dilettantism" his closely resembles, Janáček is now represented intermittently in non-Czech opera houses chiefly by *Její pastorkyňa* (*Her Foster Daughter*, 1904; changed to *Jenufa* for Janáček's 1916 revision; his libretto derived from a story by Gabriela Preissová), *Káťa Kabanová* (1921; libretto by Vincenc Červinky), *Příhody lišky bystroušky* (*The Cunning Little Vixen*, 1924; libretto by the composer), and *Věc Makropulos* (*The Makropoulos Case*, 1926; libretto by the composer), each of which has a character and milieu of its own while preserving the peculiarly individual setting of the Czech language.

Hungary and Poland. The most important Hungarian operas of the early 20th century, neither of them representing its composer at his finest, are the one-act *Duke Bluebeard's Castle* (1918; libretto by Béla Balázs), by Béla Bartók, and the ballad opera *Háry János*, by Zoltán Kodály (1926; libretto by Béla Paulini and Zsolt Harsányi), both of which have become more familiar in concert performance or excerpts than in staged productions. The most influential and popular of Polish nationalist operas, *Halka* (1854; libretto by Włodzimierz Wolski), was composed by Stanisław Moniuszko; he also wrote an admirable comedy, *The Haunted Manor* (1865; libretto by Jan Chichiński). Of 20th-century Polish operas, perhaps the most substantial is the much less popular *Król Roger* (*King Roger*, 1926; libretto by Jarosław Iwakiewicz) by Karol Szymanowski.

Spain. Spanish operatic (and generally musical) nationalism began with Felipe Pedrell, more influential as teacher-propagandist than as producing composer. Of his ten neglected operas, the most imposing were to have been contained in a trilogy, based on a Catalan libretto by Victor Balaguer, but only the first two sections, *Los Pirineos* (*The Pyrenees*) and *La Celestina*, were completed and only the first was staged (1902). Of the more familiar Spanish composers, both Isaac Albéniz and Enrique Granados composed operas of strongly Spanish colour that have lapsed from the repertory—Albéniz particularly in the comic one-act *Pepita Jiménez* (1896), Granados in the semi-veristic *Goyescas* (1916; libretto by Fernando Periquet y Zuaznabar), the score of which clearly reveals its origin in a suite of piano pieces. The best results of Spanish operatic nationalism (possibly because more than a little tinged with internationalism) are two very different operas by Manuel de Falla: the specifically Andalusian *La vida breve* (*Brief Life;* libretto by Carlos Fernández Shaw; first staged in French translation, 1913) and the one-act *El retablo de Maese Pedro* (*Master Peter's Puppet Show*, 1923; text by the composer, after a scene in *Don Quixote*), in effect a chamber opera for marionettes.

Other countries. Consciously and unintentionally nationalistic operas have been composed and staged in nearly all European countries, Latin America, Great Britain, the United States, and other parts of the world, but none of them has entered the international repertory, held the stage in its homeland, or affected importantly the morphology of opera. Sometimes viewed as an exception is George Gershwin's *Porgy and Bess* (1935; libretto by Dubose Heyward and Ira Gershwin), an uncertain crossbreed of folk opera and American musical comedy, which has had no recognizable descendant of high quality.

Chinese opera, mimed and choreographed in ways foreign to Western opera, has a repertory of traditional works. It seems unlikely in the extreme that this highly rigid and conventionalized art will ever be exported with success.

RECENT DEVELOPMENTS

England. English opera, which had languished for centuries, was revitalized by the theatrical talent of the eclectic Benjamin Britten, whose stage works show a remarkable sympathy for the human predicament expressed in readily accessible, deeply felt music. His masterpiece is the gloomy, forceful *Peter Grimes* (1945; libretto by Montague Slater). Among Britten's other operas to win widespread stagings are the chamber operas *The Rape of Lucretia* (1946; libretto by Ronald Duncan) and *Albert Herring* (1947; libretto by Eric Crozier), the all-male *Billy Budd* (1951; libretto by E.M. Forster and Crozier;

Benjamin Britten's works

based upon Herman Melville's unfinished story), the eerily effective *The Turn of the Screw* (1954; libretto by Myfanwy Piper, after the Henry James story), *A Midsummer Night's Dream* (1960; libretto by Britten and Peter Pears, from Shakespeare), three church operas to librettos by William Plomer (1964–68), and *Owen Wingrave* (1971; libretto by Myfanwy Piper). So far, less popular outside England are the idiosyncratic operas, to his own complex librettos, of Sir Michael Tippett: *The Midsummer Marriage* (1955), *King Priam* (1962), and *The Knot Garden* (1970).

United States. American contributions to international opera, after a 19th-century desert of imitation German and French operas, became much more numerous after World War II. It is possible here to mention only one composer and a few isolated operas that have evoked enduring resonance. The most often performed of contemporary operatic composers has been the Italo-American Gian Carlo Menotti. Using his own librettos, he has produced, in a variety of structural styles, a series of Puccini-derived melodramas and sentimental tragedies of considerable popular appeal, among them *The Medium* (1946), *The Consul* (1950), *Amahl and the Night Visitors* (composed for television performance, 1951), and *The Saint of Bleecker Street* (1954). He also wrote the libretto for the first, mildly successful, opera of Samuel Barber, *Vanessa* (1958; awarded 1958 Pulitzer Prize). Barber's second large opera, *Antony and Cleopatra* (1966; libretto derived from Shakespeare by Franco Zeffirelli), commissioned to inaugurate the second Metropolitan Opera House in New York, was a failure and vanished quickly from performance.

Menotti's works

A unique niche is occupied by the two operas that Virgil Thomson composed to texts by Gertrude Stein arranged by Maurice Grosser: the Spanish-tinted *Four Saints in Three Acts* (1934) and *The Mother of Us All* (1947), a delicious flow of invention around the figure of Susan B. Anthony. Their fragile but real durability has resulted from Thomson's singable, apt folk-based setting of texts that alternate among the apparently nonsensical, the satiric, and the emotionally moving. Within the United States—not to count the "workshop operas" and simplified semi-folk near-operas that many American composers recently have favoured—two of the most frequently performed recent American operas are the folklike "Western" *Ballad of Baby Doe* (libretto by John Latouche, 1956), by Douglas Moore (1893–1969) and the melodramatic, "Southern" *Susannah* (libretto by the composer, 1955) by Carlisle Floyd (1926–).

PROSPECTS

The existing audience for the standard repertory operas throughout the world is enormous. If to it be added the large number of people attending workshop, college and university, music school, amateur, and semi-amateur performances—both of the same repertory and of operas created for those special purposes—the statistics suggest that all is well with opera. Yet by the mid-20th century the art of opera had become largely a museum art. Constant repetitions of a relatively small group of operas of the past far exceed creation of new works that can be categorized with the finest of those mentioned in this article. What, then, are the future prospects for this art, now nearing four centuries of fertile existence?

The prospects for the creation of major new operas are poor. How could they be better when the two major components of opera—dramatic literature and music—are both in a period of fundamental crisis? Outside the opera house, audiences for the spoken theatre and for concert and recital have been oscillating widely while economic problems have multiplied swiftly. Some writers have seen the future of opera in new varieties of semi-operatic "happenings" and other mixed forms, others in the numerous pieces written and composed specifically for workshop and school staging. For the large paying audience, however, opera continues to mean more or less traditional performances of the operas of Mozart, Verdi, Wagner, Puccini, Richard Strauss, and a few others.

Revivals of long-neglected operas have meanwhile attracted audiences in many opera houses (notably, to speak only of the United States, with such companies as the New York City Opera and those in Chicago, Dallas, San Francisco, and Santa Fe). That trend, which freshens the repertory in the absence of new operas, has brought back most noticeably some of the bel canto masterpieces of Rossini, Donizetti, and Bellini. These revivals, in turn, have affected the otherwise tradition-bound activities of record-publishing companies, whose reluctance to issue operas in any idiom more recent than that of Britten has reflected general public taste. Ballet, which entered a period of notable flowering between the two world wars, has fallen heir to what might, under different conditions, have become a large audience for operas employing "advanced" harmonic and melodic idioms.

The bel canto revival

Until the harmonic and melodic idioms of contemporary composers and the taste of the large paying audience converge, until the crises in style and subject matter no longer prevent librettists from writing meaningfully for that same audience, the present situation in opera houses can be expected to continue with only an occasional foray into less immediately hospitable territory. Predictions about future developments in any art are especially hazardous, and the fact that opera has survived more than three and a half centuries of social, political, literary, musical, and other changes without losing either its audience or its particular glamour strongly suggests that it will evolve ways out of its current predicaments. What remains true is that if this greatest of musicodramatic forms is to approach its absorbing best, it must, in one of numerous possible ways, be what Livia Miragoli (1924) defined it as being:

> a work of unique art, then, in which the value of the literary element is higher or lower as it is better or less well adapted to being combined with music, the musical element as it is a better or a less good response to the contents of the text.

BIBLIOGRAPHY. Books on all aspects of opera are overwhelmingly numerous, particularly in Italian, German, French, and English. The following suggested list is confined to books written in English, a few indicative titles excepted. Unique in its coverage of opera (as well as of the spoken theatre, ballet, the cinema, and the circus) is the 12-volume Italian *Enciclopedia dello Spettacolo* (1954–68). Among books on opera in general, useful basic information and informed opinion may be found in: WALLACE BROCKWAY and HERBERT WEINSTOCK, *The World of Opera* (1962); EDWARD J. DENT, *Opera* (1940); DONALD JAY GROUT, *A Short History of Opera*, 2nd ed. (1965); JOSEPH KERMAN, *Opera As Drama* (1956); GUSTAV KOBBE, *Complete Opera Book*, rev. and enlarged by the EARL OF HAREWOOD (1954), particularly useful for its libretto stories; ALFRED LOEWENBERG (comp.), *Annals of Opera, 1597–1940*, 2nd ed., 2 vol. (1955), the basic source for data on premieres and the dates and places of important later productions; and ERNEST NEWMAN (ed.), *Stories of the Great Operas* (1927, reprinted 1948), *More Stories of Famous Operas* (1943), and *Seventeen Famous Operas* (1954), which extensively analyze both libretto and music.

Among books treating opera in individual cities and opera houses, reliable data may be found in: (German) ANTON BAUER, *Opern und Operetten in Wien* (1955); ARTHUR J. BLOOMFIELD, *The San Francisco Opera, 1923–1961* (1961); JOHN FREDERICK CONE, *Oscar Hammerstein's Manhattan Opera Company* (1966); RONALD L. DAVIS, *Opera in Chicago* (1966); QUAINTANCE EATON, *The Boston Opera Company* (1965); (Italian) CARLO GATTI, *Il Teatro alla Scala (1778–1963)*, 2 vol., the second, compiled by GIAMPIERO TINTORI, being a detailed chronology of operatic and other performances (1964); IRVING KOLODIN, *The Metropolitan Opera, 1883–1966* (1966); MARCEL PRAWY, *The Vienna Opera* (1970); HAROLD D. ROSENTHAL, *Two Centuries of Opera at Covent Garden* (1958); WILLIAM H. SELTSAM (comp.), *Metropolitan Opera Annals: A Chronicle of Artists and Performances* (1947; also two supplements, 1957, 1968); and (French) STEPHANIE WOLFF, *Un Demi-siècle d'opéra-comique, 1900–1950* (1953) and *L'Opéra au Palais Garnier, 1875–1962* (1962).

A 122-page bibliography, including periodical and monographic articles of importance, may be found in vol. 2 of the first, 2-volume, edition of DONALD JAY GROUT, *A Short History of Opera* (1947). A prime source of operatic events since 1950 is the volumes (with annual index) of the London periodical *Opera*.

(H.We.)

Operations Research

Operations research is the application of scientific method to the management of organized systems. It is called operational research in the United Kingdom, where it originated. Operations research attempts to provide those who manage organized systems with an objective and quantitative basis for decision; it is normally carried out by teams of scientists and engineers drawn from a variety of disciplines. Thus, operations research is not a science itself, but is the application of science to the solution of managerial and administrative problems, and it focusses on the performance of organized systems taken as a whole rather than on their parts taken separately. Usually concerned with systems in which human behaviour plays an important part, operations research differs in this respect from systems engineering, which, using a similar approach, tends to concentrate on systems in which human behaviour is not important. Operations research was originally concerned with improving the operations of existing systems rather than developing new ones; the converse was true of systems engineering. This difference, however, has been disappearing as both fields have matured.

The subject matter of operations research consists of decisions that control the operations of systems. Hence, it is concerned with how managerial decisions are and should be made, how to acquire and process data and information required to make decisions effectively, how to monitor decisions once they are implemented, and how to organize the decision-making and decision-implementation process. Extensive use is made of older disciplines such as logic, mathematics, and statistics, as well as recent scientific developments such as communications theory, decision theory, cybernetics, organization theory, the behavioral sciences, and general systems theory.

The Industrial Revolution

In the 19th century, what is coming to be called the First Industrial Revolution involved mechanization or replacement of man by machine as a source of physical work. Study and improvement of such work is the objective of industrial engineering. The contemporary Second Industrial Revolution is concerned with automation or mechanization of mental work. The primary technologies involved are: mechanization of symbol generation (observation by machines such as radar and sonar); mechanization of symbol transmission (communication by telephone, radio, and television); and mechanization of logical manipulation of symbols (data processing and decision making by computer). Operations research applies the scientific method to the study of mental work and provides the knowledge and understanding requisite to make effective use of men and machines to carry it out.

History. In a sense, every effort to apply science to management of organized systems, and to their understanding, was a predecessor of operations research. It began as a separate discipline, however, in 1937 in Britain as a result of the initiative of A.P. Rowe, superintendent of the Bawdsey Research Station, who led British scientists to teach military leaders how to use the then newly developed radar to locate enemy aircraft. By 1939 the Royal Air Force formally commenced efforts to extend the range of radar equipment so as to increase the time between the first warning provided by radar and the attack by enemy aircraft. When the scientists involved recognized that additional gains could be made if the time between the first warning and the deployment of defenses could be reduced, they began to study the communication system that connected detection centres to defenses. At first they analyzed physical equipment and communication networks, but later they examined behaviour of the operating personnel and relevant executives. As the number of early-warning stations was increased, it was observed that there was a substantial variation in performance between them, even when operated by the same group of test operators. Analysis revealed ways of improving the operators' techniques and also revealed unappreciated limitations in the network.

The scientists working on different aspects of this problem were brought together in September 1939 at Fighter Command headquarters. The section steadily extended its scope of activities beyond the use of radar and, by the time of the Battle of Britain, was consulted on an ever-widening variety of problems.

By the summer of 1941 it was decided to establish operations research sections very widely in the Royal Air Force. Similar developments took place in the Army and the Royal Navy, and in both cases radar again was the instigator. In the Army, use of operations research had grown out of the initial inability to use radar effectively in controlling the fire of antiaircraft weapons. In the course of studying this problem it was found that radar equipment that worked perfectly in testing laboratories often failed to operate in the field. Thus, since the traditional way of testing equipment did not seem to apply to radar gunsights, scientists found it necessary to test in the field under operating conditions, and the distinguished British physicist and Nobel Laureate P.M.S. Blackett organized a team to solve the antiaircraft problem. Blackett's Anti-aircraft Command Research Group included two physiologists, two mathematical physicists, an astrophysicist, an Army officer, a former surveyor, and subsequently, a third physiologist, a general physicist, and two mathematicians. In March of 1941 Blackett and some of the members of his group moved to the Coastal Command, where they became involved in radar detection of ships and submarines, and in May of that year various members of Blackett's original group formed the Operational Research Group of the Air Defense Research and Development Establishment, which later became the Army Operational Research Group. Thus, within two years after the beginning of the war, formal operations research groups had been established in all three of Britain's military services. In addition, operations research was later employed in civil defense activities; the group of 40 researchers assembled for this purpose included several Americans who subsequently continued their activities with the U.S. Air Force. This group's work was supplemented by studies on the effects of bomb explosions upon human beings.

Radar testing problem

Development of operations research paralleling that in Britain took place in Australia, Canada, among the Free French Forces, and, most significantly for future developments, in the U.S., which was the beneficiary of a number of contacts with British researchers. Sir Robert Watson-Watt, who with A.P. Rowe launched the first two operational studies of radar in 1937 and who claims to have given the discipline its name, visited the U.S. in 1942 and urged that operations research be introduced into the War and Navy departments. Reports of the British work had already been sent from London by American observers, and James B. Conant, then chairman of the National Defense Research Committee, had become aware of operations research during a visit to England in the latter half of 1940. Another stimulant was Blackett's memorandum, "Scientists at the Operational Level," of December 1941, which was widely circulated in the U.S. Service departments.

The first organized operations research activity in the United States began in 1942 in the Naval Ordnance Laboratory. This group, which dealt with mine warfare problems, was later transferred to the Navy Department from which it designed the aircraft mining blockade of the Inland Sea of Japan. In May of 1942 the Antisubmarine Warfare Operations Research Group, which reported to both the Army and Navy, was organized. This group was later expanded into the Operations Research Group on the staff of the Commander in Chief, U.S. Fleet. It dealt with submarine and antisubmarine warfare, aircraft and amphibious operations, and antiaircraft and new weapons analysis.

As in Britain, radar stimulated developments in the U.S. Air Force. In October 1942, all Air Force commands were urged to include operations research groups in their staffs. By the end of the war there were 26 such groups in the Air Force. In 1943 General George Marshall suggested to all theatre commanders that they form teams to study amphibious and ground operations.

At the end of the war a number of British operational research workers moved to government and industry.

Nationalization of several British industries was an important factor. One of the first industrial groups was established at the National Coal Board. Electricity and transport, both nationalized industries, began to use operations research shortly thereafter. Parts of the private sector began to follow suit, particularly in those industries with cooperative research associations; for example, in the British Iron and Steel Research Association.

The early development of industrial operations research was cautious, and for some years most industrial groups were quite small. In the late 1950s, largely stimulated by developments in the United States, the development of industrial operations research in Britain was greatly accelerated.

Industrial involvement in U.S.

Although in the United States military research increased at the end of the war, and groups were expanded, it was not until the early 1950s that American industry began to take operations research seriously. The advent of the computer brought an awareness of a host of broad system problems and the potentiality for solving them, and within the decade about half the large corporations in the U.S. began to use operations research. Elsewhere the technique also spread through industry.

Societies were organized, beginning with the Operational Research Club of Britain, formed in 1948, which in 1954 became the Operational Research Society. The Operations Research Society in America, formed in 1952, now has about 8,000 members. Many other national societies appeared; the first international conference on operations research was held at Oxford University in 1957. In 1959 an International Federation of Operational Research Societies was formed. By 1970 23 national societies had joined.

The first appearance of operations research as an academic discipline came in 1948 when a course in nonmilitary techniques was introduced at Massachusetts Institute of Technology. In 1952 a curriculum leading to a master's and doctoral degree was established at Case Institute of Technology. Since then about 30 major academic institutions in the United States have introduced programs. In the United Kingdom courses were initiated at the University of Birmingham in the early 1950s. The first chair in operations research was created at the newly formed University of Lancaster in 1964. In the years since, about a dozen chairs and about half as many departments have been created in Britain. Similar developments have taken place in most countries in which a national operations research society exists.

The first scholarly journal, the *Operational Research Quarterly*, published in the United Kingdom, was initiated in 1950. It was followed by the *Journal of the Operations Research Society of America* in 1952, which was renamed *Operations Research* in 1956. The International Federation of Operational Research Societies initiated the *International Abstracts in Operations Research* in 1961. In 1970 this journal contained abstracts from about 100 journals published in 21 countries.

Despite its rapid growth, operations research is still a very young scientific activity. Its techniques and methods, and the areas to which they are applied, can be expected to continue to expand rapidly. Most of its history lies in the future.

ESSENTIAL CHARACTERISTICS

The three essential characteristics of operations research are system orientation; use of interdisciplinary teams; and adaptation of scientific method to the conditions under which the research is conducted.

System orientation. The systems approach to problems recognizes that the behaviour of any part of a system has some effect on the behaviour of the system as a whole; and when individual components are performing well, the system as a whole is not necessarily performing equally well. An effort, for example, to assemble the best of each type of automobile part, regardless of make, will not necessarily result in a good automobile or even one that will run, because the parts may not fit together. It is the interaction between parts, and not the actions of any single part, that determines how well a system performs.

Thus operations research attempts to evaluate the effect of changes in any part of a system on the performance of the system as a whole and to search for causes of a problem that arises in one part of a system in other parts or in the interrelationships between parts; that is, in the structure of the system. In industry, a production problem may best be approached by a change in marketing policy; for example, the factory may fabricate a few profitable products in large quantities and many less profitable items in small quantities; long efficient production runs of high-volume, high-profit items may have to be interrupted for short runs of low-volume, low-profit items. An operations researcher might propose reducing the sales of the less profitable items and increasing those of the profitable items by placing salesmen on an incentive system that especially compensates them for selling particular items.

The interdisciplinary team. Scientific and technological disciplines have proliferated rapidly in the last 100 years. The proliferation, resulting from the enormous increase in scientific knowledge, has provided science with a filing system that permits a systematic classification of knowledge. This classification system is helpful in solving many problems by identifying the proper discipline to appeal to for a solution. But difficulties arise when more complex problems, such as those arising in large organized systems, are encountered. It is then necessary to find a means of bringing a diversity of disciplinary points of view together. Furthermore, since methods differ among disciplines, the use of interdisciplinary teams makes available a much larger arsenal of research techniques and tools than would otherwise be available. Hence, operations research is characterized by rather unusual combinations of disciplines on research teams (Blackett's group, for example), and by the use of research procedures, developed in one context, in other, very different contexts; for example, the use in economic forecasting of factor analysis, a technique that was originally developed for use in psychology.

Methodology. Until this century laboratory experiments were the principal and almost the only method of conducting scientific research. But large systems such as are studied in operations research cannot be brought into laboratories. Furthermore, even if systems could be brought into the laboratory, what would be learned would not necessarily apply to their behaviour in their natural environment, as shown by the World War II experience with radar. Experiments on systems and subsystems conducted in their natural environment ("operational experiments") are possible as a result of the experimental methods developed by the British statistician R.A. Fisher in 1923–24. For practical or even ethical reasons, however, it is seldom possible to experiment on large organized systems as a whole, even in their natural environments. This results in an apparent dilemma: to gain understanding of complex systems experimentation seems to be necessary but it cannot usually be carried out. This difficulty is solved by the use of models, representations of the system under study. Provided the model is good, experiments (called "simulations") can be conducted on it, or other methods (discussed below) can be used to obtain useful results.

Parts of a system model

A system model generally has two parts, of which the first is an equation that relates an appropriate measure of system performance (P) to variables that can be controlled (C), and to variables that are uncontrolled (U). In industry, for example, corporated management controls product prices, factory location, advertising expenditures, and other factors. Uncontrolled variables may include competitor, consumer, or supplier behaviour; the weather; and the economy. Therefore, the general structure of this equation is expressed by $P = f(C,U)$; meaning, system performance is a function of controlled and uncontrolled variables.

The second part of a system model consists of an explicit statement of the constraints within which the controlled variables can be manipulated. For example, if the total amount of time available on a machine is T and this is to be used to make three products, and the time allocated to

each is t_1, t_2, and t_3, two useful formulas can be stated: $0 \leq t_1 + t_2 + t_3 \leq T$. That is, the total time allocated (T) must be more than or equal to the sum of the separate product times (t_1, t_2, and t_3), which in turn must be more than or equal to zero. The second formula states that $t_1 \geq 0$, $t_2 \geq 0$, and $t_3 \geq 0$; that is, the amounts of time for each separate product time must be nonnegative.

Thus, a model consists of a performance function and a set of constraints. The problem to be solved can be stated in terms of the model; it is to find the values of the controlled variables (C) that, subject to the constraints and the conditions specified by the values of the uncontrolled variables (U), yield the best performance (P) of the system. These may be the values of C that either maximize or minimize P, as appropriate. If, for example, P is a measure of profit or return, the aim is to maximize it; if it is a measure of loss, cost, or risk, the aim is to minimize it. The function of P that is sought is called the "objective function." The best solution may be found exactly or approximately either by simulation or mathematical analysis. An explicit analytical procedure for finding the solution is called an "algorithm."

Even if a model cannot be solved, and many are too complex for solution, it can be used to compare alternative solutions. It is sometimes possible to conduct a sequence of comparisons, each suggested by the previous one, and each likely to contain a better alternative than was contained in any previous comparison. Such a solution-seeking procedure is called "heuristic."

A model is a simplified representation of the real world and, as such, includes only those variables relevant to the problem at hand. A model of freely-falling bodies, for example, does not refer to the colour, texture, or shape of the body involved. Furthermore, a model may not include all relevant variables because a small percentage of these may account for most of the phenomenon to be explained. Many of the simplifications used produce some error in predictions derived from the model, but these can often be kept small compared to the magnitude of the improvement in operations that can be extracted from them.

Operations-research methodology based on the use of models thus may be divided into five interdependent steps:

1. Formulating the problem: observing and analyzing the system operations to identify the relevant controlled variables, uncontrolled variables, and constraints; and formulating an appropriate measure of performance.
2. Constructing the model: assembling the variables, constraints, and measure of performance into a model. This consists primarily of finding the appropriate function (f) by which to relate the variables to the measure of performance.
3. Deriving a solution: solving the model exactly or approximately.
4. Testing the model and solution: taking steps to assure the adequacy of the representation and comparing the solution derived from it with performance that would otherwise be obtained to assure an improvement if the solution is implemented.
5. Implementing and controlling the solution: specifying who is to do what, when, and how to carry out the solution; checking results against predictions; and, if expectations are not realized, finding and correcting the cause of the deficiency.

PHASES OF OPERATIONS RESEARCH

Problem formulation. To formulate an operations-research problem, a suitable measure of performance must be devised, various possible courses of action defined (that is, controlled variables and the constraints upon them) and relevant uncontrolled variables identified. To devise a measure of performance, objectives are identified and defined, and then quantified. Objectives may be retentive, involving preservation of available resources or existing states, or acquisitive, involving attainment of additional resources or desired states. For example, a businessman may have the acquisitive objective of introducing a new product and making it profitable after one year. The identified objective is profit in one year, which is defined as receipts less costs, and would probably be quantified in terms of sales. In the real world, conditions may change with time. Thus, though a given objective is identified at the beginning of the time period, change and reformulation are frequently necessary.

Determining who makes decisions

To determine who actually makes relevant decisions and to identify the controlled and uncontrolled variables, detailed knowledge of how the system actually operates and of its environment is essential. Such knowledge is normally acquired through an analysis of the system, a four-step process that involves determining whose needs or desires the organization tries to satisfy; how these are communicated to the organization; how information on needs and desires penetrates the organization; and what action is taken, how it is controlled, and what the time and resource requirements of these actions are. This information can usually be represented graphically in a flow chart, which enables researchers to identify the controlled and uncontrolled variables that affect system performance.

Once the objectives, decision makers, their courses of action, and the uncontrolled variables have been identified and defined, a measure of performance can be developed and selection can be made of a function of this measure to be used as a criterion for the best solution. These two steps require extensive use of decision and value theory.

The type of decision criterion that is appropriate to a problem depends on the state of knowledge regarding possible outcomes. Certainty describes a situation in which each course of action is believed to result in one particular outcome. Risk is a situation in which, for each course of action, alternative outcomes are possible, the probabilities of which are known or can be estimated. Uncertainty describes a situation in which, for each course of action, probabilities cannot be assigned to the possible outcomes.

In risk situations, which are the most common in practice, the objective normally is to maximize expected (long-run average) net gain or gross gain for specified costs, or to minimize costs for specified benefits. A businessman, for example, seeks to maximize expected profits or minimize expected costs. Two objectives, not simply related, may be sought; for example, an economic planner may wish to maintain full employment without inflation. Finally, different groups within an organization may have to compromise their differing objectives, as when an army and a navy, for example, must cooperate in matters of defense.

In approaching uncertainty situations one may attempt either to maximize the minimum gain or minimize the maximum loss that results from a choice; this is the "minimax" approach. Alternatively, one may weigh the possible outcomes to reflect one's optimism or pessimism and then apply the minimax principle. A third approach, minimax regret, attempts to minimize the maximum deviation from the outcome that would have been selected if a state of certainty had existed before the choice had been made.

Each identified variable should be defined in terms of the conditions under which, and research operations by which, questions concerning its value ought to be answered; this includes identifying the scale used in measuring the variable.

Model construction. The type of model described above is called a symbolic model because symbols represent properties of the system. The earliest models were physical representations such as model ships, airplanes, tow tanks, and wind tunnels. Physical models are usually fairly easy to construct, but only for relatively simple objects or systems, and are usually difficult to change.

The next step beyond the physical model is the graph, easier to construct and manipulate, but more abstract. Since graphic representation of more than three variables is difficult, symbolic models came into use. There is no limit to the number of variables that can be included in a symbolic model, and such models are easier to construct and manipulate than physical models.

Symbolic models are completely abstract. When the

Symbolic models

symbols in a model are defined, the model is given content or meaning. This has important consequences. Symbolic models of systems of very different content often reveal similar structure. Hence, most systems and problems arising in them can be fruitfully classified in terms of relatively few structures. Furthermore, since methods of extracting solutions from models depend only on their structure, some methods can be used to solve a wide variety of problems from a contextual point of view. Finally, a system that has the same structure as another, however different the two may be in content, can be used as a model of the other. Such a model is called an analogue. By use of such models much of what is known about the first system can be applied to the second.

Despite the obvious advantages of symbolic models there are many cases in which physical models are still useful, as in testing physical structures and mechanisms; the same is true for graphic models. Physical and graphic models are frequently used in the preliminary phases of constructing symbolic models of systems.

Operations-research models represent the causal relationship between the controlled and uncontrolled variables and system performance; they must therefore be explanatory, not merely descriptive. Only explanatory models can provide the requisite means to manipulate the system to produce desired changes in performance.

Operations-research analysis is directed toward establishing cause and effect relations. Though experiments with actual operations of all or part of a system are often useful, these are not the only way to analyze cause and effect. There are five patterns of model construction, only two of which involve experimentation: inspection, use of analogues, operational analysis, operational experiments, and use of "artificial reality." They are considered here in order of increasing complexity.

Inspection. In some cases the system and its problem are relatively simple and can be grasped either by inspection or from discussion with persons familiar with it. In general, only low-level and repetitive operating problems, those in which human behaviour plays a minor role, can be so treated.

An example is the problem of the newsboy who must decide how many newspapers to order to maximize his expected profit. He buys a certain number of newspapers each day (n, the controlled variable) and either sells some but not all of them (if demand, d, is less than n); or all of them (if demand is equal to or greater than n). He pays an amount a for each paper he buys, and sells each paper for an amount b so that his profit per paper sold is $(b - a)$. Each paper not sold is returned and he receives an amount c so that his loss per paper returned is $(a - c)$. Demand varies from day to day, thus $p(d)$ is the probability that demand will equal d on a randomly selected day. Thus, a, b, c, and d are uncontrolled variables. The measure of performance to be maximized is P, the expected net profit per day, which, of course, can be negative.

The causal structure of this situation is apparent. From it can be deduced an equation whose solution produces the value of n that maximizes P.

Use of analogues. When the researcher finds it difficult to represent the structure of a system symbolically, it is sometimes possible to establish a similarity, if not an identity, with another system whose structure is better known and easier to manipulate. It may then be possible to use either the analogous system itself or a symbolic model of it as a model of the problem system. For example, an equation derived from the kinetic theory of gases has been used as a model of the movement of trains between two classification yards. Hydraulic analogues of economies and electronic analogues of automotive traffic have been constructed with which experimentation could be carried out to determine the effects of manipulation of controllable variables. Thus, analogues may be constructed, as well as found in existing systems.

Operational analysis. In some cases analysis of actual operations of a system may reveal its causal structure. Data on operations are analyzed to yield an explanatory hypothesis, which is tested by analysis of operating data. Such testing may lead to revision of the hypothesis. The cycle is continued until a satisfactory explanatory model is developed.

For example, an analysis of the cars stopping at urban automotive service stations located at intersections of two streets revealed that almost all came from four of the 16 possible routes through the intersection (four ways of entering times four ways of leaving). Examination of the percentage of cars in each route that stopped for service suggested that this percentage was related to the amount of time lost by stopping. Data were then collected on time lost by cars in each route. This revealed a close inverse relationship between the percentage stopping and time lost. But the relationship was not linear, that is, the increases in one were not proportional to increases in the other. It was then found that perceived lost time exceeded actual lost time, and the relationship between the percentage of cars stopping and perceived lost time was close and linear. The hypothesis was systematically tested and verified and a model constructed that related the number of cars stopping at service stations to the amount of traffic in each route through its intersection and to characteristics of the station that affect the time required to get service.

Operational experiments. In some situations it is not possible to isolate the effects of individual variables by analysis of operating data; it may be necessary to resort to operational experiments to determine which variables are relevant and how they affect system performance.

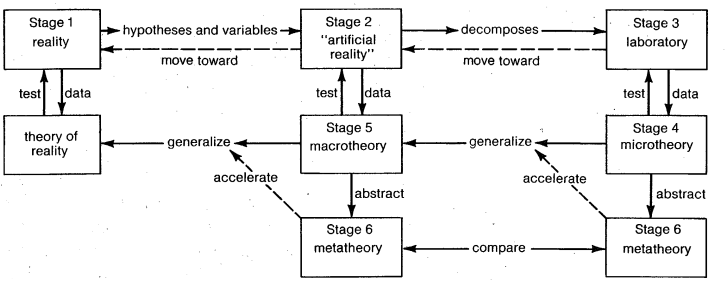
Such is the case, for example, in attempts to quantify the effects of advertising (amount, timing, and media used) upon sales of a consumer product. Advertising by the producer is only one of many controlled and uncontrolled variables affecting his sales. Hence, in many cases its effect can only be isolated and measured by controlled experiments in the field.

The same is true in determining how the size, shape, weight, and price of a food product affect its sales. In this case laboratory experiments on samples of consumers can be used in preliminary stages, but field experiments are eventually necessary. Experiments do not yield explanatory theories, however. They can only be used to test explanatory hypotheses formulated before designing the experiment, and to suggest additional hypotheses to be tested.

Testing hypotheses

Use of "artificial reality." In this last and most complex situation one cannot obtain even a good description of the system's operations, and experimentation on the system itself is ruled out by its size or character; such is the case, for example, in the problem of controlling large-scale social conflicts such as wars or strikes.

In this case model construction is a six-stage process (see illustration). In stage 1 the literature dealing with the problem (reality) is reviewed, relevant hypotheses extracted, and variables identified. In stage 2 an experimental game, called "artificial reality," is designed. The game is complex enough to permit testing most of the hypotheses formulated in stage 1. Behaviour observed in it must be capable of description in quantitative terms. In stage 3 the "artificial reality" game is broken down into the simplest possible experimental situations, which are used to generate laboratory behaviour. In stage 4 a simple theory, or microtheory is developed to explain the behaviour. When this microtheory is tested and found valid,



Model construction for experimentation on a complex system with the use of "artificial reality."

it is expanded to contain behaviour in more complex situations, and this process is repeated until a macrotheory is formulated that explains "artificial reality." In stage 5 "artificial reality" is modified in the direction of reality and stage 4 is repeated, yielding a fresh macrotheory. This process is repeated, and in stage 6 the sequences of micro and macrotheories are analyzed to find a metatheory, a theory of theory generalization: when a metatheory is found that can be applied to the whole sequence of macrotheories it can be used to extrapolate an explanation of the real problem (reality). This pattern is an elaborate way of pulling research up by its own boot straps.

The effect of data availability. It is sometimes necessary to modify an otherwise acceptable model because it is not possible or practical to find the numerical values of the variables that appear in it. For example, a model to be used in guiding the selection of research projects may contain such variables as "the probability of success of the project," "expected cost of the project," and its "expected yield." But none of these may be calculable with any reliability.

Even when the initial construction of a model has been easy, subsequent modification of it so that its variables can be estimated accurately and reliably may be very complex. This often involves a sequence of steps in which the model is complicated but made more usable.

Models not only assist in solving problems but are also useful in formulating them; that is, models can be used as guides to explore the structure of a problem and to reveal possible courses of action that might otherwise be missed. In many cases the course of action revealed by such application of a model is so obviously superior to previously considered possibilities that justification of its choice is hardly required.

In some cases the model of a problem situation may be either too complicated or too large to solve. It is frequently possible to divide the model into individually solvable parts and to take the output of one model as an input to another. Since the models are likely to be interdependent, several repetitions of this process may be necessary.

Deriving solutions from models. Procedures for deriving solutions from models are either deductive or inductive. With deduction one moves directly from the model to a solution in either symbolic or numerical form. Such procedures are supplied by mathematics; for example, the calculus.

Inductive procedures involve trying and comparing different values of the controlled variables. Such procedures are said to be "iterative" (repetitive) if they proceed through successively improved solutions until either an optimal solution is reached or further calculation cannot be justified. A rational basis for terminating such a process—known as the Las Vegas technique—involves the determination of the point at which the expected improvement of the solution on the next trial is less than the cost of the trial.

Such well-known algorithms as linear, nonlinear, and dynamic programming are iterative procedures based on mathematical theory. Simulation and experimental optimization are iterative procedures based primarily on statistics.

Simulation consists of calculating the performance of a system by evaluating a model of it for randomly selected values of variables contained within it. Most simulation in operations research is concerned with "stochastic" variables; that is, variables whose values change randomly within some probability distribution over time. The random sampling employed in simulation requires either a supply of random numbers or a procedure for generating them. It also requires a way of converting these numbers into the distribution of the relevant variable, a way of sampling these values, and a way of evaluating the resulting performance. A number of sampling and estimating procedures are available for this purpose.

Simulation in military games

A simulation in which decision making is performed by one or more real decision makers is called "operational gaming." Such simulations are commonly used in the study of interactions of decision makers as in competitive situations. Military gaming has long been used as a training device, but only relatively recently has it been used for research purposes. There is still considerable difficulty, however, in drawing inferences from operational games to the real world.

Experimental optimization is a means of experimenting on a system so as to find the best solution to a problem within it. Such experiments, conducted either simultaneously or sequentially, may be designed in various ways, no one of which is best in all situations.

Testing the model and the solution. A model may be deficient because it includes irrelevant variables, excludes relevant variables, contains inaccurately evaluated variables, is incorrectly structured, or contains incorrectly formulated constraints. Tests for deficiencies of a model are statistical in nature; their use requires knowledge of sampling and estimation theory, experimental designs, and the theory of hypothesis testing (see also STATISTICS).

Sampling-estimation theory is concerned with selecting a sample of items from a large group and using their observed properties to characterize the group as a whole. To save time and money, the sample taken is as small as possible. Several theories of sampling design and estimation are available, each yielding estimates with different properties.

The structure of a model consists of a function relating the measure of performance to the controlled and uncontrolled variables; for example, a businessman may attempt to show the functional relationship between profit levels (the measure of performance) and controlled variables (prices, amount spent on advertising) and uncontrolled variables (economic conditions, competition). In order to test the model, values of the measure of performance computed from the model are compared with actual values under different sets of conditions. If there is a significant difference between these values, or if the variability of these differences is large, the model requires repair. Such tests do not use data that have been used in constructing the model, because to do so would determine how well the model fits performance data from which it has been derived, not how well it predicts performance.

The solution derived from a model is tested to find whether it yields better performance than some alternative, usually the one in current use. The test may be prospective, against future performance; or retrospective, comparing solutions that would have been obtained had the model been used in the past with what actually did happen. If neither prospective nor retrospective testing is feasible, it may be possible to evaluate the solution by "sensitivity analysis," a measurement of the extent to which estimates used in the solution would have to be in error before the proposed solution performs less satisfactorily than the alternative decision procedure.

The cost of implementing a solution should be subtracted from the gain expected from applying it, thus obtaining an estimate of net improvement. Where errors or inefficiencies in applying the solution are possible, these should also be taken into account in estimating the net improvement.

Implementing and controlling the solution. The acceptance of a recommended solution by the responsible manager depends on the extent to which he believes the solution to be superior to alternatives. This in turn depends on his faith in the researchers involved and their methods. Hence, participation by managers in the research process is essential for success.

Operations researchers are normally expected to oversee implementation of an accepted solution. This provides them with an ultimate test of their work and an opportunity to make adjustments if any deficiencies should appear in application. The operations research team prepares detailed instructions for those who will carry out the solution and trains them in following these instructions. The cooperation of those who carry out the solution and those who will be affected by it should be sought in the course of the research process, not after everything is done. Implementation plans and schedules are pretested and deficiencies corrected. Actual performance of the solution is compared with expectations and, where diver-

gence is significant, the reasons for it are determined and appropriate adjustments made.

The solution may fail to yield expected performance for one or a combination of reasons: the model may be wrongly constructed or used; the data used in making the model may be incorrect; the solution may be incorrectly carried out; the system or its environment may have changed in unexpected ways after the solution was applied. Corrective action is required in each case.

Controlling a solution requires deciding what constitutes a significant deviation in performance from expectations; determining the frequency of control checks, the size and type of sample of observations to be made, and the types of analyses of the resulting data that should be carried out; and taking appropriate corrective action. The second step should be designed to minimize the sum of the costs of carrying out the control procedures and the errors that might be involved.

Since most models involve a variety of assumptions, these are checked systematically. Such checking requires explicit formulation of the assumptions made during construction of the model.

Effective controls not only make possible but often lead to better understanding of the dynamics of the system involved. Through controls the problem-solving system of which operations research is a part learns from its own experience and adapts more effectively to changing conditions.

PROTOTYPE PROBLEMS AND ASSOCIATED TECHNIQUES

As previously mentioned, many operational problems of organized systems have common structures. The most common types of structure have been identified as prototype problems, and extensive work has been done on modelling and solving them.

Though all the problems with similar structures do not have the same model, those that apply to them may have a common mathematical structure and hence may be solvable by one procedure. Some real problems consist of combinations of smaller problems, some or all of which fall into different prototypes. In general, prototype models are the largest that can be solved in one step. Hence, large problems that consist of combinations of prototype problems usually must be broken down into solvable units; the overall model used is an aggregation of prototype and possibly other models.

Solving allocation problems

Allocation. Allocation problems involve the distribution of resources among competing alternatives in order to minimize total costs or maximize total return. Such problems have the following components: a set of resources available in given amounts; a set of jobs to be done, each consuming a specified amount of resources; and a set of costs or returns for each job and resource. The problem is to determine how much of each resource to allocate to each job.

If more resources are available than needed, the solution should indicate which resources are not to be used, taking associated costs into account. Similarly, if there are more jobs than can be done with available resources, the solution should indicate which jobs are not to be done, again taking into account the associated costs.

If each job requires exactly one resource (*e.g.*, one person) and each resource can be used on only one job, the resulting problem is one of assignment. If resources are divisible, and if both jobs and resources are expressed in units on the same scale, it is termed a transportation or distribution problem. If jobs and resources are not expressed in the same units, it is a general allocation problem.

An assignment problem may consist of assigning men to offices or jobs, trucks to delivery routes, drivers to trucks, or classes to rooms. A typical transportation problem involves distribution of empty railroad freight cars where needed, or the assignment of orders to factories for production. The general allocation problem may consist of determining which machines should be employed to make a given product, or what set of products should be manufactured in a plant during a particular period.

In allocation problems the unit costs or returns may be either independent or interdependent; for example, the return from investing a dollar in selling effort may depend on the amount spent on advertising. If the allocations made in one period affect those in subsequent periods, the problem is said to be dynamic, and time must be considered in its solution.

Inventory. An inventory consists of usable but idle resources; these may be men, machines, materials, money, products, or facilities. An inventory problem involves determining how much of a resource to acquire, either by purchasing or producing it, and whether or when to acquire it to minimize the sum of the costs that increase with the size of inventory and those that decrease with increases in inventory. Costs of the first type include the cost of the capital invested in inventory, handling, storage, insurance, taxes, depreciation, deterioration, and obsolescence. Costs that decrease as inventory increases include shortage costs (arising from lost sales), production setup costs, and the purchase price or direct production costs. Setup costs include the cost of placing a purchase order or starting a production run. If large quantities are ordered inventories increase, but the frequency of ordering decreases, hence setup costs decrease. In general, the larger the quantity ordered the lower the unit purchase price because of quantity discounts and the lower production cost per unit resulting from the greater efficiency of long production runs. Other relevant variables include demand for the resource and the time between placing and filling orders.

Applications in inventory problems

Inventory problems arise in a wide variety of contexts; for example, determining quantities of goods to be purchased or produced, how many people to hire or train, how large a new production or retailing facility should be or how many should be provided, and how much fluid (operating) capital to keep available. Inventory models for single items are well developed and are normally solved with calculus. When the order quantities for many items are interdependent (as, for example, when there is limited storage space or production time) the problem is more difficult. Some of the larger problems can be solved by breaking them into interacting inventory and allocation problems. In very large problems simulation can be used to test various relevant decision rules.

Replacement and maintenance. Replacement problems involve items that degenerate with use, or the passage of time, and those that fail after a certain amount of use or time. Items that deteriorate are likely to be large and costly (*e.g.*, machine tools, trucks, ships, and home appliances). Nondeteriorating items tend to be small and relatively inexpensive (*e.g.*, light bulbs, vacuum tubes, ink cartridges). The longer a deteriorating item is operated the more maintenance it requires to maintain efficiency. Furthermore, the longer such an item is kept the less is its resale value and the more likely it is to be made obsolete by new equipment. If the item is replaced frequently, however, investment costs increase. Thus the problem is to determine when to replace such items and how much maintenance (particularly preventive) to perform so that the sum of the operating, maintenance, and investment costs are minimized.

In the case of nondeteriorating items the problem involves determining whether to replace them as a group, or to replace individuals as they fail. Though group replacement is wasteful, labour cost of replacements is greater when done singly; for example, the light bulbs in New York City subway stations are replaced in groups, to save labour. Replacement problems that involve minimizing the costs of items, failures, and the replacement labour are solvable either by numerical analysis or simulation.

The items involved in replacement problems may be people. If so, maintenance can be interpreted as training or improvements in salary, status, or fringe benefits. Failure can be interpreted as departure, and investment as recruiting, hiring, and initial training costs. There are many additional complexities in such cases; for example, the effect of one person resigning or being promoted on the behaviour of others. Such controllable aspects of the environment as location of work and working hours can

have a considerable effect on productivity and failure rates. In problems of this type, the inputs of the behavioral sciences are particularly useful.

Queuing. A queue is a waiting line and queuing involves dealing with items or people in sequence. Thus, a queuing problem consists either of determining what facilities to provide or scheduling the use of them. The cost of providing service and the waiting time of users is minimized. Examples of such problems include determining the number of check-out counters to provide at a supermarket, the number of runways at an airport, parking spaces at a shopping centre, or tellers in a bank. Many maintenance problems can be treated as queuing problems; items requiring repair are like users of a service. Some inventory problems may also be formulated as queuing problems in which orders are like users and stocks are like service facilities.

Sequencing and coordination. In queuing problems, the order in which users waiting for service are served is always specified. Selection of that order so as to minimize some function of the time to perform all the tasks, is a sequencing problem. The performance measure may account for total elapsed time, total tardiness in meeting deadlines and the cost of being late, and the cost of in-process inventories.

The most common context for sequencing problems is a "job-shop," a production facility that processes many different products with many combinations of machines. In this context account may have to be taken of such factors as overlapping service (*i.e.*, if a customer consists of a number of items to be taken through several steps of a process, the first items completing the initial step may start on the second step before the last one finishes the first), transportation time between service facilities, correction of service breakdowns, facility breakdowns, and material shortages.

Some processes consist of a network of unique operations that are carried out only once, some of which can be carried out in parallel, and others of which must be done in a prescribed sequence (*e.g.*, in constructing a building, in carrying out a research and development program, launching a new product, and assembling and testing complex equipment or systems). In such processes coordination consists of establishing starting times and due dates so the total cost of operations is minimized. Penalties for lateness and rewards for early completion may also have to be taken into account. Two techniques have been developed for handling this type of problem, project evaluation and review technique and critical path method.

CPM and PERT techniques

Critical path method (CPM) is an optimizing procedure applicable only to certainty-type formulations of such problems. Project evaluation and review technique (PERT) is applicable to risk- as well as certainty-type formulations but does not always yield optimal solutions. These techniques make it possible to determine labour needs, budget requirements, procurement and design limitations, and the effects of delays or speed-ups and communication difficulties.

Network routing. A network may be defined by a set of points or "nodes" that are connected by lines or "links." A way of going from one node (the "origin") to another (the "destination") is called a "route" or "path." Links, which may be one-way or two-way, are usually characterized by the time, cost, or distance required to traverse them. The time or cost of travelling in different directions on the same link may differ.

A network routing problem consists of finding an optimum route between two or more nodes in relation to total time, cost, or distance. Various constraints may exist, such as a prohibition on returning to a node already visited, or a stipulation of passing through every node once and only once.

Network routing problems commonly arise in communication and transportation systems. Delays that occur at the nodes (*e.g.*, railroad classification yards or telephone switchboards) may be a function of the loads placed on them and their capacities. Breakdowns may occur in either links or nodes. Much studied is the "travelling salesman problem," which consists of starting a route from a designated node that goes through each node (*e.g.*, city) once and only once, and returns to the origin in the least time, distance, or cost. This problem arises in selecting an order for processing a set of production jobs over a facility when the cost of setting up the facility for each job depends on which job has preceded it. In this case the jobs can be thought of as nodes each of which is connected to all of the others and setup costs are the analogue of distances between them. The order that yields the least total setup cost is therefore equivalent to a solution to the travelling salesman problem. The complexity of the calculations is such that even with the use of computers it is very costly to handle more than 20 nodes. Less costly approximating procedures are available, however. More typical routing problems involve getting from one place to another in the least time, cost, or distance. Both graphic and analytic procedures are available for finding such routes.

Competitive problems. Competitive problems deal with choice in interactive situations where the outcome of one decision maker's choice depends on the choice, either helpful or harmful, of one or more others. Examples of these are war, marketing, and bidding for contracts. Competitive problems are classifiable into certainty, risk, or uncertainty types depending on the state of a decision maker's knowledge of his opponent's choices. Under conditions of certainty, it is easy to maximize gain or minimize loss. Competitive problems of the risk type require the use of statistical analysis for their solution; the most difficult aspect of solving such problems usually lies in estimating the probabilities of the competitor's choices; for example, in bidding for a contract on which competitors and their bids are unknown.

The theory of games was developed to deal with a large class of competitive situations of the uncertainty type in which each participant knows what choices he and each other participant has; there is a well-defined "end-state" that terminates the interaction (*e.g.*, win, lose, or draw); and the payoffs associated with each end-state are specified in advance and are known to each participant. In situations in which all the alternatives open to competition, or some of their outcomes are not known in advance, operational gaming can sometimes be used. The military have long constructed operational games; their use by business is relatively recent.

Search problems. Search problems involve finding the best way to obtain information needed for a decision. Though every problem contains a search problem in one sense, situations exist in which search itself is the essential process; for example, in auditing accounts, inspection and quality-control procedures, in exploration for minerals, in the design of information systems, and in military problems involving the location of such threats as enemy ships, aircraft, mines, and missiles.

Errors in search problems

Two kinds of error are involved in search: those of observation and those of sampling. Observational errors, in turn, are of two general types: commission, seeing something that is not there, and omission, not seeing something that is there. In general, as the chance of making one of these errors is decreased, the chance of making the other is increased. Furthermore, if fixed resources are available for search, the larger the sample (and hence the smaller the sampling error), the less resources available per observation (and hence the larger the observational error).

The cost of search is composed of setup or design cost; cost of observations; cost of analyzing the data obtained; and cost of error. The objective is to minimize these costs by manipulating the sample size (amount of observation), the sample design (how the things or places to be observed are selected), and the way of analyzing the data (the inferential procedure).

Almost all branches of statistics provide useful techniques for solving search problems. In search problems that involve the location of physical objects, particularly those that move, physics and some fields of mathematics (*e.g.*, geometry and trigonometry) are also applicable.

A "reversed-search" problem arises when the search procedure is not under control but the object of the

search is. Most retailers, for example, cannot control the manner in which customers search for goods in their stores, but they can control the location of the goods. This type of problem also arises in the design of libraries and information systems, and in laying land and sea mines. These, too, are search problems, and solution techniques described above are applicable to them.

FRONTIERS OF OPERATIONS RESEARCH

Operations research is a rapidly developing application of the scientific method to organizational problems. Its growth has consisted of both technical development and enlargement of the class of organized systems and the class of problems to which it is applied. Therefore, its current frontiers lie in the techniques, organizational types, and classes of problems that it is presently exploring. In this section some of the more important of these frontiers will be identified.

Tactics and strategy compared

Strategic problems. Tactics and strategy are relative concepts; the distinction between them depends on three considerations: (1) the longer the effect of a decision and the less reversible it is, the more strategic it is; (2) the larger the portion of a system that is affected by a decision, the more strategic it is; and (3) the more concerned a decision is with the selection of goals and objectives, as well as the means by which they are to be obtained, the more strategic it is.

Strategy and tactics are separable only in thought, not in action. Every tactical decision involves a strategic choice, no matter how implicit and unconscious it may be. Since the strategic aspects of decisions are usually suppressed, an organization's strategy often emerges as an accidental consequence of its tactical decisions, not as a result of deliberate and conscious choice.

Operations research is becoming increasingly concerned with strategic decisions and the development of explicit strategies for organizations so as to improve the quality of their tactical decisions and make even the most immediate and urgent of these contribute to its long-run goals.

The system-design problem. Operations research has traditionally been concerned with finding effective solutions to specific operational problems. It has developed better methods, techniques, and tools for doing so. But operations researchers have found that too many of their solutions are not implemented and of those that are, too few survive the inclination of organizations to return to familiar ways of doing things. Therefore, operations researchers have gradually come to realize that their task should not only include solving specific problems but also designing problem-solving and implementation systems that predict and prevent future problems, identify and solve current ones, and implement and maintain these solutions under changing conditions.

The planning problem. Operations researchers have come to realize that most problems do not arise in isolation but are part of an interacting system. The process of seeking simultaneous interrelated solutions to a set of interdependent problems is planning. More and more operations-research effort is being devoted to developing a rational methodology for such planning, particularly strategic planning.

Most organizations resist changes in their operations or management. The organizational need to find better ways of doing things is often not nearly as great as is the need to maximize use of what it already knows or has. This is apparent in many underdeveloped countries that, while complaining about the lack of required resources, use what resources they have with considerably less efficiency than do most developed countries. Operations research, therefore, has been addressing itself more and more to determining how to produce the willingness to change.

Types of organization. Operations researchers have become increasingly aware of the need to distinguish between different types of organization because their distinguishing features affect how one must go about solving their problems. Two important classifications exist, the first of which is homogeneous–heterogeneous. Homogeneous organizations are those in which membership involves serving the objectives of the whole (*e.g.*, a corporation or military unit), while heterogeneous organizations are those whose principal objective it is to serve the objectives of its members (*e.g.*, a university or city). The second classification is uninodal/multinodal. Uninodal organizations are hierarchical organizations with a single decision-making authority who can resolve differences between any lower-level decision makers. Multinodal organizations have no such authority but have diffused decision making and hence require agreement among the several decision makers in order to reach conclusions.

Since current skills in operations research are largely restricted to homogeneous uninodal organizations, attempts are under way to develop methodologies adequate for improving the other three types of organization.

In order to solve any of the preceding problems more effectively, operations research requires a better understanding of human behaviour, individual and collective, than is currently available. Furthermore, what understanding the behavioural sciences claim to provide is seldom available in a form that lends itself to symbolic representation and hence to operations research methodology. Operations researchers, therefore, are increasingly working with behavioural scientists to develop behavioural theories that are expressible in a more usable form.

As the scope of problems to which operations research addresses itself increases, it becomes more apparent that the number of disciplines and interdisciplines that have an important contribution to make to their solution also increases. An attempt to provide such a higher-order integration of scientific activity is being made in the management sciences.

Oppenheimer, J. Robert

J. Robert Oppenheimer, American theoretical physicist and science administrator, directed the Manhattan Project, which produced the first atomic bomb during World War II. Accusations as to his loyalty and reliability as a security risk led to a government hearing that resulted in the loss of his security clearance and of his position as adviser to the highest echelons of the U.S. government. The case became a cause célèbre in the world of science because of its implications concerning political and moral issues relating to the role of scientists in government.

Oppenheimer.

Oppenheimer was born on April 22, 1904, in New York City, where his father, who had emigrated from Germany at the age of 14, had made his fortune by importing textiles. During his undergraduate education at Harvard University, Oppenheimer excelled in Latin, Greek, physics, and chemistry, published poetry, and studied Oriental philosophy. After graduating in 1925, he sailed for England to do research at the Cavendish Laboratory at Cambridge University, which, under the leadership of Lord Rutherford, had an international reputation for its pioneering studies on atomic structure. At the Cavendish, Oppenheimer had the opportunity to collaborate with the British scientific community in its efforts to advance the cause of atomic research.

Training in physics

Max Born invited him to Göttingen University, where he met other prominent physicists, such as Niels Bohr and Paul Dirac, and where, in 1927, he received his doctorate. After short visits at science centres in Leiden and Zürich, he returned to the United States to teach physics at the University of California at Berkeley and the California Institute of Technology.

In the 1920s the new quantum and relativity theories were engaging the attentions of science. That mass was equivalent to energy and that matter could be both wave-like and corpuscular carried implications seen only dimly at that time. Oppenheimer's early research was devoted in particular to energy processes of subatomic particles, including electrons, positrons, and cosmic rays. Since quantum theory had been proposed only a few years before, the university post provided him an excellent opportunity to devote his entire career to the exploration and development of its full significance. In addition, he trained a whole generation of American physicists, who were greatly affected by his qualities of leadership and intellectual independence.

The rise of Hitlerism in Germany stirred his first interest in politics. In 1936 he sided with the republic, during the Civil War in Spain, where he became acquainted with Communist students. Although his father's death in 1937 left Oppenheimer a fortune that allowed him to subsidize anti-Fascist organizations, the tragic suffering inflicted by Stalin on Russian scientists led him to withdraw his associations with the Communist Party—in fact, he had never joined the party—and at the same time reinforced in him a liberal–democratic philosophy.

After the invasion of Poland by Nazi Germany in 1939, the physicists Albert Einstein and Leo Szilard warned the American government of the danger threatening all of humanity if the Nazis should be the first to make a nuclear bomb. Oppenheimer then began to seek a process for the separation of uranium-235 from natural uranium and to determine the critical mass of uranium required to make such a bomb. In August 1942 the U.S. Army was given the responsibility of organizing the efforts of British and American physicists to seek a way to harness nuclear energy for military purposes, an effort that became known as the Manhattan Project. Oppenheimer was instructed to establish and administer a laboratory to carry out this assignment. In 1943 he chose the plateau of Los Alamos, near Santa Fe, New Mexico, where he had spent part of his childhood in a boarding school.

The Manhattan Project

For reasons that have not been made clear, Oppenheimer in 1942 initiated discussions with military security agents that culminated with the implication that some of his friends and acquaintances were agents of the Soviet government. This led to the dismissal of a personal friend on the faculty at the University of California. In a 1954 security hearing he described his contribution to those discussions as "a tissue of lies."

The joint effort of outstanding scientists at Los Alamos culminated in the first nuclear explosion on July 16, 1945, at Alamogordo, New Mexico, after the surrender of Germany. In October of the same year, Oppenheimer resigned his post. In 1947 he became head of the Institute for Advanced Study at Princeton University and served from 1947 until 1952 as chairman of the General Advisory Committee of the Atomic Energy Commission, which in October 1949 opposed development of the hydrogen bomb.

On December 21, 1953, he was notified of a military security report unfavourable to him and was accused of having associated with Communists in the past, of delaying the naming of Soviet agents, and of opposing the building of the hydrogen bomb. A security hearing declared him not guilty of treason but ruled that he should not have access to military secrets. As a result, his contract as adviser to the Atomic Energy Commission was cancelled. The Federation of American Scientists immediately came to his defense with a protest against the trial. Oppenheimer was made the worldwide symbol of the scientist, who, while trying to resolve the moral problems that arise from scientific discovery, becomes the victim of a witch-hunt. He spent the last years of his life working out ideas on the relationship between science and society.

The Cold War having declined, Pres. Lyndon B. Johnson in 1963 formalized Oppenheimer's reinstatement by

presenting him the Fermi Award of the Atomic Energy Commission. He retired from Princeton in 1966 and died of throat cancer on February 18, 1967, in Princeton, New Jersey.

BIBLIOGRAPHY. MICHEL ROUZE, *Oppenheimer* (1962; Eng. trans., *Robert Oppenheimer: The Man and His Theories*, 1965), is the only biography (to 1961). Oppenheimer's philosophical ideas are expressed in his two books, *Science and the Common Understanding* (1954) and *The Open Mind* (1955). His scientific work is spread in many reports, published in particular in *Physical Review*, from 1928 to 1948. ROBERT JUNGK, *Heller als tausend Sonnen: Das Schicksal der Atomforscher* (1956; Eng. trans., *Brighter Than a Thousand Suns: Moral and Political History of the Atomic Scientists*, 1958), is the story of the dramatic events lived by the nuclear physicists during World War II and the Cold War. *In the Matter of J. Robert Oppenheimer: Transcript of Hearings Before Personnel Security Board, Washington, D.C. April 12, 1954 Through May 6, 1954* (1954), is the fundamental document on Oppenheimer's trial by the Atomic Energy Commission. Among the numerous publications on this trial (all of them being in favour of Oppenheimer), see J. and S. ALSOP, *We Accuse!* (1954); J. ALVIN KUGELMASS, *J. Robert Oppenheimer and the Atomic Story* (1953); PHILIP M. STERN, *The Oppenheimer Case: Security on Trial* (1969); PETER MICHELMORE, *The Swift Years: The Robert Oppenheimer Story* (1969). HAAKON CHEVALIER, the professor denounced by Oppenheimer, describes this issue in *The Man Who Would Be God* (1959) and *Oppenheimer: The Story of a Friendship* (1965).

(Mi.Ro.)

Optical Engineering

Optical engineering is the branch of technology concerned with the design, construction, and testing of optical equipment. The word optics, of Greek origin, relates to what is seen, and optical instruments historically have been aids to vision. With the advance of technology, however, and the introduction of other means for detecting light, such as photographic films and photoelectric devices, the meaning of the term has been broadened, and today several kinds of optical instrument are recognized, including (1) systems for projecting a beam of light in a desired direction, such as the searchlight and lighthouse; (2) aids to vision such as spectacles, microscopes, and telescopes; (3) optical recording devices, such as cameras; (4) apparatus for information transfer and display, such as movie projectors, planetariums, and television sets; (5) detectors of invisible radiation; (6) measuring devices, such as surveying instruments and rangefinders; (7) instruments for measuring and analyzing light, such as photometers, colorimeters, and spectroscopes.

Though simple lenses had been in use as magnifiers for over a thousand years, and though eyeglasses had been developed in the 14th century, it is generally agreed that optical engineering began in the early 17th century with the development of the first precision optical instrument, the telescope. The microscope was developed almost simultaneously. Because manufacturing problems were little understood, and available glass was poor, early instruments were primitive. Newton, despairing of making adequate lenses for a telescope, turned to mirrors instead, while Dutch microscopist Antonie van Leeuwenhoek in 1670 found that he could see more through a small glass bead used as a magnifier than he could through his microscope.

By the early 19th century, however, excellent lenses were being made, and by the time photography was introduced by L.-J.-M. Daguerre in 1839, the art of lens design was developing rapidly (see also OPTICS, PRINCIPLES OF; TELESCOPE; and PHOTOGRAPHY, TECHNOLOGY OF).

Function of the optical engineer. Until the specialized nature and national importance of the subject were appreciated during World War I, the engineering problems involved in the design of optical equipment were given insufficient attention. Though mechanical engineers, physicists, and mathematicians were commonly involved, it was considered revolutionary when Ernst Abbe, the director of research for the Zeiss optical company in Germany, about 1870 decreed that all Zeiss instruments had to be completely designed on paper before any construction could be started. Today, a number of universities have departments entirely given over to the study of optical engineering. Because of the increasing complexity of optical devices, prospective optical engineers usually receive a broad training that includes considerable mathematics and physics, together with courses in chemistry, mechanical engineering, and electronics, in addition to studies in vision, lenses, and optics.

Training of engineers

Optical engineering students ultimately specialize in either instrument design or lens design, since the problems in optical engineering fall naturally into these two distinct parts. The determination of the exact specification of the optical system itself is the concern of the lens designer, while the design of the supporting body, which also provides the necessary movements and controls, is the job of the instrument designer. The optical device may be as simple as a pocket lens or an opera glass, or it may be a large, complex structure requiring a special building to house it.

If the instrument is very simple, or the producing company very small, the lens designer may plan and work out the whole system according to the customer's requirements and employ a draftsman or instrument designer to complete the mount design and prepare detailed drawings for the factory. After assembly, the instrument will be returned to him for testing and release. When the instrument is complex or large, and sufficient staff is available, the optical engineer having overall responsibility for the project will prepare a preliminary layout of the system to meet the customer's requirements. The lens design department will then work out in detail a suitable optical system and will specify tolerances; that is, the permissible variations in dimensions. A mechanical engineer, and if necessary an electronics expert, will develop and prepare detailed drawings for the factory. Today the design and construction of the optical parts, and sometimes electronic parts, are increasingly subcontracted to companies specializing in these fields, the original contractor then being responsible for the preliminary design, for providing metal or plastic parts, and for performing the assembly and final testing of the whole instrument.

In a large company, the industrial design and sales departments are concerned with appearance, weight, convenience, durability, cost, and any other nonscientific factors that may enter into ensuring the total satisfaction of the customer.

DESIGN PROBLEMS IN OPTICAL ENGINEERING

The optical image. The work of designing an optical instrument is not basically different from that of designing any other apparatus, so far as mechanical and electronic features are concerned. The distinctive task of the optical engineer is to develop a suitable optical system to form an image of the required sharpness at a specified position. Images—*i.e.*, optical pictures—may be real or virtual. A real image is formed outside the system where it can be projected on a screen or received on a piece of film, while a virtual image can be seen only by looking into the instrument.

Real and virtual images

To the ancients, image formation was a mystery, and not until the 17th century did the explanation of it begin to become clear. The German astronomer Johannes Kepler assumed that every point in an object emits a bundle of light rays that are either refracted (bent) at a transparent surface, or reflected at a mirror, and come together again at another point called the "image" of the original object point (see Figure 1A). An object was regarded as an assemblage of millions of separate points each of which is independently "imaged" by the optical system. An ideal or perfect lens would focus all of the rays from an object point P at an exact point P′ in the image; and, furthermore, if the object points all lie in a plane perpendicular to the lens axis, as when viewing the wall of a house, then the image points would also lie in a plane, and the image of the wall would be flat. For a perfect lens, the image magnification ratio (image size to object size or h'/h) would be constant over the entire field.

Later workers, including the German mathematician and astronomer C.F. Gauss (1777–1855), in attempting

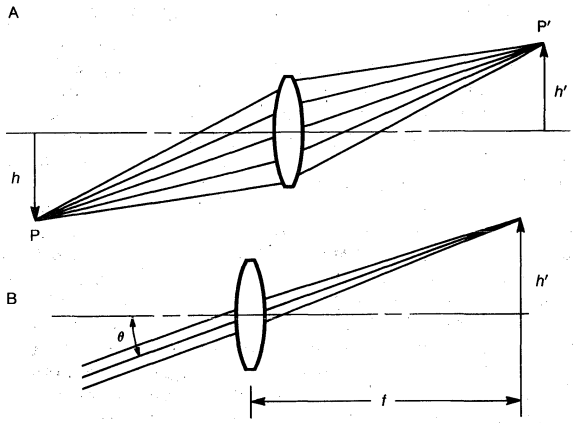

Figure 1: *Image formation.*
(A) Johannes Kepler's theory (see text). (B) Relation between focal length *(f)* and image size *(h')*; namely, $f = h'/\tan\theta$.

to develop a quantitative theory of image formation, introduced the concepts of lens power and focal length. The focal length of a lens, which determines the size of an image formed by the lens, is the distance from the centre of the lens to the point at which the image of a distant object is formed. More specifically, it is the ratio of the image height to the tangent of the angle subtended at the lens by the distant object (Figure 1B). A long-focus lens, therefore, forms a large image, while a short-focus lens forms a small image, of a distant object.

Types of lenses. A lens, named for its resemblance to the seed of the lentil plant, is a piece of transparent material, usually circular in shape, with two polished surfaces, either or both of which is curved and may be convex (bulging) or concave (depressed). The curves are almost always spherical; *i.e.*, the radius of curvature is constant. A lens has the valuable property of forming images of objects situated in front of it. Single lenses are used in spectacles, pocket magnifiers and reading glasses, projection condensers, signal lights, viewfinders, and on simple box cameras. More often a number of lenses made of different materials are combined together as a compound lens in a tube to permit correction of aberrations (see below). The simplest compound lens is a thin cemented combination of two single lenses (doublet) such as a small telescope objective (the lens nearest the object) or a component of an erector lens or eyepiece. Microscope objectives may contain as many as eight or nine elements or single lenses, some of which may be made of materials other than glass; *i.e.*, crystalline calcium fluoride to help the designer to bring all colours of light to a common focus. Photographic objective lenses may contain as few as two or as many as ten or more elements, while a so-called zoom or variable focal length lens may include as many as 18 or 20 elements in several groups, the different groups being movable along the axis by levers or cams at different rates to produce the desired change in focal length without a shift of the image plane. The design of a compound lens system is difficult and laborious; the process is outlined below.

Fluoride lens elements

Aberrations. A single lens is far from the perfect optical system envisaged by Kepler and Gauss. The cone of rays emitted by a single point in the object is not united in a perfect point by the lens but instead forms a small patch of light. In the 19th century the German scientist L. P. Seidel analyzed the defects of a single lens and identified seven distinct kinds of imperfection, now usually called aberrations, to be found in the image of a single object point. Two aberrations, field curvature and distortion, affect the position of the image point in relation to its ideal position in a flat plane; two chromatic (having to do with colour) aberrations result in displacements of the image point as the colour of the light is varied; and the remaining three aberrations (known as spherical aberration, coma, and astigmatism) are concerned with the size and shape of light patch in light of a single colour. When spherical aberration is present, rays from an object point passing through different zones of the lens come to a focus at different distances along the axis; if coma is present, the rays come to focus at different heights above the axis; and if astigmatism is present, the image of a point breaks up into two short focal lines, one being radial to the field and one tangential to it. Invariably, all three of these aberrations are present together and produce undesirable blurring of the image. Stopping the lens down to a smaller aperture (using only the central part of the lens) generally reduces the blurring, but it has little if any effect on the field curvature, distortion, or either of the chromatic aberrations.

Diffraction and resolving power. Another phenomenon that can have considerable effect on the sharpness of an image is diffraction, the slight bending of light rays around the edge of an obstacle. Because light consists of a train of waves, light rays are really only the paths along which light travels, and if a ray passes very close to the edge of an obstacle such as a diaphragm, which controls the size of the aperture opening, or a lens mount, the light is liable to bend slightly outwards and cause a blurring of the image. The magnitude of the blurring increases as the size of the lens aperture decreases, being almost negligible in a large lens but decidedly noticeable in a lens having a small opening, say less than about five millimetres (0.2 inches) in diameter. As diffraction is an inherent property of light, it cannot be eliminated by changing the structure of the lens. It must, however, be taken into account by the optical engineer when designing systems of very small aperture.

A frequently used measure of lens quality is the ability to form an image that is sharp enough to separate or "resolve" two very close dots or lines in an object. Resolving power depends on how much the various aberrations are corrected and on the diffraction of light at the rim of the lens aperture. The resolving power of a perfect telescope (expressed in seconds of arc) is about 4.5 divided by the diameter of the objective in inches, but very few astronomical telescopes are capable of resolving much less than one second of arc. The limiting factors are usually air currents and atmospheric turbulence, and not aberrations or diffraction.

Resolving power of lenses

Image brightness. A major goal in optical engineering is to achieve images that are as bright as possible. The brightness of the image of an extended object formed by a photographic lens is proportional to the brightness of the object divided by the square of the *f*-number of the lens; *i.e.*, by the square of the ratio of the focal length of the lens to its aperture, or $(2.8)^2$ for an $f/2.8$ lens. The image brightness in a telescope follows this law for an extended object such as the moon or a nebula, but for point objects such as stars the image brightness depends only on the area of the telescope objective. Thus, to see a star brightly against the continuous sky background, the telescope objective must have a large diameter and a high *f*-number, which leads to the requirement of a very long focal length.

Lens materials. Lenses are almost always made from some particular type of optical glass, although for work in the ultraviolet and infrared regions of the spectrum special crystals are used because glass is generally opaque to those wavelengths. Hundreds of different types of optical glass are manufactured today, distinguished by their ability to bend light (refractive index) and ability to separate light into different wavelengths (dispersive power). At first lenses were made from selected pieces of window glass or the glass used to make blown tableware. In the early 1800s, the manufacture of specially clear glass for lenses began in Europe. The glass was slowly stirred in the molten state to remove striations and irregularities, and then the whole mass was cooled and broken up into suitable pieces for lens making. The pieces were placed in molds of the approximate size of the lens, slowly remelted to shape, and carefully annealed; *i.e.*, allowed to cool slowly under controlled conditions. Various chemicals were added in the molten state to vary the properties of the glass: lead oxide, for example, was found to raise both the refractive index and the dispersive power. In 1884 it was discovered that barium oxide had the effect of raising the refractive index without increasing the disper-

sion, a property that proved to be of the greatest value in the design of photographic lenses known as anastigmats (no astigmatic aberration). In 1938 a further major improvement was achieved by the use of various rare-earth elements, and since 1950 lanthanum glass has been commonly used in high-quality photographic lenses.

The cost of optical glass varies considerably, depending on the type of glass, the precision with which the optical properties are maintained, the freedom from internal striae and strain, the number of bubbles, and the colour of the glass. Many common types of optical glass are now available in quite large pieces, but as the specifications of the glass become more stringent the cost rises and the range of available sizes becomes limited. In a small lens such as a microscope objective, the cost of the glass is insignificant, but in large lenses in which every millimetre of thickness may represent an additional pound in weight, the glass cost can be very high indeed (see also GLASS PRODUCTS AND PRODUCTION).

Plastic lenses

Lenses can be molded successfully of various types of plastic material, polymethyl methacrylate being the most usual. Even multi-element plastic lenses have been manufactured for low-cost cameras, the negative (concave) elements being made of a high-dispersion plastic such as styrene.

Other basic components of optical systems. These include mirrors, light sources, detectors, projection screens, reflecting prisms, dispersing devices, filters and thin films, and fibre-optics bundles.

Mirrors. Mirrors are frequently used in optical systems. Plane mirrors may be employed to bend a beam of light in another direction, either for convenience or to yield an image reversed left for right if required. Curved mirrors, concave and convex, may be used in place of lenses as image-forming elements in reflecting telescopes. All of the world's largest telescopes and many small ones are of the reflecting type. Such telescopes use a concave mirror to produce the main image, a small secondary mirror often being added to magnify the image and to place it in a convenient position for observation or photography. Telescope mirrors are commonly made parabolic or hyperbolic in section to correct the aberrations of the image. Originally telescope mirrors were made from polished "speculum metal," an alloy of copper and tin, but in 1856 Justus von Liebig, a German chemist, invented a process for forming a mirror-like layer of silver on polished glass, which was applied to telescope mirrors by the German astronomer C.A. von Steinheil. Today most mirrors are made of glass, coated with either a chemically deposited silver layer or more often one made by depositing vaporized aluminum on the surface. The aluminum surface is as highly reflective as silver and does not tarnish as readily.

A large astronomical mirror presents many problems to the optical engineer, mainly because even a distortion of a few millionths of an inch of the mirror under its own weight will cause an intolerable blurring of the image. Though many schemes for supporting a mirror without strain have been tried, including one to support it on a bag of compressed air, the problem of completely eliminating mirror distortion remains unsolved. A metal mirror, if well ribbed on the back, may be lighter than a glass mirror and therefore easier to handle, but most metals are slightly flexible and require just as careful support as glass mirrors. Since temperature changes can also cause serious distortion in a mirror, astronomers try to hold observatory temperatures as constant as possible.

Light sources. Many types of optical instruments form images by natural light, but some, such as microscopes and projectors, require a source of artificial light. Tungsten filament lamps are the most common, but if a very bright source is required, a carbon or xenon arc is employed. For some applications, mercury or other gas discharge tubes are used; a laser beam is often employed in scientific applications. Laser light is brilliant, monochromatic, collimated (the rays are parallel), and coherent (the waves are all in step with each other), any or all of these properties being of value in particular cases (see also LASER AND MASER).

Use of laser light

Detectors. The image formed by an optical system is usually received by the eye, which is a remarkably adaptable and sensitive detector of radiation within the visible region of the electromagnetic spectrum (see LIGHT). A photographic film, another widely used detector, has the advantage of yielding a permanent record of events. Since about 1925 many types of electrical detectors of radiation, both within the visible region and beyond it, have been developed. These include photoelectric cells of various kinds in which either a voltage or a resistance is modified by light falling on the device. Many new types of detector are sensitive far into the infrared spectrum and are used to detect the heat radiated by a flame or other hot object. A number of image intensifiers and converters, particularly for X-ray or infrared radiation, which have appeared since World War II, embody a radiation detector at one end of a vacuum tube and an electron lens inside the tube to relay the image on to a phosphor screen at the other end. This arrangement produces a visible picture that may be observed by eye or photographed to make a permanent record.

Television camera tubes detect real images by electronic scanning, the picture on the viewing tube being a replica of the image in the original camera. The combined application of electronics and optics has become common. An extreme example of electro-optics appears in some space cameras, in which the film is exposed, processed, and then scanned by a tiny point of light; the light passing through the film is picked up by a photocell and transmitted to earth by radio, where it is made to control the brightness of another point of light scanning a second piece of film in exact synchronism with the scanning spot in the camera. The whole system thus produces a picture on earth that is an exact replica of the picture photographed in space a few minutes earlier.

Projection screens. The simplest screen for the projection of slides or motion pictures is, of course, a matte white surface, which may be on a hard base as in outdoor theatres or on a stretched cloth indoors. A theatre screen is often perforated to transmit sound from loudspeakers placed behind it.

Improved screen materials have been developed to increase the brightness of the picture to suit the particular shape of the auditorium. A screen covered with tiny beads tends to send the light back in the general direction of the projector, and is suitable for use at one end of a long, narrow auditorium. Another type of screen is covered with fine embossed vertical grooves; this tends to distribute the light in a horizontal band across the audience with little or no vertical spread. A real advantage of these highly reflective screens is that they tend to reflect ambient room light away from the viewer as by a mirror, so that the pictures appear almost as bright and clear by day as in a darkened room.

Reflecting prisms. Reflecting prisms are pieces of glass bounded by plane surfaces set at carefully specified angles. Some of these surfaces transmit light, some reflect light, while some serve both functions in succession. A prism is thus an assembly of plane reflectors at relatively fixed angles, which are traversed in succession by a beam of light.

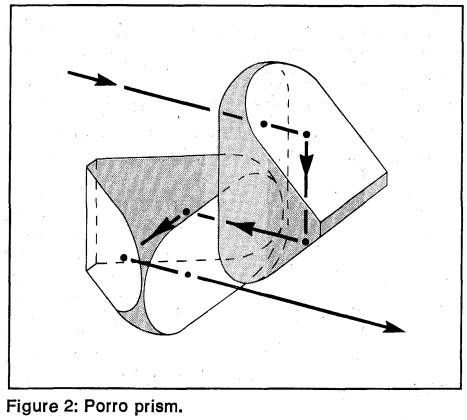

Figure 2: Porro prism.

Prism binoculars

The simplest prism is a triangular block of glass with two faces at right angles and one at an angle of 45°. The face at 45° deflects a beam of light through a right angle. The common Porro prism used in a pair of binoculars contains four 45° reflecting surfaces, two to reverse the beam direction in the vertical plane and two in the horizontal plane (Figure 2). These reflecting faces could be replaced by pieces of mirror mounted on a metal frame, but it is hard to hold mirrors rigidly and harder still to keep them clean. Some microscopes are equipped with a 45° deflection prism behind the eyepiece; this prism may provide two or three reflections depending on the type of image inversion or left-for-right reversal required.

Prisms containing a semireflecting, semitransmitting surface are known as beam splitters and as such have many uses. An important application is found in some colour television cameras, in which the light from the lens is divided by two beam splitters in succession to form red, green, and blue images on the faces of three image tubes in the camera.

Dispersing devices. There are two forms of dispersing element used to spread out the constituent colours of a beam of light into a "spectrum," namely a prism and a grating. The prism, known to Newton, is the older; it separates the colours of the spectrum because the refractive index of the glass is lowest for red light and progressively increases through the yellow and green to the blue, where it is highest. Prism spectroscopes and spectrographs are made in a variety of forms and sizes, but in all cases the blue end of the spectrum is greatly spread out while the red end is relatively compressed.

A diffraction grating is a ruled mirror or transparent plate of glass having many thousands of fine parallel grooves to the inch. It separates the colours of the spectrum by a process of diffraction. Each groove diffracts, or scatters, light in all directions, and in the case of light of one particular wavelength, there will be one direction in which the light wave from one groove lags behind the light wave from the next groove by precisely one or more whole wavelengths. This results in a strong beam of diffracted light in that direction and darkness in all other directions. Since each spectral colour corresponds to a different wavelength, the grating spreads out the spectrum into a fan where it can be observed or photographed. The red rays are bent most and the blue rays least, the opposite of the situation with a prism.

Although a prism or grating is the essential dispersing element in a spectrograph, a fine slit and additional lenses or focussing mirrors must be used to form a sharply defined spectrum. Prism spectroscopes are, of course, limited to those wavelengths for which the prism material is transparent; a reflecting grating can be used for any wavelength that the material will reflect.

Filters and thin films. A colour filter is a sheet of transparent material that modifies a light beam by selective absorption of some colours in relation to others. A neutral filter absorbs all wavelengths equally and merely serves to reduce the intensity of a beam of light without changing its colour.

Filters may be made from sheets of coloured glass, plastic, or dyed gelatin, and in some cases glass cells filled with liquid have been used. Since World War II, another type of filter depending on the interference of light has been developed in which one or more metallic or other types of films of controlled thickness have been deposited on a glass plate, the layers being so thin as to cause selective interference of some wavelengths in relation to others and thus act as a nonabsorbing filter. In this case the rejected colours are reflected instead of being absorbed.

Polarizing filters have the property of transmitting light that vibrates in one direction while absorbing light that vibrates in a perpendicular direction. These filters are used extensively in scientific instruments. In sunglasses and when placed over a camera lens, polarizing filters reduce unwanted reflections from nonmetallic surfaces. Polarizing spectacles have been used to separate the left-eye and right-eye beams in the projection of stereoscopic pictures or movies.

Fibre-optics bundles. A thin rod or fibre of glass or other transparent material transmits light by repeated internal reflections, even when the rod is somewhat curved. An ordered bundle of rods or fibres is thus capable of taking an image projected upon one end of the bundle and reproducing it at the other end. A fibre-optics bundle can be fused together into a rigid channel, or it may be left flexible, only the ends being rigidly fastened together. A flexible fibre bundle has many uses, especially in medical instruments. Because it is exceedingly delicate, however, it must be handled with care; breaking a fibre would cause a black dot to appear in the reproduced image.

Lens design. The preliminary layout of a new optical instrument consists of a number of lenses, mirrors, prisms, and other optical components forming together the basic conception of an optical system that will produce the desired image at the specified location. At this stage lenses are defined merely by their focal length, diameter, and field to be covered. The lens designer must take each item in turn and work out a precise "formula" for manufacture. A lens formula consists of a list of lens elements with their surface curvatures, thicknesses, diameters, and separations, with tolerances, and the types of glass to be used. An indication of the anticipated image quality, expressed in terms of some well-understood graphs or figures, is often included.

The process of lens design begins with the choice of a promising starting point. Company records or patent files are helpful, but if the system is totally novel, the designer relies on his own experience and imagination. Having selected a suitable starting lens, the designer must evaluate it very carefully within the limitations of his particular problem. Thus, for example, the lens may have to cover an angular field of $\pm 20°$ at an aperture of $f/6$ using red light, with a very distant object, or it may have to work at unit (one-to-one) magnification, in white light. Whatever the circumstances, the designer will trace a number of rays from each of several object points by accurate trigonometrical formulas, working to 7 decimal places and expressing angles to less than one second of arc, to see how closely the various rays come together in the focal plane after passing through the lens. The departures of the rays from their ideal meeting point are subdivided for convenience into their specific aberrations, which he will tabulate.

Minimizing aberrations

The next problem is to decide what changes to make in the structure of the lens to reduce the aberrations to a minimum. Any single change in any lens parameter, be it a surface curvature, thickness, airspace, or refractive index, will change all the aberrations and will probably make some of them better and some worse. Therefore it is necessary to make several changes simultaneously if several aberrations are to be reduced together. An experienced designer with a good background in optical theory will often know what changes should be made, but if not, he will make a small change in each parameter separately to determine the effect of this change on each aberration and assemble a table of coefficients, or rate-of-change factors. Knowing what changes are required in each of the various aberrations, the designer can then draw up a set of simultaneous equations, and by solving them he can ascertain what changes should be made in each of the variables in the system. Unfortunately, these changes will not eliminate all the aberrations, because having changed the first curvature, the rays will travel along a different path, and all subsequent coefficients will be in error. For this reason, the designer makes a small fraction of the indicated changes and then recomputes the coefficients and repeats the process.

When working by hand, using logarithms or a desk calculator, a designer becomes remarkably familiar with a particular lens and soon knows what to expect from a given change or series of changes. He therefore does not have to compute all the coefficients every time and can make various shortcuts. The designer keeps watch over many other factors. He may decide, for instance, to maintain the focal length by appropriate changes in the last surface curvature, and he watches the length of the sys-

tem and the diameters and thicknesses of the individual elements to prevent them from becoming unduly large. He also watches how the oblique light beams are trimmed down by the end apertures of the lens and strives to keep the loss of light by this "vignetting" from becoming excessive.

In the early 1950s small electronic computers became available, and lens designers were among the first to make use of them. As a result, the time taken to trace one ray through one refracting surface was reduced from about three minutes to perhaps one second. The computer also brought relief from the deadening labour of hand calculations. Soon lens designers began to think that it might be possible for the computer to do much more than merely trace rays. This hope was realized within less than ten years, and by 1965 it was possible for a very large computer to go through all the steps performed by a human designer, solving the simultaneous equations and changing every lens parameter in such a way as to improve the definition to the greatest possible degree. Furthermore, most computer programs take into consideration such matters as vignetting, focal length, lens size, and the thicknesses of the elements—even for a zoom lens or an enlarging lens that must function properly over a wide range of magnifications. Lenses designed by means of high-speed lens-improvement computer programs are much better than those designed by hand only a few years earlier.

When using a large computer the old well-known "aberrations" are often ignored, and the behaviour of a trial lens is expressed by the shape of the wave front emerging from the rear of the lens. In a perfect lens the emerging wave front would be a sphere centred about the ideal image position in the focal plane, and any departure of the actual wave front from this ideal sphere represents a degree of imperfection in the lens, and hence an "aberration." Aberrations expressed in this way are often easier to handle in a computer than the classical ray aberrations.

THE MANUFACTURE AND TESTING OF OPTICAL PARTS

The traditional processes of lens and prism manufacture are still regularly employed, and indeed the only major innovation since the 1920s is the use of diamond milling, which makes it possible to generate rapidly a close approximation to a required form, be it a lens, mirror, or prism.

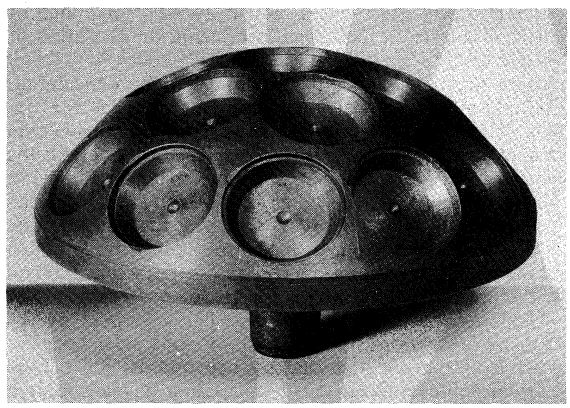

Figure 3: A recessed block to hold several lenses during smoothing and polishing.

Process of lens polishing

Grinding and polishing. Lens surfaces are ground on an iron tool, either flat or suitably curved, using progressively finer grades of wet emery or carborundum powder as abrasives. A number of fine-ground lens blanks are then mounted with pitch on a block (Figure 3) so that they can be polished together. The polishing tool is covered with a thin layer of pitch, wax, or even coarse cloth. Wet rouge or certain other mineral oxides are used as polishing materials. The polishing of glass is a slow process, requiring lenses to be oscillated back and forth, sometimes for hours, against the rotating polisher. Fairly high pressure is used. When both sides of the lens have been polished, it is held between two concentric metal cups by which the lens can be rotated about its optical axis while the edge is ground to size. If a compound objective is being manufactured, several single lenses must be mounted together in a precise coaxial arrangement; the thicknesses, separations, and centring must be kept very close to the prescribed values or the aberration corrections laboriously determined by the lens designer will not be realized.

The lens designer, with his high-speed computer, can be of great assistance to the manufacturer by providing him with a "change table," which indicates numerically how each aberration or other property of a lens changes as a result of small errors in the realization of each constructional parameter. By intelligent use of this table, together with data on the effects of a slight tilting of each surface, it is possible to establish an exact tolerance for every dimension of a lens, thus indicating to the maker just where he must take extra care and where such care is not needed. Refractive index tolerances, for example, indicate whether regular grades of optical glass can be used or whether it is necessary to purchase the glass first and then complete the design using the refractivity data on the particular glasses that will be used. The tilt coefficients indicate which are the more sensitive surfaces requiring support by a rigid ring in the mount and which are the less sensitive surfaces that may be held by other methods.

The standard processes of lens manufacture can be used to generate spherical surfaces with great accuracy, but there are many circumstances in which a nonspherical or aspheric surface is desirable, as for instance the parabolic mirror in a telescope. In spite of the efforts of many inventors, it is still virtually impossible to generate an aspheric surface by machine, and all precise aspheric lenses require a greater or lesser amount of handwork in their manufacture, making them very expensive to produce.

Cylindrical surfaces can be polished by surface contact like spheres, provided relative rotation is prevented between the work and the polisher. Such surfaces are used in lenses for wide-screen motion picture photography and projection and other applications in which the image magnification is required to be different in two perpendicular directions. The surfaces on spectacle lenses are often toric, like the outer face of a curtain ring or doughnut. These are generated by special machines and polished with a soft polisher capable of readily following whatever surface has been generated on the blank. Frequently an antireflective coating is applied to the surfaces of lens elements to reduce the amount of light that is lost by reflections.

Lens testing. A spherical lens surface is checked during manufacture by laying an oppositely polished surface on it—*i.e.*, concave on convex—and observing the interference colours formed in the thin air layer between them. A perfect fit is indicated by a single uniform colour, while any difference between the test-glass surface and the surface being polished is shown by the presence of a pattern of concentric coloured bands known as "Newton's Rings." These may be circular if there is only a difference of surface curvature, but they will be looped or irregular if the lens surface is even slightly non spherical. Aspheric surfaces could be tested in this way also, but the difficulty of making an opposite aspheric surface with sufficient accuracy is almost prohibitive.

After assembly the lens is tested by using it to form an image of a point source or other suitable test object. The image is examined through a microscope. If the lens is intended for photography, test photographs are made of an extended array of critical test charts assembled on a flat wall. A careful determination of the resolving power of the lens, in terms of how many lines per millimetre can be distinctly separated in the image, is often used to give a numerical value to the lens performance.

A more recent numerical test is based on the determination of the "modulation transfer function" of the lens at various points in the field. The test object here is a num-

ber of bar charts at progressively smaller spacing. The lens being tested is used to form an image of these charts, and a fine slit with a photoelectric cell behind it is made to traverse the images and measure the contrast; *i.e.*, the relative brightness of the dark bars and the bright spaces between them. The image contrast so determined is plotted on the vertical axis of a graph against the line spacing as horizontal axis. This graph represents the lens performance in a very complete and comprehensive way. Since about 1965 it has been possible to compute the theoretical modulation transfer function curve of a lens from the design data alone, and this has provided an excellent means for ascertaining whether the design is good enough for the particular purpose, and whether the lens has been made exactly according to formula.

Another more sophisticated test is to place the lens in one arm of an interferometer, with a convex spherical mirror behind the lens to send the light rays back through the lens along their original paths. The emerging wave front is then made to interfere with the incident light waves and produce an interference pattern that is a contour map of the wave front itself. Considerable experience is required to enable the operator to interpret the pattern he sees in this kind of test and to correlate the observations with more direct measures of lens performance.

Optics, Principles of

Originally, the term optics was used only in relation to the eye and vision. Later, as lenses and other devices for aiding vision began to be developed, these were naturally called optical instruments, and the meaning of the term optics eventually became broadened to cover any application of light, even though the ultimate receiver is not the eye but a physical detector, such as a photographic plate or a television camera. Within the present century optical methods have been applied extensively to regions of the electromagnetic radiation spectrum not visible to the eye, such as X-rays, ultraviolet, infrared, and microwave radio waves, and to this extent these regions are now often included in the general field of optics.

In the present article the image-forming properties of lenses, mirrors, and other devices that make use of light will be considered. For a survey of the design of lenses and optical instruments see OPTICAL ENGINEERING. The wave and quantum nature of light, its velocity, wavelength, polarization, diffraction, and interference may be found in LIGHT. The interrelations between light and electricity, which are involved in light sources and detectors, are treated under ELECTRON TUBE; TELEVISION. The analysis of light into its component colours by prisms and gratings forms the basis of the extensive field of spectroscopy (see SPECTROSCOPY, PRINCIPLES OF); whereas the reception of light by the retina of the eye and the interpretation of images by the brain constitute the subjects of the articles EYE AND VISION, HUMAN; PHOTORECEPTION.

An optical image may be regarded as the apparent reproduction of an object by a lens or mirror system, employing light as a carrier. An entire image is generally produced simultaneously, as by the lens in a camera, but images may also be generated sequentially by point-by-point scanning, as in a television system or in the radio transmission of pictures across long distances in space. Nevertheless, the final detector of all images is invariably the human eye, and, whatever means is used to transmit and control the light, the final image must either be produced simultaneously or scanned so rapidly that the observer's persistence of vision will give him the mental impression of a complete image covering a finite field of view. For this to be effective the image must be repeated (as in motion pictures) or scanned (as in television) at least 40 times a second to eliminate flicker or any appearance of intermittency.

The optical image

The content of this article is represented by the following outline:

I. Geometrical optics

HISTORICAL BACKGROUND

To the ancients, the processes of image formation were full of mystery. Indeed, for a long time there was a great discussion as to whether, in vision, something moved from the object to the eye or whether something reached out from the eye to the object. By the beginning of the 17th century, however, it was known that rays of light travel in straight lines, and in 1604 Johannes Kepler, a German astronomer, published a book on optics in which he postulated that an extended object could be regarded as a multitude of separate points, each point emitting rays of light in all directions. Some of these rays would enter a lens, by which they would be bent around and made to converge to a point, the "image" of the object point whence the rays originated. The lens of the eye was not different from other lenses, and it formed an image of external objects on the retina, producing the sensation of vision.

There are two main types of image to be considered: real and virtual. A real image is formed outside the system, where the emerging rays actually cross; such an image can be caught on a screen or piece of film and is the kind of image formed by a slide projector or in a camera. A virtual image, on the other hand, is formed inside an instrument at the point where diverging rays would cross if they were extended backward into the instrument. Such an image is formed in a microscope or telescope and can be seen by looking into the eyepiece.

Kepler's concept of an image as being formed by the crossing of rays was limited in that it took no account of possible unsharpness caused by aberrations, diffraction, or even defocussing. In 1957 the Italian physicist Vasco Ronchi went the other way and defined an image as any recognizable nonuniformity in the light distribution over a surface such as a screen or film; the sharper the image, the greater the degree of nonuniformity. Today, the concept of an image often departs from Kepler's idea that an extended object can be regarded as innumerable separate points of light, and it is sometimes more convenient to regard an image as being composed of overlapping patterns of varying frequencies and contrasts; hence, the quality of a lens can be expressed by a graph connecting the spatial frequency of a parallel line object with the contrast in the image. This concept is investigated fully under *Optics and information theory* below.

Optics had progressed rapidly by the early years of the

Lens theories

19th century. Lenses of moderately good quality were being made for telescopes and microscopes, and in 1841 the great mathematician, Karl Friedrich Gauss, published his classical book on geometrical optics. In it he expounded the concept of the focal length and cardinal points of a lens system and developed formulas for calculating the position and size of the image formed by a lens of given focal length. Between 1852 and 1856 Gauss's theory was extended to the calculation of the five principal aberrations of a lens (see below), thus laying the foundation for the formal procedures of lens design that were used for the next 100 years. Since about 1960, however, lens design has been almost entirely computerized, and the old methods of designing lenses by hand on a desk calculator are rapidly disappearing.

By the end of the 19th century numerous other workers had entered the field of geometrical optics, notably an English physicist, Lord Rayleigh (John William Strutt), and a German physicist, Ernst Karl Abbe. It is impossible to list all their accomplishments here. Since 1940 there has been a great resurgence in optics on the basis of information and communication theory, which is treated at length below.

Light rays, waves, and wavelets. A single point of light, which may be a point in an extended object, emits light in the form of a continually expanding train of waves, spherical in shape and centred about the point of light. It is, however, often much more convenient to regard an object point as emitting fans of rays, the rays being straight lines everywhere perpendicular to the waves. When the light beam is refracted by a lens or reflected by a mirror, the curvature of the waves is changed, and the angular divergence of the ray bundle is similarly changed in such a way that the rays remain everywhere perpendicular to the waves. When aberrations are present, a convergent ray bundle does not shrink to a perfect point, and the emerging waves are then not truly spherical.

In 1690 Christiaan Huygens, a Dutch scientist, postulated that a light wave progresses because each point in it becomes the centre of a little wavelet travelling outward in all directions at the speed of light, each new wave being merely the envelope of all these expanding wavelets. When the wavelets reach the region outside the outermost rays of the light beam, they destroy each other by mutual interference wherever a crest of one wavelet falls upon a trough of another wavelet. Hence, in effect, no waves or wavelets are allowed to exist outside the geometrical light beam defined by the rays. The normal destruction of one wavelet by another, which serves to restrict the light energy to the region of the rectilinear ray paths, however, breaks down when the light beam strikes an opaque edge, for the edge then cuts off some of the interfering wavelets, allowing others to exist, which diverge slightly into the shadow area. This phenomenon is called diffraction, and it gives rise to a complicated fine structure at the edges of shadows and in optical images (see LIGHT).

The pinhole camera. An excellent example of the working of the wavelet theory is found in the well-known pinhole camera. If the pinhole is large, the diverging geometrical pencil of rays leads to a blurred image, because each point in the object will be projected as a finite circular patch of light on the film. The spreading of the light at the boundary of a large pinhole by diffraction is slight. If the pinhole is made extremely small, however, the geometrical patch then becomes small, but the diffraction spreading is now great, leading once more to a blurred picture. There are thus two opposing effects present, and at the optimum hole size the two effects are just equal. This occurs when the hole diameter is equal to the square root of twice the wavelength (λ) times the distance (f) between the pinhole and film—*i.e.*, $\sqrt{2\lambda f}$. For $f = 100$ millimetres and $\lambda = 0.0005$ millimetre, the optimum hole size becomes 0.32 millimetre. This is not very exact, and a 0.4-millimetre hole would probably be just as good in practice. A pinhole, like a camera lens, can be regarded as having an f-number, which is the ratio of focal length to aperture. In this example, the f-number is 100/0.32=310, designated $f/310$. Modern camera lenses have much greater apertures, in order to achieve light-gathering power, of around $f/1.2$–$f/5.6$

Resolution and the Airy disk. When a well-corrected lens is used in place of a pinhole, the geometrical ray divergence is eliminated by the focussing action of the lens, and a much larger aperture may be employed; in that case the diffraction spreading becomes small indeed. The image of a point formed by a perfect lens is a minute pattern of concentric and progressively fainter rings of light surrounding a central dot, the whole structure being called the Airy disk after George Biddell Airy, an English astronomer, who first explained the phenomenon in 1834. The Airy disk of a practical lens is small, its diameter being approximately equal to the f-number of the lens expressed in microns (0.001 millimetre). The Airy disk of an $f/4.5$ lens is therefore about 0.0045 millimetre in diameter (ten times the wavelength of blue light). Nevertheless, the Airy disk formed by a telescope or microscope objective can be readily seen with a bright point source of light if a sufficiently high eyepiece magnification is used.

Airy disk

The finite size of the Airy disk sets an inevitable limit to the possible resolving power of a visual instrument. Rayleigh found that two adjacent and equally bright stars can just be resolved if the image of one star falls somewhere near the innermost dark ring in the Airy disk of the other star; the resolving power of a lens can therefore be regarded as about half the f-number of the lens expressed in microns. The angular resolution of a telescope is equal to the angle subtended by the least resolvable image separation at the focal length of the objective, the light-gathering lens. This works out at about four and a half seconds of arc divided by the diameter of the objective in inches.

The Rayleigh limit. As noted above, when a perfect lens forms an image of a point source of light, the emerging wave is a sphere centred about the image point. The optical paths from all points on the wave to the image are therefore equal, so that the expanding wavelets are all in phase (vibrating in unison) when they reach the image. In an imperfect lens, however, because of the presence of aberrations, the emerging wave is not a perfect sphere, and the optical paths from the wave to the image point are then not all equal. In such a case some wavelets will reach the image as a peak, some as a trough, and there will be much destructive interference leading to the formation of a sizable patch of light, much different from the minute Airy disk characteristic of a perfectly corrected lens. Lord Rayleigh in 1879 studied the effects of phase inequalities in a star image and came to the conclusion that an image will not be seriously degraded unless the path differences between one part of the wave and another exceed one-quarter of the wavelength of light. As this difference represents only 0.125 micron (5×10^{-6} inch), it is evident that an optical system must be designed and constructed with almost superhuman care if it is to give the best possible definition.

REFLECTION AND REFRACTION

Reflection. The use of polished mirrors for reflecting light has been known for thousands of years, and concave mirrors have long been used to form real images of distant objects. Indeed, Isaac Newton (died 1727) greatly preferred the use of a mirror as a telescope objective to the poor-quality lenses available in his time. Because there is no limit to the possible size of a mirror, all large telescopes today are of this type.

When a ray of light is reflected at a polished surface, the angle of reflection between ray and normal (the line at right angles to the surface) is exactly equal to the angle of incidence. It can be seen that a convex mirror forms a virtual image of a distant object, whereas a concave mirror forms a real image. A plane mirror forms a virtual image of near objects, as in the familiar looking glass. Plane mirrors are often used in instruments to bend a beam of light into a different direction.

Law of reflection

The law of refraction. When a ray of light meets the surface of separation between two transparent media, it is sharply bent or refracted. Because rays are really only directions and have no physical existence, the passage of

light waves through a surface must be considered if refraction is to be understood. Refraction effects are based on the fact that light travels more slowly in a denser medium. The ratio of the velocity of light in air to its velocity in the medium is called the refractive index of the medium for light of a particular colour or wavelength. The refractive index is higher for blue light than for light at the red end of the spectrum.

In Figure 1, AA' represents a plane wave of light at the instant that A' meets the plane refracting surface $A'B$ separating two media having refractive indices n and n',

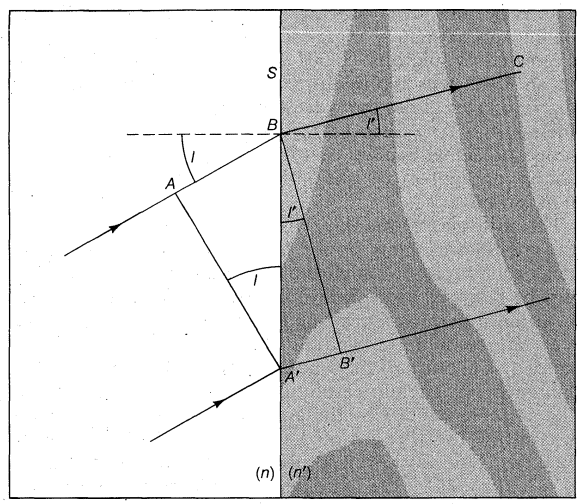

Figure 1: The law of refraction. Plane light wave at position AA' in medium of index n and BB' in medium of index n' (see text).

respectively. During the time taken by the light to travel from A to B in material n, light travels from A' to B' in material of refractive index n', forming the new wave BB' in the second material, proceeding in direction BC. Hence, the relationship $n'/n = AB/A'B'$ can be obtained; and dividing numerator and denominator by BA' gives

$$\frac{n'}{n} = \frac{AB/BA'}{A'B'/BA'} = \frac{\sin I}{\sin I'} \quad . \qquad (1)$$

The angles I and I' are called the angle of incidence and angle of refraction between the refracting surface and the incident and refracted waves, respectively.

Returning now to the convention of considering the movement of light in terms of rays because entering and emerging rays are always perpendicular to the light waves they represent, angles I and I' also denote the angles between the entering and emerging rays and the normal (perpendicular) line to the refracting surface at B.

Equation (1), known as the law of refraction, is generally written: $n' \sin I' = n \sin I$.

Dispersion. The difference between the refractive indices of a transparent material for a specific blue light and a specific red light is known as the dispersion of the material. The usual choices of blue and red lights are the so-called "F" and "C" lines of hydrogen in the solar spectrum, named by Fraunhofer, with wavelengths 4861 and 6563 angstroms (the angstrom unit, abbreviated Å, is 10^{-8} centimetre), respectively. It is generally more significant, however, to compare the dispersion with the mean refractive index of the material for some intermediate colour such as the sodium "D" Fraunhofer line of wavelength 5893 angstroms. The dispersive power (w) of the material is then defined as the ratio of the difference between the "F" and "C" indices and the "D" index reduced by 1, or,

Dispersive power

$$w = \frac{n_F - n_C}{n_D - 1} \quad .$$

Hundreds of different types of optical glass are currently available from manufacturers. These may be represented graphically on a plot of mean refractive index against dispersive power (Figure 2).

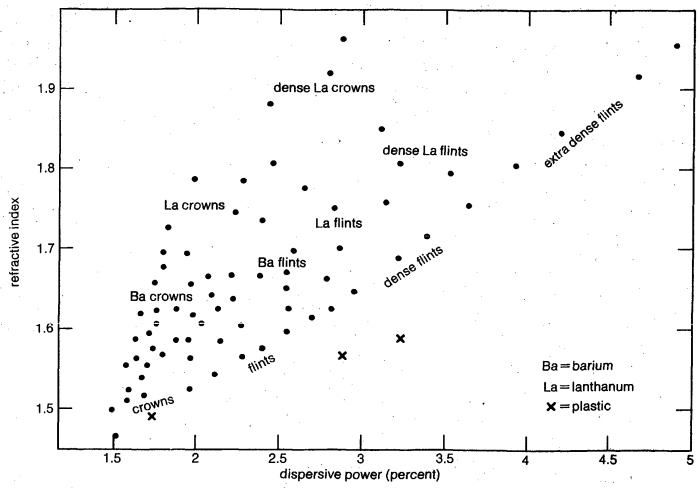

Figure 2: Some representative optical glasses and plastics, showing their refractive indices versus dispersive powers (see text).

Glasses of low dispersive power (less than 0.02) are commonly called crowns, while those of higher dispersion are called flints. These names are a relic of the early types of glass that were manufactured for windows and fine table glassware, respectively. The wide range of types now available is a tremendous help to the lens designer, although his choice is sometimes limited by the high cost of the more extreme types.

Since World War II there has been increasing use of plastic materials in the manufacture of lenses. These substances are especially advantageous for large single lenses in which glass would be excessively heavy, for spectacles when weight and brittleness are important, and since 1957 for small camera lenses in which the demands of high precision combined with low manufacturing cost can be readily met by injection molding.

Total internal reflection. When a ray of light emerges obliquely from glass into air, the angle of refraction between ray and normal is greater than the angle of incidence inside the glass, and at a sufficiently high obliquity the angle of refraction can actually reach 90°. In this case the emerging ray travels along the glass surface, and the sine of the angle of incidence inside the glass, known as the critical angle, is then equal to the reciprocal of the refractive index of the material. At angles of incidence greater than the critical angle, the ray never emerges, and total internal reflection occurs, for there is no measurable loss if the glass surface is perfectly clean. Dirt or dust on the surface can cause a small loss of energy by scattering some light into the air.

Light is totally internally reflected in many types of reflecting prism (see OPTICAL ENGINEERING) and in recently developed fibre optics technology. Long fibres of high-index glass clad with a thin layer of lower index glass are assembled side-by-side in precise order, and light admitted into one end of each fibre is transmitted along it without loss by thousands of successive internal reflections at the interlayer between the glass and the cladding. Hence, an image projected upon one end of the bundle will be dissected and transmitted to the other end, where it can be examined through a magnifier or photographed. Many modern medical instruments, such as cystoscopes and bronchoscopes, depend for their action on this principle. Single thick fibres (actually glass rods) are sometimes used to transmit light around corners to an otherwise inaccessible location.

RAY-TRACING METHODS

Graphical ray-tracing. In 1621 Willebrord Snell, a professor of mathematics at Leiden, discovered a simple graphical procedure for determining the direction of the refracted ray at a surface when the incident ray is given. The mathematical form of the law of refraction, equation (1) above, was announced by the French mathematician René Descartes some 16 years later.

Snell's construction

Snell's construction is as follows: The line AP in Figure 3A represents a ray incident upon a refracting surface at P, the normal at P being PN. If the incident and refracted rays are extended to intersect any line SS parallel to the normal, the lengths PQ and PR along the rays will be

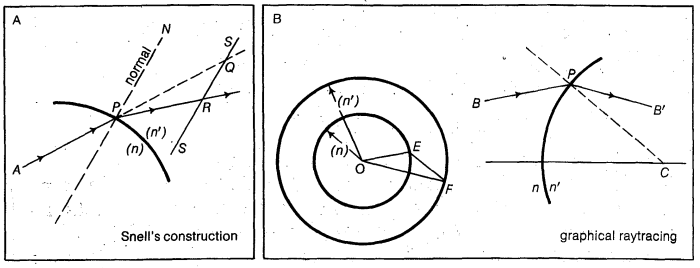

Figure 3: Graphic refraction procedures (see text).

proportional to the refractive indices n and n'. Hence, if PQ and the indices are known, PR can be found and the refracted ray drawn in.

A convenient modification of Snell's construction can readily be used to trace the path of a ray through a complete lens. In Figure 3B, the incident ray BP strikes a refracting surface at P. The normal to the surface is PC. At any convenient place on the page two concentric circles are drawn about a point O with radii proportional to the refractive indices n and n', respectively. A line OE is now drawn parallel to the incident ray BP extending as far as the circle representing the refractive index n of the medium containing the incident ray. From E a line is drawn parallel to the normal PC extending to F on the circle representing the refractive index n'. The line OF then represents the direction of the desired refracted ray, which may be drawn in at PB'. This process is repeated successively for all the surfaces in a lens. If a mirror is involved, the reflected ray may be found by drawing the normal line EF across the circle diagram to the incident-index circle on the other side.

Trigonometrical ray-tracing. No graphical construction can possibly be adequate to determine the aberration residual of a corrected lens, and for this an accurate trigonometrical computation must be made and carried out to six or seven decimal places, the angles being determined to single seconds of arc or less. There are many procedures for calculating the path of a ray through a system of spherical refracting or reflecting surfaces, the following being typical: The diagram in Figure 4 repre-

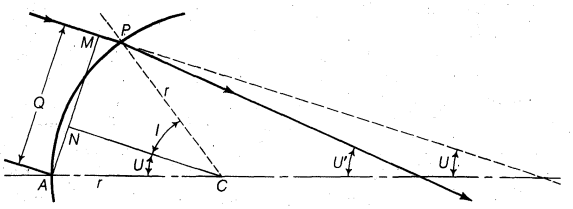

Figure 4: Trigonometrical ray-tracing (see text).

sents a ray lying in the meridian plane, defined as the plane containing the lens axis and the object point. A ray in this plane is defined by its slope angle, U, and by the length of the perpendicular, Q, drawn from the vertex (A) of the surface on to the ray. By drawing a line parallel to the incident ray through the centre of curvature C, to divide Q into two parts at N, the relation is stated as $AN = r \sin U$, and $NM = r \sin I$. Hence

$$Q = r(\sin U + \sin I). \tag{2}$$

From this the first ray-tracing equation can be derived,

$$\sin I = \frac{Q}{r} - \sin U. \tag{3a}$$

Applying the law of refraction, equation (2), gives the second equation

$$\sin I' = \frac{n}{n'} \sin I. \tag{3b}$$

Because the angle $PCA = U + I = U' + I'$, the slope of the refracted ray can be written as

$$U' = U + I - I'; \tag{3c}$$

and, lastly, by adding primes to equation (2),

$$Q' = r(\sin U' + \sin I').$$

Having found the Q' of the refracted ray, transfer to the next surface can be performed by

$$Q_2 = Q_1' - d \sin U_1',$$

in which d is the axial distance from the first to the second refracting surface. After performing this calculation for all the surfaces in succession, the longitudinal distance from the last surface to the intersection point of the emergent ray with the lens axis is found by

$$L' = \frac{Q'}{\sin U'}.$$

Corresponding but much more complicated formulas are available for tracing a skew ray, that is, a ray that does not lie in the meridian plane but travels at an angle to it. After refraction at a surface, a skew ray intersects the meridian plane again at what is called the diapoint. By tracing the paths of a great many (100 or more) meridional and skew rays through a lens, with the help of an electronic computer, and plotting the assemblage of points at which all these rays pierce the focal plane after emerging from the lens, a close approximation to the appearance of a star image can be constructed, and a good idea of the expected performance of a lens can be obtained.

PARAXIAL, OR FIRST-ORDER, IMAGERY

Paraxial rays

In a lens that has spherical aberration, the various rays from an axial object point will in general intersect the lens axis at different points after emerging into the image space. By tracing several rays entering the lens at different heights (*i.e.*, distances from the axis) and extrapolating from a graph connecting ray height with image position, it would be possible to infer where a ray running very close to the axis (a paraxial ray) would intersect the axis, although such a ray could not be traced directly by the ordinary trigonometrical formulas because the angles would be too small for the sine table to be of any use. Because the sine of a small angle is equal to the radian measure of the angle itself, however, a paraxial ray can be traced by reducing the ray-tracing formulas to their limiting case for small angles and thus determining the paraxial intersection point directly. When this is done, writing paraxial-ray data with lowercase letters, it is found that the Q and Q' above both become equal to the height of incidence y, and the formulas (3a), (3b), and (3c) become, in the paraxial limit:

$$i = \frac{y}{r} - u \tag{4a}$$

$$i' = \frac{n}{n'} i \tag{4b}$$

$$u' = u + i - i'. \tag{4c}$$

The longitudinal distance from the last surface to the intersection point of the emerging paraxial ray with the lens axis becomes $l' = y/u'$.

Because all paraxial rays from a given object point unite at the same image point, the resulting longitudinal distance (l') is independent of the particular paraxial ray that is traced. Any nominal value for the height of incidence, y, may therefore be adopted, remembering that it is really an infinitesimal and y is only its relative magnitude. Thus, it is clear that the paraxial angles in equation (4) are really only auxiliaries, and they can be readily eliminated, giving the object–image distances for paraxial rays:

$$n'(l' - r)u' = n(l - r)u \tag{5}$$

and

$$\frac{n'}{l'} = \frac{n}{l} + \frac{n' - n}{r}. \tag{6}$$

Magnification: the optical invariant. It is frequently as important to determine the size of an image as it is to

determine its location. To obtain an expression for the magnification—that is, the ratio of the size of an image to the size of the object—the following process may be used: If an object point B lies to one side of the lens axis at a transverse distance h from it, and the image point B' is at a transverse distance h', then B, B', and the centre of curvature of the surface, C, lie on a straight line called the auxiliary axis. Then, by simple proportion,

$$m=\frac{h'}{h}=\frac{l'-r}{l-r}=\frac{nu}{n'u'}.$$

Hence,

$$h'n'u' = hnu, \qquad (7)$$

Lagrange theorem

and the product (hnu) is invariant for all the spaces between the lens surfaces, including the object and image spaces, for any lens system of any degree of complexity. This theorem has been named after the French scientist Joseph-Louis Lagrange, although it is sometimes called the Smith–Helmholtz theorem, after Robert Smith, an English scientist, and Hermann Helmholtz, a German scientist; the product (hnu) is often known as the optical invariant. As it is easy to determine the quantities h, n, and u for the original object, it is only necessary to calculate u' by tracing a paraxial ray in order to find the image height h' for any lens. If the lens is used in air, as most lenses are, the refractive indices are both unity, and the magnification becomes merely $m = u/u'$.

The Gauss theory of lenses. In 1841 Gauss published a now famous treatise on optics in which he demonstrated that, so far as paraxial rays are concerned, a lens of any degree of complexity can be replaced by two principal, or nodal, points and two focal points, the distances from the principal points to their respective focal points being the focal lengths of the lens, and, furthermore, that the two focal lengths are equal to one another when the refractive indices of object and image spaces are equal, as when a lens is used in air.

The principal and focal points may be defined as follows: Figure 5 shows a lens system of any construction, with a bundle of rays entering from the left in a direction

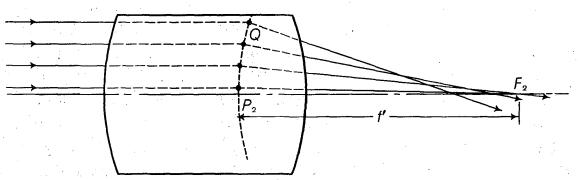

Figure 5: The Gauss theory (see text).

parallel to the lens axis. After refraction by the lens each ray will cross the axis at some point, and the entering and emerging portions of each ray are then extended until they intersect at a point such as Q. The locus of all the points Q is a surface of revolution about the lens axis known as the equivalent refracting locus of the lens. The point where this locus crosses the axis is called the principal point, P_2, and the central portion of the locus in the neighbourhood of the axis, which is virtually a plane perpendicular to the axis, is called the principal plane. The point where the emerging paraxial ray crosses the axis is called the focal point F_2, the distance from P_2 to F_2 being the (posterior) focal length f'. A similar situation exists for a parallel beam of light entering from the right, giving the anterior principal point P_1, the anterior focal point F_1, and the front focal length f. For a lens in air it can be shown that the two focal lengths are equal in magnitude but opposite in direction—*i.e.*, if F_2 is to the right of P_2, then F_1 must lie to the left of P_1, as in the case of an ordinary positive lens (one that gives a real image). In a negative lens (one that gives a virtual image), F_2 lies to the left of P_2, and the posterior focal length f' is negative.

The relation between the distances of object and image from a lens can be easily stated if the positions of the two principal points and the two focal points are known. (In using these expressions, distances are considered positive or negative depending on whether they are measured to the right or to the left from their respective origins.) For a lens in air: (a) If the conjugate distances measured from the respective focal points are x and x', and if m is the image magnification (height of image divided by height of object), then $m = -x'/f' = f'/x$ and $xx' = -f'^2$. (b) If the conjugate distances measured from the respective principal points are p and p' and if m is the image magnification, then $m = p'/p$ and $1/p' = 1/p + 1/f'$. The Lagrange equation (7) requires modification for a distant object because in that case the object height h is infinite, and the slope angle u is zero. If the off-axis distance h is divided by the object distance L, and u is multiplied by L, equation (7) becomes $h' = (n/n')f'\phi$, in which ϕ is the angle in radians subtended by the distant object at the lens. This formula provides a means for defining focal length and for measuring the focal length of an unknown lens.

Determination of focal length

The thin lens. In a thin lens such as a spectacle, the two principal planes coincide within the lens, and then the conjugate distances p and p' in the formula above become the distances of object and image from the lens itself.

The focal length of a thin lens can be computed by applying the surface-conjugate formula (6) to the two surfaces in succession, writing the l of the first surface as infinity and the l of the second surface equal to the l' of the first surface. When this is done, the lens power (P) becomes

$$P=\frac{1}{f'}=(n-1)\left(\frac{1}{r_1}-\frac{1}{r_2}\right).$$

If a number of thin lenses are assembled together in contact, assuming that the combination is still virtually a thin lens, then the power $(1/f')$ of the combination will be equal to the sum of the powers of the separate lenses. Thus, if a thin negative lens is placed in close contact with a thin positive lens of equal power, the combination will have zero power and will no longer act like a lens. This is the basis of a process used by optometrists to ascertain the power of an unknown lens by combining it with one of a series of known lenses from a trial case.

Chromatic aberration. Because the refractive index of glass varies with wavelength, every property of a lens that depends on its refractive index also varies with wavelength, including the focal length, the image distance, and the image magnification. The change of image distance with wavelength is known as chromatic aberration, and the variation of magnification with wavelength is known as chromatic difference of magnification, or lateral colour. Chromatic aberration can be eliminated by combining a strong lens of low-dispersion glass (crown) with a weaker lens made of high-dispersion (flint) glass. Such a combination is said to be achromatic. This method of removing chromatic aberration was discovered in 1729 by Chester Hall, an English inventor, and it was exploited vigorously in the late 18th century in a series of small telescopes. Chromatic variation of magnification can be eliminated by achromatizing all the components of a system or by making the system symmetrical about a central diaphragm. Both chromatic aberration and lateral colour are corrected in every high-grade optical system.

Longitudinal magnification. If an object is moved through a short distance δp along the axis, then the corresponding image shift $\delta p'$ is related to the object movement by the longitudinal magnification $(\overline{m})$. Succinctly,

$$\overline{m} = \delta p'/\delta p = m^2,$$

in which m is the lateral magnification. The fact that the longitudinal magnification is equal to the square of the transverse magnification means that m is always positive; hence, if the object is moved from left to right, the image must also move from left to right. Also, if m is large, then $\overline{m}$ is very large, which explains why the depth of field (δp) of a microscope is extremely small. On the other hand, if m is small, less than one as in a camera, then $\overline{m}$ is very small, and all objects within a considerable range of distances (δp) appear substantially in focus.

Limitation on depth of field

Image of a tilted plane. If a lens is used to form an image of a plane object that is tilted relative to the lens

axis, then the image will also be tilted in such a way that the plane of the object, the plane of the image, and the median plane of the lens all meet. This construction can be derived by the use of the lateral and longitudinal magnification relations just established above. With a tilted object the magnification at any point is given by the ratio of the distances of image and object from the lens at that point in the image, and, consequently, m varies progressively from one end of the image to the other. This arrangement is frequently used in view cameras equipped with "swings" to increase depth of field and in enlargers to rectify the convergence of parallel lines caused by tilting the camera, for example, in photographing tall buildings. The rule finds extensive application in photogrammetry and in the making of maps from aerial photographs.

OPTICAL SYSTEMS

System components. An optical system consists of a succession of elements, which may be lenses, mirrors, prisms, fibre bundles, etc., with, possibly, a light source or some form of detector or electronic image amplifier, depending on the requirements. All optical systems have an aperture stop somewhere in the system to limit the diameter of the beams of light passing through the system from an object point.

Entrance and exit pupils

By analogy with the human eye, this limiting aperture stop is called the iris of the system, its images in the object and image spaces being called the entrance pupil and exit pupil, respectively. In most photographic lenses the iris is inside the objective, and it is often adjustable in diameter to control the image illumination and the depth of field. In telescope and microscope systems the cylindrical mount of the objective lens is generally the limiting aperture or iris of the system; its image, formed behind the eyepiece where the observer's eye must be located to see the whole area being observed, called the field, is then the exit pupil.

The pupils of a lens system can be regarded as the common bases of oblique beams passing through the system from all points in an extended object. In most systems, however, the mounts of some of the lens elements cut into the oblique beams and prevent the beams from being perfectly circular, and the pupils are then not fully filled with light. This effect is known as vignetting and leads to a reduction in illumination in the outer parts of the field of view.

A common feature of many optical systems is a relay lens, which may be introduced to invert an image or to extend the length of the system, as in a military periscope. An example of the use of a relay lens is found in the common rifle sight shown diagrammatically in Figure 6.

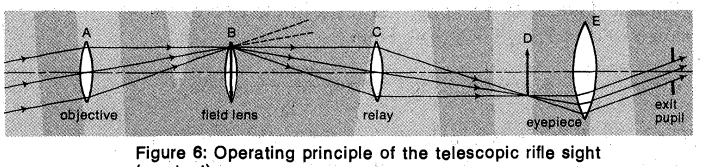

Figure 6: Operating principle of the telescopic rifle sight (see text).

Here the front lens A is the objective, forming an inverted image of the target on the cross wire or reticle at B. The light then proceeds to the relay lens C, which forms a second image, now erect, at D. Beyond this image is the eyepiece E to render the light parallel so that the image may be seen sharply by the observer. Unfortunately, the oblique beam from the objective will usually miss the relay lens, and so a field lens must be inserted at or near the first image B to bend the oblique beams around and redirect them toward the relay lens. The power of the field lens is chosen so that it will form an image of the objective lens aperture on the relay lens aperture. The iris and entrance pupil of this system coincide at the objective; there is an internal pupil at the relay lens, and the exit pupil lies beyond the eyepiece as shown in Figure 6.

Another typical optical system is used in the familiar slide projector, in which a concentrated filament lamp is imaged into the projection lens aperture by a condenser lens. The slide or film transparency to be projected is placed close to the condenser, where there is a broad area of uniform illumination, and it is in turn imaged on the screen by the projection lens.

In principle a concave mirror could be substituted for an image-forming lens in most optical systems. The aberrations of a mirror are generally less than those of a comparable lens, but the fact that a mirror forms its image within the confines of the entering beam leads to many difficulties, and mirrors are therefore used only where the large size or weight of a lens makes the use of a mirror mandatory.

Visual systems. A great many optical instruments—notably spectacles, magnifiers, telescopes, and microscopes—are intended for use in front of an observer's eye to aid vision by providing him with a sharper or larger image. The eye consists of a lens system forming a real image of outside objects on the retina, where the image is converted into nerve impulses that go to the brain and produce the sensation of vision (see EYE AND VISION, HUMAN). In a young person the power of the eye lens can be varied by unconscious muscular effort, enabling him to focus on objects from as close as ten centimetres or so to those that are substantially at infinity. This ability is known as accommodation; the range of accommodation dwindles with age, in humans finally disappearing completely at about age 75.

Accommodation

The larger the retinal image, the larger will an object appear to be, and, as an object is brought closer to the eye, its apparent size increases. The simple magnifier is a positive lens used in front of the eye to enable bringing an object closer than the nearest distance of distinct vision determined by the range of accommodation. If the object is held at the anterior focus of a magnifier, it will appear to be at infinity, and it can be focussed easily. The apparent size of the object will now be equal to the ratio of the object size to the focal length of the lens, whereas without the magnifier the apparent size was equal to the object size divided by the nearest distance of distinct vision, usually assumed to be 25 centimetres (ten inches). The magnifying power of the lens is, therefore, 25 centimetres divided by the focal length. A ten-centimetre lens will give 2.5 times magnification, and so on.

For magnifying powers exceeding about ten, a simple magnifying lens becomes impractical, and a microscope must be used instead. Here the objective lens forms a magnified aerial image of the object, which is further magnified by the eyepiece acting as a simple magnifier. Thus, the objective may magnify an object ten times, and a 2.5-centimetre eyepiece will magnify it a further ten times, giving an overall magnifying power of 100 times.

To magnify a distant object, a telescope is used. The objective lens forms a real image of the object, which is then magnified by the eyepiece. Because the object is inaccessible, the magnifying power of a telescope must be defined in a different way, namely the ratio of the angular subtense of the image to the angular subtense of the object. This turns out to be equal to the ratio of the focal length of the objective lens to that of the eyepiece, multiplied by the magnification of the relay lens, if there is one. Without a relay or other means for erecting the image, a simple telescope will provide an inverted image; this is avoided in the common opera glass by the use of a negative lens for the eyepiece. This so-called Galilean telescope covers only a narrow field and can be given only a low magnifying power. The most familiar small telescope is now the prism binocular in which the image is erected by a pair of prisms mounted between the objective and the eyepiece.

Nonclassical imaging systems. Besides the familiar optical systems so far considered, there are many nonclassical optical elements that are used to a limited extent for special purposes. The most familiar of these is the aspheric (nonspherical) surface. Because plane and spherical surfaces are the easiest to generate accurately on glass, most lenses contain only such surfaces. It is occasionally necessary, however, to use some other axially symmetric surface on a lens or mirror, generally to

Aspheric surfaces

correct a particular aberration. An example is the parabolic surface used for the primary mirror of a large astronomical telescope; another is the elliptic surface molded on the front of the little solid glass reflector units used on highway signs.

Another commonly used optical surface is the side of a cylinder. Such surfaces have power only in the meridian perpendicular to the cylinder axis. Cylindrical lenses are therefore used wherever it is desired to vary the magnification from one meridian to a perpendicular meridian. Cylindrical surfaces are employed in the anamorphic lenses used in some wide-screen motion-picture systems to compress the image horizontally in the camera and stretch it back to its original shape in the projected image.

To correct astigmatism in the eye, many spectacles are made with toric surfaces—*i.e.*, with a stronger curvature in one meridian than in the perpendicular meridian, like the bowl of a teaspoon. These surfaces are generated and polished by special machines and are made by the million every year.

Another nonclassical optical system is the bifocal or trifocal spectacle lens. They are made either by forming two or three separate surfaces on a single piece of glass or obtaining additional power by fusing a piece of high-index glass on to the front of the main lens and then polishing a single spherical surface over both glasses.

Two French scientists, Georges-Louis Buffon and Augustin-Jean Fresnel, in the 18th century suggested forming a lens in concentric rings to save weight, each ring being a portion of what would normally be a continuous spherical surface but flattened out. On a large scale, Fresnel lenses have been used in lighthouses, floodlights, and traffic signals, and as cylindrical ship's lanterns. With fine steps a few thousandths of an inch wide, molded plastic Fresnel lenses are often used as condensers in overhead projectors and in cameras as a field lens in contact with a ground-glass viewing screen.

Lenses have occasionally been made with one surface in the form of a flattened cone. Such lenses produce a long, linear image of a point source, lying along the lens axis; for this reason they are commonly referred to as axicons. They have been used to produce a straight line in space for aligning machines and shafting, but since about 1965 the beam from a gas laser has generally been used instead.

Axicons

LENS ABERRATIONS

Seidel sums. If a lens were perfect and the object were a single point of monochromatic light, then, as noted above, the light wave emerging from the lens would be a portion of a sphere centred about the ideal image point, lying in the paraxial image plane at a height above the axis given by the Lagrange theorem. In practice, however, this condition is most unlikely to occur; it is much more probable that the emerging wave will depart slightly from a perfect sphere, the departure varying from point to point over the lens aperture. This departure is extremely small, being of the order of the wavelength of light that is only half a micron, so it would be impossible to show this departure on a drawing. It can be represented mathematically, however, in the following way: The coordinates of a point in the exit-pupil aperture will be represented by x_0 and y_0, the y_0 coordinate lying in the meridian plane containing the object point and the lens axis. The departure of the wave from the ideal sphere is generally called OPD, meaning optical path difference. It can be shown that OPD is related to x_0 and y_0 by five constants S_1 through S_5, and the quantity h'_0,

$$\text{OPD} = S_1(x_0^2 + y_0^2)^2 + S_2 y_0(x_0^2 + y_0^2)h'_0 + \\ + S_3(x_0^2 + 3y_0^2)h'^2_0 + S_4(x_0^2 + y_0^2)h'^2_0 + S_5 y_0 h'^3_0.$$

Each of these five terms is considered to be a separate "aberration," the coefficients $S_1, \ldots, S_5$, being referred to as Seidel sums. These aberrations are respectively spherical, coma, astigmatism, Petzval field curvature, and distortion. The symbol h'_0 refers to the height of the final image point above the lens axis, and hence it defines the obliquity of the beam.

The five Seidel sums can be calculated by tracing a paraxial ray from object to image through the lens and by tracing also a paraxial principal ray from the centre of the aperture stop outward in both directions toward the object and image, respectively. The angle of incidence i and the ray slope angle u of each of these paraxial rays at each surface are then listed and inserted into the following expressions for the five sums. The angle u_0' represents the final emerging slope of the paraxial ray.

Calculation of Seidel sums

The calculation starts by determining the radius A of the exit pupil by $A = \sqrt{x_0^2 + y_0^2}$ and also the quantity K at each surface by

$$K = \tfrac{1}{2} y n \left(\frac{n}{n'} - 1\right)(i - u').$$

The corresponding K_{pr} for the paraxial principal ray is also determined at each surface. Then, the five aberrations may be written

$$S_1 = \frac{1}{4A^4}\sum Ki^2 \qquad S_2 = \frac{1}{A^3 h'_0}\sum Kii_{pr}$$

$$S_3 = \frac{1}{2A^2 h'^2_0}\sum Ki_{pr}^2 \qquad S_4 = \frac{u'^2_0}{4A^2}\sum \frac{n - n'}{nn'r}$$

$$S_5 = \frac{1}{Ah'^3_0}\sum\left[K_{pr}ii_{pr} + \tfrac{1}{2}h'_0 u'_0(u'^2_{pr} - u_{pr}^2)\right].$$

To interpret these aberrations, the simplest procedure is to find the components x', y' of the displacement of a ray from the Lagrangian image point in the paraxial focal plane, by differentiating the OPD expression given above. The partial derivatives $\partial\text{OPD}/\partial x_0$ and $\partial\text{OPD}/\partial y_0$ represent respectively the components of the slope of the wave relative to the reference sphere at any particular point (x_0, y_0). Hence, because a ray is always perpendicular to the wave, the ray displacements in the focal plane can be found by

$$x' = f\frac{\partial\text{OPD}}{\partial x_0} \quad \text{and} \quad y' = f\frac{\partial\text{OPD}}{\partial y_0},$$

in which f is the focal length of the lens. The aggregation of rays striking the focal plane will indicate the kind of image that is characteristic of each aberration.

This procedure will be applied to each of the five aberration terms separately, assuming that all the other aberrations are absent. Obviously, in a perfect lens x' and y' are zero because OPD is zero. It must be remembered, however, that by using rays instead of waves, all fine-structure effects caused by diffraction will be lost, and only the macroscopic image structure will be retained.

Spherical aberration. The first term in the OPD expression is $\text{OPD} = S_1(x_0^2 + y_0^2)^2$. Hence

$$x' = f\frac{\partial\text{OPD}}{\partial x_0} = 4fA^2 S_1 \cdot x_0 \quad \text{and} \quad y' = f\frac{\partial\text{OPD}}{\partial y_0} = 4fA^2 S_1 \cdot y_0.$$

These displacements can both be eliminated simultaneously by applying a longitudinal shift L to the focal plane. This changes x' by $-Lx_0/f$ and y' by $-Ly_0/f$; hence, if L is made equal to $4f^2A^2S_1$, both ray displacements vanish. The aberration, therefore, represents a condition in which each zone of the lens has a different focus along the axis, the shift of focus from the paraxial image being proportional to A^2. This is known as spherical aberration (see Figure 7).

Coma. The S_2 term in the OPD expression represents the aberration called coma, in which the image of a point has the appearance of a comet. The x' and y' components are as follows:

$$x' = fh'_0 S_2(2x_0 y_0)$$

$$y' = fh'_0 S_2(x_0^2 + 3y_0^2).$$

When this aberration is present, each circular zone of the lens forms a small ringlike image in the focal plane, the rings formed by successive concentric zones of the lens

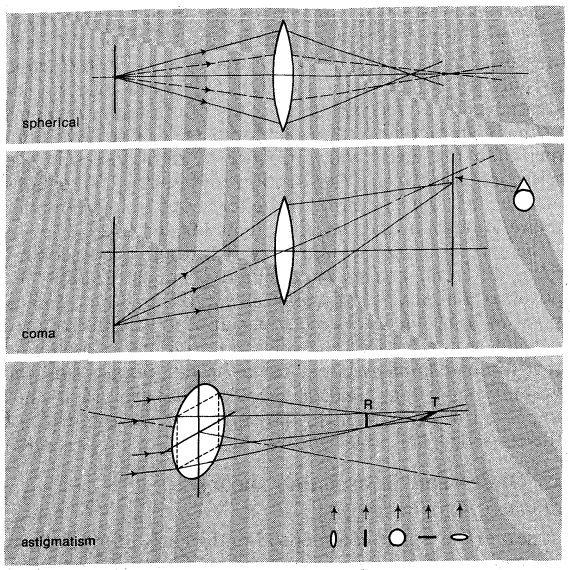

Figure 7: Lens aberrations.

fitting into two straight envelope lines at 60° to each other (Figure 7). Because the brightness of this image is greatest at the tip, coma tends to form a one-sided haze on images in the outer parts of the field.

Astigmatism. If only the S_3 term is present, then

$$x' = 2fh_0'^2 S_3 (x_0)$$

$$y' = 2fh_0'^2 S_3 (3y_0).$$

For any one zone of the lens, x' and y' describe a vertical ellipse with major axis three times the minor axis. The images formed by all the smaller zones of the lens fit into this ellipse and fill it out with a uniform intensity of light. If the image plane is moved along the axis by a distance L, as in focussing a camera, then, at $L = 2f^2h_0'^2S_3$, the ellipse shrinks to a radial focal line (R). Twice this displacement yields a circle; three times this L gives a tangential focal line (T), which is followed by an ellipse with its major axis in the x direction, as in Figure 7, bottom. The usual effect of astigmatism in an image is the appearance of radial or tangential blurring in the outer parts of the field.

Petzval curvature. For the S_4 term taken alone,

$$x' = 2fh_0'^2 S_4 \cdot x_0$$

$$y' = 2fh_0'^2 S_4 \cdot y_0.$$

The image of a point is now a small circle that contracts to a point at a new focus situated at a longitudinal distance $L = 2f^2h_0'^2S_4$ from the paraxial image. As the longitudinal displacement of the focus is proportional to the square of the image height h_0', this aberration represents a pure field curvature without any accompanying loss of definition (all lines remain sharp). It is named after the Hungarian mathematician József Petzval, who studied its properties in the early 1840s. The effect of Petzval curvature can be somewhat offset by the deliberate introduction of sufficient overcorrected astigmatism, as was done in all the pre-anastigmat photographic objectives. This added astigmatism is, of course, undesirable, and in order to design an anastigmat lens having a flat field free from astigmatism, it is necessary to reduce the Petzval sum S_4 drastically.

For a succession of thin lenses (1, 2, 3, . . . etc.) in a system, the Petzval sum becomes simply $1/f_1n_1 + 1/f_2n_2 + 1/f_3n_3 + \ldots$ etc., in which f is the focal length of each element and n is its refractive index. Therefore, to reduce the sum and minimize this aberration, relatively strong negative elements of low-index glass can be combined with positive elements of high-index glass. The positive and negative elements must be axially separated to provide the lens with a useful amount of positive power. The introduction of high-index barium crown glass with a low dispersive power in the 1880s initiated the development of anastigmat lenses.

Distortion. For the S_5 aberration,

$$x' = 0$$

$$y' = fh_0'^3 S_5.$$

When this aberration is present, the entire image point is displaced toward or away from the axis by an amount proportional to the third power of the transverse distance h_0' of the image from the axis. This leads to the formation of an image of a square that is either a barrel-shaped or a cushion-shaped figure.

Other aberrations

It is to be noted that the five Seidel aberrations represent the largest and most conspicuous defects that can arise in an uncorrected optical system. Even in the best lenses in which these five aberrations have been perfectly corrected for one zone of the lens and for one point in the field, however, there will exist small residuals of these aberrations and of many other higher order aberrations, also, which are significantly different from the classical types just described. The typical aberration figures shown in Figure 7 are, of course, grossly exaggerated, and actually it requires some magnification of a star image to render these appearances clearly visible. Nevertheless, they are important enough to require drastic reduction in high-quality lenses intended to make sharp negatives capable of considerable enlargement.

IMAGE BRIGHTNESS

General relations. All photometric concepts are based on the idea of a standard candle, lamps having accurately known candle power being obtainable from the various national standards laboratories. The ratio of the candle power of a source to its area is called the luminance of the source; luminances range from about 2,000 candles per square millimetre at the surface of the Sun down to about 3×10^{-6} candle per square centimetre (3×10^{-6} stilb) for the luminous paint on a watch dial. Ordinary outdoor scenes in daylight have an average luminance of several hundred candles per square foot. The quantity of light flux flowing out from a source is measured in lumens, the lumen being defined as the amount of flux radiated by a small "point" source of one candle power into a cone having a solid angle of one steradian. When light falls upon a surface it produces illumination (*i.e.*, illuminance), the usual measure of illuminance being the foot-candle, which is one lumen falling on each square foot of receiving surface.

It is often important to be able to calculate the brightness of an image formed by an optical system, because photographic emulsions and other light receptors cannot respond satisfactorily if the light level is too low. The problem is to relate the luminance of an object with the illuminance in the image, knowing the transmittance and aperture of the optical system. A small area A of a plane object having a luminance of B candles per square unit will have a normal intensity of AB candles. This source radiates light into a cone of semi-angle U, limited, for example, by the rim of a lens. The light flux (F) entering the cone can be found by integration to be

$$F = \pi AB \sin^2 U \text{ lumens.}$$

If the object luminance is expressed as B_L lamberts, the lambert being an alternative luminance unit equal to $1/\pi$ (*i.e.*, 0.32) candle per unit area, the flux (F) is

$$F = AB_L \sin^2 U \text{ lumens,}$$

because there are π times as many lamberts in a given luminance as there are candles per unit area.

A fraction t of this flux finds its way to the image, t being the lens transmittance, generally about 0.8 or 0.9 but less if a mirror is involved. The area of the image is Am^2, in which m, the magnification, is given by

$$m = \frac{\sin U}{\sin U'}.$$

Hence, the image illuminance (E) is

$$E = (t\pi AB \sin^2 U) \div (A \sin^2 U / \sin^2 U') = t\pi B \sin^2 U' \quad (8)$$

or

$$E = tB_L \sin^2 U' .$$

The image illuminance thus depends *only* on the luminance of the source and the cone angle of the beam proceeding from the lens to the image. This is a basic and most important relation underlying all calculations of image illuminance.

It is often more convenient to convert the angle U' into other better known quantities, such as the f-number of the lens and the image magnification. The relation here is

$$\sin U' = \frac{1}{2(f\text{-number})(1 + m/m_p)} . \quad (9)$$

Definition of f-number

The f-number of the lens is defined as the ratio of the focal length to the diameter of the entrance pupil; m is the image magnification; and m_p is the pupil magnification—*i.e.*, the diameter of the exit pupil divided by the diameter of the entrance pupil. Combining equations (8) and (9) gives

$$\text{Image illuminance} = E = \frac{\pi tB}{4(f\text{-number})^2(1 + m/m_p)^2} .$$

As an example in the use of this relation, if it is supposed that an $f/2$ lens is being used to project an image of a cathode-ray tube at five times magnification, the tube luminance being 5,000 foot-lamberts (1.7 candles per square centimetre), the lens transmittance is 0.8, and the pupil magnification is unity. Then the image illuminance will be

$$E = \frac{0.8 \times 5{,}000}{4 \times 4 \times 36} = 6.9 \text{ foot-candles.}$$

The image is very much less bright than the object, a fact that becomes clear to anyone attempting to provide a bright projected image in a large auditorium.

Distribution of illumination over an image. So far only the illumination at the centre of an image has been considered, but the distribution of illumination over a wide field is often important. In the absence of any lens, the small plane source already considered radiates in a direction inclined at an angle ϕ to the axis with an intensity $AB \cos \phi$. This light has to travel farther than the axial light to reach a screen, and then it strikes the screen at another angle ϕ. The net result is that the oblique illumination on the screen is smaller than the axial illumination by the factor $\cos^4 \phi$.

The same law can be applied to determine the oblique illumination due to a lens, assuming a uniform extended diffusing source of light on the other side of the lens. In this case, however, the exit pupil will not in general be a perfect circle because of possible distortion of the iris by that part of the optical system lying between the iris and the image. Also, any mechanical vignetting in the lens will make the aperture noncircular and reduce still further the oblique illumination. In a camera this reduction in oblique illumination results in darkened corners of the picture, but, if the reduction in brightness is gradual, it is not likely to be detected because the eye adapts quickly to changing brightness as the eyes scan over the picture area. Indeed, a 50 percent drop in brightness between the centre and corners of an ordinary picture is scarcely detectable.

Visual brightness. The apparent brightness of things seen by the eye follows the same laws as any other imaging system, because the apparent brightness is measured by the illuminance in the image on the retina. The angle U' in equation (8) inside the eye is determined by the size of the eye pupil, which varies from about one millimetre to about eight millimetres, depending on the brightness of the environment. Apart from this variation, retinal illuminance is directly proportional to object luminance, and objects having the same luminance appear equally bright, no matter at what distance they are observed.

Retinal illuminance

From this argument, it is clear that no visual instrument, such as a telescope, can possibly make anything appear brighter than when viewed directly. To be sure, a telescope having a large objective lens accepts more light from an object in proportion to the area of the lens aperture, but it magnifies the image area in the same proportion; so the increased light is spread over an increased area of the retina, and the illuminance remains unchanged. Actually, the telescopic view is always dimmer than the direct view because of light losses in the telescope due to glass absorption and surface reflections and because the exit pupil of the telescope may be smaller than the pupil of the eye, thus reducing the angle U'.

The case of a star being observed through a telescope is quite different, because no degree of magnification can possibly make a star appear as anything other than a point of light. Hence, star images appear brighter in proportion to the area of the telescope objective (assuming that the exit pupil is larger than the eye pupil), and the visibility of a star against the sky background is thus improved in proportion to the square of the diameter of the telescope objective lens. (R.K.)

II. Optics and information theory

GENERAL CONSIDERATIONS

A new era in optics commenced in the early 1950s following the impact of certain branches of electrical engineering—most notably communication and information theory. This impetus was sustained by the development of the laser in the 1960s.

The initial tie between optics and communication theory came because of the numerous analogies that exist between the two subjects and because of the similar mathematical techniques employed to formally describe the behaviour of electrical circuits and optical systems. A topic of considerable concern since the invention of the lens as an optical imaging device has always been the description of the optical system that forms the image; information about the object is relayed and presented as an image. Clearly, the optical system can be considered a communication channel and can be analyzed as such. There is a linear relationship (*i.e.*, direct proportionality) between the intensity distribution in the image plane and that existing in the object, when the object is illuminated with incoherent light (*e.g.*, sunlight or light from a large thermal source). Hence, the linear theory developed for the description of electronic systems can be applied to optical image-forming systems. For example, an electronic circuit can be characterized by its impulse response —that is, its output for a brief impulse input of current or voltage. Analogously, an optical system can be characterized by an impulse response that for an incoherent imaging system is the intensity distribution in the image of a point source of light; the optical impulse is a spatial rather than a temporal impulse—otherwise the concept is the same. Once the appropriate impulse response function is known, the output of that system for any object intensity distribution can be determined by a linear superposition of impulse responses suitably weighted by the value of the intensity at each point in the object. For a continuous object intensity distribution this sum becomes an integral. While this example has been given in terms of an optical imaging system, which is certainly the most common use of optical elements, the concept can be used independent of whether the receiving plane is an image plane or not. Hence, for example, an impulse response can be defined for an optical system that is deliberately defocussed or for systems used for the display of Fresnel or Fraunhofer diffraction patterns. (Fraunhofer diffraction occurs when the light source and diffraction patterns are effectively at infinite distances from the diffracting system, and Fresnel diffraction occurs when one or both of the distances are finite.)

The optical system as a communication channel

Temporal frequency response. A fundamentally related but different method of describing the performance of an electronic circuit is by means of its temporal frequency response. A plot is made of the response for a series of input signals of a variety of frequencies. The response is measured as the ratio of the amplitude of the signal obtained out of the system to that put in. If there is no loss in the system, then the frequency response is unity (one) for that frequency; if a particular frequency fails to pass

through the system, then the response is zero. Again, analogously the optical system may also be described by defining a spatial frequency response. The object, then, to be imaged by the optical system consists of a spatial distribution of intensity of a single spatial frequency—an object the intensity of which varies as $(1 + a \cos \omega x)$, in which x is the spatial coordinate, a is a constant called the contrast, and ω is a variable that determines the physical spacing of the peaks in the intensity distribution. The image is recorded for a fixed value of a and ω and the contrast in the image measured. The ratio of this contrast to a is the response for this particular spatial frequency defined by ω. Now if ω is varied and the measurement is repeated, a frequency response is then obtained.

Nonlinear optical systems. The analogies described above go even further. Many optical systems are nonlinear, just as many electronic systems are nonlinear. Photographic film is a nonlinear optical element in that equal increments of light energy reaching the film do not always produce equal increments of density on the film.

A different type of nonlinearity occurs in image formation. When an object such as two stars is imaged, the resultant intensity distribution in the image is determined by first finding the intensity distribution formed by each star. These distributions must then be added together in regions where they overlap to give the final intensity distribution that is the image. This example is typical of an incoherent imaging system—*i.e.*, the light emanating from the two stars is completely uncorrelated. This occurs because there is no fixed phase relationship between the light emanating from the two stars over any finite time interval.

A similar nonlinearity arises in objects illuminated by light from the Sun or other thermal light source. Illumination of this kind, when there is no fixed relationship between the phase of the light at any pair of points in the incident beam, is said to be incoherent illumination. If the illumination of the object is coherent, however, then there is a fixed relationship between the phase of the light at all pairs of points in the incident beam. To determine the resultant image intensity under this condition for a two point object requires that the amplitude and phase of the light in the image of each point be determined. The resultant amplitude and phase is then found by summation in regions of overlap. The square of this resultant amplitude is the intensity distribution in the image. Such a system is nonlinear. The mathematics of nonlinear systems was developed as a branch of communication theory, but many of the results can be used to describe nonlinear optical systems.

This new description of optical systems was extremely important to, but would not alone account for, the resurgence of optical research and development. This new approach resulted in the development of whole new branches of study, including optical processing and holography (see below). It also had an effect, together with the development of digital computers, on the concepts and versatility of lens design and testing. Finally, the invention of the laser, a device that produces coherent radiation, and the development and implementation of the theory of partially coherent light gave the added impetus necessary to change traditional optics into a radically new and exciting subject.

IMAGE FORMATION

Impulse response. An optical system that employs incoherent illumination of the object can usually be regarded as a linear system in intensity. A system is linear if the addition of inputs produces an addition of corresponding outputs. For ease of analysis, systems are often considered stationary (or invariant). This property implies that if the location of the input is changed, then the only effect is to change the location of the output but not its actual distribution. With these concepts it is then only necessary to find an expression for the image of a point input to develop a theory of image formation. The intensity distribution in the image of a point object can be determined by solving the equation relating to the diffraction of light as it propagates from the point object to the lens, through the lens, and then finally to the image plane. The result of this process is that the image intensity is the intensity in the Fraunhofer diffraction pattern of the lens aperture function (that is, the square of the Fourier transform of the lens aperture function; a Fourier transform is an integral equation involving periodic components). This intensity distribution is the intensity impulse response (sometimes called point spread function) of the optical system and fully characterizes that optical system. Figure 8 shows the impulse response for a perfect optical system (no aberration) that is limited only by its aperture.

Intensity distribution

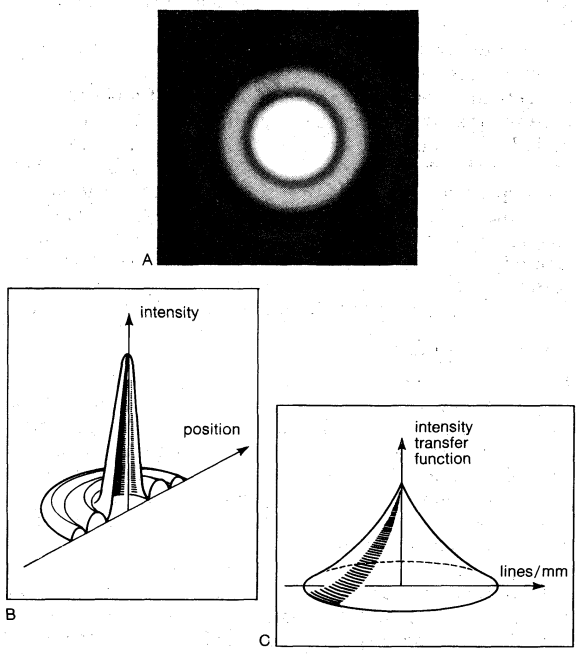

Figure 8: *The intensity impulse response of a perfect (i.e., no aberrations) optical system.*
(A) Photograph; (B) plot; (C) the transfer function of the same aberration-free system.

With the knowledge of the impulse response, the image of a known object intensity distribution can be calculated. If the object consists of two points, then in the image plane the intensity impulse response function must be located at the image points and then a sum of these intensity distributions made. The sum is the final image intensity. If the two points are closer together than the half width of the impulse response, they will not be resolved. For an object consisting of an array of isolated points, a similar procedure is followed—each impulse response is, of course, multiplied by a constant equal to the value of the intensity of the appropriate point object. Normally, an object will consist of a continuous distribution of intensity, and, instead of a simple sum, a convolution integral results.

Transfer function. The concept of the transfer function of an optical system can be approached in several ways. Formally and fundamentally it is the Fourier transform of the intensity impulse response. The transfer function for the optical system for Figure 8B is shown in Figure 8C. Because the impulse response is related to the lens aperture function, so is the transfer function. In particular, the transfer function can be obtained from a knowledge of the aperture function by taking the function and plotting the resultant overlapping areas as the aperture function is slid over itself (*i.e.*, the autocorrelation of the aperture function).

Autocorrelation

Conceptually, however, the transfer function is best understood by considering the object intensity distribution to be a linear sum of cosine functions of the form $(1 + a \cos 2\pi\mu x)$, in which a is the amplitude of each component of spatial frequency μ. The image of a cosine intensity distribution is a cosine of the same frequency; only the contrast and phase of the cosine can be affected by a

linear system. The image of the above object intensity distribution can be represented by $[1 + b \cos (2\pi\mu x + \phi)]$, in which b is the amplitude of the output cosine of frequency μ and ϕ is the phase shift. The transfer function, $\tau(\mu)$, for that frequency is then given by the ratio of the amplitudes:

$$\tau(\mu) = \frac{b}{a} e^{j\phi(\mu)}.$$

If μ is now varied, the spatial frequency response of the system is measured by determining $\tau(\mu)$ for the various values of μ. It should be noted that $\tau(\mu)$ is in general complex (containing a term with $\sqrt{-1}$), although in the example of Figure 8 it is real and positive [$\phi(\mu) = 0$ for all μ].

The transfer function, like the impulse response, fully characterizes the optical system. To make use of the transfer function to determine the image of a given object requires that the object be decomposed into a series of periodic components called its spatial frequency spectrum. Each term in this series must then be multiplied by the appropriate value of the transfer function to determine the individual components of the series that is the spatial frequency spectrum of the image—a transformation of this series will give the image intensity. Thus, any components in the object spectrum that have a frequency for which $\tau(\mu)$ is zero will be eliminated from the image.

PARTIALLY COHERENT LIGHT

Image formation is concerned above with incoherent object illumination, which results in an image formed by the addition of intensities. The study of diffraction and interference, on the other hand, requires coherent illumination of the diffracting object, the resulting diffracted optical field being determined by an addition of complex amplitudes of the wave disturbances. Thus, two different mechanisms exist for the addition of light beams, depending upon whether the beams are coherent or incoherent with respect to each other. Unfortunately, this is not the whole story; it is not sufficient to consider only the two situations of strictly coherent and strictly incoherent light. In fact, strictly incoherent fields are only approximately obtainable in practice. Furthermore, the possibility of intermediate states of coherence cannot be ignored; it is necessary to describe the result of mixing incoherent light with coherent light. It was to answer the question how coherent is a beam of light (or the equivalent one, how incoherent is a beam of light) that the theory of partial coherence was developed. Marcel Verdet, a French physicist, realized in the last century that even sunlight is not completely incoherent, and two objects separated by distances of over approximately $\frac{1}{20}$ millimetre will produce interference effects. The eye, operating unaided in sunlight, does not resolve this separation distance and hence can be considered to be receiving an incoherent field. Two physicists, Armand Fizeau in France and Albert Michelson in the United States, were also aware that the optical field produced by a star is not completely incoherent and hence designed interferometers to measure the star diameter from a measurement of the partial coherence of the starlight. These early workers did not think in terms of partially coherent light but derived their results by an integration over the source. At the other extreme, the output from a laser can produce a highly coherent field.

Partial coherence

The concepts of partially coherent light can best be understood by means of some simple experiments. A circular uniform distant source produces illumination on the front of an opaque screen containing two small circular apertures, the separation of which can be varied. A lens is located behind this screen, and the resultant intensity distribution in its focal plane is obtained. With either aperture open alone, the intensity distribution observed is such that it is readily associated with the diffraction pattern of the aperture, and it may thus be concluded that the field is coherent over the dimensions of the aperture. When the two apertures are opened together and are at their closest separation, two-beam interference fringes are observed that are formed by the division of the incident wave front by the two apertures. As the separation of the apertures increases, the observed interference fringes get weaker and finally disappear, only to reappear faintly as the separation is further increased. As the separation of the apertures is increased, these results show that (1) the fringe spacing decreases; (2) the intensities of the fringe minima are never zero; (3) the relative intensity of the maxima above the minima steadily decreases; (4) the absolute value of the intensity of the maxima decreases and that of the minima increases; (5) eventually, the fringes disappear, at which point the resultant intensity is just twice the intensity observed with one aperture alone (essentially an incoherent addition); (6) the fringes reappear with a further increase in separation of the aperture, but the fringes contain a central minimum, not a central maximum.

If the intensities of the two apertures are equal, then the results (1) through (5) can be summarized by defining a quantity in terms of the maximum intensity (I_{max}) and the minimum intensity (I_{min}), called the visibility (V) of the fringes—*i.e.*, $V = (I_{max} - I_{min})/(I_{max} + I_{min})$. The maximum value of the visibility is unity, for which the light passing through one aperture is coherent with respect to the light passing through the other aperture; when the visibility is zero, the light passing through one aperture is incoherent with respect to the light passing through the other aperture. For intermediate values of V the light is said to be partially coherent. The visibility is not a completely satisfactory description because it is, by definition, a positive quantity and cannot, therefore, include a description of item (6) above. Furthermore, it can be shown by a related experiment that the visibility of the fringes can be varied by adding an extra optical path between the two interfering beams.

Fringe visibility

The key function in the theory of partially coherent light is the mutual coherence function $\Gamma_{12}(\tau) = \Gamma(x_1, x_2, \tau)$, a complex quantity, which is the time averaged value of the cross correlation function of the light at the two aperture points x_1 and x_2 with a time delay τ (relating to a path difference to the point of observation of the interference fringes). The function can be normalized (*i.e.*, its absolute value set equal to unity at $\tau = 0$ and $x_1 = x_2$) by dividing by the square root of the product of the intensities at the points x_1 and x_2 to give the complex degree of coherence, hence

$$\gamma_{12}(\tau) = \frac{\Gamma_{12}(\tau)}{\sqrt{I(x_1)I(x_2)}}.$$

The modulus of $\gamma_{12}(\tau)$ has a maximum value of unity and a minimum value of zero. The visibility defined earlier is identical to the modulus of the complex degree of coherence if $I(x_1) = I(x_2)$.

Often the optical field can be considered to be quasi-monochromatic (approximately monochromatic), and then the time delay can be set equal to zero in the above expression, thus defining the mutual intensity function. It is often convenient to describe an optical field in terms of its spatial and temporal coherence by artificially separating out the space- and time-dependent parts of the coherence function. Temporal coherence effects arise from the finite spectral width of the source radiation; a coherence time Δt can be defined as $1/\Delta\nu$, in which $\Delta\nu$ is the frequency bandwidth. A related coherence length Δl can also be defined as $c/\Delta\nu = \lambda^2/\Delta\lambda^2$, in which c is the velocity of light, λ is the wavelength, and $\Delta\lambda$ the wavelength bandwidth. Providing the path differences in the beams to be added are less than this characteristic length, they will interfere.

The term spatial coherence is used to describe partial coherence arising from the finite size of an incoherent source. Hence, for the equipath position for the addition of two beams, a coherence interval is defined as the separation of two points such that the absolute value $|\gamma_{12}(0)|$ is some prechosen value, usually zero.

The mutual coherence function is an observable quantity that can be related to the intensity of the field. The partially coherent field can be propagated by use of the mutual coherence function in a similar way to the solution of diffraction problems by propagation of the com-

The mutual coherence function

plex amplitude. The effects of partially coherent fields are clearly of importance in the description of normally coherent phenomena, such as diffraction and interference, but also in the analysis of normally incoherent phenomena, such as image formation. It is notable that image formation in coherent light is not linear in intensity but is linear in the complex amplitude of the field, and in partially coherent light the process is linear in the mutual coherence.

OPTICAL PROCESSING

Coherent optical systems. Optical processing, information processing, signal processing, and pattern recognition are all names that relate to the process of spatial frequency filtering in a coherent imaging system—specifically, a method in which the Fraunhofer diffraction pattern (equivalently the spatial frequency spectrum or the Fourier transform) of a given input is produced optically and then operated upon to change the information content of the optical image of that input in a predetermined way.

The idea of using coherent optical systems to allow for the manipulation of the information content of the image is not entirely new. The basic ideas are essentially included in Abbe's theory of vision in a microscope first published in 1873; the subsequent illustrative experiments of this theory, notably by Albert B. Porter in 1906, are certainly simple examples of optical processing.

Abbe's ideas can be interpreted as a realization that image formation in a microscope is more correctly described as a coherent image-forming process than as the more familiar incoherent process. Thus, the coherent light illuminating the object on the microscope stage would be diffracted by that object. To form an image, this diffracted light must be collected by the objective lens of the microscope, and the nature of the image and the resolution would be affected by how much of the diffracted light is collected. As an example, an object may be considered consisting of a periodic variation in amplitude transmittance—the light diffracted by this object will exist in a series of discrete directions (or orders of diffraction). This series of orders contains a zero order propagating along the optical axis and a symmetric set of orders on both sides of this zero order. Abbe correctly speculated upon what would happen as the microscope objective accepted different combinations of these orders. For example, if the zero order and one first order are collected, then the information obtained from the image will be that the object consisted of a periodic distribution, but the spatial location of the periodic structure is not correctly ascertained. If the other first order of diffracted light is included, then the correct spatial location of the periodic structure is also obtained. As more orders are included, the image more closely resembles the object.

Coherent optical data processing became a serious subject for study in the 1950s, partly because of the work of a French physicist, Pierre-Michel Duffieux, on the Fourier integral and its application to optics, and the subsequent use of communication theory in optical research. The work was initiated in France by André Maréchal and Paul Croce, and today a variety of problems can be attempted by the technique. These include removal of raster lines (as in a TV picture) and halftone dots (as in newspaper illustration); contrast enhancement; edge sharpening; enhancement of a periodic or isolated signal in the presence of additive noise; aberration balancing in which a recorded aberrated image can be somewhat improved; spectrum analysis; cross correlation of data; matched and inverse filtering in which a bright spot of light in the image indicates the presence of a particular object.

Examples of data processing

Filtering. The basic system required for coherent optical processing consists of two lenses (Figure 9). A collimated beam of coherent light is used to transilluminate the object. The first lens produces the characteristic Fraunhofer diffraction pattern of the object, which is the spatial frequency distribution associated with the object. (Mathematically, it is the Fourier transform of the object amplitude distribution.) A filter that consists of amplitude (density) or phase (optical path) variations, or both, is placed in the plane of the diffraction pattern. The light passing through this filter is used to form an image, this step being accomplished by the second lens. The filter has the effect of changing the nature of the image by altering the spatial frequency spectrum in a controlled way so as to enhance certain aspects of the object information. Maréchal gave the descriptive title double diffraction to this type of two-lens system.

The filters can be conveniently grouped into a variety of types depending upon their action. Blocking filters have regions of complete transparency and other regions of complete opacity. The opaque areas completely remove certain portions of the spatial frequency spectrum of the object. The removal of raster lines and halftone dots is accomplished with this type of filter. The object can be considered as a periodic function the envelope of which is the scene or picture—or equivalently the periodic function samples the picture. The diffraction pattern consists of a periodic distribution with a periodicity reciprocally related to the raster periodicity. Centred at each of these periodic locations is the diffraction pattern of the scene. Hence, if the filter is an aperture centred at one of these locations so that only one of the periodic elements is allowed to pass, then the raster periodicity is removed, but the scene information is retained (see Figure 9). The

Blocking filters

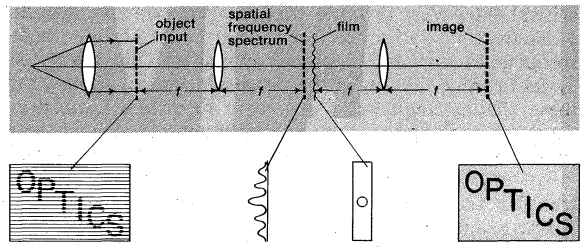

Figure 9: Two-lens coherent optical processing system, showing how the raster periodicity is removed but the scene information is retained (see text).

problem of the removal of halftone dots is the two-dimensional equivalent of the above process. Because the two-dimensional spatial frequency spectrum of an object is displayed in a coherent optical processing system, it is possible to separate out information by means of its orientation. Other applications of blocking filters include band-pass filters, which again have a direct relationship to the band-pass filters in electronic circuits.

A second type of filter is an amplitude filter that will consist of a continuous density variation. These filters can be produced to achieve the enhancement of contrast of the object input or the differentiation of the object. They are often constructed by controlled exposure of photographic film or evaporation of metal onto a transparent substrate.

Amplitude filters

Certain optical processing techniques require that the phase of the optical field be changed, and, hence, a filter with no absorption but varying optical thickness is required. Usually, both the amplitude and the phase have to be modified, however, thus requiring a complex filter. In simple cases the amplitude and phase portions can be made separately, the phase filter being manufactured by using an evaporated layer of transparent material, such as magnesium fluoride. Current practice is to fabricate the complex filter by an interferometric method in which the required complex amplitude function is recorded as a hologram (see below).

The phase-contrast microscope can be considered to be an example of an optical processing system, and the concepts understood by reference to Figure 9. Only the simplest form will be considered here. The spatial frequency spectrum of the phase object is formed and the phase of the central portion of that spectrum changed by $\pi/2$ or $3\pi/2$ to produce positive or negative phase contrast, respectively. To improve the contrast of the image an additional filter covering the same area as the phase filter is used that is partially absorbing (*i.e.*, an amplitude filter). The restriction on this process is that the variations of the

phase $\phi(x)$ are small so that $e^{i\phi(x)} \cong 1 + i\phi(x)$. With incoherent light, phase information is not visible, but many biological samples consist only of variations of refractive index, which results in optical path, and hence phase, differences. The image in the phase-contrast microscope is such that the intensity in that image relates linearly to, and hence is a display of, the phase information in the object—*e.g.*, $I(x) \propto 1 \pm 2\phi(x)$ for positive and negative phase contrast, respectively.

Correction of aberrated images

One of the important motivations for the study of optical processing methods is to achieve some correction of aberrated images. Considerable technological advantage can be gained if photographs taken with an aberrated optical system in incoherent light can be corrected by subsequent processing. Within definable limits this can be accomplished, but the impulse response or the transfer function of the aberrated system must be known. The recorded image intensity distribution is the convolution of the object intensity with the intensity impulse response of the aberrated system. This record is the input to the coherent optical processing system; the diffraction pattern formed in this system is the product of the spatial frequency spectrum of the object and the transfer function of the aberrated system. Conceptually, the filter has to be the inverse of the transfer function in order to balance out its effect. The final image would then ideally be an image of the object intensity distribution. It is critical, however, that the transfer function has a finite value over only a limited frequency range, and only those frequencies that are recorded by the original aberrated system can be present in the processed image. Hence, for these spatial frequencies that were recorded, some processing can be carried out to get a flatter effective transfer function; both the contrast and the phase of the spatial frequency spectrum may have to be changed because the transfer function is, in general, a complex function. Prime examples are for images aberrated by astigmatism, defocussing, or image motion.

HOLOGRAPHY

Theory. Holography (*q.v.*) is a two-step coherent image-forming process in which an intermediate record is made of the complex optical field associated with the object. The invention of the wave-front reconstruction process (now called holography) was first described in 1948 by Dennis Gabor, a Hungarian-born physicist, with a specific application in mind—to attempt to improve the resolution of images formed with electron beams. The technique has, however, had most of its success to date when light beams are employed particularly in the visible part of the spectrum. The first step in the process is to record (often on high-resolution film) the interference pattern produced by the interaction of the light diffracted by the object of interest and a coherent background or reference wave. In the second step, this record, which is the hologram, is illuminated coherently to form an image of the original object. In fact, two images are usually formed—a real image (often called the conjugate image) and a virtual image (often called the primary image). There are two basic concepts that underly this process: first, the addition of a coherent background (or reference) beam. Two optical fields may be considered, the complex amplitudes of which vary as the cosine of an angle proportional to the space coordinate and as the modulus (absolute magnitude) of the cosine of the angle, respectively. From a measurement of the intensity of these fields it is impossible to distinguish them because both vary as the cosine squared of the space coordinate. If a second coherent optical field is added to each of these two fields, however, then the resultant fields become $(1 + \cos x)$ and $(1 + |\cos x|)$, respectively. The measured intensities are now different, and the actual fields can be determined by taking the square root of the intensity. The amplitude transmittance of a photographic record is, in fact, the square root of the original intensity distribution that exposed the film. In a more general sense, an optical field of the form $a(x) \exp [i\phi_1(x)]$, in which $a(x)$ is the amplitude and $\phi_1(x)$ is the phase, can be distinguished from a field $a(x) \exp [i\phi_2(x)]$ by adding a coherent background; the phases $\phi_1(x)$ and $\phi_2(x)$ are then contained as cosine variations of intensity in the resulting pattern. Hence, the problem of recording the phase information of the optical field is circumvented. When the hologram is illuminated, however, the optical field that originally existed in that plane is recreated. To apply the second basic concept—that of an image-forming property—it is necessary to determine what the hologram of a point object is—in actuality it is a sine-wave zone plate or zone lens. If a collimated beam of light is used to illuminate a zone lens, then two beams are produced; the first comes to a real focus, and the other is a divergent beam that appears to have come from a virtual focus. (By comparison, the more classical zone plate has a multitude of real and virtual focuses, and a real lens has but one.) When the object is other than a point, the zone lens is modified by the diffraction pattern of the object; *i.e.*, each point on the object produces its own zone lens, and the resultant hologram is a summation of such zone lenses.

In Gabor's original system the hologram was a record of the interference between the light diffracted by the object and a collinear background. This automatically restricts the process to that class of objects that have considerable areas that are transparent (see Figure 10A). When the

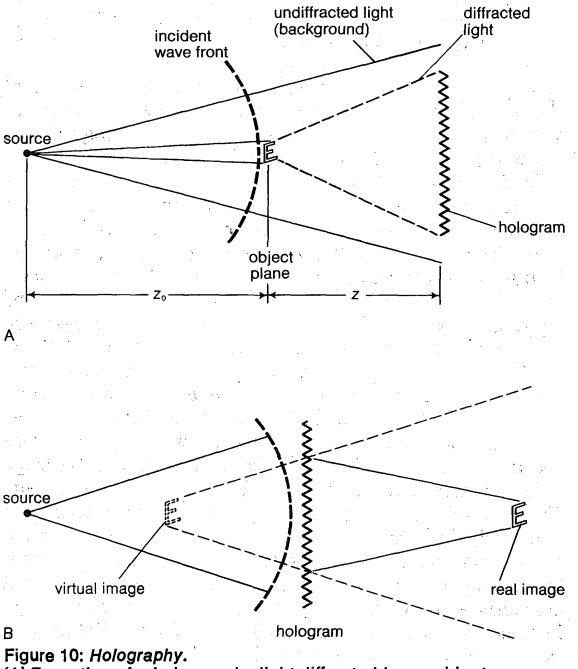

Figure 10: *Holography.*
(A) Formation of a hologram by light diffracted by an object with collinear background (Gabor's original method). (B) Image formation by illumination of the hologram.

hologram is used to form an image, twin images are formed, as illustrated in Figure 10B. The light associated with these images is propagating in the same direction, and hence in the plane of one image light from the other image appears as an out-of-focus component. This type of hologram is usually referred to as an in-line Fresnel hologram because it is the pattern of the object that interferes with the collinear coherent background. The deleterious effects of the second image can be minimized if the hologram is made in the far field of the object so that it is a Fraunhofer diffraction pattern of the object that is involved. This latter technique has found significant application in microscopy, particularly in the measurement of small particles, and in electron microscopy.

A more versatile method of recording the hologram is to add a second beam of light as a reference wave to produce the hologram. The hologram is now the record of the interference pattern produced by the light diffracted by the object and this separate reference wave. The reference wave is usually introduced at an angle to the diffracted beam, hence this method is often called off-axis (or side-band) holography. When the hologram is illumi-

Steps in the holography process

nated, the image-forming beams do not propagate in the same direction but are inclined to each other with an angle twice that between the diffracted beam and the original reference beam. Hence, the light associated with an image is completely separated from the other image.

The generalized hologram

A further technique that has some value and relates to the earlier discussion of optical processing is the production of the so-called generalized or Fourier transform hologram. Here the reference beam is added coherently to a Fraunhofer diffraction pattern of the object or formed by a lens (as in the first stage of Figure 9).

The process described so far has been in terms of transmitted light through the object. The methods involving the separate reference beam can be used in reflected light, and the virtual (primary) image produced from the hologram has all the properties of an ordinary image in terms of three-dimensionality and parallax. Normally, a recorded image is only a two-dimensional representation of the object. Full-colour holograms can be recorded by essentially recording three holograms simultaneously—one in red light, one in blue, and one in green.

Applications. *Image forming.* The applications mentioned here are in three groups: image-forming applications, non-image-forming applications, and the hologram as an optical element. It is notable that all three groups relate to the basic use of the process rather than specific holographic techniques. The first group involves those applications using image formation when, for a variety of reasons, normal incoherent or coherent image formation is not satisfactory. It is not sufficient merely to replace a normal image process by a holographic technique unless there is some significant gain—*i.e.*, the required record can be obtained more easily or more accurately. Applications that fall into this category are holographic microscopy; particle-size analysis; high-speed photography of various types, particularly of gas flows; data storage and retrieval, including displays; image formation through a random medium; and non-optical holography, particularly acoustic holography.

Non-image forming. The second group of interest involves those applications that are not image forming. One of the very real and exciting applications of holography is to the nondestructive testing of fabricated materials. An interesting example of this method is for the testing of tires for the detection of flaws (debonds) that exist between the plies of the tire. The realm of interferometry is thus extended to whole new classes of objects. In a similar but separate development, interference microscopy has been used successfully.

Optical elements. The third and final group involves those applications that use the hologram as an optical element in its own right. This includes the building of accurate, specialized gratings and the application of holographic filters in coherent optical data processing.

Holography has been adapted to the conventional microscope, which is modified by the inclusion of a separate reference beam so that the light diffracted by the object in the microscope is made to interfere with the light from the reference beam. An increase in the depth of field available is achieved by this type of recording process. The image is produced when the hologram is illuminated again by a coherent beam.

The application of holography to particle-size analysis (*e.g.*, to determine the size distribution of dust and liquid droplets) was really the first of the modern-day applications. In a sense, this, too, can be thought of as microscopy. The principles of Fraunhofer holography were developed to solve this particular problem. Because the particles are in motion, a hologram must be made instantaneously. A pulsed-ruby laser technique is therefore used. The hologram is formed between the light diffracted by the particles or droplets and the coherent background light that passes directly through the sample. In reconstruction, a series of stationary images are formed that can be examined at leisure. Hence, a transient event has been transformed into a stationary image for evaluation.

Transient holograms

Data storage and retrieval is perhaps one of the more important applications of holography, which is in the process of development. Because the information about the image is not localized, it cannot be affected by scratches or dust particles. Recent advances in materials have added a further interest to this area, particularly materials that might be erasable and reusable. Hence, holographic optical memories become a distinct possibility.

Among the non-image-forming applications are interferometry, interference microscopy, and optical processing. Holographic interferometry can be done in several ways. The basic technique involves recording a hologram of the object of interest and then interfering the image produced from this hologram with the coherently illuminated object itself. A variation on this technique would be to form two holograms at different times of the same object as it undergoes testing. The two holograms can then be used together to form two images, which would again interfere. The interference fringes seen would be related to the changes in the object between the two exposures. A third technique uses a time-average hologram, which is particularly applicable to the study of vibrating objects.

There are two applications that come under the heading holographic optical elements—the use of holographic gratings and the use of holographic filters for coherent optical data processing.

NONLINEAR OPTICS

Nonlinear effects in optics are now quite readily observable using the highly coherent and highly energetic laser beams. These effects occur when the output of a system is not linearly related to the input (*e.g.*, a nonlinear electronic amplifier can be built with a gain that increases with signal intensity). The most important nonlinear effect is probably frequency doubling. Optical radiation of a given frequency is propagated through a crystalline material and interacts with that material to produce an output of a different frequency that is twice the input frequency. For example, the 10,600 angstroms infrared output of a neodymium laser can, under suitable conditions, be converted into green light at 5300 angstroms in a crystal of barium strontium niobate. (B.J.T.)

BIBLIOGRAPHY. There are many journals and hundreds of books covering the general field of optics, some of the more familiar books include A.C. HARDY and F.H. PERRIN, *The Principles of Optics* (1932); and F.A. JENKINS and H.E. WHITE, *Fundamentals of Optics*, 3rd ed. (1957). At a somewhat more advanced level are R.S. LONGHURST, *Geometrical and Physical Optics*, 2nd ed. (1967); L.C. MARTIN, *Technical Optics*, 2 vol. (1960–61); and MAX BORN and EMIL WOLF, *Principles of Optics*, 2nd ed. (1964). In the purely geometrical field, the following can be recommended: W.T. WELFORD, *Geometrical Optics* (1962), which is fairly elementary and provides an excellent introduction to the subject; and L.C. MARTIN, *Geometrical Optics* (1956), which is somewhat more advanced.

Recommended books on the subject of information theory are EDWARD L. O'NEILL, *Introduction to Statistical Optics* (1963); JOSEPH W. GOODMAN, *Introduction to Fourier Optics* (1968); ARNOLD R. SCHULMAN, *Optical Data Processing* (1970); KENDALL PRESTON, *Coherent Optical Computers* (1972); HENRY LIPSON (ed.), *Optical Transforms* (1972); GEORGE W. STROKE, *An Introduction to Coherent Optics and Holography*, 2nd ed. (1969); JOHN B. DeVELIS and GEORGE O. REYNOLDS, *Theory and Applications of Holography* (1967); and ROBERT J. COLLIER, CHRISTOPH B. BURCKHARDT, and LAWRENCE H. LIN, *Optical Holography* (1971). For particular topics, reference should be made to the *Journal of the Optical Society of America* (monthly); *Applied Optics* (monthly); and EMIL WOLF (ed.), *Progress in Optics* (1961–).

Optimization, Mathematical Theory of

Optimization is a technique for improving or increasing the value of some numerical quantity that in practice may take the form of temperature, air flow, speed, pay-off in a game, political appeal, destructive power, information, monetary profit, and the like. Techniques of optimization assume such varied forms that no one general description is possible. With the advent of modern technology more and more emphasis has been placed on optimization of various types, and special thinking has developed to the

extent that it is meaningful to speak of a mathematical theory of optimization. Computer technology has been critically important in practical applications, such as in the optimal control of rockets. Further advances in the optimization and control of complex systems will probably depend more on mathematical theory than on technological invention.

An outline of the subject as presented in this article is as follows:

(Ed.)

I. The theory of games

Early work on mathematical optimization was extended by the development of game theory, a branch of mathematics that aims to analyze various problems of conflict by abstracting common strategic features for study in mathematical problems called *games* because they are patterned on such actual games as bridge and poker.

In game theory emphasis is placed on a correct description of the problem. By stressing strategic aspects—aspects controlled by the participants rather than by pure chance—the method goes beyond the classical theory of probability. A theory of games of strategy was broached in 1921 by a French mathematician, Émile Borel, and was established in 1928 by the Hungarian-born U.S. mathematician, John von Neumann. In 1944, von Neumann, then in America, published with the Austrian-born U.S. economist Oskar Morgenstern an account of the theory applied to competitive economic behaviour, based on the presence of several factors that are common to both actual games and economic situations: conflicting interests, incomplete information, and the interplay of rational decision and chance. The account opened a wide range of gamelike problems in sociology, psychology, politics, and war to mathematical attack.

CLASSIFICATION OF GAMES

Singular, dual, and plural games. In classifying games by the number of players, the significant figure is not the number of individuals involved but the number of parties with distinct interests actively represented in the play. It is assumed specifically that these interests are measured in terms of, for example, money or some other numerical scale of utility. This assumption is treated below under *Utility*. The presence of only one such interest, though there may be more than one participant, characterizes a game as singular. Typical are solitaire card games, many types of puzzles, and problems of an isolated economic unit with a single goal (*e.g.*, Robinson Crusoe's plight). Such games are distinguished by the absence of conflict; with no opponent to thwart his plans, the single player need only, in theory, list all his possible courses of action and then select the best, as measured on his scale of utility. Conflict enters with dual games (called by von Neumann and Morgenstern zero-sum two-person games), played by two parties in diametric opposition—what one wins, the other loses. Each party, in seeking an optimal course of action, must reckon with the possible actions of an opponent with contrary aims. This direct conflict of interests is exemplified by two-person board games such as chess, two-handed card games such as cribbage, and two-team card games such as bridge. In contrast, the presence of active interests that are not diametrically opposed such as the sales of two or more sellers in competition with each other stamps a game as plural. Sellers competing for the same market are engaged in a plural game in which the active interests (to be measured in money) are the sales. All games having more than two active interests fall into the plural class; so do two-party bargaining situations in which both parties stand to gain by reaching an agreement.

Extensive and normalized forms. From the rules of any game, two abstract forms can be obtained. The first of these, the extensive form of a game, eliminates all features that refer specifically to the means of playing it—all those features that characterize it as a card game, a dice game, or an economic conflict. Thus, the extensive form amounts to a literal translation of the rules into the technical terms of a formal system designed to describe all games. The second, or normalized form, is a more condensed version of the game, stripped of all features but the choice of over-all strategies.

The raw material for the extensive form comes from the common elements of strategic games, such as the interrelations between the players' choices, the variety and character of information available to them, and the effect of chance on the play. The object of a systematic description of these features is to isolate those junctures at which a player is called upon to make a choice and the states of information on which his choices are based. From this analysis emerges a precise definition of the first key concept on which the theory of games has been built. This is the notion of a pure strategy for a player; namely, a complete set of advance instructions that specifies a definite choice for every conceivable situation in which the player may be required to act. Such a set of instructions represents a total plan that covers all contingencies the player may face during any playing of the game, whether these are attributable to choices of other players or to events governed by chance; its execution could be delegated perfectly well to an agent without discretionary power. The complexity imposed on a single pure strategy by its completeness and the enormous number of pure strategies that may need cataloguing explain the failure of the theory to analyze most common parlour games. The practical difficulties, however, do not prevent the enumeration in theory of all the pure strategies of a game.

The notion of pure strategy

Whereas the extensive form of a game may have a large number of moves, or junctures at which a player must make a choice, in the normalized form each player makes only one move, which consists of a single choice from his set of pure strategies. As a result, the game is replaced by the following prototype: Each player chooses a pure strategy, making his choice in absolute ignorance of the

choices of the other players. After all strategies have been chosen, they are submitted to an umpire who charts the course of the play, making chance moves in accordance with the probabilities dictated by the rules and otherwise using the choices given by the players' pure strategies. In this way there is determined for each player a set of outcomes with associated probabilities, the expected value of which constitutes the player's payoff.

Finite and infinite games. In most games the number of pure strategies available to the players is finite because the rules ordinarily make the game terminate after a finite number of occasions for choice by the players, and because, at each occasion, a player is usually confronted by a finite number of alternatives.

Games with an infinite number of strategies often arise as idealizations of situations that are too complicated to be handled in their original form (such as replacing the full, but finite, range of poker hands by a continuum of numbers). It has proved possible in this way to treat problems of many sorts as normalized dual games in which the pure strategies for each player are represented by the real numbers from zero to one (called games on a square). Infinite games have also provided a fertile source of pathological examples; *i.e*, those offering a contrast to the regular properties found in the finite case. In a different direction, the making of decisions from statistical treatment of a body of data has been used to show that the general problem of statistical inference may be regarded as an infinite dual game in which the statistician is pitted against nature.

UTILITY

The fundamental problem of the theory of games is to find the methods by which a player can obtain what is called a most favourable result. In the first development of the theory, the most favourable result was identified with the greatest expected (monetary) gain, because this, or some similar assumption, is necessary if probabilistic methods are to be applied. There are, however, strong objections to the principle of maximizing expected winnings as a prescription for behaviour, and these led to a re-examination of the concept of utility.

To understand these objections and the modern theory of utility that resulted, the following situation may be considered: A player is required to choose an integer from 1, 2, $\cdots$, n, and is then paid a sum of money P_j that depends upon his choice of j. If the player always prefers more money to less, then rational behaviour is clear in this situation of certainty; namely, the player should choose j so as to make P_j as large as possible. If this situation is altered to introduce uncertainty and risk, then the rule is no longer obvious.

The St. Petersburg paradox

This can be illustrated with a classical example known as the St. Petersburg paradox. A player is confronted with a choice between the status quo and the payment of an entry fee F for an infinite set of lottery tickets numbered 1, 2, $\cdots$, n, $\cdots$. The lottery ticket n is to pay the amount 2^n with associated odds of one chance in 2^n. The rule of maximizing expected winnings counsels the purchase of the lottery tickets, no matter how high the entry fee F. Numerical examples, however, persuade many people of the advantages of the status quo; for example, with $F = \$128$, there is but one chance in 64 that a player who chooses the lottery tickets will break even, and he will otherwise lose at least \$64. If the game is to be played but once, it would mean assuming a high risk for the prospect of highly improbable winnings.

To resolve this paradox, a Swiss mathematician, Daniel Bernoulli, suggested that people do not follow monetary value as an index for preferences but rather are concerned with the moral worth of money. Further, in a situation involving risk, they seek to maximize the expected value of moral worth (what has been called moral expectation). Finally, he proposed a quite serviceable function to measure the moral worth of an amount of money, namely, its logarithm.

Whatever the defects of this function as a universal measure of preferences, there is a need for a numerical index that will reflect accurately the choices of an individual in situations of risk. Interest in this problem was first shown by the British logician F.P. Ramsey who defined utility operationally in terms of individual behaviour. Independently, von Neumann and Morgenstern confronted this problem while laying the foundations for the theory of games. Informally, they showed that if a player can consistently express his preferences between every possible pair of gambles on outcomes, then there exists a utility function defined on the possible outcomes such that its expected value is an accurate guide to the player's choices in situations of risk. This numerical measure of utility permits the definition of the most favourable result as that with the greatest utility.

Utility function

NORMALIZED DUAL GAMES

Matrix games; saddlepoints. A finite dual game, when normalized, has a simple conceptual scheme. Each of the players, A and B, chooses a pure strategy from a finite list, without knowing the other's choice. The outcome thus determined can be specified by a single number P, the payoff A stands to receive: positive, negative, or zero according as A wins from B, loses, or draws. By the diametric opposition characteristic of a dual game, B then stands to win $-P$. In this way the game is described by a rectangular array of numbers, in which each horizontal row corresponds to a pure strategy for A and each vertical column to a pure strategy for B; the entry P common to the row and column is the payoff to A from B that these pure strategies produce. The array of numbers is called the payoff matrix; normalized finite dual games presented in such form are called matrix games. (Examples appear in Tables 1 and 2; in each case the payoff matrix is the central box of arabic numbers.) Because the matrix entries represent gains to A and losses to B, A's aim is to maximize and B's to minimize the result that comes out of the matrix.

Table 1: Games of Odd and Even

As A weighs the consequences of various courses of action open to him in a dual game, the theory of games counsels him to gauge each by the gain it assures him, regardless of what B does. In effect, this is equivalent to the pessimistic assumption by A that B knows his plan and will counter it to limit his gain to a bare minimum. So, to maximize his assured gain, A is led to seek a maximum of minima, abbreviated max-min; he should act so as to make as great as possible the least gain to which B can limit him. The antithetical aim of B is to choose a course of action that will hold to a minimum the greatest loss A may inflict. Thus, B's goal is a minimum of maxima, abbreviated min-max. The clear fact that A cannot establish a floor under his possible gains that is higher than the ceiling B succeeds in placing over his possible losses is expressed by a simple formula expressed in terms of a "less than or equal to" relationship (see Box, formula 1).

Max-min and min-max

With evaluation limited to pure strategies only, this is the most precise statement that can be made for the entire class of dual games. (The effect of further restrictions is considered below under *Extensive games—a poker example.*) The highest gain-floor for A, using a single pure strategy, is obtained by choosing the strategy row in which the least entry is greatest; the lowest loss-ceiling for B, using a single pure strategy, is obtained by choosing the strategy column in which the greatest entry is least. These two values are equal only when there is an entry in the payoff matrix that is, at the same time, the least in its row and the greatest in its column. Such an entry is called a saddlepoint (*e.g.*, see Table 1, case (3), in which the entry 3 is a saddlepoint).

Mixed strategies; minimax theorem. To close the gap between max-min and min-max in the general case in which the payoff matrix contains no saddlepoint, it is necessary to broaden the concept of strategy. Although the decisive innovation of weighted averages of pure strategies occurred in 1713, it was not exploited fully until it was rediscovered by von Neumann. In the broadened concept the frequencies with which a player uses his pure strategies in the long run are specified by weights (some but not all of which may be zero). Operationally, the selection of the pure strategy to be used in a particular playing of the game is left to a suitable chance mechanism, which selects in a random manner from among the pure strategies in accordance with the weights the player has chosen (*e.g.*, in matching pennies, as ordinarily played, the pure strategy of showing heads uniformly and that of showing tails uniformly are randomized with equal weights by tossing the coin before showing it). This randomization by a chance mechanism avoids a mixture pattern from which the opponent might profit in the long run (*e.g.*, to alternate uniformly between heads and tails in matching pennies would weight them equally but be quite unwise in repeated play). Such a mixture of pure strategies, randomized in fixed proportions, is called a mixed strategy. It is clear that neither player's position is worsened by using mixed strategies, because any pure strategy is still tenable as a mixed strategy by assigning nonzero weight only to it.

Definition of mixed strategy

(1) A's gain-floor = max-min ≤ min-max = B's loss-ceiling

(2) max-min = min-max

When A's gain-floor and B's loss-ceiling are re-evaluated in terms of mixed strategies, it turns out that in any matrix game the maximum of minima and the minimum of maxima are equal (see 2). This minimax theorem of von Neumann (1928) is the main theorem of normalized finite dual games and the keystone of the whole theory. It shows that any such game has a solution consisting of (1) a minimax value (the common max-min and min-max), (2) an optimal mixed strategy for A that assures him a gain of at least the minimax value on the average, and (3) an optimal mixed strategy for B that insures him against a loss on the average of more than the minimax value.

Examples of matrix games. A and B choose whole numbers independently; A wins if the sum is odd, B wins if the sum is even. Roman numerals are used throughout in the tables to denote the numbers from which A and B make their choices. The first case shown in Table 1 is a rudimentary dual game; it is the same as matching pennies, with B winning if head (I) matches head (I) or tail (II) matches tail (II), and A winning otherwise. The other four cases are variants that suggest the range of possibilities that arise even in small-scale dual games. Directly to the right of an A choice and below a B choice there appears the resulting payoff, positive if A wins (and B loses), negative if A loses (and B wins). In the rudimentary first case the amount of the payoff is simply one unit, but throughout the other four cases in Table 1 the amount of the payoff is the sum of the numbers chosen by A and B; *e.g.*, if A chooses I while B chooses III, as in cases (3), (4), and (5), the payoff entry is −4 because 1 + 3 = 4, an even number, lost by A, won by B. The vertical column of weights listed for A in each case combines with a parallel column of payoffs to form the weighted payoff sum shown at the foot of that column; *e.g.*, in case (5), column I, 0(−2) + 15(−4) + 13(5) = 5 is the weighted payoff sum. The horizontal row of weights listed for B combines with a parallel row of payoffs to form the weighted payoff sum shown at the right end of that row. These weighted sums become weighted averages when divided by the sum of the weights, written (with ÷) at the lower right. By randomizing their choices with the particular weights listed, A and B achieve optimal strategies; on the average, A is assured of winning at least the minimax value shown and B against losing more than this value. Each solution shown in Table 1 may be verified by observing that the minimax value is both the minimum of the A-weighted average payoffs and the maximum of the B-weighted average payoffs. In case (3), the payoff matrix has a saddlepoint, viz., the entry 3.

How optimal strategies are achieved

Symmetric games. A and B each show one or two fingers, at the same time calling aloud the numbers two, three, or four in an attempt to guess the total number of fingers shown; a right call wins from a wrong call—otherwise it is a draw. This is a two-finger form of an ancient game known as morra played today in Italy. In the rudi-

mentary first version shown in Table 2, the amount of the payoff is simply one unit for a win and zero for a draw; in the somewhat more sophisticated second version the amount of a winning payoff equals the total number of fingers shown by A and B (*e.g.*, if A shows I and calls II, whereas B shows II and calls III, the payoff entry in the second version is −3, because the total number of fingers shown by A and B is $1 + 2 = 3$ and hence A's call is wrong and B's right). In either version the game is fully symmetric: both players face identical choices and rewards. This is partly disguised by the tabulation, which presents the payoffs from the viewpoint of A. To interchange A with B, not only must horizontal payoff rows be transposed into vertical columns but also the sign of each payoff must be changed (to B's viewpoint). The net result of such a twofold shift leaves the payoff arrays in Table 2 just as they are—which is the characteristic property of the tabulation of a fully symmetric dual game. As a result of the symmetry, any optimal strategy for one player must also be optimal for the other and the minimax value must be zero. Consequently, in each of the above versions of morra, the listings of weights for A and B that achieve the zero minimax could be reversed, and this shows that both players have more than one optimal strategy. Actually, in the first version, any weights p, q, q, p yield an optimal strategy; and in the second version, any weights $0, p, q, 0$ yield an optimal strategy, provided $p/(p + q)$ is a fraction between 20/35 and 21/35.

Computation of solutions. The solution of a matrix game with m columns and n rows of payoff entries amounts to the solution of a system of linear inequalities in $m + n + 1$ unknowns, A's m weights, B's n weights, and the minimax value. The system comprises n inequalities that express the A-weighted average payoffs as equal to or greater than the minimax value and m inequalities that express the B-weighted average payoffs as equal to or less than the minimax value; in addition, the $m + n$ weights must be non-negative, reduced usually to fractional form with unit sum for each set, so that the weighted payoff sums become weighted averages without division. It has been shown that any basic solution of such a system is characterized as the unique solution of a suitably chosen subsystem of linear equations. As a result, the solution (if unique) or the full set of solutions (if more than one exist) can be determined by at most a finite number of arithmetic operations, but this number increases so rapidly, as the numbers m and n of rows and columns increase, that the solution of a large-scale matrix game by this method is formidable or impracticable.

The solution of a pair of dual linear programs, which call for maximizing and minimizing linear functions of several variables subject to constraints given by linear inequalities or equations, is equivalent to the solution of a matrix game, and vice versa. Hence, the simplex method devised for linear programming can be applied to solve reasonably sized matrix games. Iterative procedures for approximating game solutions have been formulated to exploit high-speed computers.

Games on a square. In a matrix game, a finite array of payoffs may be replaced by an infinite array of payoffs,

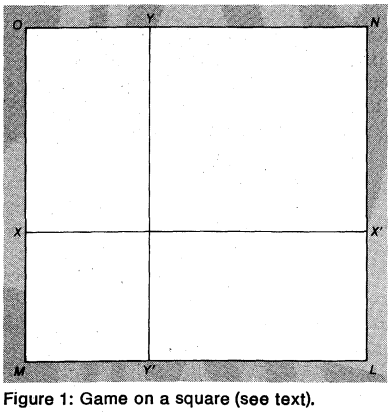

Figure 1: Game on a square (see text).

(3) $P = 4x + 2y + y^2 - x^2 - 4xy - 2$

(4) $P = 0.2 + (y - 0.6)^2$ if $x = 0.8$ and
$P = 0.2 - (x - 0.8)^2$ if $y = 0.6$

one for each point of a square $OMLN$ (see Figure 1). A may choose a point X in the edge OM and, independently, B may choose a point Y in the edge ON; then A gets from B the payoff attached to the point of intersection of the lines XX' and YY' perpendicular to OM and ON. This is an infinite dual game on a square. Figure 2 presents an example: A and B divide the area $OMJLKN$, formed by the square $OMLN$ and two isosceles right triangles MJL and LKN, by means of the lines XX'' and YY'' based on independent choices by A and B of X in OM and Y in ON; A gets the unshaded area, B the shaded area. By direct calculation, taking $OM = ON =$ one unit and $OX = x$, $OY = y$, the net payoff (A's area minus B's area) is found to be a quadratic in x and y (see 3); that is, an algebraic expression in which x and y are at most squared. A wishes to maximize the payoff P; B to minimize P (that is, to maximize $-P$).

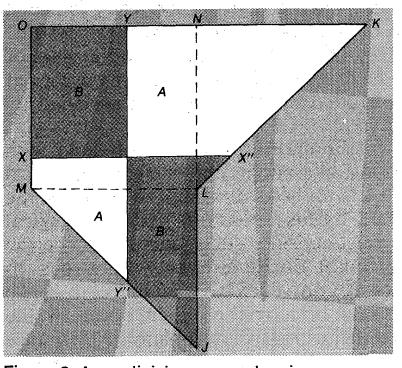

Figure 2: Area-division game showing saddlepoint division (see text).

By analogy with a matrix game, a saddlepoint for a game on a square is at the intersection of a line XX' and a line YY', for which the payoff at the point of intersection is equal to or less than every other payoff on XX', and is equal to or greater than every other payoff on YY' (see Figure 1). (A saddlepoint is so called because it appears as an actual surface saddlepoint in the three-dimensional graph of the payoff over the square.) In the area-division game (Figure 2) $x = 0.8$, $y = 0.6$ give a saddlepoint having payoff 0.2. The net payoff can be rearranged (see 4) to show that by choosing $x = 0.8$, A assures himself at least 0.2, whereas, by choosing $y = 0.6$, B guards against losing more than 0.2. The claim that this point is a saddlepoint can also be verified by geometric reasoning, based on the fact that it is the critical position at which XX'' and YY'' bisect one another (in Figure 2). The saddlepoint

The solution in pure strategies possessed by the area-division game is exceptional, because games on a square, like matrix games, do not usually possess saddlepoints. In general, each player must weight the points in his interval, OM or ON, if he is to do the best he can for himself. Such distributions of weights over an interval are known as probability distributions; they play a role analogous to that of mixed strategies in matrix games. Yet, even when both players employ probability distributions, the minimax theorem does not hold without some mild restriction on how the payoffs vary over the square. For the continuous case of payoffs without abrupt jumps, the equality of max-min and min-max was established in 1938.

EXTENSIVE GAMES—A POKER EXAMPLE

Pure strategies. The primary objective of the study of a game in extensive form is the analysis of the combinatorial structure defined by the rules and its influence on the subsequent definition of strategies. This structure can

Table 3: Simplified Poker in Extensive Form

*Indicates irrational terminal situation.

be presented in the form of a branching diagram (of the sort exhibited in Table 3) in which the junctures represent occasions at which a player or a chance mechanism (specified by the rules, such as cards, dice, etc.) is called upon to select one of the several branches that continue the course of the play. These branches contain the state of information of the next player. If the branching ceases at any stage, the play is over and the payments specified by the rules are listed.

Several junctures in the diagram may be prefixed with the same information for a single player (*e.g.*, in a card game, these may be situations that differ only in the unrevealed cards held by his opponents). For strategical purposes, a player must consider such junctures to be the same, because he cannot distinguish between two such junctures and hence cannot decide in advance to make distinct choices should one or the other occur in the course of play. This means that the problem of formulating a pure strategy for a player is solved by listing all of his junctures with distinct states of information and then making a definite choice of a branch for each. Such a plan fulfills the requirements for a pure strategy set forth previously.

Historically, the first result on games in extensive form was stated (for the game of chess) by Ernst Zermelo and given a complete proof by von Neumann. It applies to games with perfect information; that is, games in which a player is always informed of the complete previous history of the play. The theorem asserts that finite dual games with perfect information can always be solved by pure strategies without randomization. In other words, there is always a saddlepoint in the payoff matrix of such games. As regards chess, in particular, this means that exactly one of the following three alternatives is valid: (1) White has a pure strategy that wins, no matter what Black does; (2) both players have pure strategies that ensure at least a draw, no matter what the other does; (3) Black has a pure strategy that wins, no matter what White does. The theory gives no practical method, however, for deciding which assertion is true.

The three alternatives in chess

Behaviour strategies. The lack of a solution in pure strategies for a general finite dual game means that a player must randomize his actions in some manner to obtain the amount due him (as measured by the minimax value). In the extensive form of a game, it is possible to introduce a method, alternative to that of mixed strategies, for varying his choices from contest to contest of the game in an undecipherable pattern. This method specifies by weights the long-run frequencies with which a player chooses the various alternatives presented to him in a given state of information. Rather than using a chance mechanism to select a complete plan before the playing of a game, a player employs such a device throughout the play, at each occasion for choice, to select an alternative in accordance with weights he has chosen. Such a decentralized system of play, randomizing the choices for each distinct state of information in fixed proportions, is called a behaviour strategy, because these weights are the statistics of a player's behaviour that an external observer could gather from a long series of contests.

Because the number of weights needed to specify a behaviour strategy is, in general, much smaller than the number of weights in a mixed strategy, it is useful to know when they produce the same results. It has been shown that a player can use either with equal success in any game, with perfect recall; *i.e.*, any game in which a player's state of information always includes everything he has done or known previously. Poker is a game with perfect recall and hence can be played effectively with behaviour strategies. Bridge, on the other hand, does not have perfect recall because each player is a pair of persons, neither of whom is informed of the other's hand. Because there can be no correlation between the selections made by the chance devices for different states of information when a player employs a behaviour strategy, it is possible that bridge players must use mixed strategies to achieve the minimax value.

Recall in poker and bridge

Simplified poker. A simplified version of poker is played by A and B with a deck containing a large number of cards marked high (*H*) and low (*L*). First, each player provides ("antes") four chips and is dealt a single card; the four possible deals are assumed to be equally likely. Then A has two options: to "see," or to "raise" by adding two chips to the pot. If A decides to see, the higher hand wins the pot and equal hands split the pot equally. If A decides to raise, B has three options: to "fold," to see by adding two chips to the pot, or to raise by adding three chips to the pot. If B folds, A wins the pot (with no hands revealed). If B sees, the higher hand wins the pot and equal hands split the pot equally. If B raises, A has two options: to fold, or to see by adding one chip to the pot. If A folds, B wins the pot (with no hands revealed). If A sees, the higher hand wins the pot and equal hands split the pot equally.

The possible sequences of choices by the players, independent of the actual cards held, are shown at the top of Table 3. The player to act precedes, and his alternatives follow, each juncture. The possible payoffs (listed as A's gain, because this is a dual game) are given when the play is over. The precise payoff that occurs is determined by the cards held. In the body of Table 3 appears the complete branching diagram, taking account of the deal. Four-place symbols present the states of information. The first two symbols give the hand and current bet of A, the last two symbols give the hand and current bet of B. All are given as known to the player who is next to act; *e.g.*, the symbol ?6*L*4 preceding B means that B is to act, not knowing A's card, but knowing that A has bet six chips, and B holds a low card and has bet four chips. For ready reference, the actual card held is listed below each question mark. Whenever the play ends, the payoff to A is listed; if either player has folded, the symbol *X* is used to indicate that neither hand need be revealed.

Payoffs in poker

Certain terminal situations (starred in the Table) will never occur in rational play; *e.g.*, player A will never see in the second stage while holding a high card because he stands to win at least as much (and sometimes more) by raising. Similar arguments advise both players to bet the limit at every juncture in which they hold a high card. Reduced in this manner, a pure strategy for either player consists merely of how high he should carry his bet on a low card. These pure strategies are listed as two-place symbols to the left and above the payoff matrix in the left half of Table 4. The first number (7) gives the limit a player will bet on a high card, the second (4, 6, or 7) gives the limit on a low card. To compute the payoff to A when two of these strategies are played, an average is taken over the four terminal situations that can follow the four possible deals; *e.g.*, when A plays 76 against 74 for B, the play ends in *H*7*H*7, *X*6*X*4, *X*6*X*7, or *X*6*X*4 and the corresponding entry is $\frac{1}{4}(0) + \frac{1}{4}(4) + \frac{1}{4}(-6) + \frac{1}{4}(4) = 2/4$. (The unreduced payoff matrix would consist of nine rows and nine columns, labelled 44, 46, 47, 64, 66, 67, 74, 76, 77.)

Computing payoffs

The weights listed are the only weights that achieve the

Table 4: Simplified Poker

		raise	2

minimax value. Player A must play bluffing strategies (either 76 or 77) one-half of the time, whereas B must decide to bluff one-fourth of the time.

The average behaviour imposed by these optimal mixed strategies upon a player with a given state of information constitutes an optimal behaviour strategy. The optimal weights, so defined, are given in the right half of Table 4 (*e.g.*, with information *L*4?4, player A assigns the seeing pure strategy 74 the weight 6 and assigns the raising pure strategies 76 and 77 the weights 2 + 4 = 6; in common parlance this means that, in the long run, A sees as often as he raises upon being dealt a low card).

PLURAL GAMES

Economic example: noncooperative solutions. Two basically different approaches to the behaviour of parties to plural games have been proposed. The solutions that they suggest are contrasted in the following (highly simplified) problem from economics: Two sellers, A and B, in competition with each other, are contemplating a price cut of the same amount. Each knows that if they both sell at the same price they will divide the market evenly, but if one cuts his price and the other does not, then the former will capture the entire market. If the total profits at the higher and lower prices are known, this situation gives rise to a symmetric two-party plural game. The top part of Table 5 lists the payoffs for four of these games; in all cases, six units of profit are available at the higher price, whereas the lower price, in the four cases, yields four, two, zero, and minus two units of profit, respectively (negative profit is positive loss). The profits of A and B in each of the four games are shown to the right of each pair of prices (*i.e.*, pure strategies).

Table 5: Price Cut Example

prices		profits							
		(1)		(2)		(3)		(4)

low	low	2*	2*	1*	1*	0*	0*	−1	−1
coalition		maximum assured profit							
A with B		6		6		6		6	
A alone		2		1		0		0	
B alone		2		1		0		0	

*Indicates solution.

As a solution to the sellers' problem, the noncooperative theory of John Nash suggests and proves the existence of a pattern of independent action in which there is no incentive for deviation by any player alone. As such, it is an extension of the minimax theory for dual games. A price cut by each seller is an equilibrium point in each of the first three games, and if both keep the higher price, the result is an equilibrium point in the last three games. These solutions (starred in the top part of Table 5) can be checked by verifying that unilateral changes in strategy are not rewarded. In the first game, the stability of the solution derives from the fact that a lone decision by either party to sell high would decrease his profit from two units to nothing. Although it is clear in this case that both sellers would benefit from an agreement binding each other to the higher price, this pattern is considered unstable because either seller could increase his profit by unilateral action.

In like manner, a cut by a single seller can be considered a (fictitious) coalition between that seller and the buyers of the market but can be upset by lone action by the other seller to his advantage. Indeed, the dilemma posed by the first game consists of the instability, with respect to unilateral defections, of each of the three possible two-party coalitions that may form among the two sellers and the market.

Cooperative solutions. The cooperative theory of von Neumann and Morgenstern for plural games (their general *n*-person games) is built upon these coalitions and introduces the possibility that the parties to an agreement may distribute their payments so as to maintain the coalition. The bottom part of Table 5 continues the analysis of the sellers' problem from this point of view. It lists for each of the four games the maximum assured profit for A and B acting together, for A alone and for B alone (*e.g.*, the greatest profit A can assure himself in the fourth game is zero; to do this he holds to the higher price). The cooperative theory suggests, for all four games, that (1) the sellers agree to hold to the higher price; (2) that each receive at least as much from the coalition as by independent action; (3) that the remainder be distributed in some manner between them (*e.g.*, in the second game, each seller surely receives one unit and the four additional units are divided in an unspecified manner). No mode of distribution is singled out, because even though one seller may prefer one division to another, he cannot enforce it by a unilateral change of his strategy or his allegiance. On the other hand, every other distribution of the profits is less advantageous to the collective interest of the two active parties, the sellers. In general, the stability of a cooperative solution derives from these two sources: internal consistency and external domination.

Stability of a cooperative solution

Simple games; a power index. The cooperative theory has a political aspect when the only prospects of a coalition are to win or lose; this is the case in voting systems, such as legislatures, committees, and voting stockholders. Such games are called simple, and the only two possible outcomes, win or lose, for the coalitions are indicated numerically by one and zero. An a priori numerical indicator of the relative equities of the players of any cooperative game has been proposed that is easily calculated for such a situation. This power index measures the average contribution of a player to the coalitions to which he might belong, taking account of the order in which the members join the coalition; *e.g.*, a participant in a simple game contributes to a coalition only if his entrance changes it from a losing to a winning coalition.

A representative example of this class is a four-man committee composed of a chairman, with three votes, and three other members, with one vote each. A simple majority of votes win, whereas ties are considered as a loss for both sides. The 24 possible sequences in which the members might vote are listed in Table 6; the chairman is denoted by A and the three ordinary members by b, c, and d. The pivotal player, the first to complete a majority in each voting order, is starred in each column. Because the chairman is pivotal three-fourths of the time, his power index is 75 percent. The ordinary members share the remaining fourth equally and have as indices 8⅓ percent. Thus the voting ratio of 3:1 results in a power ratio of 9:1 in this simple game. (A.W.T./H.W.K.)

GAME PLAYING PROGRAMS

Many attempts have been made at writing programs for playing games on a computer. Although, in general, the programs are not based purely on the theory of games, they use many of the techniques developed in this field.

Table 6: Committee Voting Example

voting	24 possible orders																							
First	A	A	A	A	A	A	b	b	c	c	d	d	b	b	c	c	d	d	b	b	c	c	d	d

*Indicates pivotal player.

Invoking the minimax principle

Board games. The usual approach is to construct a search tree of possible moves to a given depth and to evaluate the board positions so obtained using an evaluation function based on the programmer's own knowledge of the game. The minimax principle is used to choose the next best move. For example, in Figure 3 the search tree is a depth three. Each node represents a board position and the board positions at level three are all evaluated. A position deemed beneficial to the computer is denoted by a positive score, the larger the score the better the position. If it is the computer's move next, then the move taken is that shown in the Figure. For most board games, the search space is extremely large. Various methods of reducing the search space of possible moves are used in order to keep the problem to manageable proportions. The technique of pruning was introduced in one of the early famous chess playing programs, and this technique was shown to reduce search space considerably. The program attains an acceptable level, about the standard of an average-to-good player. A successful checker (British, draughts) playing program has been written, one that is of world championship standard. In 1969, an article was published concerning playing the game of *go* on a computer. A *go* board has a grid of 19 × 19 lines and thus there is a search space of about 10^{761} nodes. The author suggests a new approach based on applying a battery of basic principles of play. Together with a simple "look-ahead," the recommendations give good positional play and avoid tactical capture traps that could lead to the loss of a stone or two.

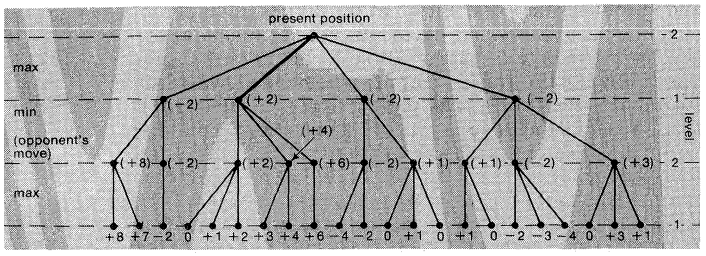

Figure 3: Search tree of depth three, showing minimax principle. The best next move after the present position is indicated by the heavy line (see text).

Other games. Straightforward programs have also been written to play card games (bridge, poker, etc.), three dimensional tic-tac-toe (British, noughts and crosses) and *kalah*. (Ed.)

II. Linear and nonlinear programming (mathematical programming)

GENERAL OBSERVATIONS

Mathematical programming may be described in terms of its mathematical structure and computational procedures or in terms of the broad class of important decision problems which can be formulated as the minimization (maximization) of a function of several variables that are subject to a system of side constraints. For example, a linear program is defined as the minimization of a linear "objective" function whose variables satisfy a system of linear inequalities.

The scope of mathematical programming

In practice, mathematical programming usually refers to such linear programs, the general study of nonlinear programs (those in which either the objective function or at least one of the constraint functions is nonlinear), integer programs (that is, linear programs with the additional restriction that some or all of the variables must be integer valued), stochastic programs (those programs involving random variables), and network flow theory (transportation or flow through networks). As such, mathematical programming overlaps, has contributed to, and has been influenced by operations research, mathematical economics, control theory, dynamic programming, and combinatorial theory.

The term programming had its origin in programming (*i.e.*, planning, scheduling) the quantity and timing of the various activities of an organization such as a factory, an airline, the defense establishment, the national economy, or world trade. (It is not to be confused with "programming" as used for the task of preparing a sequence of instructions for a computer.) The goal is to find an optimum schedule.

A simple example, "the assignment problem," illustrates the essential difficulty. A factory has 70 men with different qualifications and it is desirable to assign them to 70 jobs. If a "value" can be attached to assigning a particular man to a particular job, then the problem becomes one of selecting out of 70! (which is the product of integers from 1 to 70) possible ways of permuting the assignments the one that yields the maximum total value to the factory. Because 70! is approximately 10^{100}, it would take an electronic computer executing 1,000,000 operations per second over 10^{87} years (or many times the projected life of the universe) to examine all the permutations. Such decision problems are common and have resulted in the development of clever formulation of the mathematical models, powerful mathematical methods of solution, and efficient computer algorithms (step-by-step procedures). The solution of linear programs is said to constitute 25 percent of all the time used by computers to solve scientific problems.

ORIGINS AND INFLUENCES

Although widely used now to solve everyday decision problems, linear programming was comparatively unknown before 1947. No work of any significance was carried out before this date, even though the French mathematician Jean-Baptiste-Joseph Fourier seemed to be aware of the subject's potential as early as 1823. A Russian mathematician, Leonid Vitalevich Kantorovich, who published an extensive monograph in 1939 *Matematicheskie metody organizatsi i planirovaniya proizvodstva* ("Mathematical Methods for Organization and Planning of Production"), is credited with being the first to recognize that certain important broad classes of scheduling problems had well-defined mathematical structures. Unfortunately his proposals remained unknown both in the Soviet Union and elsewhere for nearly two decades. Meanwhile, linear programming had developed considerably in the United States and Western Europe. In the period following World War II, officials in the United States government felt that efficient coordination of the energies of a whole nation in the advent of atomic war would require the use of scientific planning techniques. The advent of the computer made such an approach feasible.

The first linear programming model

Intensive work began in 1947 in the United States Air Force. The linear programming model was proposed because it is simple, practical, and yet provided a sufficiently general framework for representing interdependent activities that must share scarce resources. The system (*e.g.*, national economy) is viewed as made up of various activities (*e.g.*, production, training, shipping, disposal, and storing). Each activity is assumed to require a flow of inputs and outputs of various types of items (*e.g.*, men, materials) proportional to the level of the activity. Activ-

ity levels are assumed to be representable in terms of positive numbers or zero. The revolutionary feature of the approach, however, was the expressing of the goal, as that of minimizing (maximizing) an objective function (*e.g.*, maximizing sorties in the case of the air force or maximizing profits in industry). Before 1947 all practical planning was characterized by a series of authoritatively imposed rules of procedure and priorities. General objectives were never stated, probably because of the impossibility of performing the calculations necessary to minimize an objective function under constraints. In 1947 a method composed of successive tests for optimality at extreme points and intervening linear movement along polygonal edges called the simplex computational method was introduced which turned out to be indeed efficient. Interest in linear programming grew rapidly and by 1951 its use spread to industry. It is almost impossible to name an industry in the early 1970s that is not using mathematical programming in some form, although its use varies greatly, even within the same industry.

The current interest in linear programming by economists appears to be an anachronism. The French economist François Quesnay's attempt in his *Tableau économique* (1758) to interrelate the role of the landlord, the peasant, and the artisan was a crude example of a linear programming model. Léon Walras, another French economist, in 1874 proposed a sophisticated approach that had as part of its structure fixed technological coefficients (as assumed in linear programs). Oddly enough, until the 1930s, the linear-type model was little exploited.

Von Neumann in a 1937 paper analyzed a steadily expanding economy based on alternative methods of production and fixed technological coefficients. As far as mathematical history is concerned, the study of linear inequality systems excited virtually no interest before 1936. In 1911 a vertex-to-vertex movement along edges of a polyhedron (as is done in the simplex method) was suggested as a way to solve a problem that involved optimization, and in 1941 movement along edges was proposed for a problem involving transportation. Credit for laying much of the mathematical foundations should probably go to von Neumann. In 1928 he published his famous paper on *Game theory*. In 1947 he conjectured the equivalence of linear programs and matrix games, introduced the important concept of duality, and made several proposals for the numerical solution of linear programming and game problems. Serious interest by other mathematicians began in 1948 with the rigorous development of duality and related matters.

The general simplex method, already mentioned (see above ***Origins and influences***) and to be discussed in detail (see below *The simplex method*), was first programmed in 1951 for the United States Bureau of Standards SEAC computer. Starting in 1952, the simplex method was programmed for use on various models of IBM (International Business Machines) computers and later for those of other companies. These programs turned out to be practical. As a result, commercial applications of linear programs in industry and government grew rapidly. New computational techniques and variations of older techniques continued to be developed.

At the present time there is much interest in solving large linear programs with special structures, for example, corporate models and national planning models that are multistaged, dynamic, and exhibit a hierarchical structure. It is estimated that certain underdeveloped countries have the potential of increasing their GNP (gross national product) anywhere from 10 percent to 15 percent per year if detailed growth models of the economy could be constructed, optimized, and implemented.

LINEAR PROGRAMMING THEORY

Linear programming in factory production

Basic ideas. A simple problem in linear programming is one in which it is necessary to find the maximum (or minimum) value of a simple function, such as $x_1 + 2x_2$, subject to certain constraints. An example of its application might be that of a factory producing two commodities. In any production run, it produces x_1 of the first type and x_2 of the second. If the profit on the second type is twice that on the first, then $x_1 + 2x_2$ represents the total profit. The function $x_1 + 2x_2$ is known as the objective function.

Clearly the profit will be highest if the factory devotes its entire production capacity to making the second type of commodity. In a practical situation, however, this may not be possible; a set of constraints is introduced by such factors as availability of machine time, manpower, or raw materials. For example, if the second type of commodity requires a raw material that is limited so that no more than five can be made in any batch, then x_2 must be less than or equal to five; *i.e.*, $x_2 \leq 5$. If the first commodity requires another type of material limiting it to eight per batch then $x_1 \leq 8$. If 1 and 2 take equal times to make and the machine time available allows a maximum of ten to be made in a batch, then $x_1 + x_2$ must be less than or equal to 10; *i.e.*, $x_1 + x_2 \leq 10$.

Two other constraints are that x_1 and x_2 must each be greater than or equal to zero, because it is impossible to make a negative number of either; *i.e.*, $x_1 \geq 0$ and $x_2 \geq 0$. These conditions result in a simple linear program that can be stated in concise algebraic form. The problem is to find the values of x_1 and x_2 for which the profit is a maximum. Any solution can be denoted by a pair of numbers (x_1, x_2); for example, if $x_1 = 3$ and $x_2 = 6$, the solution is (3, 6). These numbers can be represented by points plotted on two axes; in Figure 4

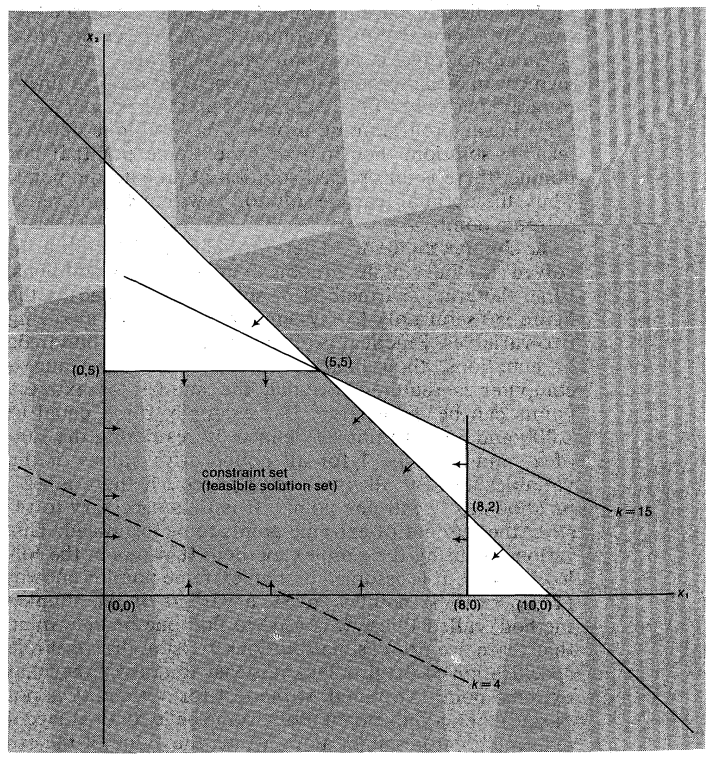

Figure 4: Constraint set bounded by the five lines $x_1 = 0$, $x_2 = 0$, $x_1 = 8$, $x_2 = 5$, and $x_1 + x_2 = 10$. These enclose an infinite number of points that represent feasible solutions.

the distance along the horizontal axis represents x_1 and that along the vertical represents x_2. An infinite number of points exist corresponding to an infinite number of solutions, but because of the constraints the feasible solutions must lie within a certain region. For example, the constraint $x_1 \geq 0$ means that points representing feasible solutions lie on or to the right of the x_2 axis. The constraint $x_2 \geq 0$ means that they also lie on or above the x_1 axis. Application of all the constraints leads to the result that points representing solutions lie within the shaded area bounded by a polygon formed by intersection of the lines $x_1 = 0$, $x_2 = 0$, $x_1 = 8$, $x_2 = 5$, and $x_1 + x_2 = 10$. These form the constraint set. For example, to make three items of commodity 1 and four of 2 is a feasible solution since the point (3, 4) lies in this region.

To find the best solution, the objective function $x_1 + x_2 = k$ is plotted on the graph for some value of k, say $k = 4$. This value is indicated by the broken line in Figure 4. As k is increased, a family of parallel lines are produced and the line for $k = 15$ just touches the constraint set at the point (5, 5). If k is increased further, the values of x_1 and x_2 lie outside the set of feasible solutions. Thus the best solution is that in which equal quantities of each commodity are made. The points (0, 0), (0, 5), (5, 5), (8, 2), and (8, 0) are the extreme points of the constraint set, and the problem involves finding the extreme point the coordinates of which yield the largest value for k.

The standard form of a linear program is expressed as an instruction to maximize (or minimize) a linear expression in n nonnegative variables, $\{x_i\}$, subject to m linear equations (see 5). In applications, the equations correspond to material balance of various items and the variables to levels of various activities (*e.g.*, production processes). Any system of linear inequalities can be reduced to this standard form by simple substitutions.

Definition of a feasible solution

A set of x_j values that is nonnegative and satisfies the equations is a "feasible" solution and corresponds to a feasible but not necessarily optimal program. Such a solution is viewed as a point in n-dimensional space.

The constraint set—*i.e.*, the set of feasible solutions—has a property known as convexity. In general, a set S is convex if and only if it contains the entire line segment between any two of its elements. An element of a convex set S is called an extreme point if it does not lie on the line segment joining two other points of S. A line segment in S is called an edge if no point on it lies also on a line segment in S that crosses it. The constraint set of a linear program has only a finite number of extreme points.

If a linear programming problem has a unique optimal feasible solution, then it is at an extreme point; if not unique, there is an optimal solution at an extreme point. Thus, the optimal feasible solution is within a finite set of extreme points.

The simplex method. There are certain difficulties involved in the simple graphical approach to solutions. First, the graphical method of solution illustrated by the figure is useful only for systems of inequalities involving two variables. Practical problems often involve hundreds of equations, thousands of variables, however, and a computer is required. Second, the number of extreme points can be quite large. For example, for n equal to 2,000 and a constraint set defined by restricting the sum of x_j and y_j to be 1 for all nonnegative values of the variables and for all n values of j (see 6), there are 2^n, or about 10^{600}, extreme points. It is thus necessary to restrict the number of extreme points to be examined. This is done by using the simplex method. It works in the following way. It is assumed that an extreme point is known. (If no extreme point is given, a variant of the simplex method, called Phase I, is used to find one or determine that there are no feasible solutions.) Using the algebraic specification of the problem, it is easy to test whether that extreme point is optimal. If the test for optimality is not passed, then a movement along some edge to an adjacent extreme point is sought along which the value of the objective function increases at the fastest rate. Sometimes one can move along an edge and make the objective function value increase without bound. If this occurs, the procedure terminates with a prescription of the edge along which the objective goes to positive infinity. If not, a new extreme point is reached having at least as high an objective function value as its predecessor. The sequence described is then repeated. Termination occurs when an optimal extreme point is found or the unbounded case occurs.

The simplex method solves the numerical example given above in the following way: The problem is put into canonical form by converting the linear inequalities into equations by introducing slack variables $x_3 \geq 0$, $x_4 \geq 0$, $x_5 \geq 0$, and the variable x_0 for the value of the objective function; the problem may then be restated as that of finding nonnegative quantities $x_1, \cdots, x_5$ and the largest possible x_0 satisfying the resulting equations (see 7). One

Slack variables

(5)
$$\begin{cases} \text{maximize } p_1x_1 + \cdots + p_nx_n \\ \text{subject to } a_{11}x_1 + \cdots + a_{1n}x_n = b_1 \geq 0 \\ \qquad a_{21}x_1 + \cdots + a_{2n}x_n = b_2 \geq 0 \\ \qquad \vdots \qquad\qquad \vdots \\ \qquad a_{m1}x_1 + \cdots + a_{mn}x_m = b_m \geq 0 \\ \qquad x_1 \geq 0, \cdots, x_n \geq 0 \end{cases}$$

(6) $x_j + y_j = 1, \quad x_j \geq 0, \quad y_j \geq 0 \quad \text{for } j = 1, \cdots, n$

(7)
$$\begin{cases} -x_0 + x_1 + 2x_2 = 0 \\ x_1 + x_3 = 8 \\ x_2 + x_4 = 5 \\ x_1 + x_2 + x_5 = 10 \end{cases}$$

(8)
$$\begin{cases} x_0 = 0, \ x_1 = 0, \ x_2 = 0, \ x_3 = 8 \\ x_4 = 5, \ x_5 = 10 \end{cases}$$

(9) $(x_0, x_1, x_2, x_3, x_4, x_5) = (10, 0, 5, 8, 0, 5)$

(10)
$$\begin{cases} -x_0 + x_1 - 2x_4 = -10 \\ x_1 + x_3 = 8 \\ x_2 + x_4 = 5 \\ x_1 - x_4 + x_5 = 5 \end{cases}$$

(11) $(x_0, x_1, x_2, x_3, x_4, x_5) = (15, 5, 5, 3, 0, 0)$

(12)
$$\begin{cases} -x_0 - x_4 - x_5 = -15 \\ x_3 + x_4 - x_5 = 3 \\ x_2 + x_4 = 5 \\ x_1 - x_4 + x_5 = 5 \end{cases}$$

(13) $x_4 \geq 0, \ x_5 \geq 0, \ x_0 = 15 - x_4 - x_5 \leq 15$

(14) $x_1 = 5, \ x_2 = 5, \ x_3 = 3, \ x_4 = x_5 = 0$

obvious solution of the resulting system of equations is found by setting $x_1 = 0$, $x_2 = 0$ (see 8), which corresponds to the extreme point at the origin in the figure. If x_1 (or x_2) were increased from zero while the other one x_2 (or x_1) is fixed at zero, the values of x_0, x_3, x_4, x_5 could be made to satisfy the equations, and the objective value x_0 would increase as desired. The variable x_2 produces the largest increase of x_0 per unit change; so it is used first. Its increase is limited by the nonnegativity requirement on the variables. In particular, if x_2 were increased beyond 5, x_4 would become negative.

At $x_2 = 5$, this situation produces a new solution (see 9) and corresponds to the extreme point (0, 5) in the figure. The system of equations is put into equivalent form (see 10) by solving for the variables x_0, x_2, x_3, x_5, which are nonzero in the above solution in terms of those variables now at zero; *i.e.*, x_1 and x_4. It is now apparent that an increase of x_1 while holding x_4 equal to zero will produce a further increase in x_0. The nonnegativity restriction on x_3 prevents x_1 from going beyond 5. The new solution (see 11) corresponds to the extreme point (5, 5) in the figure. Solving for x_0, x_1, x_2, x_3 in terms of the variables x_4, x_5 (which are currently at zero value) yields a final equivalent system of equations (see 12). It is to be noted that no variable can be changed from its present value and yield a feasible solution with a higher value than $x_0 = 15$ (see 13). Hence, an optimal solution is determined (see 14).

The dual problem. Associated with each linear programming problem is a second linear programming problem known as its dual. In this association, the original problem is referred to as the primal. Von Neumann provided a form for the primal problem (see 15) that yields an elegant statement of the dual problem (see 16).

An intimate relationship exists between a linear program and its dual. For any vector x^0 (see ANALYSIS, VECTOR AND TENSOR) satisfying the constraints of the primal and any vector y^0 satisfying the constraints of its dual, the primal objective value is never greater than the dual objective value, namely, $px \leq yb$. One implication of this relationship is that when the dual problem possesses at least one feasible vector, the primal objective function is bounded from above.

If the objective values satisfy $px^0 = y^0b$, then it is easy to show that x^0 and y^0 if feasible are optimal solutions of the primal and dual programs. If a vector x^0 is an optimal solution of the primal problem, there exists an optimal solution of the dual problem such that px^0 equals y^0b. Moreover, if $v^0 = b - Ax^0$ and $u^0 = p - y^0A$, then for optimal primal and dual feasible vectors x^0 and y^0, the relations $y_i{}^0v_i{}^0 = 0$ for $i = 1, \cdots, m$ and $x_j{}^0u_j{}^0 = 0$ for $j = 1, \cdots, n$ hold and are referred to as complementary slackness conditions. Thus, if $x_j{}^0$ is positive in an optimal solution, then the jth inequality constraint of the dual holds as an equality; *i.e.*, its slack, measured by $u_j{}^0$, satisfies $u_j{}^0 = 0$.

Complementary slackness conditions

NONLINEAR PROGRAMMING THEORY

A mathematical programming problem is called nonlinear if the objective function $f(x)$ to be minimized, in which x is a vector, or any of the constraint functions are nonlinear.

Classification of the problems. One broad class of nonlinear programming problems is that concerning minimizing $f(x)$ subject to no constraints (the unconstrained problem); another is the linearly-constrained nonlinear programs that include as a special subclass quadratic programs concerned with the minimization of a quadratic function (see 17) subject to linear constraints. Another is the chemical equilibrium problem in which the Gibbs function, a measure of the free energy of a chemical system (see 18), is to be minimized subject to (linear) mass-balance equations (see 19) and nonnegativity conditions (see 20). The x_j in the problem represent the unknown number of molecules of different types in a system under constant temperature and pressure. In the mass-balance equations the b_i are the given number of atoms of various types; the a_{ij} are the number of atoms of type i in a single molecule of type j. The c_j in the Gibbs function are related to the constants in the law of mass action and are considered as constants only for dilute solutions.

Nonlinear programs are also classified according to whether defining functions have the appropriate convexity property. A function $F(x)$ defined on a convex set S is convex if (and only if) the set of points lying on or above its graph is convex. In analytic terms, convexity is equivalent to an inequality relation (see 21). The function $G(x)$ on S is concave if and only if $F(x) = -G(x)$ is convex. A useful property of any convex function $F(x)$ defined on the convex set S is that the set of all points in S such that $F(x) \leq 0$ is a convex set. (But the set of vectors x, such that $F(x) = 0$, is not necessarily convex.)

When a quadratic function has the property that its quadratic part (see 22) is nonnegative for all choice of values for x_i, x_j, then $Q(x)$ is a convex function. Linear functions are both convex and concave.

If $f(x)$ and $h_1(x), \cdots, h_l(x)$ are convex functions, defined for each vector x appearing as the argument of the functions, then the problem of minimizing $f(x)$ subject to $h_j(x) \leq 0$ $(j = 1, \cdots, l)$ is called the convex programming problem. One important property of convex functions is the sufficiency of local conditions for idenitfying a minimum. If f is a convex function on the convex set S and x^0 is a point of S such that $f(x^0) \leq f(x)$ for all x in S that are sufficiently close to x^0, then

Convex programming problem

(15) PRIMAL: Maximize px subject to $x \geq 0, Ax \leq b$ in which $A = [a_{ij}]$ is an $m \times n$ matrix, $x = (x_1, x_2, \cdots, x_n)^T$, $p = (p_1, p_2, \cdots, p_n)$ and $b = (b_1, b_2, \cdots, b_m)^T$.

(16) DUAL: Minimize yb subject to $y \geq 0$, $yA \geq p$, in which $y = (y_1, y_2, \cdots, y_m)$.

(17) $$Q(x) = \sum_{j=1}^{n} c_jx_j + \tfrac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} d_{ij}x_ix_j$$

(18) $$F(x) = \sum_{j=1}^{n} c_jx_j + \sum_{j=1}^{n} x_j \log\left(x_j \Big/ \sum_{j=1}^{n} x_j\right)$$

(19) $$\sum_{j=1}^{n} a_{ij}x_j = b_i, \qquad i = 1, \cdots, m$$

(20) $$x_j \geq 0, \qquad j = 1, \cdots, n$$

(21) $F(\lambda x + \mu y) \leq \lambda F(x) + \mu F(y)$ for all $x \in S$, $y \in S$ and $\lambda \geq 0$, $\mu \geq 0$ such that $\lambda + \mu = 1$.

(22) $$\sum_{i=1}^{n}\sum_{j=1}^{n} d_{ij}x_ix_j$$

(23) $$\nabla f(x^0) = \left[\frac{\partial f(x^0)}{\partial x_1}, \cdots, \frac{\partial f(x^0)}{\partial x_n}\right] = (0, \cdots, 0)$$

(24) If f and g_i are differentiable and the m gradient vectors $\nabla g_1(x^0), \cdots, \nabla g_m(x^0)$ are independent, then there exist numbers $\lambda_1, \cdots, \lambda_m$ such that the vector relation $\nabla f(x^0) = \lambda_1\nabla g_1(x^0) + \cdots + \lambda_m\nabla g_m(x^0)$ holds. The numbers $\lambda_1, \cdots, \lambda_m$ are known as Lagrange multipliers.

(25) $$L(x, \lambda) = f(x) + \lambda_1 g_1(x) + \cdots + \lambda_m g_m(x)$$

x^0 is also a (global) minimum of f on S; that is, $f(x^0) \leq f(x)$ for all x in S. This property can be exploited in computational procedures aimed at calculating optimal solutions of convex programming problems.

Methods of solution. The question of identifying optimal solutions of nonlinear programs is often discussed assuming that the constituent functions are differentiable. The simplest such case is the unconstrained minimization of a differentiable function $f(x)$. If $x^0 = (x_1, \cdots, x_n)$ is an optimal solution, then the gradient vector of f at x^0 vanishes (see 23). Geometrically, this means that the tangent plane to the graph of f at the point $[x^0, f(x^0)]$ is horizontal. For a convex function f, the vanishing of the gradient is enough to guarantee that the point x^0 is a (global) minimum of f. But in general, the vanishing of the gradient can occur at points that are not even local minima, namely, at saddle points and local maxima.

The equality-constrained minimization problem is of the form: minimize $f(x)$ subject to $g_i(x) = 0$ for $i = 1, \cdots, m$ and $m < n$. If the functions $f, g_1, \cdots, g_m$ are differentiable, the attempt to isolate a (local) minimum point x^0 for this problem by finding numbers $\lambda_1, \cdots, \lambda_m$ such that $\nabla f(x^0) = \sum_{i=1}^{m} \lambda_i \nabla g_i(x^0)$ is called the method of Lagrange multipliers (see 24). In this approach, one looks for unconstrained (local) minima of an associated Lagrangian function (see 25).

When all the constituent functions are differentiable,

there is an analogous result on the necessary conditions of optimality for inequality-constrained minimization problems (see 26). These necessary conditions are closely related to the Kuhn-Tucker conditions. The mathematicians H.W. Kuhn and A.W. Tucker of the United States showed in a now classic, nonlinear programming paper that if a certain regularity condition holds, a relation is true between the gradient of f and the gradients of subsidiary functions h_j at an optimal solution x^0. In particular, if f and the functions h_j are convex, then a solution x^0 that satisfies stated conditions for some vector λ of multipliers is a global minimum.

Convex quadratic programming problems

Some methods for solving convex quadratic programming problems are closely related to the simplex method for linear programming and share with it the feature of terminating after only a finite number of iterations. Most of these methods make use of the Kuhn-Tucker conditions because the differentiability and regularity requirements are automatically satisfied. These characteristics are seldom found in nonlinear programming procedures in general. Instead of leading in a finite number of steps to an exact solution, they (at best) yield a point close to a point at which a local minimum is attained.

One of the historically important ancestors of nonlinear programming methods is the method of steepest descent due to the 19th-century French mathematician Augustin-Louis Cauchy. Its original application was to solving systems of nonlinear equations. For example, to solve the system of simultaneous equations $g_i(x) = 0$, $(i = 1, \cdots, m)$ a sum of squares of the functions appearing in the equations can be formed (see 27). An attempt can be made to obtain its unconstrained minimum. For every vector x, the functional value $f(x)$ is nonnegative because it is the sum of squares. Consequently, x^0 is a solution if and only if $f(x^0) = 0$.

The method is easily stated: From a starting point (trial solution) $x^{(1)}$, compute the direction of steepest descent, $-\nabla f(x^{(1)})$. Using a fixed step size, symbolized by the Greek letter sigma, σ, minimize the function f along the line segment of length σ issuing from $x^{(1)}$ in the direction of steepest descent. The point $x^{(2)}$ that minimizes $f(x)$ along this line segment becomes the new trial solution. In general, the preceding step is repeated from at each trial solution $x^{(k)}$ to obtain the next one $x^{(k+1)}$.

The method of steepest descent is valid under the assumption that the function f is continuously differentiable, and all points satisfying $f(x) \leq f(x^{(1)})$ lie within a fixed finite distance from the origin. The aim of the procedure is actually to locate a point x^* satisfying the necessary local conditions of optimality: $\nabla f(x^*) = 0$. Because such a point might be reached only in a limiting sense, it is customary to terminate the computational process when a point $x^{(k)}$ is reached at which the absolute value $|\partial f(x^{(k)})/\partial x_j|$ is less than a prescribed value for $j = 1, \cdots, n$. If the function f being minimized is convex, a point x^* at which $\nabla f(x^*)$ is zero must be a global minimum.

Another method deals with the linearly-constrained nonlinear programming problem: Minimize $f(x)$ subject to $Ax = b$, $x \geq 0$ in a manner that uses both linear programming and the Kuhn–Tucker conditions. It is assumed that the objective function $f(x)$ is continuously differentiable. It is then natural to replace f by its linear approximation at a feasible point and solve the associated linear program. For example, if $x^{(k)}$ is a feasible point, f can be replaced by its linear approximation (see 28). Assuming that $y^{(k)}$ is the solution of this linear program, a search can then be performed to minimize f along the line joining $x^{(k)}$ to $y^{(k)}$. The point $x^{(k+1)}$ at which the latter minimum is attained becomes the new trial solution at which the linear approximation to f can be formed for the repetition of the process. The computation can be interrupted if a point x^0 is reached at which the solution point y^0 of the associated linear programming problem satisfies $\nabla f(x^0)(y^0 - x^0) \geq 0$. It can be shown that the point x^0 must be optimal when the objective function f is convex.

Of the many algorithms for the solution of nonlinear programming problems, none is known to be superior to the generalized reduced-gradient method. Its roots lie in the reduced-gradient method (for linearly-constrained nonlinear programs) and ultimately in the simplex method itself. (G.B.D./R.W.Co.)

(26)
$$\begin{cases} \text{Minimize } f(x) \text{ subject to } h_j(x) \leq 0 \text{ for } j = 1, \cdots, l. \\ \text{Then } x^0 \text{ is a locally minimizing solution only if there} \\ \text{exist multipliers } \lambda_0, \lambda_1, \cdots, \lambda_l \text{ not all zero such that} \\ \lambda_0 \nabla f(x^0) = \lambda_1 \nabla h_1(x^0) + \cdots + \lambda_l \nabla h_l(x^0) \text{ and} \\ h_j(x^0) \leq 0, \quad \lambda_j \geq 0, \quad \lambda_j \cdot h_j(x^0) = 0 \text{ for } j = 1, \cdots, l. \end{cases}$$

(27)
$$f(x) = [g_1(x)]^2 + \cdots + [g_m(x)]^2$$

(28)
$$F(y) = f(x^k) + \nabla f(x^k)(y - x^k)$$

III. Cybernetics

The presentation to follow deals only with the principles of cybernetics and includes reference to mathematical aspects such as information theory, automata theory, and cybernetic systems. The technological aspects of cybernetics are multifold and can be found in COMPUTERS; CONTROL SYSTEMS; and ROBOT DEVICES.

DEFINITIONS OF THE TERM CYBERNETICS

The term cybernetics comes from the ancient Greek word *kybernētikos* ("good at steering") referring to the art of the helmsman. In the first half of the 19th-century, the French physicist André-Marie Ampère, in his classification of sciences, suggested that the still nonexistent science of the control of governments be called cybernetics. This term was soon forgotten until used by the United States mathematician, Norbert Wiener, as the title for his book published in 1948. In that book Wiener made reference to an 1868 article by the British physicist James Clerk Maxwell (*q.v.*) on governors and pointed out that "governor" is derived, via Latin, from the same Greek word that gives rise to the term "cybernetics." The date of Wiener's publication is generally accepted as the date of the birth of cybernetics as an independent science. Wiener defined cybernetics as "the science of control and communications in the animal and machine." This definition relates cybernetics closely first of all with the theory of automatic control and with physiology, particularly the physiology of the nervous system. Subsequently, the computer and the areas of mathematics related to it (*e.g.*, mathematical logic) had a great influence on the development of cybernetics. The reason is that the computer can be used not only for automatic calculation, but also for all conversions of information, including various types of information processing used in control systems. This ability made two different views of cybernetics possible. The narrower view, common in the Western countries, defines cybernetics as the science of control of complex systems of various types (technical, biological, and social). In many countries (for example, in the United States), particular emphasis is given to those aspects of cybernetics that are used in the generation of control systems in technology and in living organisms. In addition to cybernetics, the science of computers and the general rules of information processing is being developed in the Western countries (English—computer science; French—*informatique*).

The broader interpretation of the subject of cybernetics common in the Soviet Union includes not only control but all forms of information processing. This definition includes therefore the Western computer science as one of the component parts of cybernetics.

PRINCIPLES

Information theory. It should be emphasized that the concept of information and its conversion is an important first concept of cybernetics no matter how its subject is defined (see INFORMATION THEORY). Information arises with any act of selection or limitation of possibilities of

selection. For example, if it is known that a room can contain 100 men, then the message that the room at a given moment contains 50 men or that the number of people in the room is less than 40 carries information. The message that the number is less than 200 carries no information, because the first, fixed selection is in no way thus limited. In developing the principle of limitation of selection, Claude E. Shannon, an electrical engineer in the United States, introduced the method of changing the quantity of information.

The nature and types of signals

Information is transmitted by signals. In pure cybernetics, the physical nature of the signals is completely disregarded. It is important only that the signals can be differentiated from each other. The form of the set of possible signals and the nature of their changes are also significant. For example, a signal carrying information on the number of persons in a room cannot take on fractional values. The values of these signals change in jumps. On the other hand, a signal giving information of the temperature of the air in the room cannot change its value, say from 19° C to 20° C, without passing through all intermediate values. Signals of the first type are called discrete and of the second type, continuous. The same terms are used in relation to the information represented by these signals.

In describing continuous information within a certain accuracy, it can always be reduced to discrete information. The usual method of representation of discrete information is as a finite sequence of signals selected from a certain fixed finite set of signals called the (abstract) alphabet, for example the set of letters in the Latin alphabet, the set of decimal numbers, etc. One important but simple fact is the possibility of representing any discrete information in the form of sequences of signals of only two different types, as is done, for example, in the dots and dashes of the well-known Morse telegraph code. Problems of various forms of representation of discrete information make up the subject of a special division of theoretical cybernetics called encoding theory.

Automata as information converters. Encoding is the simplest form of information conversion. In the general case, these conversions are performed by so-called information converters, or data processors. An information converter, referred to in cybernetics as a machine or automaton (see AUTOMATA THEORY), is a device that converts a certain set of signals called the input signals to another set, the set of output signals. The input signals arrive at the converter through the input channels, the output signals leave through the output channels. Furthermore, in the general case, the processor can store signals in the form of a certain set of parameters, the different values of which determine the internal state of the processor, that is, the condition of its memory.

A processor is called continuous if all of the parameters that define it (memory, input, and output signals) are continuous. In the case of discrete processors, all of these signals must be discrete. Processors dealing both with continuous and with discrete signals are called hybrid processors.

The changes in output signals and in the internal state of any processor depend generally both on the input signals and on the internal state of the processor at a given time. For a processor without memory, the values of the output signals at any moment in time depend only on the values of the input signal at the same moment in time. If all of these dependences are fixed by fully defined, unambiguous functions (*e.g.*, single-valued), the processor is called deterministic. If there are random dependences, the processor is called probabilistic.

Information processors in which no functional components and no internal structural parts other than those described above can be distinguished are called elementary. Nonelementary processors, also called cybernetic systems, consist of networks composed of elementary (or in any case simpler) processors. A network is constructed by connecting some (or all) of the output channels of the processors composing the network to some (or all) of their input channels. A portion of the input and output channels of the elementary processors may be appropriately connected to the input and output signals of the entire system.

The concept of elementariness or nonelementariness of a processor is relative and depends on the depth of penetration into the subject. For example, if interest is confined to the functions of the brain, not in its structure, it can be analyzed as an elementary processor (although it is characterized by a tremendous number of parameters). It is known, however, that the brain is an extremely complex system, composed of more elementary processors, the neurons. In turn, upon transition to the molecular level, the neurons themselves can be regarded as extremely complex cybernetic systems.

The cybernetic approach to systems study

Study of systems. The study of systems and particularly of the complex probabilistic systems is one of the most important tasks in cybernetics. The specific feature of the cybernetic approach to the study of systems is that it abstracts itself from the actual nature of the elements of the system and the signals circulating in it. This allows a general mathematical apparatus and general methods of investigation to be developed, suitable for systems of varying nature and purpose. In the study of continuous cybernetic systems, a system of ordinary differential equations is particularly significant.

Theory of algorithms. In the discrete case, the modus operandi is the so-called theory of algorithms. An algorithm is an arbitrary, finite system of rules of any nature, allowing expressions in any alphabet to be converted to new expressions in the same (or any other) alphabet. So-called algorithmic languages are used for precise descriptions of the rules for these conversions (see AUTOMATA THEORY: *Classification of automata;* and COMPUTERS: *Language categories*).

It is extremely important that the presence in an algorithmic language of a relatively small number of means of expression can give it the property of universality. Universality of an algorithmic language means the possibility of expressing in this language any conversion of discrete information that can be defined using a finite number of rules, that is, expressed as a certain algorithm in any other algorithmic language.

The fact of existence of universal algorithmic languages means that it is possible to construct universal discrete information processors. To do this, it is sufficient to fix upon some concrete alphabet and to construct a memory device capable of storing any word (expression) in the alphabet and a device capable of performing all of the elementary rules of a certain universal algorithmic language.

Universal digital computers are such universal information processors if the limitations resulting from their finite memory volume are not considered. Until computers appeared, the only universal data processor was the natural information processor, the human brain.

The availability of technical universal data processors is highly significant for the development of cybernetics in at least two ways. First of all, this fact opens unlimited possibilities for the automation not only of the physical, but also of the mental activity of man, and this automation does not require that new technical devices be invented for each case. It is sufficient to study and describe the rules defining the type of activity to be automated and to program them; *i.e.*, express them in one of the algorithmic languages used in existing computers.

Mathematical modelling. Second, the use of universal data processors—computers—gives cybernetics a method of scientific investigation of systems that is new in principle—so-called mathematical modelling. Until this method appeared, scientists actually had only two different methods of study: experimental and theoretical. In the former, experiments were performed only with the system itself, or with an actual, physical model of the system. In the second, it was necessary to be able to solve equations describing the system.

Mathematical modelling occupies an intermediate position between these two methods: there is no necessity to construct an actual physical model of the system. It is replaced by a mathematical model; *i.e.*, a description of the system in some algorithmic language. There is also no

need to solve complex mathematical problems related to this description (*i.e.*, to solve systems of differential equations). The description of the system is simply entered into a computer that models the behaviour of the system (*i.e.*, provides precise descriptions of the system) under various conditions defined according to the purpose of the research assignment.

This method allows the scientist to produce a full description of complex systems, the individual parts of which are studied by different people or even in different sciences. One example is the human organism. Its individual parts (circulatory system, digestive system, nervous system, glandular system, etc.) are studied by different specialists, even though the parts are closely related to each other.

Modelling the human organism

To produce a mathematical model of the organism, first of all it must be divided into individual parts and the state of each part described by some system of parameters. Among these parameters might be continuous quantities (for example, the percent content of sugar in the blood) or discrete quantities (for example, qualitatively differing levels of secretory function of the liver). The next step is description of the relationships between the separate parts. One of the most typical forms of relationship for this example is expressed by a sentence such as: When organ A shifts from state m_1 to state m_2, and organ B shifts from state n_1 to state n_2 after k days (weeks, months), organ C will change its state from l_1 to l_2 with probability p. The specialists must describe all of the relations of this type with which they are familiar (called simple relationships) to form the required mathematical model. Operations with this model in the computer permit the establishment of the complex relationships (*i.e.*, the influence of organs on other organs not directly, but through still other organs). This type of model can be used to study versions of the development of various diseases, various methods of treatment, etc.

Mathematical modelling can in principle be performed in any universal data processor, including the human brain. The brain, however, being a very complex system itself, is comparatively poorly suited for such routine but laborious work as the modelling of complex systems. Consequently, only the appearance of the computer provided a qualitative jump and made it possible to perform effective study of really complex systems in various areas of knowledge. Actually, the concern is with coarse qualitative criteria, differentiating simple systems from complex; if the structure and behaviour of a system can be studied by a single man in a reasonable time, the system is called simple. If the efforts of many persons and the use of special technical equipment (computers) are required to draw the whole picture, the system is called complex.

Cybernetic systems. *Self-teaching mechanisms.* Complex tasks arise in so-called self-teaching systems, in which attempts to achieve a certain final goal lead to changes in the methods of its attainment, and the setting of various intermediate goals. One of the simplest examples of this type of system is the so-called Shannon's mouse. It is a moving automaton placed in a maze. The final purpose of the automaton is to find the "food" placed at some point in the maze.

At first, the mouse uses a simple trial and error algorithm, bumping into the walls until an exit is found. During the process of this type of search, it "learns" and memorizes the plan of the maze. After once reaching the goal (by chance), the mouse will use an entirely different, much more economical, and seemingly "intelligent" algorithm for reaching the goal in a subsequent experiment, based on "knowledge" of the layout of the maze.

Self-teaching is one type of self-improvement of control systems. In this case, the improvement occurs without changing the structure of the system. It is also possible, however, that the upper levels of a system may change the structure of lower levels in order to improve their functioning. This type of self-improvement is naturally called self-development.

By the 1970s, methods had been designed for quantitative definition of self-improvement. In this case, in pure theory, the boundary between self-teaching and self-development disappears. In practice, however, the difference between these types of self-improvement is usually rather clear.

Biocybernetics. Many control systems in biology are constructed according to the principles of self-teaching and self-development. For example, in all probability, only a small portion of the organization of the human brain is determined genetically. Everything else is produced as a result of the effects of many, rather effective, mechanisms of self-improvement.

Highly complex examples of self-development can be found in the processes of biological evolution, as well as various social processes.

For systems of the high degree of complexity characteristic of living organisms and human society, an ever greater role is played not just by control processes, but by cognition processes. These systems have highly perfected systems of sensors and effectors (for example, the eye and the hand), capable of recognizing complex patterns and performing widely varied actions. The central portion of the system has a multilevel structure; the upper links of the structure develop abstract concepts and recognize the deeper regularities existing both in the system itself and in its surroundings.

By the 1970s, cybernetics had achieved significant success in the solution of the problem of pattern recognition, automation (by computer) of the processes of logical conclusion, formation of new concepts, and other problems. This success has allowed the creation of universal robots controlled by computers and imitating rather complex forms of conscious behaviour. (Ed.)

IV. Control theory

GENERAL BACKGROUND

As long as human culture has existed, control has always meant some kind of power over man's environment. Cuneiform fragments suggest that the control of irrigation systems in Mesopotamia was a well-developed art at least by the 20th century BC. There were some ingenious control devices in the Greco-Roman culture, the details of which have been preserved. Methods for the automatic operation of windmills go back at least to the Middle Ages. Large-scale implementation of the idea of control, however, was impossible without a high-level of technological sophistication, and it is probably no accident that the principles of modern control started evolving only in the 19th century, concurrently with the Industrial Revolution. A serious scientific study of this field began only after World War II and is now a major aspect of what has come to be called the second industrial revolution.

Examples of feedback control

Although control is sometimes equated with the notion of feedback control (which involves the transmission and return of information)—an isolated engineering invention, not a scientific discipline—modern usage tends to favour a rather wide meaning for the term; for instance, control and regulation of machines, muscular coordination and metabolism in biological organisms, prosthetic devices; also, broad aspects of coordinated activity in the social sphere such as optimization of business operations, control of economic activity by government policies, and even control of political decisions by democratic processes. Scientifically speaking, modern control should be viewed as that branch of system theory concerned with changing the behaviour of a given complex system by external actions. (For aspects of system theory related to information, see below.) If physics is the science of understanding the physical environment, then control should be viewed as the science of modifying that environment, in the physical, biological, or even social sense.

Much more than even physics, control is a mathematically-oriented science. Control principles are always expressed in mathematical form and are potentially applicable to any concrete situation. At the same time, it must be emphasized that success in the use of the abstract principles of control depends in roughly equal measure on the status of basic scientific knowledge in the specific field of application, be it engineering, physics, astronomy, biology, medicine, econometrics, or any of the social sciences. This fact should be kept in mind to avoid confu-

sion between the basic ideas of control (for instance, controllability) and certain spectacular applications of the moment in a narrow area (for instance, manned lunar travel).

EXAMPLES OF MODERN CONTROL SYSTEMS

To clarify the critical distinction between control principles and their embodiment in a real machine or system, the following common examples of control may be helpful. There are several broad classes of control systems, of which some are mentioned below.

Machines that cannot function without (feedback) control. Many of the basic devices of contemporary technology must be manufactured in such a way that they cannot be used for the intended task without modification by means of control external to the device. In other words, control is introduced after the device has been built; the same effect cannot be brought about (in practice and sometimes even in theory) by an intrinsic modification of the characteristics of the device. The best-known examples are the vacuum-tube or transistor amplifiers for high-fidelity sound systems. Vacuum tubes or transistors, when used alone, introduce intolerable distortion, but when they are placed inside a feedback control system any desired degree of fidelity can be achieved. A famous classical case is that of powered flight. Early pioneers failed, not because of their ignorance of the laws of aerodynamics, but because they did not realize the need for control and were unaware of the basic principles of stabilizing an inherently unstable device by means of control. Jet aircraft cannot be operated without automatic control to aid the pilot, and control is equally critical for helicopters. The accuracy of inertial navigation equipment (the modern space compass) cannot be improved indefinitely because of basic mechanical limitations, but these limitations can be reduced by several orders of magnitude by computer-directed statistical filtering, which is a variant of feedback control.

The role of computers in feedback control

Control of machines. In many cases, the operation of a machine to perform a task can be directed by a human (manual control), but it may be much more convenient to connect the machine directly to the measuring instrument (automatic control); *e.g.*, a thermostat (temperature-operated switch) may be used to turn on or off a refrigerator, oven, air-conditioning unit, or heating system. The dimming of automobile headlights, the setting of the diaphragm of a camera, the correct exposure for colour prints, may be accomplished automatically by connecting a photocell or other light-responsive device directly to the machine in question. Related examples are the remote control of position (servomechanisms), speed control of motors (governors). It is emphasized that in such case a machine could function by itself, but a more useful system is obtained by letting the measuring device communicate with the machine in either a feedforward or feedback fashion.

Control of large systems. More advanced and more critical applications of control concern large and complex systems the very existence of which depends on coordinated operation using numerous individual control devices (usually directed by a computer). The launch of a spaceship, the 24-hour operation of a power plant, oil refinery, or chemical factory, the control of air traffic near a large airport, are well-known manifestations of this technological trend. An essential aspect of these systems is the fact that human participation in the control task, although theoretically possible, would be wholly impractical; it is the feasibility of applying automatic control that has given birth to these systems.

Biocontrol. The advancement of technology (artificial biology) and the deeper understanding of the processes of biology (natural technology) has given reason to hope that the two can be combined; man-made devices should be substituted for some natural functions. Examples are the artificial heart or kidney, nerve-controlled prosthetics, and control of brain functions by external electrical stimuli. Although definitely no longer in the science-fiction stage, progress in solving such problems has been slow not only because of the need for highly advanced technology but also because of the lack of fundamental knowledge about the details of control principles employed in the biological world.

Robots. On the most advanced level, the future task of control science is the creation of robots. This is a collective term for devices exhibiting animal-like purposeful behaviour under the general command of (but without direct help from) man. Industrial manufacturing robots are already fairly common, but real breakthroughs in this field cannot be anticipated until there are fundamental scientific advances with regard to problems related to pattern recognition and the mathematical structuring of brain processes.

Obstacles to the creation of robots

PRINCIPLES OF CONTROL

The scientific formulation of a control problem must be based on two kinds of information: (A) the behaviour of the system (*e.g.*, industrial plant) must be described in a mathematically precise way; (B) the purpose of control (criterion) and the environment (disturbances) must be specified, again in a mathematically precise way.

Information of type A means that the effect of any potential control action applied to the system is precisely known under all possible environmental circumstances. The choice of one or a few appropriate control actions, among the many possibilities that may be available, is then based on information of type B; and this choice, as stated before, is called optimization.

The task of control theory is to study the mathematical quantification of these two basic problems and then to deduce applied-mathematical methods whereby a concrete answer to optimization can be obtained. Control theory does not deal with physical reality but only with its mathematical description (mathematical models). The knowledge embodied in control theory is always expressed with respect to certain classes of models, for instance, linear systems with constant coefficients, which will be treated in detail below. Thus control theory is applicable to any concrete situation (*e.g.*, physics, biology, economics) whenever that situation can be described, with high precision, by a model that belongs to a class for which the theory has already been developed. The limitations of the theory are not logical but depend only on the agreement between available models and the actual behaviour of the system to be controlled. Similar comments can be made about the mathematical representation of the criteria and disturbances.

Once the appropriate control action has been deduced by mathematical methods from the information mentioned above, the implementation of control becomes a technological task, which is best treated under the various specialized fields of engineering. The detailed manner in which a chemical plant is controlled may be quite different from that of an automobile factory, but the essential principles will be the same. Hence further discussion of the solution of the control problem will be limited here to the mathematical level.

To obtain a solution in this sense, it is convenient (but not absolutely necessary) to describe the system to be controlled, which is called the plant, in terms of its internal dynamical state. By this is meant a list of numbers (called the state vector) that expresses in quantitative form the effect of all external influences on the plant before the present moment, so that the future evolution of the plant can be exactly given from the knowledge of the present state and the future inputs. This situation implies, in an intuitively obvious way, that the control action at a given time can be specified as some function of the state at that time. Such a function of the state, which determines the control action that is to be taken at any instant, is called a control law. This is a more general concept than the earlier idea of feedback; in fact, a control law can incorporate both the feedback and feedforward methods of control.

In developing models to represent the control problem, it is unrealistic to assume that every component of the state vector can be measured exactly and instantaneously. Consequently in most cases the control problem has to be broadened to include the further problem of state deter-

mination, which may be viewed as the central task in statistical prediction and filtering theory. Thus, in principle, any control problem can be solved in two steps: (1) Building an optimal filter (so-called Kalman filter) to determine the best estimate of the present state vector; (2) determining an optimal control law and mechanizing it by substituting into it the estimate of the state vector obtained in step 1.

In practice, the two steps are implemented by a single unit of hardware, called the controller, which may be viewed as a special-purpose computer. The theoretical formulation given here can be shown to include all other previous methods as a special case; the only difference is in the engineering details of the controller.

The mathematical solution of a control problem may not always exist. The determination of rigorous existence conditions, beginning in the late 1950s, has had an important effect on the evolution of modern control, equally from the theoretical and the applied point of view. Most important is controllability; it expresses the fact that some kind of control is possible. If this condition is satisfied, methods of optimization can pick out the right kind of control using information of type B.

Controllability

CONTROL OF LINEAR SYSTEMS

Systems with constant coefficients. The preceding considerations may be illustrated much more directly by taking the special case of linear systems with constant coefficients. The point of view and most of the results described below originated after 1950, but the beginnings of the theory are more than 100 years old dating from Maxwell's work published in 1868. In fact, this class of models is the only one for which a reasonably complete mathematical theory of control exists so far.

One may denote by $y(t)$ the number giving the value of the output of the plant at time t; similarly, the number $u(t)$ denotes the value of the input to the plant at the same time. A classical way to describe the behaviour of the plant (information of type A) is to assume that the input and output are related by a linear differential equation with constant coefficients $\alpha_1, \cdots, \alpha_n$ (see 29), which is called the open-loop equation of the plant. In this case the state vector is the list $(y(0), \cdots, y^{(n-1)}(0))$ consisting of the output at time $t = 0$ and the first $n - 1$ derivatives with respect to time of the function $y(t)$ at $t = 0$. Under these circumstances, the control law is a linear combination of the state variables, with coefficients $\beta_1, \cdots, \beta_n$ (see 30).

The fact that this control law is linear in the state is an assumption needed to assure the manageability of mathematical machinery for the problem. It is desirable to assume also that the coefficients $\beta_1, \cdots, \beta_n$ are all constants so that the same formula can be used at any time. [A minus sign in the control law (30) expresses the classical idea of negative feedback; in the general theory, this has become merely a notational convention.]

Substitution of the control law into the linear differential equation of the plant (29) leads to the closed-loop differential equation for the controlled output of the plant (see 31). Here the coefficients γ_i are the differences $\alpha_i - \beta_i$. So the effect of control is to replace the coefficients α_i of the open-loop equation with the γ_i of the closed-loop equation. Since the β_i in the control law are arbitrary, it follows that arbitrary changes can be effected in the dynamical behaviour of the plant by means of control. In particular, it is possible to make a plant stable by means of the control law because the criterion for stability is given by the positiveness of the Routh–Hurwitz determinants (see 32). These conditions can of course always be met since the γ_i can be arranged to have any values.

The criterion for stability

It is necessary to comment on this seemingly overly general (but indeed correct) result from two points of view. First, the result assumes that the plant description (see 29) is exactly true and that the state list $(y(t), \cdots, y^{(n-1)}(t))$ is known at every time t. These assumptions are never exactly correct, but they can be approximated in many cases with sufficient accuracy by restricting the output $y(t)$ to small deviations about a given steady-state value and by constructing a statistical filter to estimate the derivatives of the function $y(t)$ with respect to t. Second, the model (see 29) does not represent the most general linear system with constant coefficients; in fact, this model, because of its special form, implicitly possesses the property of controllability that may not hold for the general model in the linear, constant coefficient class.

(29) $$\frac{d^n y}{dt^n} + \alpha_1 \frac{d^{n-1} y}{dt^{n-1}} + \cdots + \alpha_n y = u(t)$$

(30) $$-u(0) = \beta_n y(0) + \beta_{n-1} \dot{y}(0) + \cdots + \beta_1 y^{(n-1)}(0)$$

(31) $$\frac{d^n y}{dt^n} + \gamma_1 \frac{d^{n-1} y}{dt^{n-1}} + \cdots + \gamma_n y = 0$$

(32) $$\gamma_i > 0, \quad \begin{vmatrix} 1 & \gamma_2 \\ \gamma_1 & \gamma_3 \end{vmatrix} > 0, \ldots$$

(33) $$\frac{dx}{dt} = Fx + gu(t), \qquad y(t) = \langle h, x(t) \rangle$$

(34) $$F = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \cdot & \cdot & \cdot & & \cdot \\ \cdot & \cdot & \cdot & & \cdot \\ \cdot & \cdot & \cdot & & \cdot \\ 0 & 0 & 0 & \cdots & 1 \\ -\alpha_n & -\alpha_{n-1} & -\alpha_{n-2} & \cdots & -\alpha_1 \end{bmatrix}, \qquad g = \begin{bmatrix} 0 \\ 0 \\ \cdot \\ \cdot \\ \cdot \\ 0 \\ 1 \end{bmatrix}$$

(35) $$\det[g \quad Fg \quad F^2 g \quad \cdots \quad F^{n-1} g] \neq 0$$

The explicit form of the controllability condition is of great practical and philosophical importance. It is a generic condition: it is satisfied by almost all systems of the linear, constant-coefficient class. Because the state-vector equations (33) accurately represent most physical systems making only small deviations about their steady-state behaviour, it follows further that in the natural world control in the small is, in principle, almost always possible. This fact of nature is the theoretical basis of practically all the presently existing control technology.

The most general system of this class (with one input and one output) is given by a pair of state-vector equations (see 33); the symbol x denotes the state vector (a list of n arbitrary numbers), F is an $n \times n$ matrix, g is an n-vector, h is an n-vector, and $< , >$ is the inner product; the symbols $u(t)$ and $y(t)$ have the same meaning as above. The equations of the plant discussed above (see 29) can always be transformed into the general case (see 33), but not necessarily vice versa.

Transforming the plant equations discussed above to the general form gives the canonical matrices F, g (shown in 34). If these expressions are substituted into the controllability criterion (see 35) for the general system (33), it is seen that the special model for the plant that was used above (see 29) is always controllable. Thus, it is clear that the true significance of the celebrated controllability concept can be grasped only after the control problem has been formulated in the state-vector style. In the classical development of control theory, too much emphasis was placed on special models for the plant (see 29); the advances since 1950 to a large extent resulted from a recognition that the most general model corresponding to the basic restrictive hypotheses of linearity and constant coefficients is given by the state-vector equations (see 33); this recognition eventually led to the discovery that for the general class there is a nontrivial controllability condition (see 35).

Control limitations in nonlinear modelling

On the other hand, little is known at present, in the scientific sense, about the ultimate limitations of control when the models in question are not linear. In particular, it is not known under what conditions control is possible in the large; that is, for arbitrary deviations from existing conditions. This lack of scientific knowledge should be kept in mind in assessing often exaggerated claims by economists and sociologists in regard to a possible improvement in human society by governmental control.

Optimal control. To reduce the arbitrariness of the control law (see 30), it is necessary to use information of type B. This is done, conceptually, in the following way. It is assumed (after a change of variables, if necessary) that the state $x = 0$ represents the ideal condition of the plant to be controlled. Any given state $x(0)$ not equal to zero at time $t = 0$ is regarded as an undesirable deviation, attributed to unavoidable disturbances acting on the system. The task of control is to restore the ideal condition $x(t) = 0$ in the best possible way. The specification of a suitable optimality criterion is frequently dictated by mathematical expediency.

The long mathematical history of the calculus of variations has suggested that the most natural criterion to consider is the minimization of an integral from zero to infinity, which measures the deviation of $x(t)$ from zero as well as the cost of control. For example, the coefficients in the control law may be explicitly determined by minimizing a quadratic integral (see 36) by the choice of the function $u(t)$ with respect to solutions of the open-loop differential equation (see 29). The applied-mathematical technique for solution is well developed and requires the solution of a nonlinear differential equation of the Riccati type, which can be conveniently carried out by digital computer. It can be shown also that this general procedure includes older techniques based on semi-quantitative engineering analyses, for instance, the idea of maximizing the loop gain.

In many respects, optimization theory represents a satisfactory solution of the control problem (in some cases even outside the linear case), but basic difficulties remain in regard to the appropriate choice of the criterion represented by the quadratic forms in the performance index (see 36).

Optimal filtering and state estimation. At least in the linear case, the solution of the state-estimation problem can be accomplished by methods similar to that for optimal control; this follows from the well-known Duality Principle which states that the dual equations (matrices and vectors replaced by their transposes) of control optimization are the equations for state estimation. The optimal filter is then a dynamical system similar to (29), in which the principal task is to determine a dual control law similar to (30).

In practice, the state estimation problem is much more important than the control problem; approximately 90–95 percent of practical controllers are devoted to state estimation, only about five percent being required for the implementation of the control law.

NONLINEAR CONTROL SYSTEMS

Whenever the controlled variable $y(t)$ is allowed to have large deviations from the steady state, the linear constant-coefficient model will cease to represent the plant accurately because of intrinsic nonlinearities involved in the description of most natural dynamical phenomena. Equally important are intentionally introduced nonlinearities that result from reasons of economy, simplicity and reliability of engineering, or from ignorance of the fact that the savings achieved by nonlinear control devices may be negated by factors resulting from the greater intrinsic difficulty of control. A good example of unavoidable nonlinearities in the object to be controlled is a space vehicle whose rockets, at the current state of technology, can only be controlled by turning them on or off. Continuously variable control action (which is desirable) in this case is technologically impossible; the high cost of rocket engines, however, justifies extremely sophisticated computer-based technology to achieve optimal control. The purpose of the computer is then simply one of switching the rockets on or off; the difficulty of the control lies in the extreme precision with which the time must be determined when this takes place.

Example of a nonlinearity

$$(36) \qquad \int_0^\infty [Q(x(t)) + R(u(t))]\,dt \qquad (Q, R \text{ are quadratic forms})$$

When the basic mathematical data can be stated in the conventional optimization framework, effective methods are available for solving the optimal control problem even in the nonlinear case. The methods for doing this are an extension of the classical methods of the calculus of variations. These methods, however, have yielded little theoretical insight and their straightforward application becomes prohibitively expensive for large-scale systems.

Even less satisfactory is the status of the nonlinear optimal filtering and state estimation problem, which, as has been noted, is a critical part of the general solution of the control problem. Because of nonlinearity, the Duality Principle no longer applies; even the formulation of the problem is controversial.

Nonlinear systems do not represent a special case, but simply everything that is not subjected to the special assumption of linearity; in a sense "nonlinear" is synonymous with "unknown." Scientific progress will undoubtedly occur by singling out special classes of systems subject to restrictive structural assumptions other than linearity.

Orange Free State

The Orange Free State—Oranje Vrystaat in the Afrikaans language—is the second smallest of the four provinces of the Republic of South Africa. It has an area of 49,866 square miles (129,152 square kilometres) and a population of over 1,600,000 of which about 1,300,000 are black Africans and about 300,000 are white. Landlocked, the province is bordered to the north by Transvaal Province, to the east by Natal Province and by the independent state of Lesotho, and to the south and west by Cape Province. The administrative capital is Bloemfontein, which is also the judicial capital of the Republic of South Africa.

More than three-quarters of the white population is Afrikaner, and the state is a stronghold of Afrikaner culture. While its undulating plains produce up to 40 percent of South Africa's maize, a quarter of its wheat, and a quarter of its wool, the Orange Free State also contains the most productive of South Africa's seven principal goldfields, from which uranium is also obtained. As South Africa's central province, the state is the focus of its transport network. (For associated physical features, see ORANGE RIVER; VELD; for general historical background, see SOUTHERN AFRICA, HISTORY OF.)

History. Before the arrival of Europeans, the region was the home of seminomadic Bantu tribes. In the 18th century, Europeans first crossed the Orange River, which forms part of the state's southern border, to enter the area. In the early 19th century, trekboers (seminomadic, pastoral farmers of Dutch descent) began to settle the area. After 1836 came the Great Trek, a migratory movement in which Boer farmers seeking freedom from British rule also moved north across the Orange River. From 1848 to 1854 the British administered the territory as the Orange River Sovereignty, after which the British withdrew, and the Boer settlers formed the independent Orange Free State. The constitution of the new state combined traditional Boer institutions with Dutch and United States constitutional theory. During the first few years of the state's existence, it was much harassed by raids from Basuto (Sotho) tribesmen from the east; the Basutos were, however, at length conquered, and part of their territory was annexed. During the South African War (1899–1902), the Orange Free State fought against the United Kingdom by the side of its sister state the South African Republic (now the Transvaal), with which it had a defensive alliance. The two Boer republics won some victories against the British army but could not finally prevail. In 1900 the Orange Free State was annexed by the United Kingdom as the Orange River Colony. Self-government was restored in 1907, after which, in 1910, the colony became the Orange Free State Province of the Union of South Africa. In 1961, when the Union of South Africa became the Republic of South Africa, the province remained unchanged in form and administration.

The Great Trek

The landscape. *Relief.* The Orange Free State is situated on the Highveld, a high plateau that rises to 6,000 feet on its eastern boundary, sloping down to the west to almost 4,000 feet. Its surface is formed by beds of sandstones and shales (laminated rock form of clays) and is extremely even, except where it is broken by the occurrence of dolerite (coarse basalt) intrusions (inflows of formerly molten rock) or by the occurrence of mesas. This general evenness results in low gradients for river courses; coupled with the semiarid climate, it also produces a peculiar type of wind-eroded pan (depression) in the west that is filled with water during the rainy season. The province is entirely drained by two rivers—the upper Orange River, which, as mentioned, forms the southern boundary of the province, and the Vaal River, which forms part of the northern boundary, together with their tributaries. The largest of the tributaries is the Caledon River, which flows into the Orange from the Drakenberg mountains in neighbouring Lesotho. The Wilge River, which drains the northeast, is the principal tributary of the Vaal. An interesting geologic feature is the Vredefort Dome, a series of incomplete circular ranges enclosing a mass of old granite partly eroded by the Vaal River.

Soils. The eastern part of the province is covered by claylike, heavy, and somewhat acidic soils. Farther to the west are alkaline soils that can be impervious to water. The northwestern region forms the so-called Sandveld, on which good crops are obtained only in years of high rainfall. The west is covered by sandy soil resembling that of the Kalahari, where successful cultivation is possible only under irrigation.

Climate. The climate varies from a warm and temperate type with an annual rainfall of 40 inches in the east to a semiarid type with a rainfall of 15 inches in the far west. Mean annual surface temperatures gradually increase from about 58° F (14° C) in the east to 62° F (17° C) in the west. Frost is common over the entire province from May to September, while dust storms normally occur during drought-stricken summer periods. Whirlwinds are common during warmer days; and hailstorms, sometimes destructive, occur on an average about seven times a year in the east but only three times a year in the west. Because rainfall is unreliable, long periods of drought are frequent each year. Thunderstorms, almost exclusively a summer phenomenon, are the normal sources of precipitation, occurring between 60 and 100 days a year. Sunshine is abundant; there are only about six days a year on which Bloemfontein has no sunshine.

Rainfall and temperatures

University of the Orange Free State, Bloemfontein.

The rate of evaporation is consequently high. Because rainfall is sporadic, much reliance is placed on underground supplies of water and on storage dams.

Vegetation and animal life. From west to east the vegetation consists of four successive zones—desert shrub, sweet grassveld, mixed grassveld, and sour grassveld. In most of the province, animal life, like the vegetation, has given way to crop cultivation and human settlement. Many animal and plant species are now protected by legislation. At Willem Pretorius Game Reserve, Highveld game animals, including herds of such species of antelope as blesbok and springbok, are plentiful; zebra and giraffe are also to be found. Golden Gate Highlands National Park was developed to restock the area with antelope species—such as black wildebeest and blesbok—and other animals and to establish a habitat for a wide variety of birds. Several of the smaller reptiles and snakes, such as adders, ringhals (venomous spitting snakes), and tree snakes, are still to be found over the entire province. The rarely observed freshwater fishes of the Orange and Vaal river systems include yellowfish, carp, and barbel.

Population. *Ethnic composition.* The 1970 population, totalling 1,649,000, included 296,000 whites, 36,000 Coloureds (racially mixed; an official designation of the Republic of South Africa), and 1,317,000 Bantu. The density averages about 33 persons per square mile. The ethnic pattern is revealed by the home language spoken. Among the white population, 84 percent are Afrikaans speaking; 13 percent speak English; and the remainder speak German, Dutch, or other European languages. Historically, the Afrikaners, whose ancestors came from the preindustrial Netherlands, tended to be farmers; while the English, who came from an industrialized Britain, tended to be city dwellers. Today, about 74 percent of the Afrikaners and 90 percent of the English live in towns and cities. In general, the rural white population increases from south to north, with Bloemfontein and the northwestern goldfields being the most densely populated regions. The Bantu population was originally largely confined to the northern and eastern districts, adjoining Lesotho, but today their numbers are rapidly increasing in the goldfield area. About 60 percent belong to the South Sotho (also known as Sotho proper or Basuto) tribe. Various other tribal groups include the Zulu to the northeast (who represent about 10 percent), the city-dwelling Xosa (Xhosa; 13 percent), and the Tswana (8 percent). Bantu densities also increase in a northerly direction. The Coloureds, almost without exception, speak Afrikaans; slightly more than 57 percent of them live in towns and cities; the remainder increase in number toward the southwest.

Bantu tribal groups

Religious affinities. Throughout the province, church buildings are dominant in towns. The Provincial Council begins the day's work with solemn prayer, and, in the distant farm house, divine worship is part of the family's evening activities. Less than 1 percent of the white population adheres to no religion. The three main Afrikaans churches (Nederduits Gereformeerde, Nederduits Hervormde, and Gereformeerde) account for 77 percent of white church membership, and the three main English churches (Anglican, Methodist, and Presbyterian) for 11 percent. White Christians feel a responsibility toward nonwhite peoples and engage in missionary activity. The Coloureds are almost entirely Christian: 68 percent are members of the above-mentioned churches, and 13 percent are Lutherans. The Bantu of the Orange Free State are more Christianized than those of the neighbouring Transvaal. Only 9 percent have no church affiliation; 19 percent are attached to Bantu Separatist Churches; and 46 percent are members of the six main churches.

Rural and urban settlement. The white population is dispersed over the country on individually owned farms and single homesteads. New discoveries of gold since World War II in the northwest have resulted in a maize and cattle country being turned into a mining and industrial belt. New towns, including Welkom (1970 population 132,000), Virginia (population 46,000), and Odendaalsrus (population 31,000), have sprung up. Welkom, the second largest town, has grown rapidly since 1950 and provides an example of modern planning, in which residential suburbs radiate from the town centre with green wedges of open spaces between them. Bloemfontein, the largest city, had about 148,000 inhabitants in 1970 and was the province's administrative, transport, educational, and cultural centre. It is also developing industrially. Kroonstad, with about 51,000 people, is the third largest town, while Sasolburg (29,000) is important for its burgeoning chemical industry. Most of the remaining towns are small, with some centres supporting a population of less than 10,000.

Administration. The Orange Free State is administered by its Provincial Council, the members elected every five years. The Council has jurisdiction on such matters as taxation to provide revenue for white education, hospitals, roads, and nature conservation. Local authorities consist of about 70 city or town councils, 10 village management boards, and 40 committees for the management of small-holding areas, and they derive their powers from the Provincial Council. Forty-nine magisterial districts control the administration of justice and, to a lesser extent, some functions of other governmental departments that do not justify offices in all districts. Of South Africa's four provinces, the Orange Free State has the smallest Bantu areas; located at Thaba 'Nchu and Basotho-Qwaqwa (formerly Basotho ba Borwa), they amount to 158,000 acres (64,000 hectares) or 0.5 percent of the total area of the province.

Social conditions. There are 13 provincial hospitals, two of them in the two Bantu homelands. Apart from the leper, mental, and tuberculosis institutions, the provincial and private hospitals and clinics have more than 1,500 and 2,000 beds for white and nonwhite patients, respectively. The province provides a wide range of health services, including a field service. Increased attention to health has led to a decline in infant mortality over the last decades.

Schooling, when available, is free for all and is compulsory for whites between 7 and 16 years of age. Where demand justifies the establishment of facilities, Coloureds between seven and 14 years are also compelled to attend schools; but Bantu education is not yet enforced, although Bantu literacy, which amounts to about 85 percent of the age group between seven and 20 years old, already has risen to a level considerably higher than in African territories outside the Republic. The University of the Orange Free State, located in Bloemfontein, has an enrollment of almost 3,000 white students. Administration of primary and secondary education and the training of teachers for whites are under provincial authority, while administration of the university and higher technical training are under the central government's Department of Higher Education. The central government is also responsible for nonwhite education.

Education

Provincial authorities, in cooperation with private organizations, undertake a wide variety of welfare services, including care for the aged, workshops and housing for the blind, and the provision of housing for the Bantu in larger urban centres.

Economy. The Orange Free State is not as rich in mineral resources as the neighbouring Transvaal. The gold resources of the Welkom district are the most important. Diamond production totalled 220,000 metric carats in 1968 alone. Estimated coal reserves of 3,400,000,000 tons are worked in the north and are mainly used in the coal-to-oil project at Sasolburg that supplies about 10 percent of the nation's gasoline requirements. Salt is derived from the pans of the semiarid region, and bentonite (a moisture-absorbing clay) is mined from a large deposit near Parys on the Vaal River.

The province forms part of the country's grain belt. The wetter area of the northeast grew about 30 percent of South Africa's annual maize output in 1965. In the northeastern and eastern districts, wheat is also grown, producing about 30 percent of the national crop for 1965. The undulating plains afford excellent grazing, and stock farming is important. The province produces almost one-quarter of South Africa's wool output, and its

Agricultural products

1,500,000 head of cattle are mainly located in the wetter northeastern districts of Harrismith, Vrede, and Bethlehem.

Water is the province's most essential resource. Apart from several storage dams—like the large Allenmanskraal, the Erfenis, and the Kalkfontein—the region will benefit enormously from the vast Hendrik Verwoerd and Van der Kloof dams, part of the great Orange River Project. The first was completed in 1972 and will provide water for Bloemfontein as well as for the gold-mining complex at Welkom; the second is due for completion in about 1974.

Transportation and communications. The state-owned railways provide a total of 1,678 track miles (231 of them electrified). Railways are supplemented by state, as well as privately owned, road motor service. There are over 2,000 miles of bitumen-surfaced national and provincial roads, exclusive of streets under the control of local authorities. The J.B.M. Hertzog Airport at Bloemfontein is the largest in the province and is of growing importance. Post office and telecommunication services expand from year to year to meet an increasing demand. The South African Broadcasting Corporation broadcasts to the province in English, Afrikaans, and several Bantu languages. There is a radio station at Bloemfontein. Television is to be installed in 1974.

Cultural life. The cultural life of the whites resembles that in Western countries. As the Orange Free State is predominantly a rural province, the more austere and moralistic aspects of the Afrikaner character are probably more in evidence here than elsewhere. The well-known hospitality, a general trait of white South African life, is a result of the stimulus of a mutual dependence that developed in an earlier era when life on the trekker's frontier was hard and sometimes dangerous. Bantu culture is still strongly influenced by tribal life; the supremacy of the chiefs is recognized, and the heritage of traditional animist religion is still in evidence, despite the influence of Christianity. The sunny climate influences all aspects of life, from clothing to food and drink and from literature to architecture. Cultural institutions such as museums and theatres are to be found in the principal towns.

Orange River

The Orange River in southern Africa, the sixth longest river on the continent and the longest south of the Tropic of Capricorn, rises as the Sinqu River in the Lesotho Highlands, flows westward across the veld as the Orange River, after which, also known as the Gariep River, it forms the southern border of the Kalahari before draining into the Atlantic Ocean at Alexander Bay, South Africa. Although the direct distance from its source to its mouth is less than 800 miles (1,300 kilometres), in its twisting, turning course it travels for 1,300 miles (2,100 kilometres). The river forms the boundary between two of South Africa's provinces, the Orange Free State and Cape Province, as well as that between South West Africa and the Republic of South Africa.

The drainage basin has an area of at least 329,000 square miles (852,000 square kilometres). The western part of the basin is generally dry, flat, and uncultivable without irrigation. The river itself is of vital economic importance to the region through which it flows. Two projects—the Orange River Project and the Oxbow Scheme—are planned to provide needed water for South Africa's arid plains and electrical power for its mines and industrial cities. (For an associated physical feature, see VELD; for historical background, see SOUTHERN AFRICA, HISTORY OF.)

The river's course. *The upper Orange.* The headwaters of the Orange River rise on the plateau formed by the Lesotho Highlands, where horizontal basaltic lavas have been cut into by numerous streams from the Drakenberg Escarpment in the east and the Maluti Mountains in the west. The main source is officially recognized as the Sinqu River, which rises near the plateau's eastern edge. The Khubedu headwater, which rises near Mont-aux-Sources to the north, is, however, better known and more accessible. Still farther north is the lesser known Madibamatso headwater, site of the Oxbow Scheme. Headwaters

The Lesotho headwaters flow over the turf soil that covers the lava, dropping 70 feet to 90 feet per mile. Below 29°40′ south, they have cut through the lava to expose sandstones; purple, red, and blue shales; and mudstones—rocks that contribute to heavy silt deposits farther down the river's course. To the west of the Lesotho boundary, the river flows south and west through more open country, where the sandstones, shales, and mudstones appear on the surface and where hard dolerite (basalt) outcrops form small hills and flat-topped mountains. Near Aliwal North, the river has eroded a broad valley with a width of some 30 miles and a depth of more than 1,000 feet. The river's channel, however, varies greatly in both width and depth because of dolerite outcrops that sometimes narrow its channel to 3,000 or 4,000 feet. Here, the average gradient is 3.5 feet per mile. The river receives the Caledon as a tributary near the town of Bethulie and then swings to the northwest.

The middle Orange. At its confluence with the Vaal, the river turns southwest and flows over limestone shales and tillite (glacial clayey deposit). At Prieska it makes another sharp bend—this time to the northwest—that marks the beginning of its middle course. Quartzites and ironstones form a "barrier zone" through which the river has cut deep *poorts*, or gorges, such as the Groot and Klein Noute (Great and Little Narrows). The gradient in this tract is about 2.5 feet per mile. At Upington the river spreads out over a granite surface to a width of about a mile. In this area the river splits up into innumerable channels, between which are islands varying in length from a few hundred yards to six or seven miles. In this stretch the river attains its greatest width—nearly four miles in places. About 40 miles downstream from Upington, however, the river bed is suddenly narrowed to about 700 yards by a bed of quartzite that forms the Neus Berg Ridge.

The lower Orange. Some 20 miles below Kakamas the river—again flowing in several channels—forms the Augrabies Falls. There, after descending about 80 feet in a series of rapids, the river plunges some 400 feet into a pool more than 140 feet deep. The river flows through an almost vertical-sided gorge, with some right-angled bends, for about 11 miles, emerging again into more open country. The lower course of the river, from the Augrabies Falls to the sea, is sometimes called the Gorge Tract. Where the rock surface is soft, the river valley is generally open. Where the river traverses harder quartzite granodiorite (a granular igneous rock) and diabase (a form of basalt), however, it is confined between almost vertical cliffs more than 1,000 feet high in places. Some of the most rugged passages are found in the last great bend of the river, as it flows north along the Richtersveld before turning west to the coastal Namib Desert. The Gorge Tract

The river reaches the sea a few miles north of the little inlet known as Alexander Bay. The mouth is about 2.5 miles wide and is nearly closed by a sandbar, which is widely breached, however, during high floods. The

gap in the southern end of the bar is maintained by the outflow of water from the river mouth during low tides and by the tidal inflow at high tides.

The riverine population. The high valleys of the Orange River's headwaters are uninhabited and are used by the Sotho (Basuto) people for grazing land. Between the Lesotho border and the town of Aliwal North, maize (corn) is cultivated on the valley's grassland, which is also used as pasturage for cattle and sheep by the South African white population. To the west, the river passes through dry shrub country that is in general suitable only for grazing. Some irrigated sections, however, occur along the river's course; the largest such areas are at the Boegoebergdam, where one-half of South Africa's cotton is grown, and between Augrabies Falls and Upington. While scattered, white-owned farms stand within reach of the river's freshwater supply, there are no large towns along the riverbank. This situation will remain little changed by the Orange River Project, as most of the water accumulated by its three large dams will be diverted to the valleys of the Fish and Sundays rivers and to the cities of Port Elizabeth, Bloemfontein, and Kimberley.

History. The first white man known to cross the river to the north bank was an Afrikaner elephant hunter, Jacobus Coetsee, who forded the Groot River, as it was then called, near the river mouth in 1760. Later expeditions across the river in the 18th century were led by Capt. Hendrik Hop; Capt. Robert Jacob Gordon, a Dutch officer; Lieut. William Paterson, an English traveller; and François Le Vaillant. They explored the river from its middle course to its mouth, and Gordon named it in honour of the Dutch House of Orange.

Throughout the 19th century, the Orange River marked the northern limit of British power in southern Africa. Beginning in the 1830s, the Boers crossed it in search of land and freedom from British rule; they named their first republic—the Orange Free State—after the river.

Climate

Hydrology. There are two distinct rainfall patterns in the river basin; each is directly related to the rate of flow. Above the Vaal River confluence, the river receives the heavy summer rainfall of 60 to 80 inches and the melted winter snows of the Lesotho Highlands and the western Maluti Mountains, as well as an annual rainfall of about 18 inches that occurs along the eastern basin. Although this section of the river comprises only 7 percent of the area of the entire catchment basin, it contributes 58 percent of the river's total flow. Downstream at Prieska, the Orange has an annual runoff of 5,500,000 acre-feet.

Below the Vaal confluence, rainfall decreases from nine inches a year to less than two inches in the coastal Namib Desert. Temperatures increase in a westerly direction and result in a higher rate of evaporation. The total annual runoff of water from the remaining 215,000 square miles of the catchment basin is reduced to 165,000 acre-feet.

Development and projects. *Navigation and bridges.* Navigation is impossible throughout the river's course because of its irregular flow, its constant interruption by falls and rapids, and the silting that occurs in its channels and at the river mouth. Many bridges cross the river along its course between Aliwal North and Oranjemund, the largest being at Upington.

Dams and future projects. Most damming is accomplished by privately owned weirs constructed for irrigation. Larger irrigation and hydroelectric projects are hampered by the enormous amount of water-borne silt that clogs up reservoirs, such as that of the concrete Boegoeberg Dam, and reduces storage capacity. Completed in 1931, it is located midway between Prieska and Upington where the river cuts through a hard, quartzite outcrop. With a storage capacity of 43,500 acre-feet, it irrigates about 42,000 acres over a distance of 150 miles.

The Orange River Project

To obtain comprehensive control, as in the Orange River Project, however, it is necessary to locate projects farther upstream. Below the Vaal River confluence the flow is too sluggish. The Orange River Project, therefore, is located between the Caledon and Vaal confluences. The plan consists of six consecutive projects that are expected to take 30 years to complete; work began in 1962. The projects include the Hendrik Verwoerd Dam (already completed), which will form the main reservoir, located just west of the Caledon confluence; the Van der Kloof Dam, with irrigation canals to both banks, 70 miles downstream; the Torquay Dam, between Hopetown and Douglas; a 52-mile tunnel to carry water from the Verwoerd Dam to the Great Fish River; an irrigation canal between the Fish and Sundays rivers; and another irrigation canal from Torquay Dam to the Kalkonfontein Dam, on the Vaal River. The three major dams will be able to store 37,000,000 acre-feet, and total storage will reach 105,000,000 acre-feet.

The new dams will be equipped to deal with heavy silt accumulation. They will be provided with deep dead-storage areas, and their high walls will be raised if necessary to allow for a higher water level. The impounded water is to irrigate some 762,000 acres of land along the Orange River and in tributary valleys extending as far west as the Sak River in northwestern Cape Province, as well as the Witsands area in the southeastern Kalahari. The project also will supply an area of 54,000 square miles in northern Cape Province and southern Orange Free State with an annual power output of about 6,000,000,000 kilowatt-hours.

Near the river's headwaters in Lesotho, another project, the Oxbow Scheme, is still in the planning stage. It is to be Lesotho's major irrigation project; South Africa will have the opportunity of purchasing large quantities of the excess water and power. The plan calls for the damming of the Madibamatso headwater about 11 miles west of Mont-aux-Sources in the Maluti Mountains. It will produce 350,000,000 kilowatt-hours of electric power a year and will supply the Orange Free State with 40,000,000 gallons of water daily.

BIBLIOGRAPHY. The earliest, and in many ways the most interesting, account of the Orange River is *The Journal of Hendrik Jacob Wikar* (1779), written in Dutch, with an English translation by A.W. VAN DER HORST (1935). There were other travellers' accounts of the river in the 19th century, but it was not until the early 20th century that a concerted attempt was made to explore economic potentialities. A.D. LEWIS traversed the river's course on foot from Pella Drift to the river mouth, recording his impressions in his "Report on Flying Reconnaissance of the Lower Orange River," *Report of the Director of Irrigation 1912–1913* (1914). Later publications include some geographical studies, one of the most comprehensive being that of J.H. MOOLMAN, "The Orange River, South Africa," *Geogrl. Rev.*, 36:653–674 (1946), illustrated. Other geographical studies include those of J.H. WELLINGTON: "The Middle Course of the Orange River," *S. Afr. Geogr. J.*, 16:58–68 (1933); "The Evolution of the Orange River Basin: Some Outstanding Problems," *S. Afr. Geogr. J.*, 40:3–30 (1958); and his book *Southern Africa* (1955), in which ch. 12 of vol. 1 is concerned with many aspects of the river and its tributaries. Less formal accounts include LAWRENCE GREEN's entertaining *To the River's End* (1948), which contains episodes and legends relating to riverine settlements. Recent literature has been connected mainly with the Orange River Project; this includes a number of papers given at the symposium arranged by the South African Association for the Advancement of Science and are contained in the Orange River number of the *S. Afr. J. Sci.*, vol. 61 (1965), where the subjects include the geological and geomorphological character of the upper part of the basin, the hydroelectrical potential, plant ecology, the freshwater fishes, and other aspects. Government publications include the *Report on the Proposed Orange Development Project* (1963), and a comprehensive account issued in an 80-page supplement, "Dykes Against Drought," *Financial Mail* (Johannesburg, April 25, 1969).

(J.H.We.)

Oratory

Oratory is the rationale and practice of persuasive public address. As a form of oral communication, it is immediate in its audience relationships and reactions, but it may also have broad historical repercussions. The orator may become the voice of political or social history. Thus Rufus Choate, an American legal advocate of the early 19th century, said, in a tribute to Daniel Webster,

> It is a peculiarity of some schools of eloquence that they embody and utter, not merely the individual genius and charac-

ter of the speaker, but a national consciousness,—a national era, a mood, a hope, a dread, a despair,—in which you listen to the spoken history of the time.

A vivid instance of the way a speech can focus the concerns of a nation was Martin Luther King's address to a massive civil rights demonstration in Washington, D.C., in 1963. Repeating the phrase "I have a dream," King applied the oratorical skill he had mastered as a preacher to heighten his appeal for further rights for U.S. Negroes to an intensity that galvanized millions.

Principles of oratory. The essentials of a given oration are a speaker; an audience; a background of time, place, and other conditions; a message; a transmission process by voice, articulation, and bodily accompaniments; and immediate and larger outcomes of the speaking event.

Rhetoric is the art of using words effectively, while oratory is the practice of that art in public speech. Oratory, like rhetoric, is instrumental and practical, as distinguished from poetic or literary composition, which traditionally aims at beauty and pleasure. Rhetoric and oratory are of the marketplace and are not so much concerned with the universal and permanent. The orator in his purpose and technique is primarily persuasive rather than informational or entertaining. He attempts to change human behaviour or to strengthen convictions and attitudes. The orator would correct wrong positions of the audience and establish psychological patterns favourable to his own wishes and platform. He uses argument and rhetorical devices: evidence and lines of reasoning, and appeals that support his aims. He uses exposition to clarify and enforce his propositions. He includes anecdotes and illustrations to heighten response.

Union of thought and feeling

The orator need not be a first-rate logician, though a capacity for good, clear thought helps to penetrate into the causes and results of tentative premises and conclusions, and to utilize analogy, generalizations, assumptions, deductive-inductive reasoning, and other types of inference. Effective debaters, who depend more heavily on logic, however, are not always impressive orators because superior eloquence also requires strong appeals to the motives, sentiments, and habits of the audience. Audience behaviour is guided by imaginative and emotional suggestion at each phase of the address. Oratorical greatness is invariably identified with strong emotional phrasing and delivery. When the intellectual qualities dominate with relative absence of the affective appeals, the oration fails just as it does when emotionality sweeps aside reason.

The ideal orator is personal in his appeals and strong in ethical proofs, rather than objective or detached. He enforces his arguments by his personal commitment to his advocacy. William Pitt, later Lord Chatham, punctuated his dramatic appeals for justice to the American colonies with references to his own attitudes and beliefs. So were personal appeals used by the Irish orator Daniel O'Connell, the French orators Mirabeau and Robespierre, and the Americans Wendell Phillips, Robert G. Ingersoll, and Woodrow Wilson.

The eloquent speaker looks to the basic foundations of reasoning and emotive expression. His utterances are concrete, but they argue broad principles. The orator, as illustrated by Edmund Burke, has a catholic attitude. Burke's discussion of American taxation, conciliation, Irish freedoms, justice for India, and the French Revolution show analytical and intellectual maturity, the power of apt generalization, and comprehensiveness of treatment.

Types of oratory. Oratory has traditionally been divided into legal, political, or ceremonial, or, according to Aristotle, forensic, deliberative, or epideictic.

Forensic oratory. Typically, forensic, or legal, oratory is at its best in the defense of individual freedom and resistance to prosecution. It was the most characteristic type of oratory in ancient Athens, where laws stipulated that litigants should defend their own causes. In the so-called Golden Age of Athens, the 4th century BC, great speakers, in both the law courts and the assembly, included Lycurgus, Demosthenes, Hyperides, Aeschines, and Dinarchus.

In the first century BC of ancient Rome, Cicero became the foremost forensic orator and exerted a lasting influence on later Western oratory and prose style. Cicero successfully prosecuted Gaius Verres, notorious for his mismanagement while governor of Sicily, and drove him into exile, and dramatically presented arguments against Lucius Sergius Catiline that showed a command of analysis and logic, and great skill in motivating his audience. Cicero also delivered 14 bitter indictments against Mark Antony, who was to him the embodiment of despotism.

Among the great forensic orators of later times was the 18th- and 19th-century English advocate Thomas Erskine (1750–1823), who contributed to the cause of English liberties and the humane application of the legal system.

Deliberative oratory. According to Aristotle, the chief problems for deliberation and policy settlement are those involved with the domestic and foreign affairs of the government, and its economic concerns. Demosthenes, the Athenian lawyer, soldier, and statesman, was a great deliberative orator. In one of his greatest speeches, "On the Crown," he defended himself against the charge by his political rival Aeschines that he had no right to the golden crown granted him for his services to Athens. So brilliant was Demosthenes' defense of his public actions and principles that Aeschines, who was also a powerful orator, left Athens for Rhodes in defeat.

Epideictic oratory. The third division of persuasive speaking, epideictic, or ceremonial, oratory was panegyrical, declamatory, and demonstrative. Its aim was to eulogize an individual, a cause, occasion, movement, city, or state, or to condemn them. Prominent in ancient Greece were the funeral orations in honour of those killed in battle. The outstanding example of these is one by Pericles, perhaps the most finished orator of the 5th century BC, in honour of those killed in the first year of the Peloponnesian War.

Webster—master of all forms

The 19th-century American speaker Daniel Webster excelled in all three major divisions—forensic, deliberative, and epideictic oratory. He brought more than 150 pleas before the U.S. Supreme Court, including the Dartmouth College Case (1819) and the *Gibbons v. Ogden* case (1824); he debated in the U.S. Senate against Robert Young Hayne and John Calhoun on the issues of federal government versus states' rights, slavery, and free trade, and he delivered major eulogies, including those on the deaths of Jefferson and John Adams.

Religious oratory. Another major type of persuasive speaking that developed later than ancient Greek and Roman rhetoric was religious oratory. The decline of Roman republican government, with its Senate and Forum, saw the passing of significant political oratory. Roman law and order prevailed, but there was little scope for provocative public address. For more than 1,000 years after Cicero the important orators were churchmen rather than politicians, lawyers, or military spokesmen. This tradition derived from the Judean prophets, such as Jeremiah and Isaiah, and in the Christian Era, from the Apostle Paul, his evangelistic colleagues, and such later fathers of the church as Tertullian, Chrysostom, and St. Augustine. Ecclesiastical speaking became vigorously polemical. The rhetorical principles of Aristotle and Cicero were adopted by ecclesiastical leaders who challenged rival doctrines and attacked the sins of the communities.

In the Middle Ages, Pope Urban II elicited a great response to his oratorical pleas for enlistment in the First Crusade. The Second Crusade was urged on with great eloquence by Saint Bernard, abbot of Clairvaux. In the 15th and 16th centuries the revolt against the papacy and the Reformation movement stimulated the eloquence of Huldrych Zwingli (1484–1531), John Calvin (1509–64), Hugh Latimer (*c.* 1485–1555), and, most notably, Martin Luther (1483–1546). At the Diet of Worms, as elsewhere, Luther spoke with courage, sincerity, and well-buttressed logic. Religious controversies in the 17th century engaged such great oratorical skills as those of Richard Baxter (1615–91), the English Puritan, and Catholic Bishop J.B. Bossuet (1627–1704) of France. In the 18th century the Methodist George Whitefield (1714–70) in England and America, and the Congregationalist Jonathan Edwards

(1703–58) in America, were notably persuasive speakers. Preachers of oratorical power in the 19th century included Henry Ward Beecher (1813–87), famous for his anti-slavery speeches and his advocacy of women's suffrage from his Congregational pulpit in Plymouth Church, Brooklyn, New York, and William Ellery Channing (1780–1842), American spokesman for Unitarianism.

Oratory as a reflection of its audience. Because the orator intuitively expresses the fears, hopes, and attitudes of his audience, a great oration is to a large extent a reflection of those to whom it is addressed. The audience of Pericles in ancient Greece, for example, was the 30,000 or 40,000 citizens out of the state's total population of 200,000 or 300,000, including slaves and others. These citizens were sophisticated in the arts, politics, and philosophy. Directing their own affairs in their Assembly, they were at once deliberative, administrative, judicial. Speaker and audience were identified in their loyalty to Athens. Similarly, the senatorial and forum audience of Cicero in ancient Rome was an even smaller elite among the hundreds of thousands of slaves and aliens who thronged the Roman world. In the Forum the citizens, long trained in law, and with military, literary, and political experience, debated and settled the problems. The speeches of Cato, Catiline, Cicero, Julius Caesar, Brutus, Antony, Augustus, and the others were oratory of and for the Roman citizen.

In the Christian Era, however, the religious orator often found himself addressing an alien audience that he hoped to convert. To communicate with them, the Christian often appealed to ancient Greek and Roman thought, which had achieved widespread authority, and to Judean thought and method, which had the sanction of scripture. By the time of the Reformation, however, Christian dogma had become so codified that most of the disputation could be carried on in terms of doctrine that had become well known to all.

Trend toward common speech

The history of the British Parliament reveals a continuing trend toward common speech and away from the allusions to ancient Greek and Roman thought that abounded when the members consisted largely of classically educated aristocrats.

In the golden age of British political oratory of the late 18th century, greater parliamentary freedom and the opportunity to defend and extend popular rights gave political oratory tremendous energy, personified by such brilliant orators as the elder and younger William Pitt, John Wilkes, Charles James Fox, Richard Sheridan, Edmund Burke, and William Wilberforce. Parliamentary reforms of the 19th century, initiated and promoted by Macaulay, Disraeli, Gladstone, and others of the century, led to more and more direct political speaking on the hustings with the rank and file outside Parliament. Burke and his contemporaries had spoken almost entirely in the Commons or Lords, or to limited electors in their borough homes, but later political leaders appealed directly to the population. With the rise of the Labour Party in the 20th century and the further adaptation of government to the people, delivery became less declamatory and studied. The dramatic stances of the 18th-century parliamentary debaters disappeared as a more direct, spontaneous style prevailed. As delivery habits changed, so did the oratorical language. Alliteration, antithesis, parallelism, and other rhetorical figures of thought and of language were sometimes carried to extremes, in speeches addressed to those highly trained in Latin- and Greek-language traditions. These devices gave way, however, to a clearness of style and vividness consonant with the idiom of the common man and later with the vocabulary of radio and television.

Similarly, American speech inherited and then gradually discarded British oratorical techniques for its own speaking vernacular. John Calhoun, in his addresses to Congress on behalf of the South, absorbed much of the Greek political philosophy and methods of oral composition and presentation, and his principal opponent in debate, Daniel Webster, too, had the marks of British communicative tradition. This inheritance was absorbed into the speaking adjustments indigenous to those later peoples of New England, the West, and the South. The orator whose speech preceded Lincoln's at Gettysburg—Edward Everett, statesman and former professor of Greek literature at Harvard—was a classical scholar. Lincoln, on the same platform, had address born of his native Middle West yet expressed with authentic eloquence.

In the 20th century, the era culminating in World War II saw the development of two leaders who applied oratorical techniques in vastly different ways with equal effect. It was primarily through his oratory that Adolf Hitler whipped the defeated and divided Germans into a frenzy of conquest, while Winston Churchill used his no less remarkable powers to summon up in the English people their deepest historical reserves of strength against the onslaught. Subsequently, though the importance of persuasive speech in no way diminished, television so reshaped the method of delivery that much of the theory of traditional oratory often seemed no longer to apply. In the televised debates of John F. Kennedy and Richard Nixon during the U.S. presidential campaign in 1960, for example, the candidates might be said to have been most persuasive when they were least oratorical, in the traditional sense of the term. Nonetheless, even conventional oratory persisted as peoples in newly developing nations were swept up into national and international political struggles.

(A.C.B.)

Orchestration and Instrumentation

Most authorities make very little distinction between the terms orchestration and instrumentation. Both deal with musical instruments and their capabilities of producing

various timbres or colours. Orchestration is somewhat the narrower term since it is frequently used to describe the art of instrumentation as related to the symphony orchestra. Instrumentation, therefore, is the art of combining instruments in any sort of musical composition, including such diverse elements as the numerous combinations used in chamber groups, jazz bands, rock ensembles, ensembles employing chorus, symphonic bands, and, of course, the symphony orchestra. Included under this designation are the various instrumental groups that play non-Western music, such as the gamelan orchestras of Bali and Java and the traditional ensembles of India, Africa, the Far East, and the Middle East.

Constituents of the orchestra

In Western music there are many standard or traditional groups. The modern symphony orchestra usually comprises the following instruments, although they are not necessarily used in every composition:

1. Woodwinds: four flutes (one doubling, or duplicating the part of the piccolo), four oboes, English horn (cor anglais), three clarinets, bass clarinet, three bassoons, contrabassoon (double bassoon);
2. Brass: four trumpets, four or five French horns, three trombones, tuba;
3. Strings: two harps, first and second violins, violas, violoncellos, double basses;
4. Percussion; four timpani (played by one player) and at least three general percussion players.

The orchestra has arrived at this complement through centuries of evolution; the present size is needed to perform repertory from the Baroque, Classical, Romantic, and Impressionistic periods, as well as the repertory of the 20th century.

The various sections, with the exception of percussion, divide themselves in somewhat the same manner as a choir. The woodwinds, for example, divide into flutes (sopranos), oboes (altos), clarinets (tenors), and bassoons (basses), although this distinction must be greatly qualified. Instrumental range is larger than vocal range, and the clarinets of an orchestra may play higher than the flutes in a woodwind passage.

The standard instrumental groups of Western chamber music include the string quartet (two violins, viola, and violoncello), the woodwind quintet (flute, oboe, clarinet, French horn, and bassoon), the combinations employed in sonatas (one wind or string instrument with piano), and the brass quintet (frequently two trumpets, French horn, trombone, and tuba). In addition to these standard groups there are, however, hundreds of other possible combinations.

Other groups that deserve mention are those used in the popular music of the 20th century. The dance band, popular in the 1930s and 1940s, consisted of five saxophones, four trumpets, four trombones, double bass, piano, guitar, and drums. The basic rock ensemble consists of two electric guitars, electric bass, electric organ (doubling electric piano), drums, and frequently includes one or more singers. The concert band, which is particularly popular in North America, consists of mixed wind and percussion players totalling from about 40 to well beyond 100 players.

The music of the non-Western world is most frequently performed by groups of chamber music size. In this category would fall the music played by the Javanese gamelan orchestra (consisting mainly of tuned gongs and other metal instruments), Japanese *gagaku* music (performed on flutes, mouth organs, lutes, drums, and gongs), and Chinese music (with a traceable history of about 4,000 years) consisting of sacred, folk, chamber, and operatic music.

TYPES OF INSTRUMENTATION

The approach to the art of instrumentation is naturally greatly influenced by the type of group for which the composer is writing. He cannot treat a string quartet or a group of brass instruments in the same manner as he would a symphony orchestra. In general, the larger and more diverse the instrumental group, the more coloristic possibilities it presents to the composer. The smaller instrumental groups often have a sound character of their own, and the composer is challenged to find new and interesting ways to deal with this limitation.

The symphony orchestra has had definite traditions in relation to orchestration. The composer of the 18th century was likely to use the orchestral instruments at least part of the time in the following manner: the flutes doubling the same part as the first violins (frequently the melody); the oboes doubling the second violins or the first violins in octaves; the clarinets (by the end of the century) doubling the violas; and the bassoons doubling the violoncellos and double basses. French horns were often used as harmonic "filler" and in conjunction with every section of the orchestra because of their ability to blend easily with both string and wind instruments.

These traditional doublings were not so often used in the orchestration of the 19th and 20th centuries because of the great improvement in the making of wind instruments and their consequent ability to function in a solo capacity. Wind instruments became used more and more for colouring; the flutes, for instance, were noted for their bright tone quality and great technical agility, the clarinets for all the aforementioned qualities, and the bassoons for their special tone quality. Brass instruments had to await the development of valves, which increased greatly the musical proficiency of brass players and overcame previous typecasting of these instruments as bugles and hunting horns.

Development of wind instruments

String techniques. The string quartet has long been considered one of the greatest challenges to the composer because the contrast to be achieved by changing from one type of instrument when writing for a full orchestra is simply not available. The composer has had to rely on varying timbres to be arrived at by different playing techniques, such as pizzicato (plucking the strings), tremolo (the quick reiteration of the same tone), sul ponticello (bowing near the bridge of the instrument), sul tasto (bowing on the fingerboard), the use of harmonics (dividing the string in such a way as to produce a high flute-like tone), col legno (striking the strings with the wood of the bow), and many special bowing techniques.

Wind techniques. Special playing techniques also can alter the timbres of wind instruments. For instance, on many, tremolos can be played on two different notes. Some wind instruments—and the flute is particularly agile in this respect—can produce harmonics. Flutter tonguing (produced by a rapid rolling movement of the tongue) is possible on most wind instruments; so are many other tonguing techniques that affect the quality of sound in orchestration.

Muting. The string mute is a device that softens the tone of the instrument. Muting is also used by brass instruments, particularly the trumpet and trombone, a development that took place in 20th-century popular music and then came into common use in all types of music. Mutes—of which there are various kinds—provide the trumpet and trombone with a different tone colour. Mutes on woodwind instruments have been experimented with, but the results have not been satisfactory.

Percussion instruments. Percussion instruments have become a favourite source of colour for the 20th-century composer, both in the concert and popular fields. Instruments from all over the world are now commonly available and are divided into two categories: of definite and of indefinite pitch. The former include the xylophone, marimba, vibraphone, glockenspiel, timpani, and chimes. Instruments of indefinite pitch exist by the hundreds. Some of the more common ones are the snare drum, tenor drum, tom-tom, bass drum, bongos, Latin American *timbales*, many types of cymbal, maracas, claves, triangle, gongs, and temple blocks.

The availability of these instruments and the great improvement in percussion playing has resulted in an enormous increase in the number of compositions for percussion instruments. The percussion ensemble, a group of from four to eight players, is a chamber group that has existed only in the 20th century, particularly since the late 1940s. One of the interesting features of such an ensemble is that each player in it is capable of playing many instruments. An ensemble of four players, for in-

stance, can easily handle 25 or 30 instruments, once again showing the rich palette available in a single composition.

Keyboard instruments. Since the 17th century, keyboard instruments have played an important role in orchestration. Those commonly available today are the harpsichord, celesta, organ (both pipe and electric), and electric piano, in addition to the instrument for which most of the standard literature has been written—the piano. Keyboard instruments vary greatly in the manner in which they produce a sound: the harpsichord has quills that pluck the strings; the piano has hammers that strike the strings; the celesta has hammers that strike a metal bar; the pipe organ sends air through a pipe; the electric organ employs electronic oscillators to produce its sound. The resulting colours are naturally very different.

The piano, with its wide range (more than seven octaves), has been used in conjunction with virtually every instrument and instrumental combination. In the 18th century it gradually replaced the harpsichord as the common keyboard instrument because of the piano's ability to alter dynamics rapidly and its ability to sustain sounds. There is a vast amount of literature for the piano as the accompanying instrument in sonatas, partly because the piano can function as a "one-man orchestra." Many composers of the 20th century have discovered facets of the piano that had been previously ignored. The inside of the grand piano is a harplike body that has presented many new possibilities to the composer, such as the "prepared" piano. To prepare a piano, objects such as bolts, pennies, and erasers are inserted between the strings, thus producing many different sounds. The piano strings can be plucked or played with percussion mallets and can produce harmonics in the manner of non-keyboard stringed instruments, much to the dismay of piano tuners and traditional pianists.

The "prepared" piano

Electronic instruments. The electric piano is one of a number of instruments that have gained in popularity in recent times. These instruments either produce sound by means of electronic oscillators or are amplified acoustic instruments. The sound produced by ensembles playing this type of instrument is distinctive. The rock ensemble is the best known, but rock musicians are by no means the only instrumentalists to employ electric instruments. For the composer, amplified or electric instruments pose certain problems. Balances can be achieved or ruined simply by turning an amplifier up or down. The timbres produced by rock ensembles and other groups employing electronics are unusual for a number of reasons. The electric guitar has such devices as reverberation controls, "wa-wa" pedals, and filters that enable the performer to change timbre radically in the middle of a performance. Composers since the early 1960s, being much concerned with coloristic possibilities of instruments, have found the electronic ones most attractive.

Voices. The largest quantity of literature in Western music has been written for the chorus. The choir, an instrument capable of great subtleties of colour, has been a favourite of composers for centuries. The range of most individual singing voices is rather limited. Choral singers, who usually have a limited amount of training, are capable of a range of about an octave and a fifth, which is considerably smaller than the range of individual instruments. Singers are usually not capable of singing wide leaps, that is to say, notes that are far apart in range. Great skill is required in the musical setting of the text in a choral work. Attention must be paid to the vocal qualities of vowel sounds as well as to the way in which the consonants are treated.

For centuries composers have been intrigued with the combination of voices and instruments, and many of the most important compositions in Western music have been written for chorus and orchestra. Almost every major composer of the past three centuries has written for choir and large instrumental ensembles.

HISTORY AND DEVELOPMENT OF WESTERN INSTRUMENTATION

The development of the art of using instruments for their individual properties did not really begin in Western music until about 1600. The known history of musical instruments, however, has been traced back 40,000 years, although nothing is known about the music these early instruments produced. The Greeks have left mostly musical theories and only a very small amount of extant music. The Romans used instruments particularly in military bands, but, again, little is known of their specific use. The music of the Middle Ages and Renaissance was primarily vocal, although instruments were frequently used in compositions to accompany or reinforce the individual vocal line. String, brass, woodwind, and percussion instruments were added not so much for their coloristic potential but because of their availability. Another practice in the Middle Ages was to make literal instrumental versions of vocal compositions, which, of course, has rather little in common with the modern art of instrumentation.

Baroque. Orchestration in a modern sense probably began in the 16th century with Giovanni Gabrieli, organist of St. Mark's in Venice. He was the first composer to sometimes designate specific instruments for each part in a composition, as in his *Sacrae symphoniae* (1597). Claudio Monteverdi, one of the great composers in Western music, made important contributions to the art of orchestration. His opera *Orfeo* was first performed at Mantua (now Mantova, Italy) in 1607 with an orchestra of about 40 instruments including flutes, cornetts, trumpets, trombones, strings, and keyboard instruments. For the first time, a composer, in order to heighten certain dramatic moments, specified exactly which instruments were to be used.

Monteverdi's orchestra

The century after the first performance of *Orfeo* was characterized by a rise in the use of string instruments that were similar to the modern ones. Although that trend helped set the stage for the modern orchestra, it was not a period that made great strides in the art of orchestration: the prevalent practice of writing out only the melody and the bass line of a composition did not lend itself easily to creative scoring. By the end of the 17th century, however, the groundwork had been laid for new developments. Instruments and instrumentalists had improved steadily. Johann Sebastian Bach created works that occasionally exploited the coloristic capabilities of instruments, but in a rather limited way. In some of Bach's music the stringed instruments are played pizzicato, although this practice had already been employed by Monteverdi. Bach also wrote for muted strings. Wind instruments were treated occasionally for their special sounds, although more frequently they were simply employed on a musical line that their range happened to fit.

Handel, whose life covered the same period as Bach's, had a keener sense of orchestral effect. He introduced the clarinet into his orchestra, although it was not to become standard until the 19th century, and in his operas Handel often used instrumental colour in a way that did not become common practice until much later. Jean-Philippe Rameau, the leading French composer of the 18th century, also contributed much to the development of orchestration. Rameau, like Handel, was principally famous as an opera composer, and the overtures and dances of his operas represent the most advanced uses of instruments during that period. Rameau was probably the first composer to treat each instrument of the orchestra as a separate entity, and he introduced interesting and unexpected passages for the flutes, oboes, and bassoons.

By the middle of the 18th century the symphony orchestra was beginning to resemble the modern instrumental group, yet it was still considerably smaller. The orchestra at the court of Mannheim, Germany, consisted of 20 violins, four violas, four cellos, two double basses, two flutes, two oboes, two bassoons, four French horns, one trumpet, and kettledrums. Baroque composers frequently could not count on a fixed orchestra and therefore had to write the various parts so that they could be played on more than one instrument. The contrapuntal style that prevailed from the time of Monteverdi until the mid-18th century usually meant simply assigning instruments to each line in a composition; the basic considera-

The court orchestra in Mannheim

tion was whether that line stayed within the range of the chosen instrument. The fixed personnel of such orchestras as the Mannheim group, therefore, freed the composers to experiment with the capabilities of the instruments within the group. Musical style was also changing, the contrapuntal style of the Baroque giving way to a style that relied more heavily on melodic invention supported by harmony.

One of the more important composers of the period between the Baroque and Classical eras was Johann Sebastian's son, Carl Philipp Emanuel Bach. In C.P.E. Bach's symphonies the strings become melodic instruments, and the winds—two flutes, two oboes, one or two bassoons, two horns—fill out chords and provide body to the orchestration.

Classical. The Classical period, which covers roughly the second half of the 18th century, is one of the most significant periods in the development of orchestration. The most talented composers of this period were Mozart and Haydn. Many important developments took place during this time. The orchestra became standardized. The Classical orchestra came to consist of strings (first and second violins, violas, violoncellos, and double basses), two flutes, two oboes, two clarinets, two bassoons, two or four French horns, two trumpets, and two timpani. Toward the end of his career, in the *London Symphonies*, Haydn introduced clarinets as part of the woodwind section, a change that was to be permanent. Haydn also introduced the following innovations: trumpets were used independently instead of always doubling the horns, cellos became separated from the double basses, and woodwind instruments were often given the main melodic line. In the *Military Symphony* (*No. 100*) Haydn introduced some percussion instruments not normally used in the orchestras of this time, namely, triangle, hand cymbals, and bass drum, and, what is still more unusual, they are employed in the second movement, which in the Classical tradition is normally the slow movement.

Standardization of the orchestra

In Haydn's music a method of composition appeared that had a bearing on orchestration. This consisted of the conscious use of musical motives; motive is defined in the *Harvard Dictionary of Music* as: "The briefest intelligible and self-contained fragment of a musical theme or subject." Perhaps the best known musical motive in Western music is the four-note group with which Beethoven's *Fifth Symphony* begins. These musical cells became the musical building blocks of the Classical period, particularly in the middle or development section of a movement, with the composer moving the musical motive from instrument to instrument and section to section, giving a new facet to the orchestration. The art of orchestration was thus becoming a major factor in the artistic quality of the music.

Mozart's special contribution

Mozart, too, was responsible for great strides in the creative use of instruments. His last two symphonies (*Nos. 40*, K. 550, and *41*, K. 551) are among the most beautifully orchestrated works of this or any period. For his 17 piano concertos, Mozart exhaustively explored the combination of piano and orchestra.

Romantic. Beethoven began his career under the influence of the Classical composers, particularly Haydn, but during his lifetime he transformed this heritage into the foundation of a new musical practice that was to become known as Romanticism. The Classical composers for the most part attempted to orchestrate with a sense of grace and beauty. Beethoven occasionally made deliberate use of new, intense, often even harsh orchestral sounds. He also, in his later symphonies, augmented the orchestra with a piccolo, contrabassoon, and third and fourth horn. The *Ninth Symphony* has one passage calling for triangle, cymbals, and bass drum, a combination identified with the imitations of Turkish Janissary music in vogue in previous years.

The Romantic period was characterized by great strides in the art of instrumentation, and, in fact, the use of instrumental colour became one of the most salient features of this music. The piano really came into its own as a source of interesting sonorities; the orchestra expanded in size and scope; new instruments were added; and old instruments were improved and made more versatile. The Romantic period saw the appearance of the first textbook on the subject of orchestration. It was the French composer Hector Berlioz' *Traité d'instrumentation et d'orchestration modernes* (1844; *Treatise on Instrumentation and Orchestration*, 1856). Berlioz was one of the most individual orchestrators in the history of music, and his *Symphonie fantastique* (1830) is one of the most remarkable pieces of music to come out of this era. Berlioz made use of colour to depict or suggest events in his music, which was frequently programmatic in character. He called on large forces to express his musical ideas, an idea that persisted throughout the 19th century and into the 20th. Berlioz' *Grande Messe des morts* (*Requiem*, 1837) calls for four flutes, two oboes, two English horns, four clarinets, 12 French horns, eight bassoons, 25 first violins, 25 second violins, 20 violas, 20 violoncellos, 18 double basses, eight pairs of timpani, four tam-tams (a type of gong), bass drum, and ten pairs of cymbals; four brass choirs placed in various parts of the hall, each consisting of four trumpets, four trombones, two tubas, and four ophicleides (a large, now obsolete brass instrument); and a chorus of 80 sopranos, 80 altos, 60 tenors, and 70 basses.

First treatise on orchestration

The coloristic ideas in Berlioz' music were carried on in various ways by other important 19th-century composers and reached a culmination in the music of the German composer Richard Strauss and the Austrian Gustav Mahler—both of whom demanded a virtuoso orchestra—and were orchestrated in a complex fashion, although Mahler was capable of very delicate effects.

Post-Romantic and 20th century. Claude Debussy in France was probably the most important composer of the Impressionistic period, which lasted roughly from 1880 until the turn of the century. The Impressionist composers attempted to describe scenes and evoke moods by the use of rich harmonies and a wide palette of timbre. No composer has ever handled the colours of the orchestra with greater subtlety. Naturally, this is also dependent on his use of harmony, melody, and rhythm, but the dominant impression of a Debussy work is focussed on his use of orchestral instruments to create light and shadows. Works that exemplify his techniques are *Prélude à l'après-midi d'un faune* (*Prelude to the Afternoon of a Faun;* 1894), *Nocturnes* (1899), and *La Mer* (*The Sea;* 1905). In *Nocturnes* he uses a wordless women's chorus as a section of the orchestra, functioning as another source of timbre rather than as the transmitter of a text.

The Impressionist school

Many of the composers who followed Debussy and Mahler brought about radical changes in the use of the orchestra. A good example of some of these changes is in *The Rite of Spring* (1913), by the Russian-born composer Igor Stravinsky. The strings frequently do not assume a dominant role but, rather, often play music that is subservient to the brass or woodwind. Percussion instruments greatly increased in importance and have continued to do so. In 1931, Edgard Varèse composed an important work, *Ionisation*, for 13 percussion players, a landmark in the emergence of percussion instruments as equal partners in music.

The period between World War I and World War II was dominated by two main schools of composers with vastly differing results for orchestration. One was responsible for the Neoclassic style; the other, gathered around the Austrian composer Arnold Schoenberg, drew heavily on the Romantic movement for its direction. The Neoclassic composers sought to free music from the influence of Impressionism. Whereas the Impressionist and Romantic composers had frequently employed the instrumental forces at hand to create a deliberate sense of vagueness, the Neoclassic composers, beginning in about 1917 with a group of Frenchmen known as Les Six, attempted to recreate the clarity of the classic period by turning to models found in the popular music of the period, the music of the dance halls and cabarets. The Neoclassic composers also turned away somewhat from the orchestra as a medium, finding the forces of chamber music more suitable for their ideals. Neoclassic music returned

to a clearer concept of "sections" in orchestration. The music of a composer such as Paul Hindemith in Germany is closer to the music of Mozart in its sense of instrumentation than it is to Romanticism or Impressionism.

The music of Schoenberg and the Austrian Alban Berg drew heavily on the Romantic movement and eventually became known as Expressionism, which stressed inner experience. Emphasis on the inner man produced a music that was thick, dark, and intense.

Importance of electronic music

The first half of the 20th century saw the emergence of electronic music, although it did not become important until after 1950. The principal reasons for the inclusion here of electronic music, which is dealt with in the article ELECTRONIC MUSIC AND INSTRUMENTS, are that electronic sounds, either taped or live, frequently are included in a composition combined with traditional instruments, and it has had a decided influence on orchestration. By the 1960s many composers were writing works for electronic sounds and instruments. The electronic sounds provide a dimension to instrumentation never before possible. A number of things are noteworthy. Electronic sounds are capable of incredibly subtle changes of timbre, pitch, and mode of attack. When combined with traditional instruments they add a rich new spectrum of colour. This in turn has influenced the composer to attempt to produce "electronic" sounds with standard instruments. The result has been a great extension of the sound possibilities of Western instruments.

Another 20th-century trend was away from large orchestras and toward chamber ensembles, often of nontraditional combinations. Compositions for such ensembles may excel in economy of means and focussing on individual instrumental timbres. To achieve this, unusual playing techniques may be required.

NON-WESTERN INSTRUMENTATION

Much of music outside the West has entirely different aesthetic aims; the music of the Hindu world, best known to the West through the classical music of India, provides an example. Indian music always has had strong ties with mythology and religion and thus produced an art that is as different from Western music as Hinduism is from Christianity. It achieves unity through similarity rather than through change and is based on a more purely sensual approach that does not lend itself to detailed intellectual analysis as does much Western music. Hindu music is divided, for example, into *rāgas*, or melody types. The word *rāga* means colour or mood. Combined with the *rāgas* are *tālas*, or rhythmic patterns. The possible combinations of *tālas* and *rāgas* are many, producing a music that is wonderfully subtle.

Instruments of Indian and Balinese music

The instruments for this music consist of various drums made of terra-cotta, wood, or metal; cymbals also serve as percussion instruments. Probably the instrument best known to Western audiences is the *ṭablāh* a two-drum set capable of very subtle changes in sound. The two best known string instruments are the sitar (plucked) and the tambura, a four-stringed instrument that provides the omnipresent drone accompaniment. In addition, there are various wind instruments, such as the bamboo flute, the *shahnā'ī* (oboe), and a trumpet that frequently measures more than two yards long.

Balinese and Javanese music is centred on the gamelan orchestra, the instruments of which include the *saron* and *gender* metallophones (like xylophones but with metal, not wooden, keys), the *gambang kayu* xylophone, tuned gongs, flutes, and the *rebab*, a violin-like instrument with two strings. All the instruments follow the same nuclear melody but elaborate it in different ways. The heavy reliance on tuned percussion instruments has given this music a brilliant quality that Western audiences have found extremely attractive. The gamelan orchestra, for instance, influenced Debussy, who first heard the music at the Paris Exposition in 1889.

The approach to instrumentation in the music of India and Bali is quite different from that of Western music. The concept of contrast created through the various "choirs" of the Western orchestra is not a primary concern. In Indian music a sameness of colour is created through the use of the drone played on the tambura. This is not to say that this music is uncolourful, but that a specific timbre is established for an entire composition. Since the time of Debussy, Western composers have come increasingly into contact with, in particular, the music of India, Bali, and Japan. A comparison of Balinese gamelan music with the *Sonatas and Interludes* for prepared piano by the 20th-century American composer John Cage would show how profound this influence can be.

ARRANGEMENT AND TRANSCRIPTION

A practice that has been much employed in the 20th century, although by no means confined to it, has been the writing of transcriptions and arrangements. Though little distinction is made between the two terms, there are, at least in current practice, differences. A transcription is essentially the adaptation of a composition for an instrument or instruments other than those for which it was originally written. An arrangement is a similar procedure, although the arranger often feels free to take musical liberties with the original score. This is especially true of arrangements for jazz or rock groups and of popular compositions or songs from musical comedies.

In the 18th and 19th centuries, chamber and orchestral music was transcribed for the piano for the purpose of study and, of course, for the pleasure of playing at home the music that had been heard at a concert. This practice has continued to the present day. Piano versions of many 18th- and 19th-century orchestral works exist in two- and four-hand arrangements. Another common practice is to reduce the orchestral parts of concertos to a keyboard version to enable students to study and play these works without an orchestra.

Piano versions of orchestral works

The symphonic band, despite its popularity in North America, was faced with a dearth of repertory written specifically for it. In the past, one answer was to transcribe orchestral works for band, substituting particularly the clarinets, with their wide pitch range, for the strings of the symphony orchestra. The necessity for that substitution is no longer so great because in recent times much more music has been written specifically for the symphonic band.

The jazz or rock arranger has done much more than simply transcribe the keyboard version of a song. All forms of popular music in the 20th century have been involved in the art of improvising. Musicians working in this field almost always embellish the music as they perform it. The jazz or rock arranger in a sense improvises on manuscript paper. In making an arrangement for a group of musicians the arranger will embellish both the harmonic structure and the melody of the composition; or the arrangement will be worked out in rehearsal and memorized or written down later. Usually, the arranger keeps enough of the original material to enable the listener to recognize the source. His skill depends on how well he can manipulate the materials of the original and on his originality in scoring the composition for the group at his disposal. The men who work in this field are frequently composers of popular music themselves.

The dance band predominant in the 1930s and 1940s is treated roughly in the following way by arrangers: the saxophones carry the melody more frequently than the other sections; the trumpets provide embellishment or figures that work around the melody; the trombones either are combined with the trumpets or serve as a melodic instrument; the piano and guitar provide harmonic filler and the double bass and set drums the rhythm.

Orchidales

Orchidales is an order of monocotyledonous flowering plants (monocots comprise one of two great groups of flowering plants and are roughly equivalent to plants having parallel-veined leaves, grasses being a familiar example) considered by most authorities to contain only one family, the Orchidaceae, or orchid family. The small family Burmanniaceae has sometimes been included within the orchid order, however, and the subfamily Apostasioideae, included here, has sometimes been considered as a separate family (Apostasiaceae) in the order Hemodorales.

The orchid family is regarded by most botanists as the largest family of flowering plants, although it is not yet possible to give an accurate estimate of the size of the family. Educated guesses range from 15,000 to 35,000 species in 400 to 800 genera, but the lower estimates usually fail to consider the diversity of the family in the tropical regions.

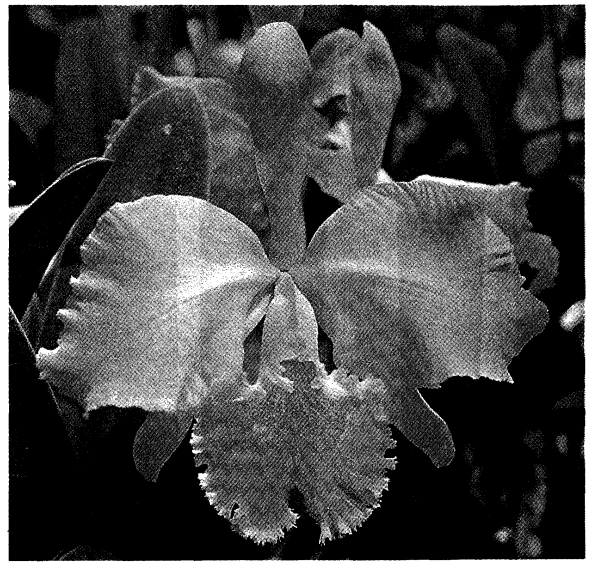
GENERAL FEATURES

Discussions about orchids, whether among professional botanists or amateur orchid enthusiasts, often leave the impression that orchids are "somehow different" from other plants. As a group, they are different from other plants but only in the morphological (structural) characters that tend to distinguish them. These characters are associated with the flower and its organization. Even the special characters of orchid flowers, such as the masses of pollen called pollinia, the joining of the stamens (male organs) and pistil (female organ) to form the column, and the tiny seeds without endosperm (starchy nutrient tissue) or organized embryos, are found individually in other groups of flowering plants. Therefore, no single character distinguishes the orchids; however, through the combination of several characters, a family of flowering plants, the Orchidaceae, emerges.

Diversity of structure. Orchids are primarily herbaceous (nonwoody), although some species may be vines, vinelike, or somewhat shrubby. The plants may be free-living or, in a few cases, saprophytic (*i.e.*, obtaining their food from the organic matter of dead and decaying plants), and they may be terrestrial or epiphytic (not rooted in soil but living among tree branches or on other aerial supports). They may even be parasitic on fungi. Orchid flowers vary tremendously in size from the minute flowers of some species of the genus *Pleurothallis*, which are no more than 2 millimetres (about 0.1 inch) in diameter, to the large ones of *Brassia*, which may be more than 15 inches (about 38 centimetres) from the tips of the lateral sepals (petallike structures) to the tip of the dorsal sepal. Although vegetatively orchid plants are somewhat uniform and do not show the wide range of diversity that may be found in some other families, the plants do offer a number of different growth types. Growth habits vary from those in which the plant is reduced to no more than roots (*Dendrophylax*) to saprophytic plants apparently lacking chlorophyll (*Corallorhiza*) to gigantic plants (*Arundina*) that superficially resemble a bamboo.

Growth forms

The diversity of structure among orchid flowers can be attributed mainly to the methods of pollination found in the family or to the fact that the family is adapted for the utilization of a number of different types of pollinators (animals that carry pollen from one flower to another).



Large, attractive orchids: wild and cultivated.

(Left) Sven Samelius, (right) Derek Fell

Orchids range from above the Arctic Circle to the tropics, but the majority of species are found in the latter.

Importance to man. The orchid family is probably one of the most important of plant families from a horticultural point of view. Nevertheless, of the 400 or more genera in the family, only about 50 genera are commonly cultivated. A plant group as large as the orchid family might be expected to contain enough different types of plants to satisfy any horticultural desire, but in the past 100 years over 60,000 orchid hybrids (crosses between different species) have been produced. A number of these hybrids are used in the cut-flower trade, and a large number of the plants are grown and exhibited with the flowers intact. The large number of corsage orchids and flowers for the cut-flower trade, however, derive from only about 150 species. Several species from distinct genera are grown as hedges in tropical areas, and a number of species are used as ornamentals in warmer regions.

Other than the horticultural uses to which orchids are put, the family is notably lacking in species from which products are derived. The only commercially important product derived from orchids is vanilla. Most vanilla is produced from one species, *Vanilla planifolia,* although two additional species are also cultivated commercially (*V. pompona* and *V. tahitensis*). In recent years the use of artificial vanilla has even reduced the use of natural vanilla.

The principal vanilla-growing areas are Madagascar, Mexico, French Oceania, Réunion, Dominica, Indonesia, French West Indies, Seychelles islands, and Puerto Rico. Vanilla is grown from sea level to about 2,000 feet (600 metres) in elevation. The plant is a climbing vine that is indigenous throughout the tropical regions of the Western Hemisphere.

Although the flowers of vanilla are rather attractive, they last only for a day or so and are not useful for the floral industry.

Folk uses of orchids

Primitive peoples throughout the world use various other orchids for a variety of folk medicines and cures. In the West Indies, the bulbs of *Bletia purpurea* are boiled, and the liquid is thought to cure poisoning from fish. In Malaya, women take a drink made from the boiled leaves of *Nervilia aragoana* to prevent sickness after childbirth. In Malacca, boils are treated with a poultice made from the entire plant of *Oberonia anceps.* In Chile, *Spiranthes diuretica* is known to be a strong diuretic. In certain parts of Ecuador, the mucilage from *Catasetum* is thought to be good for broken bones. In various parts of the world, certain orchids are also used for food or food supplements. In Malaya, the leaves of one species of *Anoectochilus* are sold as a vegetable, and the leaves of *Dendrobium salaccense* are cooked as a seasoning with rice. In certain parts of the Asian tropics, the tubers of some species of *Gastrodia* are eaten like potatoes. Throughout the world several species of orchids are used as a glue substitute. In most cases the glue is derived from the pseudobulbs. Salep is derived from the tubers of several species of *Orchis.* The tubers are boiled, then dried and powdered. The resulting preparation is often used as a flour substitute. It is also used as a substitute for gum arabic.

FORM AND FUNCTION

The flower. The primary characters that distinguish the orchids as a group are found in the flower. At the bottom of an unspecialized non-orchid flower is the stem that supports it, called the pedicel. Directly above, and at the base of the flower itself, is a whorl of green, leaflike organs called sepals. Above and inside the sepals is a second whorl of coloured petals. These are the asexual parts and are developed to protect the flower or to attract pollinators. Inside (also arranged in whorls) are the sexual portions of the flower. First are the male stamens, which consist of a filament (the slender stalk that supports the anther) and an anther (usually an arrangement of four sacs filled with loose pollen grains). There may be several whorls of stamens. In the centre of the flower is the female pistil, which is composed of an enlarged portion (the ovary) topped by a stalklike style with a stigma at its apex. The pollen in the anther is powdery and is usually carried from the anther of one flower to the stigma of another flower by a pollinating agent.

Structure of orchid flowers

The previous description is of a generalized flower, and it must be kept in mind that many types of variations may be found. Even though it is a generalized flower, it is not to be considered a primitive flower. The generalized orchid flower is also supported on a pedicel. The ovary, however, with its ovules seems to be an integral part of the pedicel because it is embedded within the upper portion of the pedicel below the attachment of the petals. The orchid flower is thus said to have an inferior ovary. The sepals and petals are usually similar, often highly coloured, and in sets of three. One petal is developed as a landing platform for the pollinator and is called the lip (or labellum).

Sexual organs. The sexual portions of the orchid flower are quite different from other generalized flowers and they tend to characterize the family. The filaments, anthers, style, and stigma are reduced in number and are usually fused into a single structure called the column. In

one relatively small group (the lady's slippers), two anthers are present, one on each side of the column (some members of the primitive subfamily Apostasioideae have three anthers). The majority of the orchids, however, retain only a single anther at the apex of the column.

In the orchid the ovary is composed of three structures called carpels. The carpels have fused so that the only outward evidence of their existence is the three ridges on the outside of the seed pods. The mature seed pod does not open along the lines of juncture but rather down the middle between the lines of juncture. The ovules, which are arranged along the ridges inside the ovary, do not develop until some time after the flower has been pollinated, thereby contributing to the long delay between pollination and the opening of a ripened pod.

Orchid petals. In most monocots the sepals and petals are so similar that they are not distinguished but fall under the collective term perianth. In the orchids, however, they are usually quite distinct and therefore retain their separate identification. The petal opposite the fertile stamen is the one called the lip, or labellum. Often two, or even all three, of the sepals are joined, and the lip, petals, or the sepals may be joined to the column for some distance. One of the characteristic differences between the orchid family and other advanced monocots is that the fertile stamen or stamens (that is, the one or more that are not completely reduced) are all on one side of the flower opposite the lip. This makes the flower bilaterally symmetrical.

The lip is oriented upward in the bud, but as it later develops, twisting takes place in the pedicel or ovary so that the lip is usually oriented downward by the time the flower opens, a process called resupination.

The presence of the labellum as a landing platform for insect pollinators and the reduction of the stamens and pistil of a flower to a single structure, the column, is certainly the apex of floral adaptation to insects as pollinating agents. Once achieved, this combination provides a foundation for all kinds of specializations for attraction of specific pollinators. The development of the strange and complex reorganizations found in the flowers of many orchid genera are directly attributable to evolutionary forces interplaying on the basis of such a pre-existing foundation.

Nectar-producing organs. There are several types of nectaries in the orchids, including extrafloral types that secrete nectar on the outside of the buds or inflorescence (flower cluster) while the flower is developing. Shallow cuplike nectaries at the base of the lip are common. Some nectaries are in long spurs produced either from the joined sepals or from the base of the lip. Members of the *Epidendrum* complex have long tubular nectaries embedded in the base of the flower alongside the ovary. Nectaries on the side lobes of the lips are known, and general nectar secretion along the central groove of the lip is common. The nectaries of many species of the Liliales order, a possible ancestral group, are within the septa of the ovary, but the nectaries of the Orchidales are present on the sepals or petals, if they are present at all.

In most of the orchids, the stamen and style are fused completely into a single organ—the column; however, in *Cypripedium, Apostasia,* and some higher orchids such as *Spiranthes,* they are only partially united. In some cases an extension of the base of the column with the lip attached at its apex forms the column foot. In many instances this structure exudes nectar.

Anthers and pollen. In most of the orchids the anther is a caplike structure located at the apex of the column. The anther of some of the more primitive orchids is superficially similar to that of a lily or amaryllis. In *Habenaria* and its allies the anther projects beyond the apex of the column but is thoroughly attached. Sometimes the two halves of the anther are widely separated and have led some botanists to believe that they represent two anthers. In one subfamily, Cypripedioideae, two anthers do occur and are attached on each side of the column. These orchids are usually considered to be primitive.

In most orchids the pollen grains are bound together by threads of a clear, sticky substance (viscin) in masses called pollinia. Two basic kinds of pollinia exist: one has soft, mealy packets bound together to a viscin core by viscin threads and is called sectile; the other kind ranges from soft, mealy pollinia, through more compact masses, to hard, waxlike pollinia. *Goodyera, Haberaria,* and *Spiranthes* have the former, and the latter are found in *Sobralia, Phajus, Cattleya,* and *Oncidium* (becoming harder in that sequence). The hard, waxy pollinia usually have a small amount of mealy pollen with viscin strands that attach the pollinia to each other or to a viscidium. This portion of the pollinium is termed the caudicle.

Structure of orchid pollinia

The stigma is usually a shallow depression on the innersides of the column. It is composed of the three stigmatic lobes found in the typical monocot flower, but the three lobes are thoroughly grown together. Faint lines often can be seen on the surface of the stigma, dividing it into three parts.

In the majority of the orchids, a portion of one of the three stigma lobes is specialized and forms a structure called the rostellum. The rostellum projects down in front of the anther in the form of a flap. As the visiting insect begins to back out of the flower, it brushes the rostellum, which is covered with sticky stigmatic liquid. The pollinia are then picked up from the anther and stick to the body of the insect. Some primitive species have no rostellum, and the pollinia simply stick to stigmatic liquid that is first smeared on the back of the insect. A further specialization occurs in more advanced orchids in which the caudicles of the pollinia are already attached to the rostellum and a portion of it comes off as a sticky pad called a viscidium. In the most advanced genera a strap of nonsticky tissue from the column connects the pollinia to the viscidium. This band of tissue is called the stipe and should not be confused with the caudicles, which are derived from the anther. Orchids that have a stipe also have caudicles that connect the pollinia to the apex of the stipe. The pollinia, stipe, and viscidium are called the pollinarium.

Seeds and their dependence on fungi. Orchid seeds are extremely small and contain an undifferentiated embryo that lacks endosperm. A single seed pod produces a large number of small seeds, which are ideally suited for dispersal by wind. Orchid seeds need the presence of a fungal mat in order to germinate and grow in nature. This mat is called a mycorrhiza. The fungus apparently penetrates the seed and contributes to the growth of the seedling by producing or supplying some of the necessary nutrients for growth. It has not yet been firmly established whether or not the fungus is necessary for the continued growth of the mature plant, but it appears likely that the presence of the fungus aids in the uptake of nutrients and prevents the leaching of nutrients from the root material of epiphytic species. Although it is possible to grow and germinate some orchids without the fungus in artificial cultures, it is thought that a fungus is necessary for germination and growth in nature.

Mycorrhizal fungi and seed germination

In some cases the presence of a specific species of fungus is necessary, while in other cases several fungi may have the ability to become involved in the process. The fungi that are involved with mycorrhiza in orchids are of two taxonomic groups: the Fungi Imperfecti (Deuteromycetes) and the Basidiomycetes (fungus order Agaricales), the latter group being that to which the familiar mushrooms belong. Although most, if not all, orchids have mycorrhiza, mycorrhiza are not limited to the orchid family but are found in a large number of other plant families.

Growth habits. The majority of the tropical orchid species are epiphytes; that is, they grow on trees without connection with the ground. Nearly all of the orchids in the temperate zones, however, are terrestrial.

The predominant growth form in a wide range of monocots has been shown to be a type known as the sympodium, and this may reasonably be considered to be the primitive condition in the orchids. Sympodial growth is a creeping habit and it consists of an axis that appears continuous but is, rather, made up of a succession of elements that each originate not from a terminal bud but

Extreme variations employing habitat.
(Left) *Neottia nidus-avis*, bird's nest orchid, is a nongreen saprophytic orchid. (Right) *Taeniophyllum zollingeri* is epiphytic, with flattened green roots that act as organs of attachment and in place of leaves for photosynthesis.
(Left) C. Foord—EB Inc., (right) W.H. Hodge

as a fork of a dichotomy, the other fork being weaker in growth or suppressed entirely. The usual form of a sympodium is a horizontal rootlike stem structure called a rhizome that turns up at the ends of each "branch." Most primitive orchids have a rather ordinary monocot appearance with a short rhizome stem and erect, nonthickened annual stems having scattered, spirally arranged leaves and a terminal inflorescence (flower cluster).

Another major type of growth form found in the orchid order is the monopodial habit, in which the stem has unlimited apical (terminal) growth and roots are not restricted to its basal portion. In some systems of classification this has been considered to be a distinguishing mark of the subtribe Sarcanthinae; however, the monopodial habit occurs in the subtribes Vanillinae, Cymbidiinae, Maxillariinae, Pachyphyllinae, Thelasiinae, and Oncidiinae, and possibly in other groups as well. In some of these groups there exists a graded series from sympodial plants to related monopodial types.

A great many orchids, especially the epiphytic groups, show variously thickened stems, or "pseudobulbs." While these structures are quite diverse in form, they fall into a limited number of morphological types and seem to show some evolutionary trends. One of these seeming trends is from pseudobulbs (or corms, bulblike stem structures) of several or many internodes (nodes are stem regions at which leaves attach, internodes are the stem areas between such nodes) to pseudobulbs of a single internode (as in *Bulbophyllum* and the subtribes Maxillariinae and Oncidiinae). Thickened stem bases may be found in either terrestrial or epiphytic groups, but pseudobulbs of a single internode are restricted to primarily epiphytic groups.

Saprophytic orchids

Saprophytic orchids, those that obtain their food from dead organic matter instead of by photosynthesis, are found in at least 12 subtribes of orchids. The majority of orchids pass through a saprophytic seedling stage, which may last for months, especially in terrestrial species. Thus, the evolution of a completely saprophytic life cycle in different groups of orchids is not surprising. The wholly saprophytic orchids pose special classification problems. The adaptations for saprophytism drastically change the vegetative features of the plant, thus obscuring some of the characteristics normally used for determining relationships. Even the reproductive features may be affected by these adaptations. In the genus *Corallorhiza*, for example, the pollen bearing structures are more simple than in the related genera *Oreorchis* and *Tipularia*. In the absence of these two closely allied genera, *Corallorhiza's* relationship to the Cyrtopodiinae subtribe would be much less clear. The saprophytes are difficult to cultivate and are poorly represented by herbarium specimens, which further complicates their study. Autogamy (self-fertilization) is frequent, and an autogamous saprophyte is nearly the ultimate in taxonomic difficulty.

NATURAL HISTORY

Life. The life cycle of an orchid is not essentially different from any other flowering plant. When the pollinator leaves the pollinia on the stigma (the pollen receiving structure of the female flower parts), the pollen tubes germinate and grow down the centre of the column to reach the ovary. This often causes the sides of the stigma to swell around the stigma and the enclosed pollinia. When the pollen tubes reach the ovules (this often takes six weeks or more, during which time the ovules have been developing), one or more enters and the sperm unites with the egg. The fertilized egg, or zygote, begins to divide to form the mass of cells destined to become the embryo. Most other plants have a slightly different development from that of the orchid. There is usually a double fertilization, one of which forms the zygote and the other an endosperm that nourishes the developing plant upon germination until the plant is able to manufacture its own food.

Orchid seeds

The orchid seed, however, has no endosperm. The seed consists of a simple, dry, outer coat enclosing a small mass of undifferentiated cells that form a pro-embryo. This extremely small and light unit can easily be carried in air currents and may travel long distances before coming to rest. The number of seeds in a single orchid capsule is nearly astronomical: close to 2,000,000 seeds have been reported from a single capsule of *Catasetum*. These extreme numbers undoubtedly are correlated with the unlikelihood of falling in a favourable spot.

Ecology. Orchids have a rather wide ecological distribution when the entire family is considered. Although the family is primarily tropical, a number of species are found in the northern and southern temperate zones. At least four or more species have been reported from north of the Arctic Circle. A number of species of the North Temperate Zone are found in bog situations, as well as on the prairies, grasslands, and in the hardwood forests.

Several species of *Spiranthes*, *Habenaria*, and other orchids are found in roadside ditches, often in wet, boggy situations. In some areas of the United States, *Habenaria ciliaris* might almost be considered a weed. The introduced Asian species *Zeuxine strateumatica* in southern Florida is now widespread and may be considered a weed.

Orchids grow from sea level to at least 15,000 feet (4,600 metres) in elevation. The greatest number of orchid species are found in cloud forest associations in tropical

regions. These are usually on forested mountainsides where the clouds brush the mountain day and night. Such forests are literally covered with mosses and lichens, and the inclination of the ground permits sunlight to penetrate through the vegetation to the ground. This is a perfect habitat for epiphytic orchids as well as aroids (family Araceae), ferns, gesneriads (family Gesneriaceae), and numerous other epiphytic groups of plants.

Contrary to popular belief, rain forests on generally flat terrain are poor localities for orchids. At Iquitos, on the Amazon River in Peru, only about 125 species of orchids have been reported, and many of these are quite rare. Orchids that do occur in rain forests tend to be in the tops of large trees with little variation in each tree. Often great quantities of a single species inhabit a tree, while another nearby tree may have only one or two additional species. The tropical-deciduous seasonal hardwood forests of the tropics, where marked wet and dry periods occur, often have numerous orchid species; however, this also tends to be the best farmland and therefore does not last long after colonization by man.

A wide range of ecological tolerances are shown by orchids. In addition to those species that are found above the Arctic Circle, a few species of orchids are found in desert conditions; for example, in the dry areas of northern Peru, several species of orchids are found epiphytic on cacti. On the Peninsula de Santa Elena in western Ecuador, two species of *Oncidium* as well as one species of *Brassia* are found on cacti. In parts of Central America one species of *Brassavola* is found growing on mangrove roots, often at, or only slightly above, the level of high tide. In Jamaica several species are found growing on bare rocks. In the Everglades, on the other hand, one species of *Habenaria* is almost aquatic. In western Mexico, one species of *Pleurothallis* is epiphytic on lichens.

Desert-dwelling orchids

Orchids vary from those species that are very widespread, such as the species found throughout most of the tropical regions of the Western Hemisphere (*e.g., Ionopsis utricularioides*), to some species that seem to be restricted to a single mountain (some species in the subtribe Pleurothallidinae). In the West Indies, each of the major islands seems to have a fair number of such restricted species.

Pollination. The total orchid flower is an instrument adapted for exact modes of pollination. The function of pollen deposition is centralized precisely in the median plane opposite the lip, or labellum (the large central petal of the flower). Being directed back toward the centre of the flower, the anther deposits pollen on the most advantageous side of the visitor, considering efficiency in reception and deposition. This precision is also expressed by a tendency of orchids to deposit the pollen as one mass, the pollinarium.

The published data are insufficient to establish accurately the relative importance of pollinating agents in the family; however, a rough estimate may be given as in the Table. Such extreme divergence in pollinators testifies for youth, continuing evolution, and adaptive radiation in the family.

Pollinator Spectrum of the Orchid Family* (percentage)

Hymenoptera		other agents	
Wasps	5	Moths	8
Lower bees	16	Butterflies	3

Euglossine bees	10	Flies	15
Social bees	8	Mixed agents	8
Mixed bees	10	Self-pollination	3

*The numbers represent an estimate of the relative importance of various pollinating agents in terms of the percentage of orchid species pollinated by each group.

Orchids as a group have nectar as the major attractant, whereas pollen, sought by pollinators among lower plant families as a protein-rich food, has been withdrawn. This is tied to the exactness of the mechanics of pollination, but it also means that orchids can no longer provide the only source of sustenance for the pollinator, and other flowers must be present in the biosphere to maintain visitors.

Nectar in orchids is provided in tubular nectaries (*Brassavola, Angraecum, Comparettia,* and other genera), in grooves on the labellum (*Listera, Epipactis,* etc.), and at the base of the column and lip (*Dendrobium, Scaphyglottis,* etc.). It has been estimated, however, that as many as 8,000 species of orchids, one-third of the family, are nectarless. These orchids have developed other means of attracting pollinators, largely consisting of deceptive attractants in one form or another.

Many orchids produce pseudopollen for the attraction of pollinators. A powdery mass resembling pollen occurs on the labellum of a number of species of *Maxillaria* and *Polystachya.* Sometimes the grains are detached outgrowths called papillae, sometimes disintegrated multicellular hairs filled with starch. It has been demonstrated that this pseudopollen is collected by bees at least from the orchid genus *Maxillaria.* In none of the species producing such pseudopollen is nectar produced.

Pseudopollen

Bee pollination. Flowers pollinated by bees tend to produce agreeable odours, have bright colours, to be open during the day, to provide a landing platform, to have nectar guides in the form of coloured lines running into the depths of the flower, and to have concealed nectaries. The basal portions of the orchid lip are usually formed into a tunnel with the column forming its upper side. The bee enters the tunnel to get at the nectary, and in backing out, some of the stigmatic fluid may be rubbed on the back of the bee. As the bee backs farther, the pollinia become attached to the sticky material and are carried with the bee to the next flower. In more advanced orchids the pollinia may be attached to a sticky pad, the viscidium, which becomes detached from part of the stigma and sticks to the pollinator.

Some species of orchids are pollinated by bees that are attracted by deceit. The flowers of the large genus *Oncidium,* for example, are pollinated by male *Centris* bees in what appears to be a case of pseudo-antagonism. The flower appears to simulate an enemy insect, which the male bee tries to drive away from his territory. In the process of striking at the flower, the pollinia are attached to the head of the bee.

The most exciting and unusual examples of deceit, traps, and manipulation of pollinators are to be found in those orchids that are pollinated by male euglossine bees (species of the bee tribe Euglossini). The syndrome of flowers pollinated by male euglossini is based on the attraction of the male bees to the odour of the flower. In no case does the male euglossine bee receive food from the orchid that it visits for the purpose of collecting odour. So far as has been determined, all members of the orchid subtribes Stanhopeinae, Catasetinae, Lycastinae, and Zygopetalinae are pollinated by male euglossine bees, as also are certain genera of the subtribes Oncidiinae and Ornithocephalinae. The euglossine male bees visit other nectar-producing flowers for their food, but when the male bees visit the non-nectar-producing orchid flowers, they rub the surface of the lip with their front feet and collect in special tarsal brushes the odour that is produced there. The bees then launch into the air and transfer the odour to their hind tibiae (leg segments), which are noticeably swollen. It is in the process of transferring the odour to the hind tibiae that the bee is manipulated by the orchid.

Odour-collecting bees

The pollination phenomena of the Stanhopeinae subtribe are based on the same principles as in the Catasetinae, but with the separation of sexes in the flower being in time rather than in space. Self-pollination in the Stanhopeinae subtribe is averted by differences in the maturing time of the male and female reproductive parts, whereas in the Catasetinae there are separate flowers of each sex. The stigma is narrow when the bee first visits, and the pollinia are thick before drying and therefore cannot be inserted into the stigma of the same flower. Powerful fragrances for attraction are present. In the Catasetinae, the male flowers are organized to position the bee perfect-

Manipulation of bees by orchid flowers

ly so that when the pollinarium is discharged the viscidium becomes attached at a specific location on the bee. In this manner it will fit properly in the stigmatic cleft of the female flower when the bee visits it. In most species of the Stanhopeinae, the flowers are organized to take advantage of the erratic flight habits and slowed reflexes of the male bees that are collecting odour components. Their pollination mechanisms, in the more spectacular forms, manipulate the bees so as to make them fall either through a chute, down a slide, or into a "bucket" of water.

In the genus *Stanhopea*, for example, some species face downward with the lip and column pendent while the sepals and petals are reflexed upward. The base of the lip is saccate (baglike) and is separated from the arched column. The bee enters here rather than at the apex of the lip and column, which are close together, forming a chute. The rostellum (beaklike apex of the female flower parts), with the attached viscidium, projects into the chute. After the bee has landed and brushed at the base of the lip in order to collect the odour, it attempts to fly out of the flower. The column interferes with its flying equilibrium, and it falls, abdomen first, down through the chute, picking up the viscidium under its body (metathorax) as it passes.

Calaway H. Dodson

Manipulation of pollinators.
(Left) *Coryanthes albo-purpurea* has a water bucket into which a visiting pollinator bee falls. The pollinarium is deposited on the abdomen of the bee as it exits by way of a special tunnel, and pollination occurs when the bee visits another plant. (Right) After rubbing for odour at the base of the lip, a visiting bee *(Eulaema meriana)* falls through the specialized chute of *Stanhopea gibbosa* and either picks up or delivers the pollinarium.

Another variation of pollinator manipulation by orchids is found in the genus *Coryanthes*. The flowers are very large and might even be considered grotesque. The sepals and petals fold back out of the way when the flower opens —like sails on a boat—revealing the strangely formed lip. The lip is divided into three parts: a globular- or hood-shaped portion called the hypochile above; an elongate, sometimes fluted part, the mesochile; and a bucket-shaped epichile. The epichile is partially filled with water during the last few hours before the flower opens and for a short time afterward by two faucet-like organs located at the base of the column, which drip water. Male euglossine bees are attracted by the strong odour produced by the hypochile, where they scratch. In trying to launch into the air to transfer the odour to their hind legs, the bees occasionally fall into the water-filled bucket. The sides of the bucket are vertical and are very waxy, so that the bee is not able to climb out of the bucket. The only way out is through a small tunnel formed by the apex of the column and the apex of the epichile of the lip. As the bee forces its way out of the tunnel, the pollinarium is deposited on its thorax. The pollinia may then be deposited in the stigma of another flower on a next visit, provided the original pollinia of that flower have already been removed and the stigmatic cleft has opened sufficiently to become receptive.

Moth and butterfly pollination. Moths normally fly at night and are attracted to flowers that produce strong odours and are white or light coloured. Moths that visit flowers are usually strong fliers and are capable of hovering in front of the flower while extracting the nectar. The typical moth-pollinated flower has a long, slender nectar tube containing abundant nectar. The fragrance produced is typically sweet or musky and the flowers usually are horizontal or hanging. Butterflies, on the other hand, are day fliers and go to highly coloured flowers that may or may not be fragrant. Butterflies tend to be somewhat erratic fliers and, lacking the ability to hover, usually land on the flower. The flowers are, therefore, usually erect and provide platforms for landing. Often the platform simply consists of a head of erect, densely packed flowers. Butterflies detect colours well, and butterfly-pollinated flowers are usually brightly coloured with red, orange, or yellow predominating. Nectar is commonly abundant and is hidden in deep nectar tubes.

Characteristics of butterfly-pollinated orchids

In an often cited case, Charles Darwin, the English evolutionist, predicted that a moth with a 10-inch- (26-centimetre-) long proboscis would eventually be found on the island of Madagascar as the pollinator of the orchid *Angraecum sesquipedale*, since a moth would need a long tongue to reach the nectar hidden in the very long nectary of this species. Such a moth has been found but has not yet been observed to pollinate the flowers of this amazing orchid.

The nectar tube of *Angraecum sesquipedale* is formed by the base of the lip. In most of the moth-pollinated, butterfly-pollinated, as well as bird-pollinated orchids, the nectar tube is arranged to guide the tongue or beak in such a manner that the pollinia are correctly attached to the pollinating organism.

Bird pollination. Flowers adapted to pollination by birds are usually brightly coloured, with reds, blues, and yellows predominating. They are usually tubular in form, often with a long nectary, and nectar is almost always present. Birds have little or no sense of smell, and bird-pollinated flowers tend to lack odour; however, the bright colours serve to attract the birds. Bird-pollinated orchids tend to follow the pattern of other bird flowers; however, in some cases they diverge considerably. Many orchids of the Western Hemisphere appear to have adapted to bird pollination as an extension of butterfly pollination, and, as in the case of *Epidendrum secundum*, birds and butterflies act as copollinators. In such cases, orchid flowers already adapted to butterflies are not greatly changed morphologically. On the other hand, orchids that have adapted directly to hummingbirds from bee-pollinated ancestors have changed fundamentally. The genera *Cochlioda*, *Sophronitis*, *Elleanthus*, *Isochilus*, *Comparettia*, *Hexisea*, and *Meiracyllium* are all bird pollinated and are remarkably similar in certain aspects. All have bright colours, tubular form, and a callus or hump in the interior of the tube, on the lip, which acts to force the beak of the bird against the column.

Fly pollination. Some flies are important pollinators of flowers and certain families of flies (*e.g.*, the Syrphidae and Bombyliidae) are restricted to flowers for their food. Unspecialized flowers may attract flies to nectar, which is present in open, shallow nectaries and may emit sweet odours. The flies eat the nectar and do not store it as do bees. More specialized fly flowers may attract flies through deception, imitating decaying substances, dung, or carrion. Many kinds of flies are then attracted and act as effective pollinators. Fly-pollinated flowers have often developed traps for catching and holding unadapted visitors. They commonly have large landing surfaces and "tails" produced from the flower parts, which function as guides. Their colours are usually checkered or blotched and tend toward dull green, brown, purple, or red. The odours produced are commonly putrescent. Orchids pollinated by flies are common throughout the world. In most fly-pollinated orchids, special adaptations have developed—superimposed on the basic pattern of the bee-pollinated orchid flower—to guide the somewhat poorly oriented flies. Certain of the five petals may be long and taillike (as in *Bulbophyllum* and *Masdevallia*) or joined to form a flat radial flower (as in *Stelis*). The flowers themselves may be arranged to form a larger radial, compound "flower" (as in *Cirrhopetalum*). The petals or lip may be fringed with motile clublike hairs that vibrate in the wind and attract the flies (*Bulbophyllum* and *Cirrhopetalum*). Often the sepals are joined or the lip is saccate to form a trap (*Pragmopediium* and *Pterostylis*) into which the flies fall and from which they must crawl by

Adaptations to fly pollination

way of a tunnel that passes the stigma and anther. A common contrivance by which orchids exploit flies is a hinged, balanced lip that tips with the weight of the fly and launches the pollinator into the flower.

In orchids it is often difficult to decide when simple fly pollination ends and deception based on carrion mimicry begins. Many genera have some species whose pollination is based simply on attracting various flies on the basis of sweet odours and nectar production, while others attract flies on the basis of rotten odours but provide no food.

Three major groups of orchids have become predominantly fly pollinated: the subtribe Pleurothallidinae in tropical America, containing about 1,000 species pollinated by flies; the *Bulbophyllum* group of about 1,000 species found mainly in the Old World; and the large genus *Pterostylis* and its relatives (in Australia).

Several reports of fly pollination in species from genera otherwise known for bee- or moth- and butterfly-pollinated flowers have been made. *Epidendrum fimbriatum* is pollinated by flies of the family Tachinidae. In the northern United States, several species of *Habenaria* have been shown to be pollinated by mosquitoes.

Self-pollination in orchids. Self-pollination occurs in a significant number of orchids. Several degrees of this phenomenon may be found in a single genus, from species in which accidental self-pollination results in fertilization to those in which the flowers never open, yet produce fertile seed. In many orchids, self-fertilization is not possible due to genetically controlled self-incompatibility, in which pollen from a plant having a particular combination of genetic factors will not fertilize its own ovules or those of any other plant having the same combination.

In most species the pollen is kept separate from the stigma by a structure called the rostellar flap. This physical barrier is normally quite effective; but in some species, forms occur in which the rostellum degenerates or becomes stigmatic, and self-pollination results when the pollen germinates on the stigmatic fluid. In most of these forms, normal plants are also found in the same population. Self-pollination may also occur as a result of simple falling of old pollinia, a means of averting sterility at the end of a long normal period when the flower is open but no pollinator arrives.

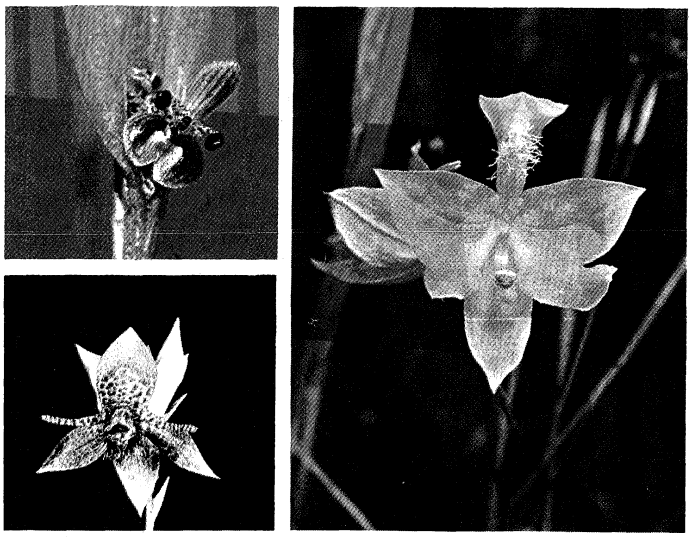
A kind of mechanical self-pollination occurs in some orchids in which the tissues connecting the viscidium and the pollinia bend downward and carry the pollinia into place on the stigma. Generally speaking, self-fertilization in orchids seems to be a means of averting extinction in plants growing under conditions adverse for normal pollination relationships. Examples include some species of *Orchis* in Europe and several orchids in Florida, such as *Epidendrum nocturnum, Encyclia cochleata,* and *Bletia purpurea,* all of which have cross-pollinated forms in other areas. Seeds blow into Florida from the Caribbean area where normal pollinators exist, but those plants that survive tend to be self-pollinated because they lack their customary pollinators, which are not found in Florida.

Self-pollination for survival

Probably more than 200 species of orchids have been reported to be more or less regularly self-pollinated, and undoubtedly many more exist.

Mimicry and deception—pseudocopulation. Flowers of the genus *Ophrys* deceive and manipulate pollinators mainly through odours, imitating those produced by the abdominal glands of female bees or wasps. Flower shapes, colours (including ultraviolet reflection), and tactile stimuli by the hairs on the lip operate on the sensory organs of the visiting males leading ultimately to the same behaviour as that observed during the initial phases of copulation with female bees. No ejection of sperm occurs, however, but the supernormal olfactory stimulation ensures that the male will remain for a long stay on the flower.

This act of pseudocopulation takes place in such a way that the pollinia are carried off and redeposited on a different plant. Four genera of solitary bees and wasps appear to be the principal pollinators. The species of *Ophrys* that are pollinated by the wasps *Trielis, Gorytes,* and the bee *Eucera* induce the insects to attempt copulation with the apex of the lip. Those pollinated by *Andrena* appear, for the most part, to stimulate the bee to reverse its position and copulate with the base of the lip. In the former group the pollinarium is affixed to the head of the pollinator, while in the latter it is attached to the abdomen. Only the introductory behaviour is necessary for pollination of the flower, and the bees do not encounter structures that lead to ejection of sperm. The behaviour is elicited by tactile stimulation from the hairs on the labellum, but the male "suitor" requires simultaneous and continued olfactory stimulation. The glistening pseudonectaries apparently imitate the eyes of the female bee. Metallic-blue mirrorspots similar to those found in the females enhance the effect. Dimensions of the flowers in the various species of *Ophrys* help in determining specificity and success.



Deception of pollinators.
(Top) *Pleurothallis raymondi* and (bottom) *Trichoceros antennifera* resemble female insects and attract the corresponding males, which carry out pollination while attempting to copulate with the flowers. (Right) *Calopogon pulchellus* has false stamens that act as an attraction to pollen-eating insects.
(Top) G.C.K. Dunsterville, (right) Walter Dawn, (bottom) Robert L. Dressler

Australian orchids of the genus *Cryptostylis* are pollinated by ichneumon wasps of the genus *Lissopimpla.* The wasp, after backing into the stigma, attempts to copulate with the flower by bending its body into an arch, with the base of the lip of the flower held by the claspers of the wasp. The upper side of the apex of the abdomen comes in contact with the viscidium, and the pollinarium becomes cemented in place. The wasp, after a short pause, then flies to another flower and the same behaviour delivers the pollinia to the stigma.

The South American orchid *Trichoceros antennifera* has flowers that simulate the female flies of the genus *Paragymnomma* to a remarkable degree. The column and base of the lip are narrow, barred with yellow and red brown, and they extend laterally to simulate the extended wings of a sitting fly. The base of the lip has no particular similarity to the head and thorax of a fly, but this is probably not necessary to complete the illusion. The stigma of the flower is located more or less at the apex of the "false abdomen" of the flower and reflects sunlight, as does the genital orifice of the female fly. The viscidium, extended over the stigma on the slender rostellum, projects up through the bristles and becomes attached to the basal portion of the abdomen of the fly. The viscidium is flat and padlike in this genus. The male flies, deceived by the similarity to the female fly and stimulated by the signal from the genital-orifice-like stigma, strike the flower for only a moment and then pass on to other flowers in the same area. The action is sufficient, however, to pick up the pollinarium. The long, slender stipe of the pollinarium bends down slightly and is forced into the stigma when the fly visits a succeeding flower.

Orchid flowers resembling female flies

Insects attracted for protection. A number of species of orchids have developed nectaries located in places

other than the flower. These seem to act to attract ants, which in turn scare away bees that would otherwise rob the flower of its nectar by cutting into the back of the flower. Such extrafloral nectaries also attract wasps, which function in scaring away insects that might rob the nectar from the flower. These ants and wasps are also thought to keep away grasshoppers, crickets, caterpillars, and other insects that eat the flowers. The symbiotic relationship (*i.e.*, two organisms living together with mutual benefit) between ants and the orchids that grow only in ant nests (*e.g.*, *Coryanthes* and some species of *Gongora, Epidendrum*, and *Schomburgkia*) may depend on this defensive mechanism. The plants and flowers of these orchids are extremely susceptible to damage by chewing insects if the ants are destroyed. The ants involved in this relationship do not pollinate the orchids; indeed, no ants are known to pollinate orchids.

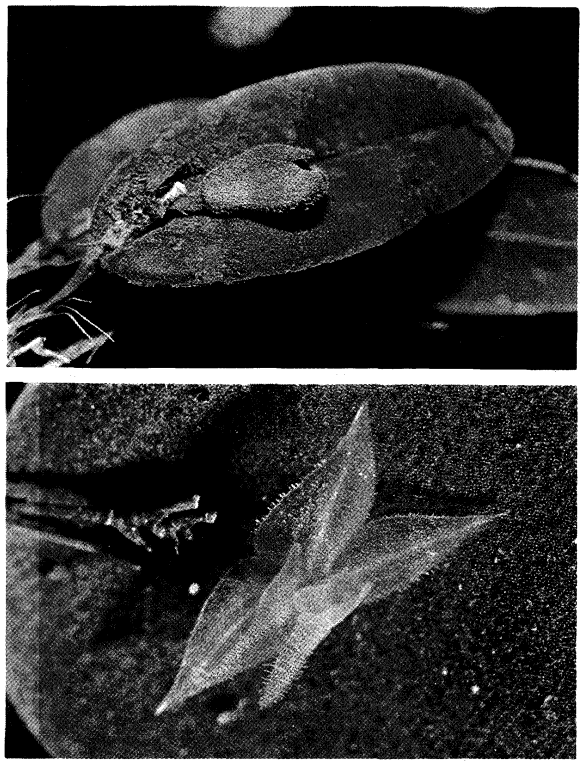
EVOLUTION

There are two extremes in the variation patterns shown by living plant groups, apparently depending on rates of evolution and amount of extinction. At one end of the spectrum stand such families as the Magnoliaceae, Annonaceae (both of order Magnoliales), and Nymphaceae (order Nymphaeales). These families have the appearance of being "old" groups, in which evolution is proceeding at a leisurely pace and extinction has greatly affected the pattern of variation. The delimitation of genera and tribes within the Magnoliaceae or the Nymphaeaceae is not difficult; however, students of evolution are at a loss in trying to understand relationships or phylogeny (evolutionary descent) in these groups.

Rapid evolution in orchids

The orchids are near the other end of the spectrum. They show little evidence of great age, show signs of relatively rapid evolutionary diversification in geologically recent time, and give much less evidence of extinction. Genera are often difficult to define, and higher categories within the family often seem even more difficult. These hazy boundaries between tribes and subtribes, however, may give clues to the patterns of phylogeny within the family. This is not to say or imply that living groups are derived from other living groups, but excellent evolutionary series can be found for nearly every morphological feature within the orchids. In recent years there has been a healthy skepticism concerning phylogenetic schemes. Even when a good morphological series can be found in some feature, it is often difficult to decide in which direction or directions evolution has occurred. This problem is not so serious in a highly derived group such as the orchid order. In comparing the genera *Cephalanthera* and *Oncidium*, there can be little doubt as to which is derived and which is primitive. In nearly every feature in which these two differ, it is *Cephalanthera* that is the ordinary monocot, easily comparable with other monocot families, while *Oncidium* is so advanced that it can scarcely be understood without comparing it with the less specialized members of the family.

In dealing with the primitive orchids and their evolution from groups now extinct, the bewildering parallelisms to be found in the more advanced groups must be borne in mind. It is probable that the subfamilies Neottioideae, Orchidoideae, and Epidendroideae evolved from a series of related species or genera having partial union of filaments and style, androecial zygomorphy (bilateral symmetry in the male parts), and a close association of the stigma and the median anther—all features that would predispose the groups to parallel patterns of evolution. Some of the ancestral populations may have been quite similar to the subfamily Apostasioideae, while others were similar to the genus *Selenipedium*, and yet others quite unlike either. The orchid family is not "unnatural" or polyphyletic (derived from more than one ancestral group) in the strict sense, since the ancestral group was, itself, a natural and closely interrelated group, even though it may have differed from the modern orchids in a number of features. It is fairly certain that the stipe, divided pollinia, and the viscidium have evolved independently in different groups of orchids. It is quite possible that the rostellum has evolved independently in two or more separate lines and that the reduction to a single median anther is similarly polyphyletic in the unusually "natural" family Orchidaceae.



Extremely small orchids.
The flowers of (top) *Pleurothallis pertusa* and (bottom) *Lepanthes* are only a few millimetres long.
Norris H. Williams

None of the living tribes of orchids could readily be derived from another living tribe, but their derivation from similar or common ancestors is easily visualized. The subfamily Cypripedioideae (lady's slipper orchids) is not very closely related to any other group, its relationship to the subtribe Limodorinae of the Neottioideae subfamily being perhaps quite as marked as its few resemblances to the subfamily Apostasioideae. The lady's slippers clearly diverged early from the main lines of orchid evolution. The Apostasioideae subfamily more nearly approaches the hypothetical ancestral type, the median anther being functional in *Neuwiedia*. It, too, represents a small relic group of somewhat isolated phyletic position, though perhaps closer to the other orchids than to the Cypripedioideae. The Orchidoideae subfamily presumably is derived from *Cephalanthera*-like types, but it would stand quite isolated if it were not for the relic subtribe Epipogiinae, which shows some relationships to both the Neottioideae and the Epidendroideae subfamilies. The Epidendroideae subfamily might be derived from somewhat Neottioideae-like ancestors, but it shows more primitive seed structure in the Vanillinae subtribe than any living species of Neottioideae, and the two subfamilies have apparently diverged at an early level in orchid evolution. The subtribes of the Neottioideae subfamily that are grouped with the Limodorinae subtribe are among the more generalized and primitive of the living orchids and would constitute a typically relic group if it were not for the great evolution of this group in Australia, where several striking specializations occur.

The subfamily Epidendroideae has the most examples of adaptive radiation to various types of pollinators. Apparently evolution in this subfamily has been accentuated by adaptive radiation to different types of pollinators. In this subfamily are found all types of pollinator classes with the exception of bat, rain, and wind pollination.

CLASSIFICATION

Distinguishing taxonomic features. The Orchidales order may be separated from the Liliales, a closely relat-

ed order, on the basis of their having an undifferentiated embryo and little or no endosperm, very tiny seeds, the stamens reduced to one (rarely two or three), the fertile stamen adnate (fused) to the style to form a column, the flowers usually strongly zygomorphic (bilaterally symmetrical), the pollen usually coherent in masses called pollinia, and the ovary inferior always. The relationships between the subfamilies of the Orchidaceae are based on the number of fertile stamens, the character of the leaves, the consistency of the pollinia, the number of pollinia, and the associated structures of the pollinarium.

Criteria used to classify orchid groups

Annotated classification. The following classification is a recent one of wide acceptance among orchid taxonomists. Each subfamily is broken down into tribes, and in those cases in which more than one subtribe is found in a given tribe, the tribe is broken down into subtribes.

ORDER ORCHIDALES

Perennial herbs; terrestrial, epiphytic, or saprophytic, sometimes vinelike. Stems leafy or scapose, of sympodial or monopodial growth. Flowers solitary or in spikes, racemes, or panicles; bisexual, rarely unisexual, zygomorphic, always bracteate, mostly resupinate; perianth typically of 6 segments in 2 series, the outer series of 3 sepals green or often coloured and petaloid and usually all similar, the inner series of 3 petals with the central petal usually larger, often highly modified in colour and shape. Ovary inferior, of 3 carpels, ovules very numerous and minute. Style, stigmas, and stamens variously adnate into a singly highly complex structure (the column). Stamens 1 and then terminal on the column, or 2 and lateral (rarely 3), each anther 2-celled and introrse, the pollen usually in pollinia of 2 to 8 per anther. Fruit a capsule. Seeds abundant, minute, without endosperm, the embryo undifferentiated. A large order, variously estimated at 400 to 800 genera with 15,000 to 35,000 species, all in the single family Orchidaceae.

Family Orchidaceae

The only family in the order, it has the characters of the order.

Subfamily Apostasioideae

Perianth essentially regular, lip never deeply saccate; fertile anthers 2 or 3, elongate; style slender. One tribe with 10 to 15 species, restricted to Indo-Malayan region.

Tribe Apostasieae. Two genera: *Apostasia* and *Neuwiedia,* mostly terrestrial.

Subfamily Cypripedioideae

Perianth irregular with a deeply saccate lip; fertile anthers 2, subglobose; a conspicuous, flattened median staminode present; style relatively thick. One tribe with about 100 species of worldwide, but mostly tropical, distribution.

Tribe Cypripedieae. Four genera: *Cypripedium, Paphiopedilum, Phragmopedium,* and *Selenipedium,* mostly terrestrial in habitat.

Subfamily Neottioideae

Fertile anther 1, more or less erect, often dorsal, pollinia 2 to 4, soft and mealy; stems without corms or other thickenings, leaves not jointed at base. One tribe with about 1,000 mostly terrestrial species distributed mainly in the temperate zones of the world.

Tribe Neottieae. Nine subtribes: Chloraeinae, Cryptostylidinae, Diuridinae, Limodorinae, Neottiinae, Prasophyllinae, Pterostylidinae, Rhizanthellinae, and Spiranthinae.

Subfamily Orchidoideae

Fertile anther 1, erect or reclinate (rarely incumbent), persistent, usually broadly joined to the column, pollinia in soft masses, caudicles arising from the base of the pollinia. One tribe with about 1,000 temperate zone terrestrial species.

Tribe Orchideae. Four subtribes: Coryciinae, Disinae, Epipogiinae, and Orchidinae.

Subfamily Epidendroideae

Fertile anther 1, often incumbent, pollinia 2 to 12, usually hard, waxy, sometimes mealy, without caudicles or these terminal; leaves often jointed at the base. Four tribes with numbers variously estimated at 12,000 to 30,000 species. Distributed worldwide, but mostly in the tropics; both terrestrial and epiphytic forms occur.

Tribe Gastrodieae. Pollinia mealy, 2 or 4; plants saprophytic or green; leaves (if present) more or less fleshy (except in *Nervilia,* with fan-shaped leaves), not jointed at the base. Three subtribes: Gastrodiinae, Pogoniinae, and Vanillinae.

Tribe Epidendreae. Pollinia mealy to compact and hard, 2 to 12, usually club shaped or laterally flattened (except in *Coelogyne* and some species of *Polystachya*); viscidium present (usually more or less liquid) or absent; stipe rarely present (in *Polystachya*); leaves usually jointed at base. Eleven subtribes: Adrorhizinae, Arethusinae, Bletiinae, Coelogyninae, Eriinae, Laeliinae, Pleurothallidinae, Ridleyellinae, Sobralinae, Thelasiinae, and Thuniinae.

Tribe Malaxideae. Pollinia 2 to 4, completely naked, without caudicles of any sort; viscidia or stipes (usually double) rarely present. Four subtribes: Dendrobiinae, Genyorchidinae, Malaxidinae, and Thecostelinae.

Tribe Vandeae. Pollinia 2 to 4, dorsoventrally flattened if 4; viscidium normally always present; stipe almost always present. Ten subtribes: Catasetinae, Cymbidiinae, Cyrtopodiinae, Lycastinae, Maxillariinae, Ornitocephalinae, Oncidiinae, Sarcanthinae, Stanhopeinae, and Zygopetalinae.

Subtribes of uncertain affinity. Grobyinae and Pachyplectrinae.

Critical appraisal. Although the classification presented here is a recent one, there is still some need of examination of relationships in the orchids. The evolution of similar vegetative and floral structures in different orchid groups (convergent evolution) leading to the exploitation of the same types of pollinators has resulted in a situation in which many groups appear to be superficially similar. This same adaptation to pollinators has often obscured the actual relationship of numerous other groups.

(C.H.D.)

Ordovician Period

The Ordovician System was proposed in 1879 by Charles Lapworth for rocks exposed in the Arenig Mountains and eastward across the Bala District of North Wales (Figure 1). This area was part of that inhabited by the ancient British tribe of the Ordovices. It lies between an anticlinorium on the west, which exposes Cambrian rocks, and a synclinorium on the east, in which Silurian rocks are contained. Thus the type section is dominantly eastward-dipping, but it is complicated by subsidiary faulting and folding and, particularly in lower ground, is exposed only sporadically through a cover of Pleistocene glacial deposits. The sequence is approximately 3,450 metres (11,380

feet) thick and consists of graywackes, fine sandstones, and siltstones. Interbedded lavas and ashes occur in the lower portion, and some thin (two metres maximum) limestones are present in the upper part. Fossils occur at intervals throughout the sequence.

In proposing a new systemic name for the geological time scale (*q.v.*), Lapworth was, in part, offering a solution to the classic controversy over limits of the older Cambrian and younger Silurian systems. Lapworth was primarily concerned, however, with formally recognizing that Lower Paleozoic rocks contained three major faunas. This had become increasingly clear to contemporary students of these rocks. The basis for his Ordovician System was thus the distinctive characters of the fossils it contained, and this remains the basis for the system today, because the rocks have otherwise no unique characters for determining stratigraphic boundaries.

Strata of the Ordovician System are widely recognized in the continents of the Northern Hemisphere (but not in Africa from the Sahara southward or in peninsular India), in the Andes of South America, in Australia, in limited areas in New Zealand, but not in the Antarctic. Following the appearance and evolution of varied kinds of animals in the Cambrian Period, the Ordovician is notable for a great rise in numbers and variety of marine animals with a mineralized skeleton or shell. Some of these groups evolved rapidly, and the changes shown in the fossil record give the basis for classification and correlation of the Ordovician System. Few radiometric dates can be accurately related to this evolutionary record, but it is generally believed that the Ordovician Period began about 500,000,000 years ago and was about 70,000,000 years in duration.

Ordovician rocks of economic importance include a variety of building stones; road metals; slates from fine-grained, cleaved rocks; and decorative marbles (that is, massive limestones of unusual colour that often are derived from reef mounds). Some of the pure limestones are used in cement making. Some gypsum deposits are of Ordovician age, and various metalliferous deposits also occur. The latter include syngenetic iron ores, gold, and lead-zinc ores in limestones. Certain porous Ordovician sandstones are important as sources of water.

This article also treats the rocks, life forms, and environments of Ordovician time. See CAMBRIAN PERIOD and SILURIAN PERIOD for related coverage of the prior and subsequent time intervals, and FOSSIL RECORD for further details of Ordovician in vertebrate paleontology.

ORDOVICIAN ROCKS

Figure 2 shows areas in which Ordovician rocks crop out and which were covered by the sea for all or part of the period. No land plants or animals are known in Ordovician rocks so that terrestrial sediments cannot be recognized, if they exist. The history of Ordovician lands therefore is unknown. The marine successions are of two major types: those in geosynclines, which are thick and may be deformed and metamorphosed, and the thinner, less complete, shelf successions, which transgress over shield areas and are little deformed and unmetamorphosed. The geosynclines are situated outside the edges of the shield areas of Precambrian rocks: in North America on all sides of the shield; in South America and Australia on the western and eastern edge, respectively; and in northern Europe on the northwestern and southern edges of the Baltic shield. The folded Paleozoic rocks of the Urals lie between the Baltic Shield and the Angara Shield of Siberia, and a central Asian geosyncline lies to the south of the latter shield. Although the main deformation in these geosynclines was in the Middle or Late Paleozoic, intense deformation did take place earlier in some geosynclines during the Ordovician.

Geosynclines

One of the best-known geosynclinal regions is that which runs through Norway, northwestern Britain, Newfoundland, the Appalachians of northeastern North America, and parts of east Greenland and Spitsbergen. In this long and relatively narrow, tectonically active downwarp, there may have been a central zone in which fine-grained sediments accumulated slowly. In southern Scotland, for example, 30 metres of rock represent the entire Upper Ordovician. This central belt was flanked by intensely active zones, in which sequences, of the order of 4–5 kilometres, of graywackes and volcanic rocks accumulated. These sediments were derived in part from rising, narrow welts within the basin and in part from piles of volcanic lava and ash, rapidly extruded and building up to and above sea level and accompanied by intrusions.

Faults were active in these geosynclinal regions. Thick wedges of conglomerates may have accumulated on the downthrown side of a fault bounding an area being rapidly eroded. The trough between two such faults may have preserved a far thicker sequence than the relatively raised areas on either side. Rapid changes in sedimentary facies (*q.v.*) thus characterize the rocks of such zones. During the Ordovician Period the most active part of the mobile zone was strongly folded, metamorphosed, and upraised; and in some areas slices of rock were carried many kilometres laterally on thrust planes. Outside the zone of intense deformation, graywackes and volcanic sequences were strongly folded; and these pass laterally into successions that, although still thick as a result of continued subsidence, were built of limestone, sandstone, and shale. These rocks were deposited on the shield side of the geosyncline, adjacent to areas of low relief not undergoing active uplift and erosion. Here the supply of sediment was less and sands were better sorted. There is every transition between these sequences, with wedges of graywacke extending into the limestone-shale succession or of limestones extending basinward during periods of lesser activity.

In Britain, the Ordovician rocks of Wales and the Lake District include graywackes and volcanics, with rare, thin limestones that are strongly folded and faulted; in northern Scotland, Ordovician and older rocks were deformed and metamorphosed during the Early Ordovician and

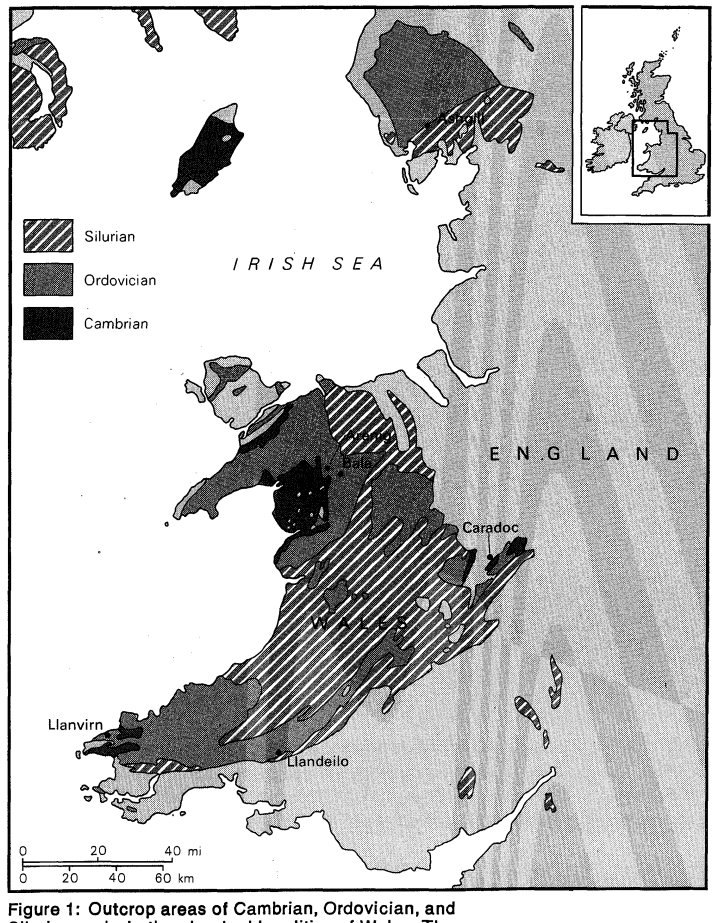

Figure 1: Outcrop areas of Cambrian, Ordovician, and Silurian rocks in the classical localities of Wales. The differentiation of these systems was initially based on studies of this region.

represent the most active zone of the geosyncline. The central and southern Appalachians of eastern North America are partly formed by a thick Ordovician limestone and shale sequence into which extend tongues of graywackes and red sandstones derived from welts raised in the active geosynclinal zone to the east. In the Great Basin area of the western United States, the Ordovician is represented by 500 metres (1,600 feet) of limestone and quartzite, over which dark shales and cherts of a different sequence were thrust from the west. Geosynclinal regions in other continents show the same broad features; *i.e.*, the graywacke-volcanic-chert facies that characterizes the most tectonically active zones and beyond this zone the limestone-sandstone-shale successions.

Shelf areas

At the margins of the geosynclines in the Northern Hemisphere and Australia, the seas spread onto the shields; and a thin and incomplete series of sediments, dominantly limestone, was lain down. These were the shelf areas. In central North America and the Arctic islands, Upper Ordovician limestones typically contain corals and large cephalopods. There are associated evaporite deposits. These shelf sediments were transgressive on Precambrian rocks of the shield.

On the Baltic Shield, the Ordovician limestone and shale sequence is relatively complete and rests on essentially undeformed Cambrian strata. In central Sweden, small algal reefs developed in the shallow Upper Ordovician seas, associated with a rich trilobite-brachiopod-mollusk-an fauna. Notably, angular deposits at the margin of the reefs were formed by debris broken from them, and between the reefs were mudstones and muddy limestones with a different trilobite-brachiopod fauna and a variety of echinoderms. On the Siberian Platform a moderately thick sequence of carbonate rocks was deposited with abundant shallow-water faunas and associated gypsum-bearing beds; similar rocks are found in central and western Australia.

ORDOVICIAN LIFE

Ordovician invertebrate faunas differ from those of the Cambrian in the much greater variety of groups with calcareous shells. Most localities in fossiliferous Cambrian rocks yield abundant trilobites accompanied by species of inarticulate brachiopods and primitive mollusks. Other groups occur more rarely. In contrast, Ordovician rocks yield quite different trilobites, which at many localities are outnumbered by a variety of brachiopods, bryozoans, mollusks, echinoderms, corals, and representatives of other groups.

Marine fossils

Trilobites underwent a major evolutionary change during the latest Cambrian and earliest Ordovician, so that only a few representatives of Cambrian families persisted, outnumbered by a variety of new groups, each of which evolved rapidly. Broadly speaking, Ordovician trilobites had fewer thoracic segments and a relatively larger pygidium (tail section) than Cambrian ones, and families with proparian sutures (a type of molt line on the head) were an important part of the faunas. Other arthropods are rare in Ordovician rocks, except for the calcareous, bivalved shells of ostracods, which became abundant in the later Lower Ordovician and were varied throughout the Upper Ordovician.

A great increase in kinds and numbers of articulate (hinged) brachiopods is evident in the Early Ordovician, and succeeding strata yield the shells of a variety of rapidly evolving groups. Bryozoans are almost unknown in the Cambrian, but by the late Lower Ordovician their massive and branching colonies, supported by a calcareous skeleton, became an important element in shallow-water faunas, even building small reeflike mounds on the sea bottom. The expansion of these extinct bryozoan groups continued through the period. The abundance of gastropod shells and of straight, curved, and coiled shells of cephalopods (distantly related to the living pearly *Nautilus*) is characteristic of Ordovician rocks from the earliest part of the system; pelecypods became abundant in the Late Ordovician.

In the Early Ordovician, species of groups that survive today—the starfish, brittle stars, and crinoids—were present, and the number and variety increased during the period. Of extinct echinoderm groups, the cystoids were the most varied and important during the Ordovician. Thus, by the late Lower Ordovician, echinoderms were sufficiently numerous for parts of their skeletons to accumulate and form limestone beds. The calcite of echinoderm skeletons is lain down in crystal continuity and when broken shows cleavage planes, so that these beds have a distinctive character not seen in older limestones. Corals, both solitary forms with prominent radially arranged septa (tetracorals) and colonies in which horizontal plates divide the corallites (tabulate corals), were present in the late Lower Ordovician and widespread before the end of the system. Bryozoa, colonial corals, and sponges with thick calcareous or siliceous skeletons played their part in building small reeflike mounds or in forming thin but extensive sheets of limestone in late Lower and Upper Ordovician time.

Graptolites were colonial, mainly pelagic, animals with a skeleton of tough, organic, chitin-like material. They evolved rapidly throughout the Ordovician, and while they are conspicuous in dark shales because they may be the only abundant fossils, they occur in all other types of sedimentary rocks.

Small (2–44 millimetres) toothlike fossils of organic material (scolecodonts, the jaw apparatus of worms) or calcium phosphate (conodonts, a group of uncertain affinity since the complete animal is unknown) are abundant fossils. Conodonts show a succession of widespread types indicating a considerable evolution. Dissociated and broken plates of true bony structure indicate the presence of vertebrates—probably primitive, jawless fish. These are so rare and fragmentary that the form of the animal is unknown.

The remains of vascular plants are not known in the Ordovician, but a variety of calcareous algae have been recognized. Microscopic organic fossils such as flask-shaped Chitinozoa or spherical, spiny acritarchs have been extracted from limestones, siltstones, and sandstones by special techniques.

Stratigraphically important fossils

Fossils of importance for zonation and correlation are those that are abundant in a wide variety of rocks over large areas and are of organisms that evolved rapidly. The hard parts must be preserved in a manner that enables them to be separated from the rock and studied in detail. For the Ordovician Period, brachiopods and trilobites fulfill these conditions and have been studied long and intensively so that, in most areas in the world, stages and zones are based on them. The small bivalved shells of ostracods are also abundant and widespread and show considerable evolution but have not been studied so intensively. In limestones, where brachiopods and trilobites may be abundant, nautiloid cephalopods and gastropods may also occur in considerable numbers. The cephalopods evolved rapidly. Thus, in the Lower Ordovician limestone-dolomite facies in North America, zonation and correlation is in part based on the remains of these animals.

In the Upper Ordovician, corals became widespread and varied and are also used to a limited extent in correlation. In the late Lower and Upper Ordovician sections, Bryozoa are common in rocks of shallow-water facies, but stratigraphic usefulness requires detailed preservation of the complete skeleton so that it may be studied in thin section. Since only casts of the skeleton are usually preserved in shales, mudstones, and sandstones, they cannot be so studied; and the use of these fossils in correlation is limited.

In recent years there has been increased emphasis on study of fossils obtained by dissolving rocks in acid. Such work has shown the apparently worldwide distribution and abundance of conodonts. Though each conodont is only one element in the assemblage of an individual, study of relative numbers and kinds of these elements shows groupings that are proving valuable in correlation. Other potentially useful fossils revealed by acid digestion of rocks are chitinozoans and acritarchs.

It was discovered long ago that in black shale and fine silts graptolites were the most conspicuous and abundant

fossils. A scheme of graptolite zones for the Ordovician of Britain was erected by Charles Lapworth and his students in the early years of this century. Many of the forms appear to be worldwide in distribution, so that the British zones are often quoted as a world standard, though a quite different scheme for the Lower Ordovician is used in Australia. Graptolites do occur in rocks of all types but generally are rare and poorly preserved in siltstones and sandstones. In limestones they occur much less commonly, though certain limestones and associated cherts have yielded the best-preserved and most completely known graptolites.

This rather general restriction of abundant graptolites to dark shales and the restriction of varied brachiopod-trilobite-mollusk-bryozoan faunas to limestones, sandstones, and siltstones has led to the greatest problem in Ordovician correlations: that between these two sedimentary facies and their separate zonal schemes. The relations between facies are revealed where they interfinger, but such interfingerings are not well enough known to establish detailed correlations. It appears that the best-developed graptolite shale sequences were in parts of the geosyncline far from the shelves, and on the shelves strata rich in brachiopods and trilobites were deposited. These two general regions have had different structural histories, so that the original relation between them is complicated and obscured by folding and faulting. Thus in the western United States the graptolite facies is best known from thrust plates overlying limestones, and the transition zone, if it existed between the facies, is unknown.

Faunal realms

A faunal realm is a large region, which may include parts of more than one continent, in which the assemblage of genera of one or more groups of fossils was similar during a substantial portion of the time considered. In general, during the Ordovician Period, such realms were marked in the lower part but in the upper became progressively less distinct. Study of the distribution of trilobite genera has shown that in the Lower Ordovician there were two realms, one including almost all of North America and the Arctic islands, Greenland, western Ireland, Scotland, Spitsbergen, northern Europe, and the U.S.S.R. The other realm included the Andean region of South America, northern Florida, central Europe (including England and Wales), the Mediterranean area, the Himalayas, China, Southeast Asia, Australia, and New Zealand. Certain family groups and particular genera of other families were confined to one region or the other, and few were common to both regions.

In the Upper Ordovician the distinctiveness of these realms began to break down. Genera previously confined to one region then appeared in both. In the Late Ordovician the genera of a single fauna were widely distributed in the Northern Hemisphere. The distribution of brachiopods exhibits this pattern. In the early Upper Ordovician the brachiopod faunas of Scotland and the Appalachians were remarkably similar but very different from the contemporaneous faunas of central Europe.

The worldwide distribution of genera of other groups of shallow-water fossils is not well known; cephalopod distribution in the Lower Ordovician shows some parallels and some contrasts with that of trilobites. Modern shallow-water faunal realms are partly determined by water temperature and ocean currents. The latter influence distribution by transporting the floating larval stages. Barriers to such distribution are land masses and wide stretches of deep water. The larvae cannot survive the required transportation and thus cannot settle and colonize the sea floor.

The paleogeography of the Ordovician, the oceanic circulation, and water temperatures presumably, were important factors in determining the faunal realms, but because there is as yet no clear understanding of the distribution and shape of Ordovician continents and oceans, it is impossible to determine oceanic circulation. Organisms that float either by attachment to other organisms (*e.g.*, graptolites attached to floating masses of seaweed) or by possessing structures containing gas or fat or organisms that swim in the surface oceanic waters may be distributed widely. In the Upper Ordovician, graptolites were so distributed, the rapidly evolving successions of kinds being closely similar all over the world. Lower Ordovician graptolites were probably also floating forms but do show a provinciality. The kinds and their stratigraphical arrangement are remarkably similar in the Americas, Australia, and China but differ in both kinds, relative abundance, and stratigraphical range from those of Europe. This does not mean that the oceans in these areas were completely separated from each other but that some factors restricted migration and mixing, factors that were not operative in the Upper Ordovician. Patterns of ocean currents are obviously such a factor, and it may be that these patterns changed markedly between Early and Late Ordovician time, so that by the Late Ordovician both floating and benthonic faunas were similar over large areas of the world.

Evolution during the Ordovician Period

The Ordovician was preeminently the time of major expansion of the invertebrates, and many new species, genera, and families of major groups (classes or orders) appeared. Trilobites, which dominated the Cambrian record in individual numbers as well as kinds, began to be rivalled and then overshadowed in the Ordovician by corals, bryozoans, brachiopods, mollusks, and echinoderms. This reflects the evolutionary success of these groups in colonizing the shallow sea floor, a success that came long after their first appearances. The nautiloid cephalopods were expanding rapidly in the earliest Ordovician and, if feeding like the living *Nautilus*, they would have been formidable predators. Their varied forms suggest a variety of living habits.

It may be that the increase in forms with a hard protective shell is related to the rise of these (or other) predators. If such a relationship existed, however, it may have been far more complex than this. An increase in food supplies and changes in the salts in solution in the oceans may have created the conditions for this evolution, and predatory forms may have evolved as a response to an increased food supply of bottom-dwelling invertebrates. The fossil record is biassed in favour of forms with a mineralized shell. Since soft-bodied animals are rarely preserved, their numbers and kinds cannot be estimated. Thus the picture is incomplete, revealing but not explaining this great expansion of hard-shelled invertebrates. The Ordovician is notable for the first records of vertebrates in the form of bone fragments.

CLASSIFICATION AND CORRELATIONS OF ORDOVICIAN ROCKS

In the quarter century following Lapworth's proposal of the Ordovician System it gained acceptance, and in Britain the names for the series composing it, shown in the Table, became established. Each series is a sequence of rocks exposed in a particular area (Figure 1). The Arenig rocks were mentioned by Lapworth as the basal unit of his system, resting unconformably (a break in continuous deposition) on the Tremadoc Series of the youngest Cambrian. The rocks and fossils of the Llandeilo and Caradoc areas had been described earlier by Sir Roderick Murchison as part of his Silurian System and were familiar to British geologists. The Llanvirn Series contained distinctive graptolite faunas, and the Ashgill section was recognized as including the youngest faunas. These standard series are in different areas, not part of a single continuous section; in the Arenig-Bala area (the type sequence of the system) no rocks of Llandeilo age are recognized, and the strata of Arenig, Llanvirn, Caradoc, and Ashgill age are fossiliferous at only a limited number of widely spaced horizons. Thus the standard section is a composite, and all but the Llanvirn Series are rocks mainly in the shelly facies, that is, shallow-water sediments with brachiopod-trilobite faunas.

Facies problems

Early in the 20th century the graptolites of Britain were described and a zonal scheme for Ordovician rocks proposed. These zones are commonly quoted as a standard, but they were based on studies of dominantly black shale or black shale and graywacke sequences exposed in areas other than those of the type series. These zones are difficult or impossible to define exactly in the type Arenig, Llandeilo, or Caradoc areas. Such difficulties of corre-

Major Divisions of Ordovician Rocks and Their Correlation

lating between the shelly and graptolitic facies are common in the study of Ordovician rocks in all continents. Sections that show some interfingering of the facies are important in correlation but are rare and do not show the relationship clearly or completely. Correlation is also hampered by the lateral changes in shelly faunas and the existence of faunal realms; it is almost impossible, for example, to correlate the type Caradoc Series with rocks of the same age in Scotland because the shelly faunas have little in common. Rare occurrences of graptolites in the shelly sequences have to be used for correlation. Similarly, intercontinental correlations between the shelly standard divisions of other countries (see the Table) and Britain are largely based on graptolites; and even with these relatively widespread fossils there are difficulties arising from faunal realms, particularly in the Lower Ordovician.

System boundaries

Definition of the upper boundary of the Ordovician System has offered relatively little difficulty. It is based on the changes in the widespread Late Ordovician brachiopod-trilobite fauna and the graptolite fauna from Ordovician to earliest Silurian.

The lower boundary (Table) is variously defined in different countries. Lapworth originally designated the base of the Arenig Series as the base of his system, but he subsequently and erroneously modified his view and included part of the Tremadoc Series in the Ordovician. His Scandinavian colleagues adopted his modification and included all the Tremadoc Series in the Ordovician, whereas the United Kingdom Geological Survey adhered to his original view. In the United States the Canadian Series is taken as the earliest Ordovician. It now appears likely that the earliest Canadian rocks may correlate with the upper part of the Tremadoc Series only. Thus in existing practices the base of the system appears to be placed at three different levels (Table). In Britain it has been customary to divide the Ordovician System into an upper and lower portion, the base of the upper being at the base of the most widely recognized graptolite zone. A threefold division has been used in other countries, but the boundaries between these divisions are placed at different positions. Thus, care has to be exercised in interpreting these terms, and the twofold division has been used here.

ORDOVICIAN PALEOGEOGRAPHY AND CLIMATE

The areas of the present continents on which shelf or geosynclinal sediments were deposited in Ordovician time are shown in Figure 2. Seas covered these areas and probably other areas from which Ordovician rocks have been eroded, as well as areas in which Ordovician strata may be concealed by younger rocks. Further, the elongated geosynclines appear narrower than they originally were because of the contraction resulting from folding and faulting. A sea probably covered the Cordilleran area of South America and was connected to one covering much of North America, western Europe, and North Africa. From the Mediterranean region a sea probably extended continuously along the present mountain areas into the Himalayas, southeastern Asia, and on to cover parts of present Australia and New Zealand. The Urals and probably much of northern Asia were also covered. The similarities of faunas between the deposits suggest these connections. The major land areas of the Ordovician appear to have been the eastern half of South America, Africa from the Sahara southward, peninsular India, and the Antarctic.

Figure 2 is plotted on present-day geography, for lack of any real alternative. In the north Atlantic areas the rocks, their faunas, and structures reveal evidence suggesting that during the Ordovician Period they were much closer to each other than at present. There is also evidence accumulating to suggest that the Atlantic Ocean is geologically young and that the ocean of Ordovician time was narrower and in a different position. For example, it may have separated northern England from Scotland and parts of present northeastern North America from each other.

It has long been suggested by geologists considering continental drift (*q.v.*) that in the Late Paleozoic the present areas of eastern South America, Africa, peninsular India, Australia, and the Antarctic were in close juxtaposition. A large part of this continent appears to have been land or covered only by shelf seas (Australia) during the Ordovician Period. Did it form a single continental mass in the Ordovician? If so, what were the positions relative to it of the Canadian, Baltic and Angara shields and of the marginal geosynclines?

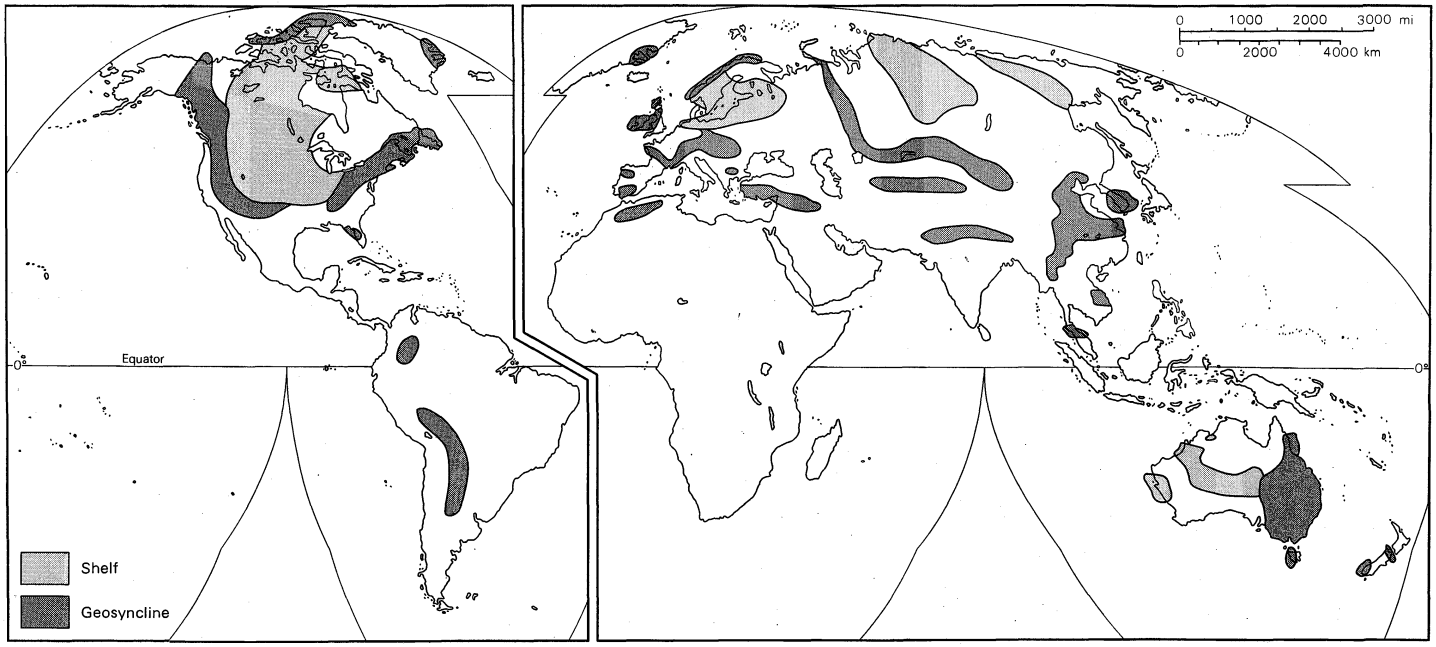

Figure 2: World distribution of Ordovician deposits showing the location of shallow seas (shelf areas) and geosynclinal areas during Ordovician time.

These unanswered questions make it impossible to draw a meaningful paleogeographical map of the world in Ordovician times. Further, other lines of evidence from rock magnetism suggest that the magnetic poles have changed in position during geological time. If there has always been a close relation between the magnetic and rotational poles of the earth, then the poles of rotation have varied in position relative to particular areas of today's continents. Since Ordovician geography cannot be reconstructed, the positions of the oceans and land areas relative to the Ordovician poles cannot be determined. Hence Ordovician climate remains mysterious, except as one interprets evidence within a single present continental area.

In the Late Ordovician shelf seas of northern North America, large nautiloid cephalopods and coral faunas were characteristic, and gypsum-bearing rocks (formed by evaporation of sea water) were associated. On the Siberian Platform limestone was the dominant Ordovician rock, and gypsum deposits occur. Evidence of this kind suggests that these present northern regions were warm water areas in the Ordovician, lying adjacent to the Equator. The variety and abundance of certain faunas in these areas also suggest warm waters. Which regions may have been cooler is difficult to establish. There is no evidence of extensive glaciation during the Ordovician, so that ice caps do not appear to have existed; and climate may have been less extreme than that of today.

Ore Deposits

The word ore is derived from an Anglo-Saxon expression referring to metals such as copper and alloys such as bronze. It is used to mean a concentration of metals or metalliferous minerals that can be separated from the associated rock and mined at a profit. Present usage includes elements such as sulfur, when the sulfur is extracted from the mineral pyrites, and nonmetalliferous minerals such as fluorite and barite that occur in veins and require separation from the associated rock.

The profitability of mining any concentration of minerals can, and frequently does, change from year to year depending on a number of technological and economic factors. For these reasons the quantity and quality of ore in any particular concentration, or association of concentrations, must be defined on the basis of tonnages and grades of proven, probable, and possible ore. Grades refer to the actual metal content of the ore, commonly expressed in pounds, ounces, or metric units of weight of a particular metal per unit weight of ore. Proven ore refers to a known volume of ore of defined limits that has been blocked by drilling. Probable ore relates to extensions of proven ore, and the limits are not precisely defined. Possible ore is classed as a prospective volume where spatial or geological relationships to known ore deposits warrant the assumption that mineral concentrations of economic value may be found.

Associated with the ore minerals in an ore deposit is worthless material called gangue, consisting of rock and unwanted minerals, which is mined with the ore minerals, subsequently separated in the milling processes, and discarded as dumps of waste. The unwanted minerals contained in these dumps may eventually become valuable, and, if the grade of such dumps is sufficiently high, they may be reworked at a profit. Also associated with an ore

deposit is the country rock, or host rock, enclosing the deposit. The country rock can be of any type, although igneous and metamorphic rocks (those formed at high temperatures and pressures) are generally better host rocks for metalliferous ore deposits than are sedimentary rocks. Many exceptions are now known, but regardless of rock type, mineral prospecting and development generally require drilling, open-cut operations, or underground mining before a reliable assessment can be made of the reserves present and the feasibility of mining them for profit.

Metals and metalliferous minerals

Some metals, including copper, silver, gold, and platinum are mined in the native state. Others are rarely found in this state and only in quantities too small to be of economic importance. The outstanding deposits of native copper are in the Lake Superior area of Michigan, where the copper occurs in interbedded conglomerate (sedimentary rock with particles of diverse size) and basaltic lava flows, many of which are vesicular or amygdaloidal (that is, the minerals were deposited in cavities, or amygdules, after the flow formed). In the conglomerate the copper fills interstices and replaces matrix and pebbles; in the lava flows the copper fills the vesicles. Originally discovered by Indians who manufactured ornaments from the malleable copper and later noted by the Jesuits in the 17th century, these native copper deposits were first mined in 1845.

Native silver was found in quantity in the Cobalt District of Ontario during the early years of the 20th century. Some of the ore was phenomenally rich, ranging from 200 to 1,000 ounces of silver per ton. Slabs of up to 725 kilograms (1,600 pounds) containing 40 percent by weight have been extracted from the Cobalt silver mines. The silver occurs in veins that have filled fissures in conglomerate and other sedimentary rocks.

Gold commonly occurs in the native state alloyed with copper and silver. It originally formed in fracture-filling veins associated with chalcopyrite, pyrite, and other sulfides, with silicate minerals such as quartz, sericite, and tourmaline, and with the carbonate minerals calcite and ankerite. Erosion of such veins results in the eventual transportation of the released gold by streams and rivers in the form of fine particles, flakes, and nuggets; these become concentrated, as in crevices of the bedrock underlying the gravel or at the upstream end of sandbars, and are called placer deposits.

Platinum is mined chiefly in the native state; it occurs alloyed with other metals of the platinum group, namely, osmium, iridium, palladium, rhodium, and ruthenium. It also occurs as platinum arsenides and sulfides. Invariably associated with nickel and chrome mineralization in basic igneous rocks (those rich in iron and magnesium), it is mined mainly in the Ural Mountains of the U.S.S.R., in the Sudbury District of Ontario, and in the Bushveld District of South Africa. Production from the U.S.S.R. is derived principally from placer deposits that have been derived from magmatic concentrations of platinum in olivine and pyroxene-rich igneous rocks called dunite and pyroxenite. In the Sudbury District, the platinum is associated with massive copper–nickel sulfide ores, which are the principal metals sought. In South Africa, platinum is mined from magmatic concentrations associated with copper–nickel sulfides in dunite pipes.

Metalliferous minerals are chemical compounds of metals, commonly sulfides and oxides, that are found in the rocks. Some are common and some are rare. Copper, nickel, lead, and zinc are chiefly mined as sulfides, some of which have a metallic appearance; iron, aluminum, and uranium are mined as oxides, many of which have an earthy appearance. Where these minerals are concentrated they form metalliferous deposits that can be defined as ore deposits. High concentrations, such as veins of copper and lead ore, may warrant underground mining; low concentrations, such as porphyry copper deposits, where the copper minerals are disseminated throughout a large mass of fractured rock, can be mined economically only by open-pit operations handling large tonnages. Some deposits of iron and most deposits of aluminum lie at the surface.

Nonmetallic industrial minerals

Nonmetallic industrial minerals include those extracted from ore, such as diamonds and asbestos. They also include minerals that form deposits in themselves, such as beds of gypsum, salt, and sulfur. Other nonmetallic minerals used in industry are feldspar, quartz, mica, spodumene, gemstones, fluorite, barite, magnesite, sylvite, and many others. Spodumene and magnesite are also metalliferous because they are mined for the extraction of the metals lithium and magnesium, respectively.

A distinction must be drawn between industrial minerals and industrial materials such as soapstone, pumice, limestone, and shale, which are rocks, and clays such as kaolin, which are mixtures of hydrous aluminum silicates derived from the weathering of rocks.

Strategic minerals

Essential minerals that are in short supply, or that are found mainly in certain areas of the world from which they must be imported, are known as strategic minerals. The list of such minerals will vary from country to country and from time to time. Some countries are dependent on others for supplies of strategic minerals or their concentrates. Withholding such minerals from the world markets can cause serious shortages and consequent price rises on the international metal exchanges. The movement of minerals is affected not only by the amounts produced but also by political and economic considerations. Stockpiles of strategic minerals, concentrates, or the metals derived from them are hedges against the possibility of world shortages and high prices.

Worldwide exploration by mining companies, and the consequent discovery of new ore deposits, tends to modify the dependence of one country on another for strategic minerals. Antimony and titanium are examples of essential metals derived from strategic minerals. For many years China supplied two-thirds of the world's requirements for antimony, a metal that has the property of expanding upon cooling, a property that is used for type metal and hard lead alloys. China is still an important producer on the world market, but discoveries of the principal antimony sulfide mineral (stibnite) in other parts of the world have tended to lower the dependence on exports from China. Titanium, a light, strong, extremely heat-resisting metal of increasing importance to the aerospace industry, is mainly derived from the titanium oxide mineral rutile, which is supplied largely from beach sand-mining operations in Australia, South Africa, and India.

Conservation and future sources

Conservation of an ore deposit means the utilization of the deposit in such a way that the maximum amount of ore is ultimately mined. This means further that within reasonable economic limits the lower grades of ore are not sacrificed by mining methods that deplete too rapidly the higher grades for the sake of immediate monetary gain. Higher grades of ore are usually mixed with lower grades to average a uniform grade for the daily intake of a mill. The milling of highgrade ore only is seldom justified and frequently results in mining practices that preclude the subsequent recovery of large tonnages of lower grade. Such practices are infrequent, and mine management now generally fosters the long life of a mine.

Conservation is particularly important because ore deposits are nonrenewable natural resources. Although new ore deposits may continually be formed, they do so over periods of many thousands of years, commonly at depths of hundreds or thousands of feet; thus it is probable that the existing ore deposits are the only ones that man will ever be able to use. As known deposits have been depleted in the past, new ones have been found. To date these have been either extensions of known deposits, deposits that crop out in explored parts of the world but which hitherto have escaped discovery, or unexposed deposits lying just below a surface covered by soil or vegetation. As time goes on fewer of the exposed deposits will be found, and discovery will depend increasingly on geophysical and geochemical methods to find the hidden deposits. In those parts of the world that have not been explored and mapped in some detail on the ground, exposed ore deposits may be found for many years to come. Whether or not such deposits are mined will depend on their economic viability at the time of discovery.

Technological developments increasingly have made possible the economic mining of low-grade deposits. This trend may continue and in the future make available large low-grade deposits that are not mined today. Technological developments involving dredging, suction, and other methods may in the future be used to mine phosphate nodules from deeper parts of the ocean floor, and rutile, zircon, ilmenite, and gold from ancient beaches now under a shallow sea. Magnesium has been commercially extracted in large quantities from seawater for many years, but the vast volume of seawater required to produce relatively small quantities of most metals is an inhibiting factor.

The manufacturing of synthetic minerals used for their crystallographic or mineralogical properties will continue to be developed in the future; such synthetics include diamonds, sapphires, rubies, quartz, and certain micas.

This article treats the nature, origin, and classification of ore deposits, the kinds of earth processes that are involved in their formation, and the world distribution of the various types of deposits. For further information on the kinds of rocks and minerals of concern see IGNEOUS ROCKS; METAMORPHIC ROCKS; SEDIMENTARY ROCKS; MINERALS; and the several articles on individual mineral groups, such as NATIVE ELEMENTS; and SULFIDE MINERALS. See also GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES; ROCK METAMORPHISM, PRINCIPLES OF; and ROCK DEFORMATION for additional details on earth processes of relevance to ore formation.

NATURE, GENESIS, AND CLASSIFICATION OF ORE DEPOSITS

Size, shape, and depth distribution. Ore deposits show considerable variations in size, shape, and depth of occurrence. They can range in size from a few hundred to many hundreds of millions of tons of ore. High-grade vein deposits of the copper minerals chalcopyrite, bornite, and chalcocite, for example, will generally have considerably less tonnage than low-grade copper porphyry deposits containing the same minerals. The latter commonly contain tens of millions (some contain hundreds of millions) of tons of ore averaging a fraction of 1 percent copper by weight. This fraction, or average grade, is an important factor in evaluating the worth of the deposit and the viability of developing it as a mine. The range of grades found that can economically be mined are commonly 0.4–0.8 percent copper, but the economic limit or cutoff grade may subsequently be lowered by technological developments.

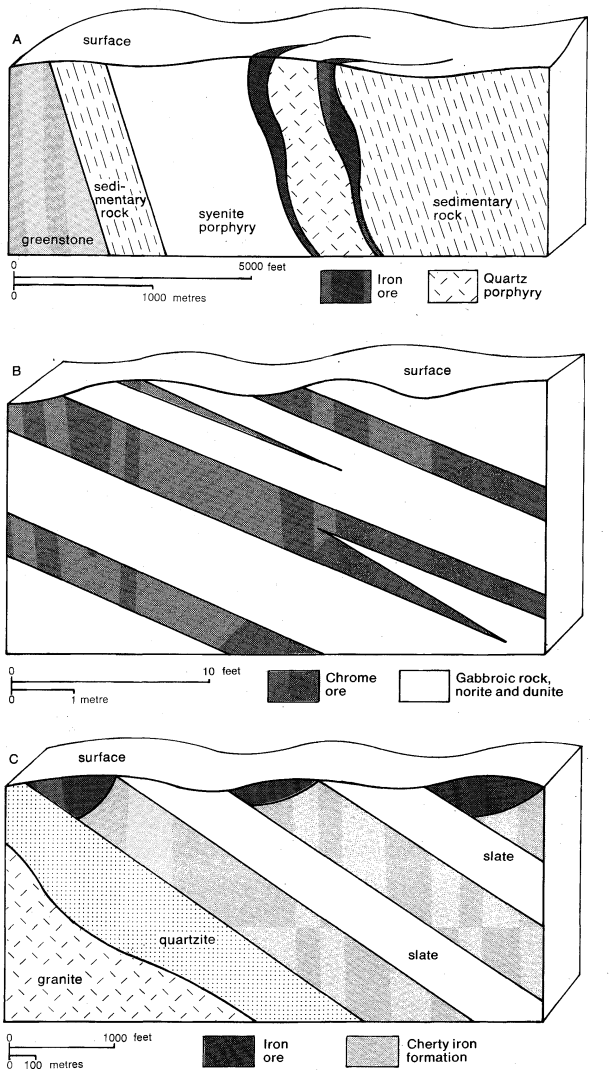

Figure 1: Deposits of (A) magnetic iron ore, Kiruna, Sweden; (B) chrome ore, Bushveld, South Africa; and (C) residual iron ore, Mesabi, Minnesota.

Iron-ore deposits

Iron-ore deposits, largely consisting of the iron oxide minerals magnetite and hematite, also show a great range in size depending on their nature and genesis. Deposits of magmatic origin such as the magnetite ores at Kiruna (Figure 1A) in Sweden, and of metasomatic (replacement of minerals by solution and redeposition) origin such as the magnetite ores at Cornwall, Pennsylvania, are small compared to the bedded deposits of residual origin such as the hematite ores of Lake Superior (Figure 1C) and Western Australia. The Kierunavaara Deposit, the largest in the Kiruna District, probably contains a few hundred million tons of iron averaging somewhat more than 60 percent iron by weight. The ore body is sill-like (that is, in the form of a tabular body that parallels the structures of host rocks) and has been emplaced between Precambrian (older than 570,000,000 years) syenite porphyry in the footwall and quartz porphyry in the hanging wall. The iron-ore deposits at Cornwall, Pennsylvania, lie within the contact-metasomic zone of Cambrian (500,000,000 to 570,000,000 years ago) limestone intruded by Triassic (190,000,000 to 225,000,000 years ago) igneous dikes (tabular intrusive body that cuts across host rock structures) and sills of quartz diabase. Associated with silicate minerals such as diopside, actinolite, and phlogopite, the iron ore consists mainly of magnetite that constitutes 40–60 percent of the ore. The ore body contains several tens of millions of tons of ore averaging slightly more than 40 percent iron by weight. The Lake Superior iron-ore deposits of hematite are residual ores formed in iron-rich beds of Precambrian metamorphosed sedimentary beds called banded iron formation (BIF). The iron originally was present within the beds as hematite and in the form of the iron silicate greenalite and the iron carbonate siderite. Weathering of the outcropping beds of iron formation and consequent alteration of the iron-bearing minerals to oxides has resulted in a concentration of hematite at and near the surface. These concentrations that form the ore deposits contain several thousand million tons of ore ranging in grade from 50 to 60 percent iron by weight. Similar iron-ore deposits in Western Australia have been formed by concentrations in Precambrian iron-bearing sedimentary beds. Several of these contain thousands of millions of tons of ore averaging more than 60 percent iron; the known cumulative reserves amount to approximately 20,000,000,000 tons of ore.

Fractures, fissures, and veins

Ore deposits have a variety of shapes. They may be formed as discrete veins and lenses, irregular masses, pipes or carrot-shaped bodies, networks of fractures, disseminations of minerals in crushed rock and sedimentary beds, or as sedimentary deposits themselves. Their shapes depend on their nature and genesis and on the stratigraphic and structural conditions that existed during their time of formation. Subsequent earth movements such as faulting and folding may displace or contort ore bodies, resulting in the development of zones of fracturing or crushing within the ore body in which further mineralization can take place. This sequence of formation of the minerals of an ore deposit is termed paragenesis.

A fissure vein (Figure 2A) is a fracture in the country rock that has been filled with minerals. Some of these minerals may be valuable, whereas others constitute

gangue. The vein material and the minimum quantity of adhering wall rock that must be mined with it constitutes ore. Mineralization of the space formed by a fracture may result in some cases from the forceful intrusion of magmatic differentiates; but most examples are hydrothermal in origin; that is, they have been formed by deposition of minerals from hot water and gaseous solutions moving through fractures in the country rock at depths of hundreds or thousands of feet. The force exerted by growing crystals, particularly by those aligned perpendicular to the walls of the fracture can force apart the walls of a fracture, thus creating more space for growth. The asbestos minerals chrysotile, crocidolite, and tremolite commonly form in this way.

Because the original fractures occupied by veins were formed by tension within the rock, they commonly show a relationship to the vectors of tension, or directions of forces, that caused them. This arrangement, known as a fracture pattern, indicates the orientation of these vectors and, consequently, the sense of displacement of the country rock by faulting or folding. Where there have been several periods of earth movements it may be difficult or impossible to unravel the sequence of fracture patterns. A common type of vein fills tension or gash-fractures, which may have an en echelon arrangment (essentially parallel and overlapping in plan view) due to the tension created by rotation of the rock mass in which they were formed. Other types of vein fillings are anastomosing (braided), subparallel, or fan-shaped, and commonly they are offset by numerous minor faults. The grade of ore within larger veins varies spatially. It may be higher near the footwall or hanging wall, and it may show variations with depth. Where the ore deposit consists of an interlacing network of veinlets less than an inch wide and a few feet long the entire rock mass is mined. Concentrations of mineralization within the veins that can be mined as richer ore are termed ore shoots.

(B) Saddle reef of gold ore (shaded) within a faulted fold of quartzite and slate.

Because they may be conspicuous at the surface, vein deposits have been mined since ancient times, particularly for copper and gold. Other minerals found in vein deposits in important mines in various parts of the world include native silver, lead, zinc, antimony, nickel, cobalt, mercury, uranium, and tungsten minerals.

Lenticular, irregular, and pipelike bodies

All veins terminate and many pinch out to form irregular, sheetlike bodies that are markedly elongate but lenticular in cross section. For this reason a clear-cut distinction cannot always be made between veins and lenses of ore. In some circumstances the ore deposits may be formed in distinct lenses or in lenticular bodies of quartz, examples being the saddle reefs (Figure 2B) of Bendigo, Australia. These gold-bearing deposits form inverted V-shaped lenses in the domes of anticlinal folds of Lower Ordovician (about 500,000,000 years ago) quartzites and slates. The quartzite tends to fracture rather than bend with folding, and the saddle reefs containing the ore are commonly found at or near the intersection of a fault with the trend of the fold. Saddle reefs containing gold ore are also found in association with folded beds of slate in the Salmon River District of Nova Scotia.

In some cases ore deposits form irregular masses that do not show any clear-cut stratigraphic or structural relationships. Some of these are the result of secondary and tertiary periods of deformation and mineralization that have obscured the original pattern. Other irregular masses, including some deposits of the manganese oxide minerals hausmannite and psilomelane, and the aluminum oxide minerals diaspore, gibbsite, and boehmite, which are collectively known as bauxite, have formed by a process of lateritization, or long-continued weathering (*q.v.*) *in situ* near the surface (Figure 3). Such irregular mass-

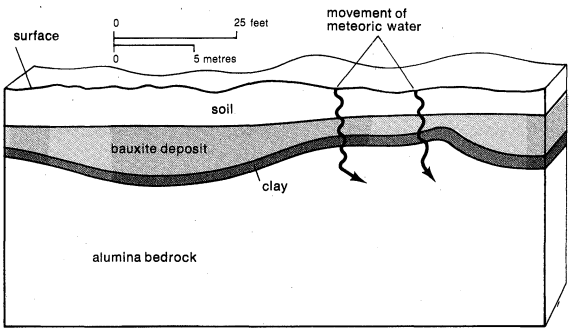

Figure 3: Relationship of bauxite deposit to alumina bedrock and overlying soil. Arrows indicate water percolation.

es may form disconnected pockets in the underlying bedrock, partly connected pockets, or irregular sheets commonly ranging in thickness up to 15 metres (50 feet). Lateritic deposits of the nickel silicate minerals garnierite and noumeite are also found.

Important lateritic deposits of manganese, aluminum, and nickel are mined in the following countries: manganese in the U.S.S.R., India, Brazil, South Africa, Morocco, China, Australia, and Ghana; aluminum in Australia, Guinea, and Jamaica; and nickel in New Caledonia and Cuba.

Pipes are irregular, cylindrical or funnel-shaped ore bodies that commonly extend vertically, or nearly so, to depths of hundreds or thousands of feet. They have been formed either as volcanic necks (central conduit of a former volcano) or as crushed zones bordering the intersection of the planes of two steeply dipping faults, fissures, or dikes. The diamond pipes of South Africa are carrot-shaped volcanic necks, up to 700 metres (2,300 feet) deep, tending to be oval near the surface but becoming narrower at depth. They consist of fragmental and weathered basic igneous rock termed kimberlite in which the diamonds are disseminated. Mining was carried out initially by open-pit operations and subsequently by underground methods. Other pipes, sometimes referred to as chimneys, are formed by various combinations of structure and stress that cause disruption of the country rock, by upward stoping (removal of rock) caused by solutions, or by the washing of rock debris into limestone caves. Consisting of brecciated rock, or rubble, these pipes have been channels for mineralizing solutions. Ore-bearing pipes are commonly less than 30 metres (100 feet) in diameter but may be several hundred feet in length.

Ore bodies formed by mineralizing solutions also can consist of disseminations of minerals in crushed or finely fractured rock and in porous limestone and sandstone. Porphyry copper deposits are in the former category. These consist of disseminated copper minerals in the crushed or cracked periphery of intrusive igneous bodies of granitic rocks such as quartz monozonite and diorite porphyry. Mineralization also extends into the intruded and disrupted country rock. These porphyry copper bodies, which commonly contain valuable amounts of molybdenum sulfide minerals, are large, low-grade deposits that are usually mined by giant open-pit operations. Irregular in shape, but tending to be tabular, porphyry copper deposits may have dimensions ranging up to several thousand feet horizontally and several hundred feet vertically. Large porphyry copper deposits are mined in the United States, the Solomon Islands, and Canada.

Ore bodies in sedimentary rocks

Ore bodies are also formed as irregularly shaped mineralized masses that have developed in zones of higher permeability through which mineralizing solutions have permeated beds of limestone or sandstone. In the U.S., Missouri, Oklahoma, and Kansas have notably large deposits of the zinc sulfide mineral sphalerite, associated with galena, a lead sulfide, in Cambrian dolomite. The ore deposits occur as patchy replacements in silicified zones of the dolomite; they are commonly tabular bodies 3 to 4.5 metres (10 to 15 feet) thick and several hundred feet wide.

Lead–zinc deposits of similar shape are found in Triassic dolomites of the Silesian region of Czechoslovakia and Poland. An irregular and tabular body of lead–zinc ore is also mined from a Devonian (345,000,000 to 395,000,000 years ago) limestone reef at Pine Point in northern Canada.

Ore deposits also are found in sandstone beds where they have formed by precipitation of ore minerals in the interstices between the grains of sandstone. The loci of deposition have been determined by variations in permeability of the sandstone, the mineralizing solutions moving more freely through certain portions of the bed and possibly in some cases by selective precipitation caused by the catalytic action of particular variations in the sedimentary content of the sandstone. As these factors are stratigraphic, they result in the formation of fairly regular, usually elongate and tabular bodies of ore lying parallel to the bedding.

In Zambia the disseminated copper sulfide mineralization, chiefly chalcocite, chalcopyrite, and bornite, within Lower Roan Group feldspathic sandstones, is characterized by uniformity over considerable distances, the ore deposits following the configuration of the folded sandstone beds. Other examples of ore deposits formed by mineralization of particular portions of a sandstone bed are the uranium—vanadium deposits in the Jurassic (136,000,000 to 190,000,000 years ago) Morrison Formation and the Triassic Chinle Formation and Shinarump Formation of the Colorado Plateau in the United States. The deposits were selectively developed within fluvial channels, forming sinuous belts of elongate ore bodies. Commonly associated with carbonized fossil wood fragments and plant material, the minerals form a complex association that includes the uranium minerals uraninite and brannerite and the vanadium minerals roscoelite and montroseite. The ore bodies are elongate and tabular, or podlike, commonly ranging in thickness up to 6 metres (20 feet) and in length up to 304 metres (1,000 feet). They are more or less parallel to the bedding but locally discordant.

Some very large ore deposits consist of minute particles of minerals disseminated in layers parallel to the bedding planes of a sedimentary rock. A few examples are the lead–zinc deposits containing the sulfide minerals galena and sphalerite disseminated in argillaceous sedimentary rocks, in the Gulf of Carpentaria and Mt. Isa areas of Australia; the Kupferschiefer copper deposits of Germany, which consist of black, bituminous shale that mainly contains finely divided particles of the copper sulfide minerals bornite, chalcocite, and chalcopyrite but also contains galena and sphalerite; and the cherty banded iron formations called taconite, itabirite, or jaspilite, consisting of disseminated hematite, magnetite, siderite, or greenalite, found in many parts of the world, including the Lake Superior region. These deposits (BIF) are tabular to sheetlike in shape, usually only a few feet thick, and in places may be traced along the layers of sediments for several miles.

Little is known about the precise depths at which ore deposits are formed or the maximum ranges of depth. Diamonds probably were formed as crystals in a basic kimberlite magma that was extruded upward, possibly from a depth of several miles, into volcanic pipes that form the ore deposits today. Sulfide minerals are formed within a depth range of several hundred to many thousands of feet. The limit of depth probably varies geographically and certainly depends on the limiting depth of fracturing and circulation of water vapour. Many ore deposits probably form within a temperature range of 300°–500° C (570°–930° F) and at depths of up to 16 kilometres (10 miles).

Geochemistry and mineralogy. The geochemistry of an ore deposit includes the physicochemical reactions involved in the formation of individual minerals, and mineralogy is the study of those minerals and their physical and crystallographic properties. Studies of the genesis of ore deposits, of the relationships of ore deposits to the depths and temperatures at which they formed, and to the petrology of country rock, therefore involve geochemistry and mineralogy. Many variations of physicochemical processes can be involved in the genesis of an ore deposit, which may involve several episodes of mineralization. A few examples are discussed here.

Physicochemical processes of importance

The Kiruna iron ore deposits in Sweden consist of magnetite and fluorapatite that appear to have first formed as a magmatic differentiate in the form of an immiscible magnetite–apatite liquid melt. Forceful intrusion of this melt into fractures in the country rock resulted in the formation of the ore deposits. The geochemistry of this deposit is clearly related to the physicochemical properties of solutions in molten rocks and the minerals that can crystallize from them under certain conditions of temperature and pressure.

The hot volatile gases, including water vapour, given off by molten magma intruding the country rock are important mineralizing agents. Permeating the country rock through fissures and brecciated zones above the intruding magma, these aqueous and gaseous solutions deposit minerals as they become cooler. There are many examples of ore deposits formed as veins, stockworks, or disseminations by high-temperature (hypothermal), medium-temperature (mesothermal), and low-temperature (epithermal) solutions.

Residual ore deposits of the manganese oxides psilomelane and hausmannite, and of the aluminum oxides collectively referred to as bauxite, are formed by chemical processes in the weathering *in situ* of soil, subsoil, and underlying alumina-rich or manganiferous rock. These processes are not thoroughly understood but are known to be the result of meteoric water (water of atmospheric origin) penetrating downward, removing silica and leaving a concentration of manganese or aluminum oxides. The drainage of meteoric waters through the soil and into streams and rivers results in the solution and transportation of minute amounts of elements such as copper, lead, and zinc that are in the surficial material derived from the weathering of underlying mineralized rocks; these elements can be detected by chemical or spectrometer analyses. In the search for ore deposits, particularly those that are hidden by soil and vegetation, geochemical surveys that collect and analyze soil and water samples are among the principal methods employed.

Geochemistry also is a factor in the formation of sedimentary ore deposits, referred to as syngenetic deposits. Some of these may have formed originally as mechanical concentrations of mineral particles within the sediments. There is evidence, for example, that the gold in the conglomerate beds of Witwatersrand in South Africa was emplaced as a placer deposit, although it subsequently has been partly redistributed. Similar evidence can be shown for the origin of the uranium in conglomerate beds of the Blind River area in Canada. But other deposits, with the possible inclusion of the lead–zinc mineralization in the Gulf of Carpentaria and Mt. Isa areas of Australia, appear to have formed by the contemporaneous deposition of metallic sulfides with the sediments. Deposition of lead and zinc sulfides in mud are known to be taking place in certain low areas of the Red Sea floor where water of higher salinity and density is concentrated. The physicochemistry and possible biochemistry involved in such processes is under study, and the stratigraphic implications, insofar as exploration for ore deposits is concerned, are far-reaching.

Temperatures and pressures of formation. Ore deposits have been formed under great ranges of temperature and pressure, depending on depth. Magmatic segregation deposits resulting from the differentiation within a molten

magma of immiscible melts, such as that believed to have formed the magnetite–apatite deposits at Kiruna in Sweden, have originated under conditions of very high temperature and pressure. Another example of an ore magma is a sill-like body of magnetite and hematite with minor amounts of apatite at Lago Sur in northern Chile. These metallic facies (aspects) of magmas are not common at the eroded surface of the earth's crust but may be more abundant at depth. It is not known whether they also include metallic sulfides or are confined to the oxides.

Allied to deposits formed by ore magmas are the tabular to lenticular chromite deposits of Cuba, which are thought to have originated as a crystal mush of ore magma and chromite crystals injected into the country rock. Other chromite deposits that seem to have had a similar origin are those of South Africa (Figure 1B) and Turkey.

The temperature ranges under which ore magmas are emplaced exceed 500° C, in many cases probably by several hundred degrees. The pressure ranges are in the order of several thousand pounds per square inch. Temperature and pressure ranges obtained during the formation of ore deposits of hydrothermal origin are generally lower.

Hydrostatic gradients and mineral precipitation

T.S. Lovering, U.S. economic geologist, says

> Of many physical factors that may induce precipitation, changes in temperature and pressure seem the only ones likely to be important during ore deposition. It is generally assumed that pressure increases directly with depth, and rock pressure at any specified depth below the surface is usually calculated as equal to the weight of the column of rock above it. Similarly, it has been assumed that the pressure of a mineralizing solution at any point below the surface corresponds to the hydrostatic head existing at that depth. It should be noted that pressure on a small area is transmitted in an outward flaring cone of diminishing intensity and it is thus possible for pressure to build up in a localized area that is greatly in excess of the rock pressure calculated for that depth. Although the pressure gradient in an open channel filled with liquid is approximately the hydrostatic head of any given depth, this is not true of a hypogene solution passing through a conduit that has marked constrictions between the point of entrance and the exit of the fluid. At any place the pressure is that of the hydrostatic head plus the driving force required to overcome friction. Below a marked constriction the pressure may be very much in excess of that above it, resulting in a rapid change of pressure. In any conduit the steepest pressure gradient would be at the greatest constriction. The places of greatest constriction may change from time to time because of mineral deposition, mineralization stoping, or intramineralization movements, and the sudden access to a new channel may move the position of the steepest pressure gradient either toward or away from the source of the solution.

From the foregoing it is evident that the pressure–temperature relationships that obtain during the formation of an ore deposit can be complex. Geothermal gradients vary from place to place and may be in excess of 1° C (2° F) per 100 feet of depth. Hydrostatic gradients depend on the density, or salinity, of the underground water and are commonly in the range 40–45 pounds per square inch per 100 feet (3 kilograms per square centimetre per 30 metres) of depth. Geostatic or rock pressures are two to three times the hydrostatic pressures at the same depth.

Paragenesis of ore minerals. Paragenesis means the sequential order in which various minerals within an ore deposit are formed. Variations in temperature, pressure, and chemical constituents of a mineralizing solution will result in the precipitation of different minerals at different times within the same deposit. Further complications in paragenesis arise where the ore deposit has been formed by more than one period of hydrothermal activity. A simple example of paragenesis can be seen where minerals line the walls of a fissure or cavity (Figure 2A). The earliest formed minerals grow inward from the wall rock forming an outer layer, and later formed minerals grow as inner layers or rings filling the void. More complex relationships are seen by examination of polished sections of ore under the microscope, which shows the manner and sequence in which crystallization and replacement of one ore mineral by another have occurred.

Studies of many hydrothermal ore deposits throughout the world have established a general sequence of mineral deposition based on mineral stability ranges. Commonly, the first minerals formed are silicates and carbonates, which constitute gangue. Of these, quartz and calcite, both of which are common in ore deposits, continue to be deposited during the later stages of development. The minerals chlorite, sericite, tourmaline, albite, adularia, barite, siderite, fluorite, ankerite, and rhodochrosite are also formed at an early stage. Secondly, the oxide minerals magnetite, ilmenite, chromite, specularite, and uraninite are formed. Thirdly, the minerals pyrite, arsenopyrite, cassiterite, tantalite, wolframite, molybdenite, pyrrhotite, pentlandite, and the nickel and cobalt arsenides are crystallized. Fourthly, the minerals chalcocite, bornite, chalcopyrite, sphalerite, galena, native silver, gold, the tellurides, stibnite and cinnabar are precipitated. This arrangement shows that in general the oxides are deposited early; that the sulfides and arsenides of iron, nickel, cobalt, and molybdenum are contemporaneous with or slightly younger than the oxides; and that the sulfides of lead and zinc are even younger. Later, the native metals and tellurides are formed, and the last to be deposited are antimony and mercury sulfides.

Sequence of mineral deposition

Related to paragenesis is the zoning of ore deposits (Figure 4). As mineralizing solutions move through channels in the rock they undergo changes in temperature, pressure, and chemical composition that may result in the deposition of different mineral concentrations at increasing distances along the course of deposition, and presumably from the magmatic source. This zoning is common but is not always present in ore deposits. In general, minerals of tin, tungsten, and bismuth lie closer to the magmatic sources of the mineralizing solutions than do those of the copper minerals. Lead and zinc minerals are more distant; native gold and silver, and minerals of gold and silver, are still farther away; and the most distant of all from their source are the minerals of antimony and mercury.

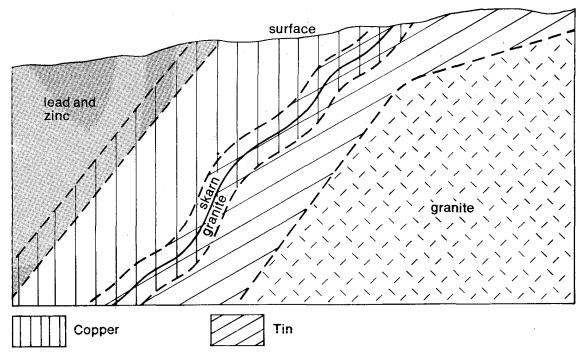

Figure 4: Relationship of mineralized zones to the granite from which the mineralizing solutions are believed to have emanated.

Experimental models. Some of the conditions under which minerals are formed can be simulated in the laboratory. Very high temperatures can be attained in electric furnaces and very high pressures in pressure bombs. But time, a factor in forming ore deposits that is measured in hundreds or thousands of years, cannot be duplicated. The physicochemical conditions required to form certain minerals have been determined, with some limitations, by means of synthesis. Much of the experimental work on synthesis of minerals has been carried out with dry components, under conditions that do not exist in nature. One method is to heat certain components in a closed container, under constant pressure. The lowest temperature at which a particular mineral will crystallize at a constant which minerals are formed can be simulated in the labo-pressure is taken as a control point. A series of control points determined at various pressures can then be shown graphically. These and similar approaches to geothermometry are limited and equivocal in their application to the understanding of the formation of ore deposits.

Geothermometry and mineral inclusions

The determination of melting points for magnetite and chromite may give an approximation of the temperature

at which certain magmatic ores were formed. Certain inversion points (conditions at phase changes), such as that of the silver sulfide system, are reliable indicators of the temperatures at which ore deposits were formed. Silver sulfide, for example, changes at about 180° C (365° F) from the isometric (possessing three equal and mutually perpendicular crystal axes) crystal form known as the mineral argentite, which is stable at high temperatures, to the monoclinic (one crystal axis is inclined) mineral acanthite, which is stable at low temperatures.

Some minerals formed at high temperatures contain impurities, which, as the mineral cools, will crystallize out as laminae and blebs (small, irregular masses) of other minerals within the original crystal. This process, known as exsolution, takes place at certain temperatures for each mineral; the resulting relationships can be observed in polished sections or thin sections under the microscope and are also useful indicators of the temperature range under which an ore deposit was formed.

Another method of determining the temperature of ore formation involves the study of fluid inclusions in vacuoles (enclosed cavities) within a crystallized mineral. It is inferred that at the time of growth of the crystal the vacuoles were filled with gas. At room temperature the vacuoles are filled with liquid and gas. Where the inclusion is more than half liquid, it is inferred that the mineralizing solution forming the ore was hydrothermal (a high-temperature liquid solution); and where it is mainly gas, that the solution was pneumatolytic (gaseous). On heating the crystal the fluid within a vacuole will disappear as a single gaseous phase is reached at a certain temperature. This is considered to be the minimum temperature at which the mineral could have formed.

These and other experimental methods have been applied to particular ore deposits with fairly consistent results and may be useful in solving some problems of hydrothermal versus syngenetic origin.

Genetic and other classifications. To be useful, a classification of ore deposits must be simple and usable in the field. Unfortunately, ore deposits cannot always be clearly defined by type. In many cases they have been formed by complex physicochemical processes, and in some cases their genesis is still in question. Classifications can be derived from the agents that form ore deposits, such as magmas, hydrothermal solutions, pneumatolytic solutions, syngenetic processes such as precipitation in a body of water, weathering, and mechanical processes. Other classifications can be built on temperature and depth relationships, on stratigraphic and structural relationships, and on mineralogical and chemical relationships. Each classification may satisfy certain categories of ore deposits, but any comprehensive classification of all ore deposits must of necessity be general and, consequently, of limited application.

Bases and limitations of classifications

There are three broad classifications of ore deposits in use. The Niggli classification has two main divisions, namely plutonic, or intrusive, and volcanic, or extrusive. The former division has three categories: orthomagmatic, pneumatolytic to pegmatitic, and hydrothermal. The Schneiderhöhn classification has four main divisions: intrusive and liquid-magmatic, pneumatolytic, hydrothermal, and exhalation. The Lindgren classification has two primary divisions: deposits produced by chemical processes and deposits produced by mechanical processes. The first division contains three categories: ore deposits formed by differentiation in magmas, ore deposits formed in bodies of rock, and ore deposits formed in bodies of water.

Whatever classification is used, the critical point is that it must serve a purpose. Each classification has its limitations and is subject to modifications.

EARTH PROCESSES INVOLVED IN THE FORMATION AND DISTRIBUTION OF ORE DEPOSITS

Magmatic concentration. Magma is molten rock at depth; when it rises to the surface through fissures and volcanic vents it is called lava. Lava cools quickly and is consequently fine grained to glassy, or frothy like pumice. Magma cools slowly and is medium to coarse grained. As the temperature of a magma is lowered the melting points of various minerals that can exist in equilibrium with the melt are reached in a known sequence. In a basic magma, namely, one high in ferromagnesian constituents, the accessory minerals apatite, magnetite, ilmenite, chromite, titanite, rutile, and zircon are the first to crystallize, followed closely by essential silicates such as olivine and the orthorhombic pyroxenes. Other silicate minerals such as the clinopyroxenes (those crystallizing in the monoclinic crystal system) and plagioclase crystallize later.

Where cooling proceeds very slowly the earliest crystals to form, particularly magnetite, chromite, and apatite, are able to settle by gravitation through the magma and so become concentrated. Stresses resulting in the flow of magma may cause further concentration by squeezing off the liquid fraction from the crystalline mush, a process known as filter-pressing.

Concentrations of magnetite and chromite formed as magmatic concentrations are typically within sill-like, dikelike, or lenticular bodies of basic igneous rock. But whether they originated as the result of differential crystallization and concentration of the early formed crystals of magnetite and chromite by means of gravitational settling or filter pressing, or whether they originated as the result of magmatic differentiation is not always clearly indicated by the ore deposits.

From A.M. Bateman, *Economic Mineral Deposits* (1954); John Wiley & Sons, Inc.

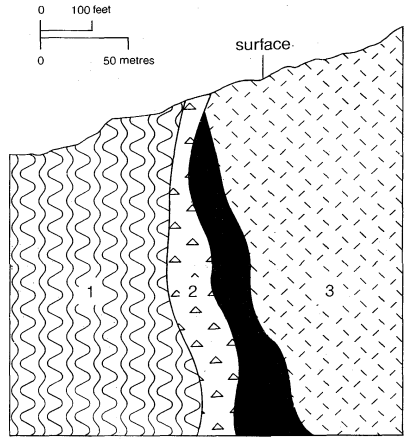

Figure 5: Hydrothermal deposit of massive pyritic copper ore (solid black) forming a lens in (3) sheared quartz porphyry that intrudes (1) slate and is in turn cut by (2) a dolerite dike, Río Tinto, Spain.

Differentiation within the magma itself can result in the separation of distinct melts of the oxides magnetite and chromite with apatite and olivine. The immiscibility of a magnetite–apatite fluid within a silicate melt has been demonstrated in the laboratory, and field investigations have led to the belief that the same segregation can take place in nature. What is not known is the extent to which magmatic differentiation can occur with reference to sulfide and silicate melts. Magmatic segregation processes and hydrothermal activity are to some extent overlapping, and this is of importance in the interpretation of certain sulfide deposits. Massive sulfide or arsenide bodies, such as those of the Río Tinto District, Spain, and the Sudbury District, Ontario, were for many years considered to be direct products of magmatic segregation. With regard to Sudbury, the original hypothesis was discarded in favour of a hydrothermal theory, because the ores did not seem to be simple fractions of magmatic differentiation. Studies of ore localization indicated that the sulfide ores were related to fractures and other structural features. Later investigations led to a compromise. The essential nature of the problem is that the ore deposited by magmatic segregation may subsequently be remobilized during metamorphism and igneous intrusions. Hence, the deposits actually have a dual origin. This may also be true of the copper deposits at Río Tinto (Figure 5), which may have in part originated as sulfide melts.

Magmatic differentiation and segregation

Contact metasomatism. Metasomatism means replacement, and commonly refers to the replacement of a volume of rock by an aggregate of minerals (Figure 6). This replacement can be on a microscopic or megascopic scale and may preserve the external shape and internal features of the original rock. Selective replacement of certain layers and laminae within a rock can occur, and some examples have given rise to controversy over the criteria by which such selective replacement and syngenetic deposition can be distinguished.

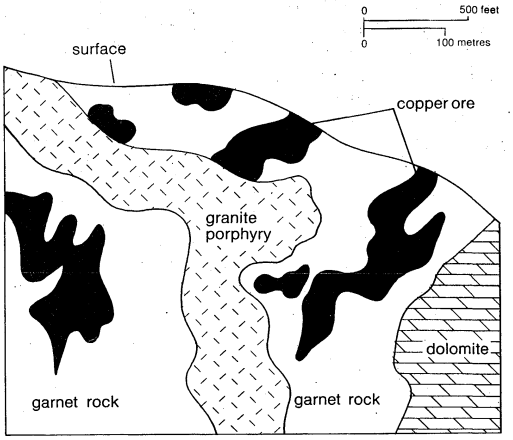

Figure 6: Contact-metasomatic deposit of copper ore (solid black) in garnet rock that has been formed as an alteration product of dolomite by the intrusion of granite porphyry.

The means by which such replacement takes place are not well understood but are thought to be caused by the diffusion of hydrothermal and pneumatolitic solutions that selectively dissolve the country rock and deposit an aggregate of minerals in its place. This mineralization can consist of gangue minerals only, such as carbonates and silicates, or of ore minerals associated with the gangue. The chemical reactions upon which deposition depends are in part controlled by the chemical composition of the rock replaced, in part by the chemical composition of the mineralizing fluids or gases, and in part by temperatures and pressure. When the temperature exceeds the critical temperature of water, the mineralizing solution is gaseous, regardless of pressure, and highly penetrating. Rocks that have very low permeability to water at surface temperatures are capable of absorbing water vapour like a sponge at high temperatures. The vapour penetrates the rock through intergranular interstices, minute fractures, and other openings that allow it to replace and mineralize the rock by diffusion.

The problem of volume-for-volume replacement

One problem that has always intrigued geologists is the question of how a large volume of rock can be removed by the same solutions that deposit the ore body. This replacement is generally volume for volume, although the replacement of one mineral by another usually results in a change of crystal volume. Where limestone is dolomitized by magnesia-rich solutions, for example, the volume of rock altered may remain the same, although replacement of the mineral calcite by the mineral dolomite, involving replacement of calcium by magnesium in the crystal structure of the carbonate mineral calcite, causes a shrinkage of crystal volume. This shrinkage is taken up within the volume of rock itself as an increase in pore or intergranular space.

The term contact metasomatism implies replacement of the country rock in contact with an intrusive body of magma. The mineralogic changes and the distance at which these changes are effected from the intrusive body depend on many factors, including the chemical composition, water-vapour content, and temperature of the magma, and the chemical composition and permeability of the intruded country rock. Intrusion of a quartz sandstone will result only in silicification, by infilling of intergranular space with quartz or recrystallization of the quartz grains, to a quartzite. Intrusion of a pure limestone may result only in recrystallization of the calcium carbonate to marble or in the diffusion of iron and magnesia-rich solutions that will react with the calcium carbonate to form an assemblage of calcium–magnesium silicates and oxides, including actinolite, tremolite, wollastonite, epidote, diopside, scapolite, grossularite, garnet, and magnetite. Some important iron-ore deposits of magnetite and hematite—such as those at Cornwall, Pennsylvania; Iron Mountain, New Mexico; and Iron Springs, Utah—were formed by the replacement of limestone intruded by basic igneous rocks.

Ore deposits of the platinum arsenide mineral sperrylite, associated with the copper and nickel sulfide minerals chalcopyrite and pentlandite, have been formed by contact metasomatism where norite has intruded the carbonate rock dolomite and banded ironstone, in the Bushveld Complex of South Africa.

The tungsten mineral scheelite is associated with grossularite garnet and epidote in contact metasomatic deposits formed by the replacement of limestone beds intruded by granodiorite at Mill City, Nevada. One of the largest deposits of scheelite in the world, on King Island, Australia, is also of contact-metasomatic origin and was formed by the replacement of dolomite, intruded by granite, with a skarn containing garnet, pyroxene, and scheelite.

It is not always possible to differentiate clearly between contact metasomatism and subsequent hydrothermal alteration. Some metalliferous deposits, including certain of the copper sulfide deposits at Bisbee, Arizona, and a deposit of the zinc sulfide mineral sphalerite at Hanover, New Mexico, are of contact-metasomatic origin. Other deposits of copper, lead, and zinc sulfides form ore bodies in skarn (a garnetiferous silicate rock) as the result of secondary mineralization and partial replacement of the skarn. These ore bodies may be the result of subsequent hydrothermal and pneumatolytic mineralization rather than primary contact metasomatism.

Hydrothermal processes. Hydrothermal processes are the physicochemical means by which hot aqueous solutions effect alterations and replacement of rock, such as sericitization (a form of feldspar alteration), silicification, and sulfide mineralization (Figures 7, 8), along

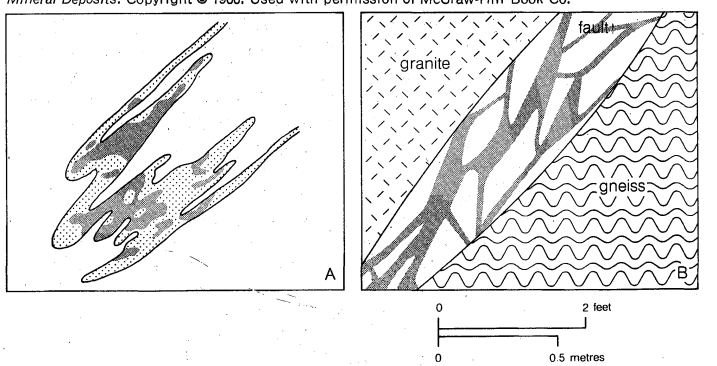

Figure 7: *Hydrothermal processes.*
(A) Plan view on 3,050-foot level of hydrothermal deposits of gold ore (shaded) in folded beds (stippled), Homestake Mine, South Dakota. (B) Hydrothermal deposit of zinc ore (shaded) forming a vein in crushed granite along a fault between gneiss and granite, Georgetown, Colorado.

the channels and zones through which the solutions move. Hydrothermal solutions have been classified as epithermal with an upper limit of 200° C, mesothermal with a limit of 300° C, and hypothermal in the range of 300°–500° C. These limits are arbitrary, and there is no clear distinction between the hypothermal range of hydrothermal solutions and pneumatolytic solutions.

Hot-water brines

Hot-water solutions, particularly heavy brines, are known to carry in solution exceptionally high concentrations of metals. Samples of sediments taken from highly saline depressions in the Red Sea floor contain metallic sulfides, and anomalous concentrations of heavy metals, produced at a depth of over 1,520 metres (5,000 feet) in

the Salton Sea area, California, represent a similar case. The brine, at a temperature exceeding 300° C (570° F), contains copper, silver, potassium, lithium, antimony, lead, arsenic, boron, beryllium, bismuth, gallium, and gold. On cooling through a discharge pipe, a dark, siliceous sludge was formed that contained 20 percent copper and 2 percent silver. During a period of three months an estimated five to eight tons of sludge was formed. Such a solution moving upward through fractures serving as conduits or pipes would deposit copper, silver, and other minerals.

Pure water is not a good solvent. With increasing alkalinity, commonly resulting from higher contents of sodium and potassium carbonates, the ability of a hot-water solution to dissolve quartz and other constituents in the rock is greatly increased, particularly under high pressure and temperature. The source of such hydrothermal solutions is not always easy to define, but probably all were originally meteoric waters that seeped down through crevices into hot parts of the earth's crust, to be subsequently forced upward by tectonic (vertical motions of the earth's crust) and magmatic forces, or else were connate (original or primeval) waters trapped with the original sediments and subsequently mobilized during metamorphism of the sedimentary rocks.

Of particular significance to ideas concerning the movement of hydrothermal solutions at depth is the realization in recent years, resulting from experimental work and field observations, that fluids under high pressure can fracture the enclosing rock and so inject themselves into zones of lower pressure. This process may account for some mineralized veins formed in fractures.

Sericitization and silicification are common processes in wall rock alteration associated with mineral deposits. Hydrothermal solutions permeate the adjacent country rock, altering or replacing it by removing certain constituents and depositing the minerals sericite, chlorite, and quartz. Sericite is more common in mesothermal deposits; the more abundant chlorite has a greater temperature range

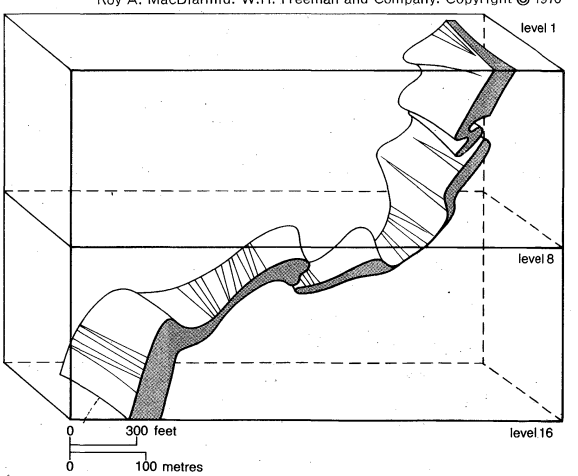

Figure 8: Hydrothermal deposit of massive lead–zinc–copper ore forming connected lenses along a pipelike body of aplitic rock intrusive into dolomite. Levels shown indicate principal zones of mining.

but is particularly common in epithermal deposits. Silicification of carbonate rocks and shales associated with ore deposits can form jasperoid, a cryptocrystalline silica that has the appearance of reddish chert, or a hard, fine-grained brittle rock.

Sublimation and evaporation. Sublimation is the volatilization of a solid by means of heat. On cooling, the vapour is deposited as an amorphous solid or as crystals.

Fumarole deposition

Sublimation of sulfur occurs in the fumaroles of volcanoes. Many nonvolatile substances can be dissolved and transferred by water vapour at high temperature, and it is not always possible to define clearly mineralization effected by sublimation and that effected by pneumatolytic or gaseous action. For example, incrustation of minerals in the fumaroles of the Valley of Ten Thousand Smokes, Alaska, contain magnetite in the early phase and galena and sphalerite in the later stages. Fluorides, borates, and other sulfides also are present, having been deposited by gaseous exhalations from hot, rhyolitic pyroclastics (rocks consisting of volcanic ejecta). These exhalations contained a high percentage of superheated steam. Other solid hydrocarbons, including gilsonite, wurtzilite, and grahamite are found as veins, the origin of which is now known. They may have been formed by some pneumatolytic process, the hydrocarbons being derived from a deep-seated source. Large veins of gilsonite are mined in Utah. The products include high-quality carbon used as anodes in the electrolytic production of aluminum ingots, gasoline, and other petroleum products used in a variety of industrial processes. Certain nonvolatile hydrocarbons, insoluble in organic solvents, and known as pyrobitumens because of their possible origin as sublimates, are found as disseminations in cavities and fissures in sedimentary rocks.

Evaporite deposition

Evaporation has been one important process in the formation of certain mineral deposits such as beds of calcium, sodium, magnesium, and potassium salts; but it is not a process that, by definition, forms ore deposits. A salt bed has no appreciable gangue, whereas an ore consists of valuable minerals that must be separated from the nonvaluable gangue. Salt beds, including common salt known as the mineral halite, are either mined or exploited by injecting hot water through bore holes and pumping up the resulting brine. Important mineral deposits of salts, including gypsum, halite, carnallite, kieserite, and sylvite, are found in many parts of the world.

Salt beds, referred to as evaporites are bedded deposits. Subsequent deformation of the enclosing sedimentary beds and solution and redeposition of the salts have in many places formed irregular or dome-shaped bodies of salt. The genesis of salt beds apparently requires conditions in which a shallow and restricted sea is subject to rapid evaporation together with continual replenishment of seawater. Deepwater origin is also possible (see EVAPORITES). Salt beds are commonly associated with primary dolomite formed by magnesia-rich seawater altering the calcium carbonate mineral aragonite, precipitated as carbonate ooze, to the calcium-magnesium carbonate mineral dolomite.

Precipitation. Precipitation means the deposition of a substance or mineral from a solution. This process has taken place in the formation of many hydrothermal deposits, particularly in the zones of secondary enrichment, and also in the formation of certain deposits on the sea floor, such as concentrations of phosphatic and manganiferous nodules. Precipitation of the sulfides of base metals is known to occur in localities on the floor of the Red Sea, where the salinity is abnormally high; and syngenetic deposits in sedimentary beds, believed to have possibly formed in this way, have been described in many parts of the world.

Precipitation in seawater

Precipitation does not imply crystal growth. The assemblage of minerals in many deposits has formed as crystals growing in a mineralizing solution. Precipitation does imply the deposition of minute crystals or colloidal particles. This process can involve rapid changes of temperature. Where the sea over shallow carbonate banks and reefs is warmed by the sun, for example, white patches caused by the sudden precipitation of minute crystals of aragonite have been observed to form suddenly. Warming of the water causes the release of dissolved carbon dioxide, which in turn lowers the solubility of calcium carbonate in seawater. As the saturation point is reached, precipitation takes place.

A well-known reaction is the precipitation of colloids on mixing with salt water. This may take place where river water mingles with the sea, or where there occur changes in salinity and temperature of the sea itself. Precipitation of colloids is a common reaction in the supergene zone of secondary enrichment and is indicated by the development of radiating and colloform structures, and rare dessication cracks in nodules and encrusting masses of minerals. Colloform structure has been observed in bauxite,

psilomelane, garnierite, chrysocolla, malachite, pitchblende, chalcedonic quartz and opal, marcasite, cassiterite, and other minerals. The precipitated colloidal particles coagulate to form a gel that subsequently hardens by loss of water. Reduction in volume may take place with the development of dessication cracks; but as these are not always apparent it is postulated that where hardening of a layer takes place before deposition of the overlying layer, no reduction in volume occurs. Among the classic examples of colloidal origin for ore deposits are the lead–zinc deposits of Upper Silesia in Poland, where the galena and sphalerite occur in dolomitized limestone; and the sulfide ores on the islands of Honshu and Hokkaido, Japan, which include chalcopyrite, sphalerite, galena, martite, and tetrahedrite in brecciated and altered volcanic and sedimentary rocks.

Sedimentation and mechanical concentration. Bedded mineral deposits of salts are products of sedimentation, as are diatomite, calcium-rich limestone, and some beds of phosphatic rock. These are mineral deposits, but they are distinguished from ore deposits on the basis of their lack of gangue. Diatomite is formed by the accumulation of siliceous skeletons of diatoms that rain down through the sea. Limestone and phosphatic rock are formed by depositional processes that include the accumulation of particles of sediment and the precipitation of ooze.

In some cases, precipitation of minerals has resulted in the formation of deposits that cannot be defined clearly as mineral deposits or ore deposits, such as the iron and manganese oxides formed in beds and restricted lakes. These have been formed by the precipitation of hydroxides, subsequently converted to oxides and carbonates of iron and manganese. A classic example, among the large manganese deposits of the world, is the Chiaturi Deposit of the Caucasus Mountains, U.S.S.R. This consists of oolitic pyrolusite and psilomelane, with the iron oxide mineral braunite, in a bed of marly sand of Oligocene age (about 26,000,000 to 38,000,000 years old).

Other syngenetic accumulations of minerals in sediments, such as those formed by the precipitation of sulfides of base metals, are defined as ore deposits because they require separation from the rock material. In many cases, later fracturing of the syngenetic deposit has resulted in partial solution of the sulfides and deposition within the fractures as secondary mineralization, which clearly places the deposit in the category of an ore deposit. In some syngenetic deposits—for example in the Gulf of Carpentaria area of Australia, where there are very large deposits of disseminated galena and sphalerite in metamorphosed sedimentary rocks—the sulfide particles are so fine that separation from the rock has proved extremely difficult in the milling process.

Placer deposits

Mechanical processes of sedimentation are also important agents in forming some types of ore deposits. Placer deposits of gold, the platinum metals, diamonds and other gemstones, cassiterite, rutile, and zircon are mined in many parts of the world. Some of these deposits are in modern or ancient river gravels, others are in beach sands. They have been formed by the mechanical action of moving sand and gravel transporting the mineral particles of higher density and winnowing them into concentrations.

Important placer gold deposits have been found worldwide, but those of platinum are mainly in the Ural Mountains, U.S.S.R. Large alluvial diamond deposits have been mined in Sierra Leone, Ghana, South Africa, South West Africa, and Zaire, and alluvial deposits of cassiterite in Malaysia. Among the large alluvial deposits of rutile and zircon are those found in the beach sands of Queensland, New South Wales, and Western Australia.

Residual deposits. Residual ore deposits are formed as concentrations of minerals at or near the surface by chemical decomposition and mechanical disintegration of the country rock or ore deposit in which they are contained. This definition includes laterite deposits, which, strictly speaking, are products formed from residue. Lateritic material and residue, whether formed by chemical or mechanical processes, are essentially concentrations formed *in situ*. Chemical decomposition of alumina-rich country rock, produced by weathering in a warm, humid environment where vegetation cover prevents mechanical disintegration and erosion, results in the formation of hydrated aluminum oxides known collectively as bauxite. The chemical reactions are not well understood, but they involve the removal of silica by downward percolating meteoric water. Underlying the bauxite deposits, and separating them from the decomposed bedrock, there is invariably present a layer of clay. It is probable that chemical decomposition of the rock forms clay that is subsequently converted to bauxite. Among the large bauxite deposits of the world are those of Australia, Guyana, and Jamaica.

Formation of bauxite and other deposits by weathering processes

Large residual deposits of manganese oxides formed by the chemical decomposition of manganiferous rocks are mined in India, Ghana, and Morocco. The ores of this type in India and Ghana are formed from the decomposition of metamorphic rocks called schists, which contain spessartite garnet, and other manganiferous silicates. The Moroccan deposits have been formed by decomposition of the sedimentary rock dolomite, which contains manganese carbonates. Other important residual ore deposits are those of nickel silicates, including garnierite, in New Caledonia, the Philippines, and Cuba. These have been derived from the weathering of nickeliferous serpentine, which is a soapstone type of rock formed as an alteration product of ultramafic igneous rocks such as dunite and gabbro.

Extremely rich deposits of gold ore have been mined in gossan deposits (oxidized cappings) formed at the surface by the weathering and consequent chemical decomposition of gold-bearing mineralized zones. The gold is resistant to chemical alteration and thus becomes concentrated downward *in situ* while other minerals, including the gangue, are removed by solution. Gossans are characterized by their vugular structure (cavities and cavity fillings) and rusty appearance caused by the abundance of limonite, a mixture of the hydrous iron oxide minerals goethite and lepidocrocite. Although such concentrations of gold result from chemical decomposition of the enclosing ore body, they are essentially formed by the physical movement downward of gold particles. Deposits of kyanite in India, forming surficial concentrations resulting from the weathering of a kyanite–quartz granulite, and deposits in the United States formed from the weathering of kyanite schist, have been mined.

Supergene or secondary enrichment. Supergene minerals are those that have formed during a period of secondary mineralization by the alteration of primary min-

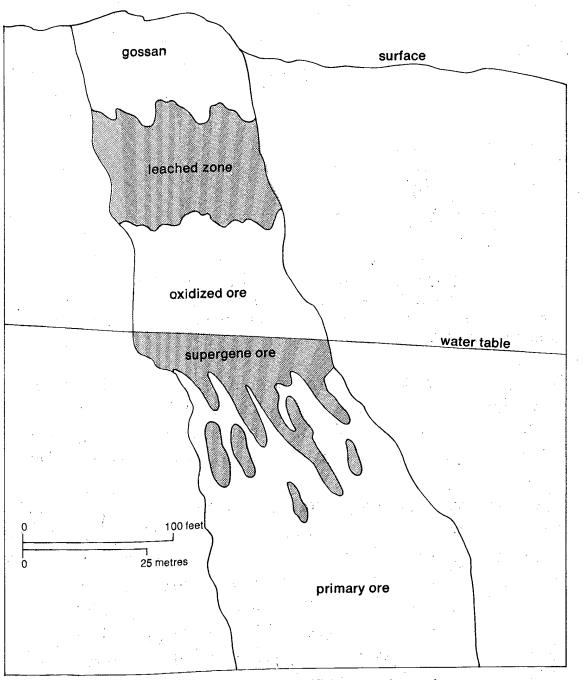

Figure 9: Supergene or secondary sulfide ore deposit (see text).

erals. They are alteration products that have commonly formed near the surface by the action of weathering and descending meteoric water (Figure 9). Where an ore body extends to the surface and weathers *in situ* a gossan is formed in the zone of oxidation above the water table. Meteoric water seeping downward through the zone of oxidation becomes a leaching solution that dissolves minerals in the upper zone and deposits minerals in lower zones. Above the water table and below the gossan and leached zone, carbonates, oxides, and silicates are commonly formed. Below the water table, and above the zone of primary mineralization in the ore body, enrichment takes place. Below the gossan or rusty cap rock the leached zone may be barren of minerals with the exception of gold, which, although not chemically inert, tends to remain unaltered.

Enrichment of sulfide deposits

Minerals can be dissolved and removed, and their constituents deposited elsewhere as other minerals, or they can be replaced. Chemical alteration of sulfide minerals within the zone of oxidation results in the formation of acids; these, in turn, enable the meteoric water to act as a solvent. For example, the iron sulfide pyrite, a common mineral in ore deposits, weathers to ferric sulfate and sulfuric acid. Ferric sulfate reacts with the sulfide minerals of copper, lead, and zinc to form sulfates of these metals. Sulfuric acid is a potent solvent of carbonates such as the gangue minerals calcite, dolomite, and siderite. The metals removed by solution are carried downward, and secondary enrichment takes place in a range extending from immediately below the water table to considerable depths in the zone of primary mineralization. It has been demonstrated in the laboratory that metals in solution are precipitated as sulfides in the presence of sulfides of other metals; and that, in the order of solubility, the sulfide of iron is higher than the sulfides of zinc and lead, which in turn exceed copper sulfide. In solutions of metal and sulfide ions, when the latter are not sufficient to unite with all the former, only the least soluble sulfides will crystallize. In the zone of secondary enrichment copper minerals such as chalcocite and covellite not only replace other copper minerals, including chalcopyrite, but also the lead and zinc minerals galena and sphalerite. The paragenesis of these relationships can be complex, and interpretation may depend not only on examination of polished sections of the ore under a microscope but on analysis by X-ray equipment such as the microprobe.

Supergene sulfide enrichment can be of considerable economic significance in a mining operation. In the case of large, low-grade, copper porphyry deposits that average less than 1 percent copper by weight, the grade has been increased by secondary enrichment to as much as 5 percent and is commonly over 2 percent.

Alteration of minerals, rocks, and ore bodies

Metamorphism and crustal movements. Metamorphism means a change in form and refers to the mineralogic reconstitution that occurs in a rock or mineral deposit that is subjected to variations in pressure, temperature, and hydrothermal agencies. Under increased pressure and temperature an alumina-rich shale can be converted to a schist characterized by the minerals kyanite, sillimanite, andalusite, or garnet, all of which are industrial minerals. Under similar conditions an ore deposit of metalliferous minerals such as galena, chalcopyrite, or stibnite can develop flow structures and become gneissic, that is to say streaked and banded in appearance. In such cases the origin of the ore is not easily determined, particularly as to whether it was syngenetic or a replacement of earlier foliation. Crustal movements producing intense folding can result in ore bodies that show highly contorted laminae of mineralization.

The physical properties, including the stability ranges, of sulfide minerals under dynamothermal metamorphism are not well known. Some, in particular galena, are readily deformed in a manner suggesting plastic flowage, but the deformation is caused by a mechanism known as translation, whereby movement takes place along crystallographic planes without rupturing the mineral grains. Galena deformed in shear zones can have the appearance of shiny, striated steel.

Metamorphism and crustal movements may also be the mechanisms whereby low concentrations of metalliferous sulfides in sedimentary beds can be mobilized and driven off, to be concentrated in zones of lower temperature and pressure. It is recognized that some metallogenic provinces may have had close genetic and spacial relationships to sedimentary beds containing disseminated copper, lead, zinc, and other sulfides. Much work remains to be done along these lines before the origin of many ore deposits that appear to have been altered or formed by metamorphism can be stated unequivocally.

METALLOGENIC EPOCHS AND PROVINCES

Ore deposits in Precambrian rocks

The world is more than 4,600,000,000 years old. Most of this long span of time, up to 570,000,000 years ago, is known as the Precambrian; the subsequent span is divided into the Paleozoic, Mesozoic, and Cenozoic eras. Many ore deposits are found in Precambrian rocks, including the iron deposits of the Lake Superior region in North America, the Kiruna district in Sweden, and Western Australia; the nickel–copper deposits of Sudbury, Ontario; the chromium deposits of South Africa; and numerous deposits of lead, zinc, manganese, tin, tungsten, asbestos, platinum, cobalt, silver, and gold. This does not mean that the ore deposits found in Precambrian rocks today are necessarily of Precambrian age. The iron ore deposits of Western Australia and Lake Superior are of recent origin, having formed as residual concentrations of the original iron content of carbonates, silicates, and oxides in the Precambrian sedimentary rocks. Many ore deposits of Precambrian age must have been transformed by metamorphism or mobilized in whole or in part by heat, pressure, and hydrothermal agents.

During the Paleozoic Era (225,000,000 to 570,000,000 years ago) there were several periods of igneous activity and orogenic movement (mountain building) of the earth's crust, accompanied by mineralization in various parts of the world, notably in Europe, Asia, and Australia. Many deposits of salts, gypsum, phosphatic rock, and sedimentary copper and iron ore in North America and Europe were formed during the Paleozoic and the succeeding Mesozoic Era (65,000,000 to 225,000,000 years ago). The Mesozoic was also a time of igneous activity and orogeny. In western North America these disturbances resulted in copper, lead, zinc, gold, and silver mineralization in the marginal zones of the intrusive granitic rocks. Similar mineralization occurred about the same time in Japan, the U.S.S.R., and other parts of the world.

The Tertiary Period of the Cenozoic Era (2,500,000 to 65,000,000 years ago) was also a time of widespread crustal disruption and igneous intrusion. In western North America several large deposits of porphyry copper–molybdenum ore lie in the peripheral zones of intrusive bodies of granodiorite and monzonite emplaced during the early Tertiary. Alpine intrusions of Tertiary age in Europe resulted in lead–zinc mineralization. In other parts of the world, mineralization associated with Tertiary intrusives include ores of gold, silver, copper, lead, zinc, antimony, tungsten, tin, and mercury.

The Precambrian shields of the world, and the orogenic belts that exposed bodies of intrusive rock, are the main prospective provinces for metalliferous ore deposits, particularly those of hydrothermal origin that are spatially controlled by magmatic and structural features. Other provinces, including those of syngenetic origin such as the Kupferschiefer copper deposits in Germany, and some of probable hydrothermal origin such as the lead–zinc deposits of the Tri-State district, Mississippi Valley, are controlled by stratigraphic factors. Within broad geographical limits certain areas are noted for their deposits of gold and copper; copper and molybdenum; lead, zinc, and silver; cobalt and silver; chromium and the platinum metals; tin and tungsten; diamonds, and other associated minerals. These associations are, from field observations, related to geological situations, but the reasons for the relationships are not always clear. Although many large ore deposits may yet be found, production from known deposits indicates that it is unlikely that ore deposits are distributed uniformly throughout the world.

Oregon

Admitted to the Union as the 33rd member in 1859, Oregon comprises a region of startling physical diversity, from the moist rain forests and mountains and the fertile valleys of its western third to the naturally arid and climatic harshness of its eastern deserts. Mountains, plateaus, plains, and valleys of different geological ages and materials are arrayed in countless combinations, including such natural wonders as the Columbia River Gorge, Oregon Caves National Monument, Crater Lake National Park, the majestic snow-covered peaks of the Cascade Range, and the "moon country" of central Oregon.

An overview of the state

Historically, Oregon comprised all of the United States' Pacific Northwest, a region that today includes the states of Oregon, Washington, and Idaho, and a small portion of Montana west of the Rocky Mountains. To the north of the state's 96,981 square miles (251,181 square kilometres) of land and inland water lies Washington, from which Oregon receives the waters of the Columbia River; to the east, Idaho, much of its border formed by the winding Snake River and its Hells Canyon, the deepest gorge on the North American continent; to the south, Nevada and California, with which Oregon shares its mountain and desert systems; and, to the west, the Pacific Ocean, to the beneficent influences of which Oregon owes the moderate climate of its western lands.

The forested mountains of western and northeastern Oregon have supplied the traditional core of the state's economy. Its many forest-product plants produce more than one-fifth of the nation's softwood lumber, one-half of its plywood, one-fourth of its hardboard, as well as large quantities of pulp and paper. In addition, the multipurpose development of the Columbia River System provides huge quantities of electricity, water for irrigation and industry, shipping channels, and water for recreation. The heartland of Oregon, however, is the Willamette Valley, containing the major cities of Portland, Eugene, and Salem (the capital) and a rich and diversified agriculture. (For information on related topics, see UNITED STATES; UNITED STATES, HISTORY OF THE; NORTH AMERICA; PACIFIC COAST RANGES; and COLUMBIA RIVER.)

THE HISTORY OF OREGON

The Indian cultures of Oregon

When the first white men arrived in the Oregon Country —a region vaguely defined at the time but roughly comparable to the present Pacific Northwest—about 125 Indian tribes with a population estimated at 100,000 to 180,000 lived in and around the area. In what became present-day Oregon, the leading tribes were the salmon-eating Chinook, along the lower Columbia River; the Tillamook, Yamel, Molaha, Clackamus, and Multnomah in the northwest; the Santiam and Coos in the southwest; the Cayuse, Northern Paiute, Umatilla, Nez Percé, and Bannock in the dry lands east of the Cascade Range and in the Blue–Wallowa Mountains; and the Klamath and Modoc in the south central area. Their mode of life was responsible for their small population. Since they had no form of agriculture and no domesticated animals other than the dog, they depended entirely upon the natural fauna and flora of the land and water, existing with crude implements by gathering, hunting, and fishing. The tribes along the Columbia River, known as the Canoe Indians, fashioned excellent canoes from logs.

The explorers. The first white men to see the Oregon coast were Spanish sailors searching for a northwest passage to facilitate trade with the Orient. In 1579 the English buccaneer Francis Drake, in quest of Spanish loot and a northwest passage in his "Golden Hind," anchored in an inlet north of the Golden Gate and with a brass plate "took possession" of the country for Queen Elizabeth I. Until the third quarter of the 18th century, when the Spanish renewed exploration along the coast, the Oregon Country remained unexplored. In 1778 the English sea captain James Cook visited Oregon. His men bought beaver and other skins, which they sold at huge profits in China.

In 1787 Boston merchants sent two ships to the Oregon Country under the command of Captains Robert Gray and John Kendrick. On his second voyage, Gray entered the harbour that bears his name (in Washington), and in May 1792 he sailed over the bar of the Columbia River and named it after his ship, the "Columbia." This was the first United States claim to the Pacific Northwest by right of discovery.

The Northwest also was approached by land. Two English fur companies, the Hudson's Bay Company and the North West Company, raced across the continent to open routes to the Pacific; the Americans were not far behind. Meriwether Lewis and William Clark reached the mouth of the Columbia in 1805, strengthening the United States claim to the region.

John Jacob Astor, at the head of the Pacific Fur Company, began the white settlement of the Oregon Country with the establishment of a trading post at Astoria in 1811. The Hudson's Bay Company established Ft. Vancouver in 1824. Dr. John McLoughlin was appointed to head this company's far-flung operations, and for the next 22 years he was the dominating figure in the region.

Permanent settlement. From 1830 onward, thousands of Americans from the Middle West migrated to the Pacific Northwest. Missionaries played a role in settlement. In 1834 the Methodists, headed by Jason Lee, established the first permanent settlement in the Willamette Valley. The migrations that carved deep wagon wheel ruts still visible in the Oregon Trail began in the early 1840s. These settlers pressed for a practical answer to the undetermined ownership of the Oregon Country. After 1838 United States claims and rights to the region were constantly before Congress. American settlers in the Willamette Valley made known their desire to become part of the United States. In 1843 representatives met at Champoeg to organize a provisional government; a set of laws patterned after those of Iowa was accepted. By 1844 the British government had concluded that the Columbia River as the boundary line would have to be abandoned, and the Hudson's Bay Company moved its chief Northwest depot to Ft. Victoria. In spite of the "Fifty-four Forty or Fight" slogan of the presidential campaign of 1844, the 49th parallel was accepted by both nations as the boundary, and the Oregon Country was added to the United States in 1846.

Disputes over ownership

The influx of population led to political agitation, and in 1853 the Washington Territory was given independent status; the Idaho Territory gained similar status in 1863.

Statehood and growth. By 1883, following several "wars," most of the Indians of Oregon were on reservations. The same year saw the beginning of the linkage of Oregon with the rest of the nation by railroad, vastly improving the opportunity for economic growth. Agriculture and forestry were especially stimulated, and by the turn of the 20th century, two-thirds of the people of Oregon lived in rural areas.

The 20th century has witnessed rapid growth of cities, and since 1940 there has been significant diversification of the economy. Today two-thirds of the people live in urban areas.

THE NATURAL AND HUMAN LANDSCAPE

The great diversity of landforms and climates in Oregon is reflected in the different patterns of human settlement and varying bases of economic activity throughout the state.

The natural environment. *Physical regions and vegetation.* Oregon has nine major landform regions: the Coast Range, the Klamath Mountains, the Willamette Valley, the Cascade Range, the North Central Oregon Plateau, the Blue–Wallowa Mountains, the High Lava Plains, the Basin and Range Province, and the Malheur–Owyhee Upland.

Elevations

The forest-blanketed Coast Range, which borders the Pacific Ocean from the Coquille River northward, is the lowest of Oregon's main mountain systems. Its elevations are usually below 2,000 feet, but Marys Peak, southwest of Corvallis, reaches 4,097 feet (1,249 metres), the highest point in the range.

The Klamath Mountains, which extend into Oregon from California, lie south of the Coast Range and west of the Cascades. Composed of ancient resistant rocks, they have had a complicated geologic history. They are higher and more rugged than the Coast Range and lack the north–south orientation. The famous Rogue River, bisecting the area, provides the major drainage. Thick forests grow on these mountains, which also contain the state's richest mineral deposits.

The Willamette Valley is essentially an alluvial plain that has been produced by burying stream-modified lowland with enormous quantities of sediments brought by tributary streams from the bordering mountains. The low hilly areas in the central and northern portions are composed of resistant rocks. This valley contains the prime land of the state and is its population centre. Its soils support intensive agriculture.

The Cascade Range in Oregon forms a broad lava plateau. The wider western section is deeply eroded by numerous streams fed by heavy precipitation. The eastern section, less dissected, is crowned with a chain of volcanic peaks. Mt. Hood, reaching 11,245 feet (3,427 metres) above sea level, and Mt. Jefferson, rising to 10,499 feet (3,200 metres), are the highest. The western slopes of the Cascades are mantled with Douglas fir forests; on the upper slopes western hemlock and true firs become dominant. The forests of the drier east side are largely of ponderosa pine.

In the North Central Oregon Plateau, a portion of the Columbia River Basin, streams are entrenched and provide some bold relief. The interstream areas are broad, little-dissected, smoothly rolling surfaces that provide the land for Oregon's great wheat ranches.

The Blue–Wallowa Mountains comprise two separate highland masses in the northeastern part of the state. The name Blue Mountains refers to the eroded plateaus and ranges extending westward from the agriculturally important Grand Ronde and Baker valleys. Basins and valleys, the headquarters for large cattle ranches, are scattered through the Blue Mountains. The Wallowa Mountains, beyond the Grande Ronde and Baker valleys and near the Idaho border, contain the highest elevations in northeastern Oregon. They were strongly glaciated and display some of the most spectacular scenery to be found in the American West.

The area of the flat High Lava Plains, or High Desert, is located south of the Blue Mountains and eastward from the Cascade Range. The smoothness of the surface, however, is broken by cinder cones, buttes, and craters. Immaturity of erosion and localized interior drainage are other features. Low precipitation, short and erratic growing seasons, and the absence of soil in many places result in an arid landscape of skimpy vegetation, with the details of the surface features commonly visible.

The Basin and Range Province to the south, which merges with the High Lava Plains, is a youthful high lava plain interrupted by mountains and fault troughs. Small volcanoes are numerous in the western portion, where an extensive sheet of pumice greatly modifies surface runoff, vegetation, and land use. Irrigation agriculture is practiced in the Upper Klamath Lake area, and hay is grown with irrigation in a number of other basins and valleys, but most of this region is used by range livestock.

The Malheur–Owyhee Upland of southeastern Oregon is for the most part a high, warped plateau. It contains older lava and has been more dissected than the High Lava Plains. The major drainage system, the Owyhee River, has incised several notable canyons in an area locally called the "Rimrock Country." Along the Snake River in the east central portion of the state there is highly productive irrigation agriculture, but most of this region is livestock-grazing country.

Climatic variation

Climatic regions. Oregon's climates range from equable, mild, marine conditions on the coast to continental conditions of dryness and extreme temperature in the interior. Location with respect to the ocean, prevailing wind and storm paths, and topography and elevation are the principal controls. Six climatic areas can be recognized.

The narrow coastal area and the bordering mountain slopes are marine influenced. Temperatures are mild and equable: July averages 55° to 60° F (13° to 16° C), January about 40° F (4° C). Summers are relatively dry but receive only half of the possible sunshine; other seasons are cloudy and wet. Annual precipitation ranges from 60 to 120 inches (1,500 to 3,000 millimetres) or more.

The lowlands of the Willamette, Umpqua, and the Middle Rogue rivers are warmer in summer, slightly cooler in winter, and have less precipitation than the coast. July averages 67° to 72° F (19° to 22° C) and receives 65 to 70 percent of the possible sunshine; January averages about 40° F (4° C). The rainy season extends from October through April, with precipitation averaging 35 to 40 inches (875 to 1,000 millimetres) except in the Middle Rogue Valley, where 20 to 25 inches (500 to 625 millimetres) are common.

The Cascade Range has copious winter precipitation, including phenomenal snow depth, and short, dry, sunny summers. Above 3,000 feet, January average temperatures are below 32° F (0° C). Snow begins to fall in October and remains through April, with large patches persisting until July. The higher peaks support snowfields and small glaciers throughout the year. July average temperatures range from 50° to 60° F (10° to 16° C) depending on elevation.

The North Central Oregon Plateau, stretching from northern Wasco County through northern Umatilla County, is sufficiently elevated and exposed to receive ten to 20 inches (250 to 500 millimetres) of precipitation. Distribution is fairly even, but winter has the majority of the rainy days. Summers are sunny, with July average temperatures 70° to 75° F (21° to 24° C). The brisk winters have considerable sunny weather, and January temperatures average 31° to 33° F (−1° to 1° C). The plateau area of central and southeastern Oregon has climatic characteristics similar to the north central plateau except for somewhat lower precipitation and lower temperatures at higher elevations.

The Blue–Wallowa Mountains have variety in climatic detail. The intermontane basins and valleys are similar to the north central plateau, with colder winters. The higher, exposed elevations receive comparatively heavy precipitation, much in the form of snow during winter.

Human imprints. At least five major patterns of human land use emerge from the tangle of Oregon's natural landscapes and climates. The forested mountains—the Coast Range, the Cascades, the Klamath, and the Blue–Wallowas—show relatively little evidence of human habitation or modification except for the harvest pattern of block cutting in the Douglas fir region, the logging and forest-management roads, and scattered roadside homesites at lower elevations. Most loggers—few in number because of technological efficiency—live in the valley towns.

Man's uses of the land

The western valleys, dominated by the Willamette, are

Oregon's main centres of population, industry, and transportation. Most persons live close to well-populated centres. The nearly 1,300 small sawmills that in 1947 were located in valley towns or up tributary valleys into the forested mountains have dwindled to fewer than 250; but these are large, integrated operations producing a multiplicity of forest products.

In the rolling, sparsely populated wheat country of north central Oregon, ranches commonly exceed 1,500 acres in the eastern portion and double that size to the west, where wheat-fallow rotation is practiced. In regions of natural erosion, alternate bands of crop and fallow occur. Farmsteads are widely separated, and owners often live in towns.

The growth of natural feed in wide-open range country is relatively poor, and cattle scatter over enormous areas; seldom do more than a few cluster. Appurtenances of the area include fences and occasional watering places with a metal tank. Ranchsteads are few and far between, and ranchers travel about in four-wheel-drive pickup trucks.

Most of the eastern Oregon towns, except Pendleton, lie in the area of irrigated agriculture, on the eastern slopes of the Cascades or near the Idaho border. Farming is highly mechanized.

THE PEOPLE OF OREGON

Composition. Oregonians are predominantly United States-born. The less than 4 percent of foreign birth comprise mainly older persons who immigrated from the Scandinavian countries, Finland, and Canada. Roman Catholics form the largest single religious denomination in Oregon, but about 77 out of 100 church members are of the Protestant faiths. Methodists, Baptists, Presbyterians, Disciples of Christ, and Lutherans are the major Protestant groups.

Contemporary demography. The 1970 census reported that Oregon had 2,091,385 inhabitants, an 18.2 percent increase since 1960. The people are unevenly distributed, 87 percent living west of the crest of the Cascade Range and 69 percent in the Willamette Valley. Average densities in eastern Oregon are, for the most part, low: Harney County had a 1970 average of 0.7 person per square mile, Lake County, 0.8, and Wheeler County, 1.1.

Rural and urban Oregon

About two-thirds of the Oregonians lived in urban areas; and rural population declined in 22 of the 36 counties, while only seven showed losses of urban population.

Approximately two-thirds of all Oregonians live in the three Standard Metropolitan Statistical Areas of the state, Portland, Eugene, and Salem. Portland, near the confluence of the Willamette and Columbia rivers and the largest city in the state, is a leading West Coast port and the major commercial, industrial, service, and cultural centre of the state. Eugene and Salem, the second and third cities, are important for trade and processing. Salem, the state capital, is among the nation's leading food-processing centres. The major cities outside the Willamette Valley are Medford, in the Rogue Valley; Klamath Falls, in south central Oregon; and Pendleton, in the north central plateau.

THE STATE'S ECONOMY

Traditionally, Oregon has had a resource-oriented economy, strongly dependent upon its forests and farms. In recent years diversification has occurred as various new industries have been established and trade and service activities have grown.

Components of the economy. *Manufacturing.* Forest-products manufacturing still ranks as Oregon's leading industry. It accounts for about one-half of the state's 5,000 manufacturing establishments, of its manufacturing employment, and of the value added by manufacturing. About one-half the land area of the state is forested. Public agencies control about 85 percent of Oregon's commercial forest, private owners about 14.9 percent. Another 4,100,000 additional acres of forest are reserved for recreation and watershed use. The forests are capable of permanently sustaining a wood-based sector in the economy of the present size.

Forestry as the economic base

The forest industry began as a producer of lumber; since 1938 Oregon has been the leading state in softwood lumber. In recent years the products have been changing radically, and now only 40 percent of the forest income is from lumber. About one-quarter of the logs harvested go into plywood, which accounts for about one-third of the value of forest products. Pulp and paper plants and hardboard and particle-board plants contribute most of the remainder.

Food processing adds about $325,000,000 to the value of agriculture and fishery commodities and employs about 25,000 workers. The development of sources of electricity, the availability of natural gas via pipeline, abundant water, and the growth of population are the assets upon which new industries have been based. The metals-related group of industries—including primary metals, fabricated metals, electrical and other machinery, and transportation equipment—has been the pacesetter. In the 1960s, employment in these industries doubled, and the value added now exceeds that of food processing. The greatest concentration of metals-related industries is in the Portland metropolitan area, but an aluminum smelter is located at The Dalles, and Albany has two metal-processing plants.

Agriculture and fishing. The agricultural land base of Oregon includes about 5,400,000 acres of cropland, 11,500,000 acres of farm pastures and ranges, and 20,900,000 acres of public range; about 1,700,000 acres are irrigated. Livestock products contribute nearly one-half of the total commodity value, led by cattle and calves; dairy and poultry products are also significant. Wheat is the leading crop, with vegetables and fruits among the other major crops.

Chinook, silver, blueback, and pink salmon are the most valuable fishery products, contributing about 12 percent of the fishery volume and 25 percent of the value. Shellfish amount to about 25 percent of both volume and value; other fish include flounder, tuna, ocean perch, and rockfish.

Mining. Oregon mines $60,000,000 to $70,000,000 worth of minerals annually; sand and gravel make up the bulk of the value. Quarrying occurs in every county, but the greatest quantities are taken near the growing urban areas. The only nickel mine in the nation is located near Riddle. Mercury is also mined.

Transportation. In 1970 Oregon had more than 41,000 miles of highways and roads under the jurisdiction of the State Highway Commission, the Federal-Aid Secondary Highway System, and counties and municipalities. In addition, more than 52,000 miles of forest development roads, national park roads, and military and Indian reservation roads are controlled by federal agencies and various local governments. Some 5,000 miles of railroads provide north–south and east–west routes. The largest airport is Portland International Airport; other significant commercial airfields are at Eugene, Medford, Pendleton, and Corvallis.

Waterways and shipping

Through its entire history, water transportation has been important to Oregon, and today the state has 23 port districts. Six are located on the Columbia above the head of deep navigation, where barge traffic is composed principally of grain and petroleum downstream and cement and structural steel upstream. Portland, open to oceangoing vessels, is by far the most important port. The other districts stretch along the Oregon coast and up the Columbia on the deep-draft channel. Astoria, Newport, and Coos Bay, in addition to Portland, have regular shipments to and from foreign countries.

ADMINISTRATION AND SOCIAL CONDITIONS

The "Oregon System": initiative, referendum, and recall

Structure of government. Oregon has been in the vanguard of several innovative movements in American government collectively known as the "Oregon System." In 1902 the concepts of initiative and referendum were introduced, by which voters were able to initiate and vote upon statutes or constitutional revisions; these were supplemented in 1908 by the system of recall, under which the removal of elected officials could be initiated by the voters. The state was also one of the earliest to impose a state income tax, in 1923.

The state level. State government follows the pattern of most states, though the governor is perhaps stronger than in many. Limited to two four-year terms within any 12-year period, he supervises the state budget, agency heads, boards, and commissions, and coordinates their activities, initiates future planning, and is the focus of federal–state interaction. He may also veto individual items in appropriation bills.

Legislative power is shared by the people of Oregon, through the system of initiative and referendum, and their elected legislators. The legislature comprises the Senate, with 30 members serving four-year terms, and the House of Representatives, with 60 members serving for two-year terms.

The court system is headed by the seven-justice Supreme Court, which has general administrative authority over all other courts. The justices, elected for six-year terms, elect one of their members as chief justice.

Local government. Oregon gives its towns and cities home rule, the right to choose their own form of government. Most cities with populations greater than 5,000 have the council–manager form of government, whereas smaller cities are governed by a city council and a mayor. Portland is governed by four commissioners and a mayor.

In 1958 home rule was extended to counties, but to date few have taken action under this privilege. In most counties, a county judge and two commissioners or a board of three commissioners exercise the powers of government. These officials usually are elected for terms of three years.

Political life. The Republican Party has dominated Oregon's politics through much of its history. Although with industrial growth in recent decades Democrats have come to outnumber Republicans in registration, Republicans continue to control the governorship and most major elective offices. An unusual number of Oregonians have made their mark in the U.S. Congress by their independent stances, perhaps a reflection of continuing frontier attitudes.

The social milieu. Although crime and related problems have increased, Oregon in the early 1970s was far less beleagured than many other states by issues related to such social ills as deteriorating inner cities and inadequate tax bases to pay for rising costs in education, welfare, and health care. Racial problems have been few, and only Portland, since World War II, has had a significant black community.

Areas of state involvement. Oregon's biennial budget consists of segments supported by General Fund and Other Fund revenues. The General Fund is derived from personal and corporate income taxes, excise, inheritance, and insurance taxes, and liquor sales. Other Fund revenue comes from federal grants, use taxes, trust funds, licenses, and the sale of services and commodities.

Funding of state and social activities

Health, education, public welfare, corrective institutions, legislative and judicial functions, and general government administrative functions are supported out of the General Fund. Activities substantially supported by the Other Fund include transportation programs, employee-protection programs, regulatory activities such as public utilities, banking, and corporations, and some natural resources functions. In 1971 the legislature passed a far-reaching program to deal with air and water pollution.

Education. French Prairie, present-day Wheatland, was the site of Oregon's first school, in 1834; 15 years later the first free public school system was created by the territorial legislature. Today a board of education, appointed by the governor, and an elected superintendent of public instruction oversee the system.

Opportunities for education after high school are provided by 12 community colleges, a state system of higher education comprised of three universities, four regional colleges, and 19 independent colleges. The community colleges (operating under state law and guidelines established by the State Board of Education) are administered by lay boards, locally tax supported and especially responsive to local needs in their curricula.

Reed College in Portland is a private liberal arts institution with a relatively short (founded 1911) but distinguished history. It has an extraordinary record in the proportion of its graduates who go on to advanced degree elsewhere. Willamette University, in Salem, granted its first degree, "Mistress of English Literature," in 1859.

CULTURAL LIFE AND INSTITUTIONS

As a relatively young region of the United States, and one in which the imprints of man are scarcely visible over vast stretches of land, Oregon has not developed a cultural identity equivalent to those of the longer-settled or more heavily populated regions. Its people, however, no less in the sparsely settled areas of the east than in the Willamette Valley centres, take full part in the increasingly homogeneous character of American life. Television, radio, and newspapers are available in all corners of the state. Theatrical and musical groups are found in the cities and larger towns, and the Oregon Shakespearean Festival in Ashland draws thousands of viewers each summer to its productions. University and college communities have available many public offerings in the arts or other cultural activities.

The cultural milieu

Popular culture. In addition to the ubiquitous sporting events, both spectator and participatory, Oregon offers a number of attractions related to its history and its location. These include the Pendleton Round-Up (held ironically in wheat country), which attracts participants from across the West and spectators from around the Northwest. Albany's World Championship Timber Carnival, which takes place each July 4, features logger events, carnivals, a parade, and the like. Portland's Rose Festival in early June is perhaps the most famous of the state's communal celebrations.

Libraries and museums. Oregon has about 100 free public library systems, including about 20 county libraries and several travelling libraries, or bookmobiles. The Multnomah County Library, in Portland, was the first to serve the public on a large scale; it began membership service in 1864 and free service in 1902. The Oregon State Library in Salem maintains a general reference service and loan collection for use by the public either directly or through local libraries.

The Oregon Historical Society in Portland and the Horner Museum at Oregon State University own large collections of items of pioneer days in the Oregon Country. The Oregon Museum of Science and Industry in Portland features demonstrations of science at work in Oregon industries. The Portland Art Museum features Northwest Indian art and pre-Columbian Mexican art in its collection. The Murray Warner Collection of Oriental Art at the University of Oregon is one of the largest collections of its type in the United States.

PROSPECTS

A retrospective look over Oregon's development suggests a romantic early period, with a succession of voyagers by sea, overland explorers, traders and trappers, and pioneer settlers. In the recent period, the pattern is more prosaic. Economic growth, reflected in national patterns of employment and income, has been similar to that of the nation as a whole, and this industrial development has been characterized by intensification in forest products other than lumber and by utilization of electric power and skilled labour. Growth in trade and services has responded to population growth, improved transportation, and urbanization. The outdoor recreation attractions have been increasingly discovered by Americans, popularizing the state as a vacation land. With the state's increased concern with its environment, it is likely that Oregon will continue to offer the appurtenances of amenable modern living and a close relation to its natural wonders.

Organ

A keyboard instrument in which the sound is produced by pipes to which wind is supplied through a mechanism under the control of an operator is an organ. Its technical classification is aerophone, or wind instrument. The word organ derives from Greek *organon* and Latin *organum*, an instrument. By common usage, organ has come to embrace any keyboard instrument capable of producing indefinitely sustained sounds, but these should be particularized as reed organ (harmonium) or electronic organ. Organ, alone, implies an organ with pipes, and the term pipe organ is tautologous. This article describes the mechanical aspects, tone production elements, and historical development of the organ as an instrument and relates national schools of composers and their works.

PARTS, MECHANISM, AND PRODUCTION OF SOUND

Basic parts. An organ is divided into three main parts. At one end of the instrument are the keyboards, or manuals, and other controls that collectively are called the console. At the other end are the pipes that produce the tone. Between these two is the mechanism, or action, that accounts for a large part of the bulk and cost of any organ. The simplest type of organ has one keyboard and one pipe to each note. The pipes stand in a row on an airtight box or chest that is supplied with wind, through a trunk, from bellows. Under each pipe is a valve, or pallet, connected by a system of cranks and levers to its respective key of the keyboard. A reservoir is interposed between the bellows and the wind-chest, appropriately weighted to keep the supply of wind at a constant pressure. This reservoir has a blowoff valve that comes into operation when the reservoir is full. Although the bellows may resemble basically the familiar domestic type that is operated by hand or feet, wind is normally supplied from an electrically driven rotary blower.

Elements of simple organs

The pitch of each note is determined by the length of the pipe; the longest pipe makes the deepest note, the shortest pipe the highest note. If two comparable pipes sound an octave apart, the effective length of the higher-pitched pipe is exactly half that of the lower-pitched.

Since the tone of a pipe sounding on a constant pressure of wind is immutable, both as to quality and quantity, the uses of an organ with only one pipe to each note are strictly limited. Even the smallest organs, therefore, have at least three pipes to each note, and organs of cathedral size commonly have as many as 100 to each note. These sets, or ranks, of pipes are arranged in parallel rows on the wind-chest. The pallet controlled from each note admits wind to all the pipes belonging to that note; but, in order that the organist may be able to use at will all, none, or any of the sets of pipes, an intermediate mechanism is provided by which he may stop off any set or sets of pipes. From this function the control at the console by whose operation the pipes are stopped off has come to be known in English as a stop, a term also used loosely for each rank of pipes.

Mechanism. *Tracker (mechanical) action.* The operative part of the stop mechanism lies between the pallet and the footholes of the pipes. It normally consists of a strip of wood or plastic running the full length of the set of pipes, or stop. In it is drilled a series of holes. One hole registers exactly with each pipe. The strip of wood is placed in a close-fitting guide in which it may be moved; when it is moved longitudinally a short distance, so that its holes no longer register with the pipes, wind will no longer reach that set of pipes, even when the organist opens the pallets. These strips are therefore called sliders, and wind-chests in which the stops are operated in this way are called slider chests. There are other ways of working the stops, both ancient and modern, which will be referred to later; but the slider chest was in almost universal use before the 20th century, and many modern organ builders consider it the best. The slider is connected to the console by a system of levers and cranks, and it terminates in a knob that the organist pulls toward him to bring the stop into play or pushes in to silence it.

The importance of two manuals

It often happens that the organist needs either to play polyphonic music (*i.e.*, with interweaving of several voices) in two or more contrasted parts, to give prominence to a melody against a softer accompaniment, or to play loud and soft passages in rapid succession. None of these effects can be achieved on an organ with one keyboard, or manual, as so far described. Loud and soft passages can be played to some extent, but to change the stops between each alternation takes time, which is not always available. For this reason, organs of more than about seven or eight stops usually have two manuals, each controlling its separate wind-chest and stops. Each manual department is self-contained, so that the organ is really a composite instrument. By pre-arranging the stops on the manuals, the organist may perform in any of the three ways mentioned above. The organist, therefore, may vary the sounds he produces in one or both of two ways: by changing the stops on the manuals he is playing or by leaving the stops as they are and changing from one manual to another.

Since the 18th century he has had yet a third way of controlling the volume of sound. The pipes of one or more manuals are usually placed in a box, one side of which consists of hinged and movable shutters (similar to vertical Venetian blinds) that are connected to a pedal at the console. By opening and closing the shutters, the sound from the stops of the manual concerned is made louder or softer. Such boxes are called swell boxes.

Since the 14th century, one department of the organ has commonly been played from a keyboard, or more properly a pedalboard, controlled by the organist's feet. The pedal department is basically like the manual departments but controls the longer pipes.

The organist sometimes wishes to combine the stops of two different manuals or to couple one or more of the manuals to the pedals. This is effected by a simple mechanism, called a coupler, that is controlled by a stop knob at the console (stops that control a set of pipes are called speaking stops).

Certain combinations of stops on each manual are more commonly needed than others; in order that these combinations may be readily available, the console is provided with a number of short pedals disposed above the pedalboard. Each of these pedals is connected to one commonly needed combination of stops. When a pedal is depressed, the stops connected to it are drawn on, and any others that are already drawn are pushed off. These pedals are called combination (composition) pedals.

In the simplest mechanical action, the connection from key to pallet is by a series of cranks and levers. The overall distance may be considerable, and the main distance is bridged by trackers, slender strips of wood, metal, or plastic, that always work in tension.

The trackers

The mechanism of the organ as described so far is entirely mechanical, and such organs are said to have tracker action. Tracker action is used in many modern organs, especially in Germany, The Netherlands, Scandinavia, and increasingly in the United States and Canada; many organists prefer it to all other forms because it is so direct and sensitive in response. Organs may, however, have pneumatic, direct electric, or electropneumatic action, although these actions result in a loss of touch and responsiveness. In very large organs with tracker action, considerable strength may be necessary to depress the keys. Also, where the layout of the building is inconvenient and the departments of the organ have to be widely separated, tracker action is not practicable. To overcome these difficulties, especially with the object of lightening the touch, other forms of action were devised.

The Barker lever

The first effective system was developed (after a device invented by David Hamilton of Edinburgh in 1833) by Charles Spackman Barker, an Englishman. It consisted of a series of small, high-pressure pneumatic bellows, or motors, one attached to each note of the main manual at

the console. When a note was depressed, compressed air was admitted to the motor, which, in turn, operated the tracker action. Lacking encouragement at home, Barker went to France, where the great French builder Aristide Cavaillé-Coll employed the Barker lever almost exclusively from 1840 on.

Tubular pneumatic action. Later, the trackers were supplanted by lead tubes, and the connection from key to pallet was solely by compressed air travelling through these tubes. This system was called tubular pneumatic action. At its best, it was remarkably effective, being reliable, long-lived, reasonably silent in action, and perfectly prompt in operation. At anything but its best, it was none of these things, and its worst fault usually lay in sluggish operation. Tubular pneumatic action is almost never used in modern times.

Electric action. As early as 1860, electric action was used experimentally, and in 1888 it was employed by the English builder Henry Willis at Canterbury Cathedral. His action remained in satisfactory use there for 50 years before it needed to be replaced. The modern type of electric action was pioneered by Robert Hope-Jones in Britain at the end of the 19th century. Direct electric action may be used, but a combination of electric and pneumatic mechanism is more general. In this system the depression of a key completes an electrical circuit, which energizes an electromagnet, allowing wind to enter a pneumatic motor attached to the wind-chest, and this motor opens the pallet. The stops may be operated in exactly the same way, but, where they are operated electrically, the sliders are often replaced by a series of valves, one to each pipe. The organ is then said to have a sliderless chest, and the most usual type is the pitman chest, so called because it contains a type of floating valve called a pitman. This action is commonly known as electropneumatic.

The pitman chest

The combination pedals can also be operated electropneumatically. They are usually supplemented by a series of buttons, or pistons, placed in the keyslips on each manual, where they are conveniently operated by the organist's thumbs. The pistons may easily be made adjustable so that the organist can quickly alter the combination of stops controlled by each one.

No electric action has yet lasted more than 50 years without needing a comprehensive rebuilding, and many have lasted for much shorter periods. But, with improvements in design and standardization of parts, it may be anticipated that rebuilding will become less frequent and expensive. On the other hand, there are small tracker-action organs working satisfactorily after 300 years, and even large ones have continued to operate for more than a century, despite almost total neglect.

Electric auxiliaries to tracker action

A compromise has been used successfully with tracker action for each department, with the coupler action operated electrically. This arrangement has considerable merit, since the coupling together of three or four manuals with tracker action results in a very heavy touch. Electric stop action may also be combined with tracker key action, enabling the use of electric (including solid-state) combinations—an invaluable aid, especially in larger instruments.

Tone production. The pipes are the most important part of an organ. There are two main categories: flue pipes and reed pipes.

Flue pipes. Flue pipes (made either of wood or metal; their construction is basically similar in principle) account for about four-fifths of the stops of an average organ. Figure 1 shows a front view and a vertical section of the most typical sort of metal flue pipe. The pipe consists of three main parts: the foot, the mouth, and the speaking length.

The pipe stands vertically on the wind-chest, and wind enters at the foothole. The foot is divided from the speaking length by the languid, a flat plate; the only airway connection between the foot and the speaking length is a narrow slit called the flue. The wind emerges through the flue and strikes the upper lip, producing an audible frequency, the pitch of which is determined by and amplified in resonance by the speaking length of the pipe. A pipe of this kind is, in fact, identical in principle with a recorder or a tin whistle; but, whereas they have holes along the speaking length, which the player covers and uncovers with his fingers to secure the notes of the musical scale, in an organ there is a separate pipe for each note.

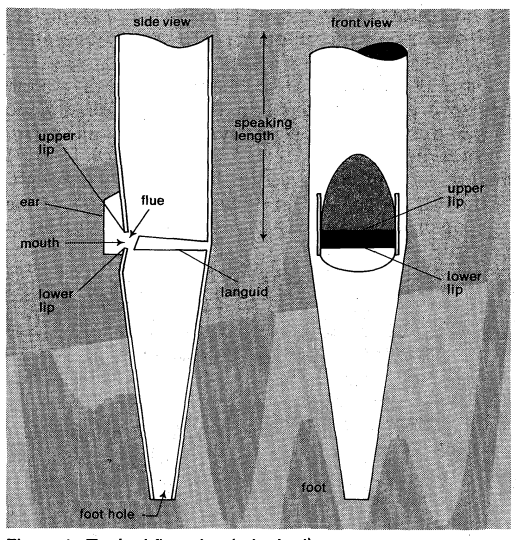

Figure 1: Typical flue pipe (principal).

The tone of a pipe is determined by many factors, including the pressure of the wind supply, size of foothole, width of flue, height and width of mouth, and the scale, or diameter, of the pipe relative to its speaking length. The material of which the pipe is made also exerts an influence; it may be metal (*i.e.*, an alloy of lead and tin), wood, or, more rarely, pure tin or copper, and for the bass pipes zinc. The pipes may also vary in shape, a common variant being an upward taper in which the pipe is smaller in diameter at the top than at the mouth. Or, the top of the pipe may be completely closed by a stopper. Such a pipe is said to be stopped; a stopped pipe sounds an octave lower in pitch than an open pipe of the same speaking length.

Open pipes of large diameter are said to be of "large scale," and open pipes of small diameter are said to be of "small scale." Large-scale pipes produce a dull or foundational quality of tone that is free from the higher harmonics (the numbered series of partials, or component tones). Small-scale pipes produce a bright quality of tone that is rich in harmonics. Stopped pipes can be particularly foundational in tone, and they favour the odd-numbered at the expense of the even-numbered partials. Tapered pipes are somewhere between stopped and open pipes in tone quality.

Tuning and voicing

Flue pipes are tuned by increasing or decreasing the speaking length. In the past, several methods of tuning were employed, but in modern times this is often done by fitting a cylindrical slide over the free end of the speaking length and sliding it up and down, lengthening or shortening the pipe as required. In stopped pipes the stopper is pushed farther down to sharpen the pitch or is pulled upward to lower it.

The pipe maker thus broadly fixes the type of tone that a pipe will produce; but this is further controlled within fairly wide limits by the wind pressure and, finally, by the voicer, who adjusts the tone of each pipe by manipulating the foothole, flue, and upper and lower lips. The attack of the note may also be greatly influenced by cutting a series of small nicks in the edge of the languid. Heavy nicking, so commonly practiced in the early 20th century, produces a smooth and sluggish attack. Light nicking or no nicking, as used up to the 18th century and in more advanced modern organs, produces a vigorous attack, or chiff, somewhat like tonguing in a woodwind instrument. This enhances the vitality and clarity of an organ. The voicer is the artist upon whom the ultimate success of any organ depends, although the tonal designer or architect is hardly less important. It is he who decides upon the choice of stops, their disposition in the organ, and the

scales to be followed by the pipe maker. A completely successful organ depends upon the effective cooperation of designer and voicer.

Reed pipes. Reed stops have beating reeds of a kind that finds several counterparts in the orchestra, and no doubt organ reeds were originally copied from instrumental prototypes.

The shallot, seen in cross section in Figure 2, is roughly cylindrical in shape, with its lower end closed and the upper end open. A section of the wall of the cylinder is

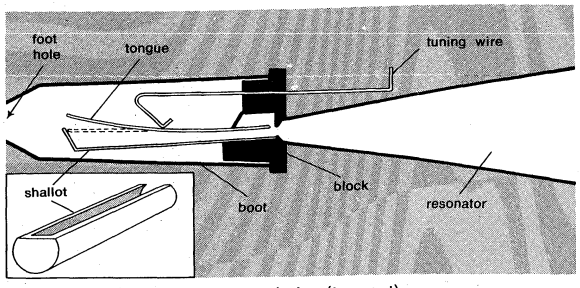

Figure 2: Section through a reed pipe (trumpet).

cut away and finished off to a flat surface, as shown in the inset to Figure 2. The slit, or shallot opening, thus formed is covered by a thin brass tongue that is fixed to the upper end of the shallot. The tongue is curved and normally only partially covers the shallot opening. But, when wind enters the boot, the pressure of the wind momentarily forces the tongue against the shallot, completely closing the opening. Immediately, the elasticity of the brass asserts itself, and the tongue reverts to its curved shape, thus uncovering the opening. This process is repeated rapidly. The frequency of the pulsations of air that enter the shallot is determined by the effective length of the reed and, in turn, determines the pitch of the note. Thence, the pulsations pass out into the tube, or resonator, which further stabilizes the pitch and decides the quality of the note. Most reed resonators have a flared shape, as shown in Figure 2. As in flue pipes, a wide scale favours a fundamental tone, and a narrow scale favours a bright tone. Cylindrical resonators produce an effect similar to that of stopped flue pipes, the note being an octave lower than the equivalent flared pipe and the tone favouring the odd partials. Some reed pipes, such as the Vox humana, have very short resonators of quarter or eighth length. Pipes the resonators of which have no mathematical relationship to the pitch are known as regals; regal stops were very popular in the 17th century, particularly with the North German school, and their use has been revived in modern times. Their short resonators have varying and peculiar shapes, which produce a highly characteristic snarling tone; they can be difficult to keep in tune.

Reed length and pitch

Reed pipes are tuned by moving the tuning wire, thus shortening or lengthening the tongue (Figure 2). As in flue pipes, the scale and shape of the resonator largely determine the quality of tone to be produced; but the wind pressure, shape and size of the shallot, and thickness and curvature of the tongue also have important influence. The tongues may also be weighted with brass or felt; this weighting produces a smoother quality of tone, especially in the bass notes.

Organ reeds have been referred to as beating reeds because the tongue is larger than the shallot opening and therefore beats against it. In a free reed, on the other hand, the tongue is smaller than the opening and so vibrates through rather than against it. Harmoniums and harmonicas have free reeds, which are almost never used in organs.

Choruses. It has already been explained that the pitch of any pipe is proportional to its length. Most modern organs have a manual compass of five octaves, from the second C below middle C to the third C above; an open pipe sounding the low C is about eight feet (2.5 metres) in speaking length (64 vibrations per second). The shortest pipe in the same rank is thus about three inches (eight centimetres) long (2,048 vibrations per second).

The most characteristic tone of the organ is produced by its diapason, or principal, stops. These are of medium scale (usually about 6-in. scale at the 8-ft open pipe) and moderate harmonic development—*i.e.*, neither particularly dull nor bright. Such a tone quality becomes boring if heard for a long time. Also, when greater power is required, there is a distinct limit to what can be done by adding more stops of unison pitch. From the earliest times, stops, especially the principals, were arranged in choruses, and the principal chorus is the very backbone of any organ; without a complete principal chorus, an organ is hardly worthy of the name.

Diapasons, or principals

A chorus consists of stops of roughly similar quality and power but at a great variety of pitches. A unison principal is known as Principal 8 ft because of its longest (8-ft) pipe, and the figure 8 appears on the stop knob or tablet (rocking tablets are often used in place of knobs with electric action) at the console to give an indication of its pitch. The first step toward a chorus is to add a stop sounding an octave above 8-ft ranks (*i.e.*, at octave pitch), the largest pipe of which is therefore four feet long. Next comes a 2-ft stop, while in the other direction the suboctave pitch may be represented by a 16-ft stop. The top pipe of a 2-ft stop has a speaking length of only three-quarters of an inch, and this is about the practical upper limit. Nevertheless, an organ with nothing higher in pitch than a 2-ft stop would be lacking in brilliance, especially in the lower parts of the compass.

From the earliest times, organs have, therefore, been supplied with what are known generically as mixture stops, which have several high-pitched pipes to each note. But, since, for example, a 1-ft rank could not be carried right up to the top note, it breaks back an octave at some convenient point in the compass. Ranks pitched even higher will break back more than once. Thus, in the bass, a mixture adds definition to the slow-speaking, low-pitched pipes; in the treble, where the small pipes tend to be lacking in power, it duplicates the unison and octave ranks. A mixture, therefore, helps to maintain a balance of power between bass and treble, while adding harmonious power of a kind that is completely peculiar to the organ and can be produced in no other way.

Mixtures and mutations

Mixture stops also contain ranks sounding at pitches other than in octaves with the 8-ft principal. In chorus mixtures these sound at a fifth above the unison (*e.g.*, G above C), although ranks sounding at a third above and even at a flat seventh (*e.g.*, E and B♭ above C) and their respective octaves are also found; but these are best restricted to mixtures intended for somewhat special effects. The theoretical justification for these quint- (fifth) and third-sounding ranks is that they reinforce the natural upper partials of the harmonic series, but they were included in organs long before this was understood. The fact is that they were found to sound well, and any attempts to build organs without mixtures and off-unison ranks have been completely unsuccessful. The colourfulness and vitality of any organ depend largely upon copious, artistically voiced mixtures.

Off-unison ranks are also available as separate stops, mostly sounding at an interval of a 12th (an octave and a fifth; 2⅔ ft), 17th (two octaves and a third; 1⅗ ft), or 19th (two octaves and a fifth; 1⅓ ft) above the unison. These are used melodically to colour the unison and octave stops, and they may be wide or narrow in scale. Such stops are known as mutation stops, as opposed to the mixtures, or chorus stops. Their use is essential for the historically (and therefore artistically) correct performance of organ music written before 1800 and of much modern music as well. After a period of disuse throughout the 19th century, they are again included in all modern organs that have any pretensions to being artistically competent.

HISTORY OF THE ORGAN TO 1800

Early history. The earliest history of the organ is so buried in antiquity as to be mere speculation. The earliest surviving record is of the Greek engineer Ctesibius, who lived in Alexandria in the 3rd century BC. He is credited with the invention of an organ very much on the lines of

The hydraulis

the single-manual, slider-chest organ already described, except for its wind supply, which made use of a principle that was most ingenious, though applicable only to a very small instrument. A piston pump supplied air through an ordinary clack valve to a reservoir; at its upper end, this reservoir communicated directly with the wind-chest. The reservoir, cylindrical in shape and with no bottom, was placed in a large drum-shaped container that was partly filled with water. As the reservoir became filled with air, the air would escape around its lower edge. In this way a more or less equal pressure of air was maintained inside the reservoir. Because of this arrangement the instrument was known as a hydraulis. A clay model of a hydraulis was discovered in 1885 in the ruins of Carthage (near modern Tunis, Tunisia), and the remains of an actual instrument were found in 1931 at Aquincum, near Budapest, Hungary.

The development of the organ during the early Middle Ages is obscure, but by the 8th or 9th century it was being used in Christian churches. In the 10th century the famous instrument in the cathedral at Winchester, England, was constructed, of which the monk Wulfstan left a much quoted but manifestly garbled description ending: "the music of the pipes is heard throughout the town and the flying fame thereof is gone out over the whole country."

The artistic history of the organ begins with the development of the chromatic keyboard (*i.e.*, having 12 keys per octave) in the late 12th and early 13th centuries. By 1361 the cathedral organ at Halberstadt, Germany, had three chromatic keyboards and pedals; the keys, however, were much wider than those of the modern keyboard. The modern size of keys was fairly generally established by the end of the 15th century. Although the Halberstadt organ had three manuals, it had no stop mechanism. The main keyboard controlled a huge mixture stop, and the other keyboards controlled reduced groups of stops.

Ctesibius' slider arrangement was probably rediscovered some time in the early 15th century, and it became common soon after 1450. Reed stops began to appear at the same time, and by 1500 the organ had reached a stage in northern Germany in which all the important features of the modern organ were present. Each department had separate choruses; stopped, tapered, and open flue pipes; mutation stops; and reeds. The North German organ builders continued to be pre-eminent until about 1700, when the southern German builders took the lead.

Portable organs

During the Middle Ages and the Renaissance, three diminutive forms of the organ were widely used. These were, first, the positive (in which category are included most chamber organs of the period), a small organ capable of being moved, usually by two men, either on carrying poles or on a cart. The second type, the portative, was smaller still, with only one set of pipes and a manual of very short compass. It was carried by the player and was supported by a strap around his neck. He worked the bellows with one hand and played the keys with the other. Such instruments were used in processions and possibly in concerted instrumental ensembles. In between the last two in size was the third type, the regal, which usually had only one reed stop, a regal, as previously described.

Since national styles of organ building vary widely and it is necessary to know something about them before the music of each nation can be performed intelligently, the more important styles must next be considered briefly. Of the basic medieval organ, prior to the development of national styles, little if any material survives, except in the old cathedral at Sion in Switzerland, where a large proportion of the seven-stop organ appears to date from about 1400. Although voiced on very low wind pressure, the tone of the chorus is brilliant, colourful, and amazingly powerful. Not much is known about the precise uses of church organs in the Middle Ages. The organ hardly began to possess a literature of its own before the last portion of the 15th century.

Italy. Italy is mentioned first because its organs developed to their maturity soon after 1500 and remained relatively unaltered until about 1800. The Italian organ had one manual and usually only an octave of pedal keys, which had no pipes of its own (except an occasional independent 16-ft *contrabasso*) but was coupled permanently to the manual. The manual chorus (*ripieno*) had the peculiarity that there was no collective mixture; all the ranks were drawn by separate stops. Each rank broke back an octave as it reached the 1½-in. pipe. In addition, there were flute stops of 4-ft, 2 ⅔-ft, and 2-ft pitch and a register called the *fiffaro* or *voce umana* (not to be confused with the French *voix humaine* or German *Vox humana*, which are regals), a principal rank found only in the treble and tuned sharp so that when it is played together with the *principale* one hears an audible beat. It was the forerunner of the similarly constructed *voix céleste* stop popular in the 19th-century romantic organ. The scale of the classic Italian *principale* was not much different from its counterpart in the north, but its mouth was narrower, its voicing more delicate, and there was a notable lack of chiff. Reeds were not found until late in the 16th century and were never considered essential. There are well-preserved 16th-century instruments surviving, especially in Brescia and Bologna.

These simple resources were adequate for the performance of the keyboard works of Andrea (*c.* 1520–86) and Giovanni (*c.* 1556–1612) Gabrieli and Girolamo Frescobaldi (1583–1643). Organ music of these men and their contemporaries was not clearly differentiated from that for harpsichord, as indicated by the collections *"per organo o cembalo."* The organ enjoyed some popularity: in Rome, according to Baini, no less than 30,000 people flocked to the square of St. Peter's hoping to find entrance to the cathedral to hear Frescobaldi's magic organ playing.

Spain and Portugal. The Iberian organ followed the Italian tradition, but, later, many reeds were added, most notably the *trompetas reales* ("royal trumpets") and other horizontal (*en chamada*) reeds arrayed in fanlike projections from highly ornamental cases. These reeds were on extremely low wind pressure and achieved amazingly full sounds that filled the huge edifices.

The divided manuals of Iberian organs

Like their Italian counterparts, Spanish and Portuguese organs had only a few rudimentary pedals. The manuals, however, were divided, with notes up to middle C controlled by a draw knob to the left and notes up from C sharp by a draw knob to the right. This enabled the playing of a solo voice against an accompaniment on the same manual.

A unique feature of Iberian churches was the presence of several separate and distinct instruments. The 13th-century Toledo Cathedral, for example, houses three organs: one over the Lion's Gate (south transept), known as the Emperor's organ (*c.* 1543), in an elaborate stone case that now houses a later 18th-century instrument; on both sides of the choir are separate organs—the Epistle organ from 1758 and the Gospel organ completed by the builder José Verdalonga in 1791. These two instruments have horizontal reeds projecting from both sides: into the choir and into the side aisles, enabling interesting uses of antiphony, or contrasting masses of sound. Toledo's three are surpassed in number at Mafra, Portugal, by the six organs in the monastic church, located in a sumptuous building considered Portugal's national monument. The reasons for multiple instruments have never been entirely clear. The use in services of different altars may have dictated the course, or perhaps when one instrument fell into disrepair it may have seemed simpler to add another; at least numerous organs have not been in playable condition for many years.

The leading composers of this era wrote for the instruments at hand. Their music is exciting on these instruments but is seldom effective elsewhere. Likewise, northern European literature is not satisfactory on the Iberian instrument.

In Spanish cathedrals the custom prevailed of alternating verses between organ and singers at the liturgical offices (Matins, Lauds, and Vespers) as well as for the ordinary (Kyrie, Gloria, Sanctus, and Agnus Dei) of the mass. The organ verses were invariably improvised, and the organist could change his registration during the choir verses between. Because improvisation was the

norm, comparatively little written music exists from this period.

Antonio de Cabezón (1510–66) is the most illustrious of the historic Spanish composers. Others include Sebastián Aguilera de Heredia (1570–?) and Juan Cabanilles (1644–1712). Carlos Seixas (1704–42) is known as the Portuguese Bach.

Germany. From 1500 to 1800 Germany led the world in organ building and the composition of organ music. The organ builders reached the peak of their achievement about 1700 in the work of Arp Schnitger. His was the organ of the high Baroque; but his countrymen Andreas and Gottfried Silbermann were equally the masters of the slightly later, more sophisticated style of the mid-18th century.

The Schnitger organs

Schnitger made organs with four manuals, pedals, and as many as 60 speaking stops, but he made some instruments with less than 30 speaking stops that are capable of dealing with the whole pre-Romantic repertory. The finest surviving examples in this size are at Steinkirchen, near Hamburg, and at Cappel, near Cuxhaven. Two great larger examples are at Zwolle and Alkmaar, The Netherlands, both restored to excellent condition in the mid-20th century.

Seventeenth- and 18th-century German organs were usually constructed on *Werk*-principle lines: each department of the instrument, or *Werk,* was separately cased, the Hauptwerk (main manual) in front of and above the player, with the Pedals at each side and the Positiv (auxiliary manual) behind on the gallery railing. Each department, including the Pedal, had its own principal chorus, complete up to at least one mixture. All departments were roughly equal in power but varied in pitch, having, respectively, a 16-ft, 8-ft, and 4-ft preponderance (and 32-ft and 2-ft as well in larger instruments). Each manual department had a set of flutes and mutations that could be combined in a variety of ways to provide accompaniment and melody or the balanced but contrasting tone qualities essential for duet and trio passages. Although the pedal department consisted mainly of its principal chorus, it could be coloured for solo and obbligato passages by 2-ft flute and reed stops. The reeds were not much louder than the flue stops, and the Pedal 16-ft and 8-ft reeds were frequently drawn with the principal chorus for improved definition. When used in this way, they by no means caused the Pedal to overwhelm the Hauptwerk. Such an instrument could deal with the requirements of all 15th- through 18th-century organ music, although its limited supply of manual reeds placed it at some disadvantage in French music of the period.

The earliest organ music consisted of simple arrangements of vocal and instrumental music. A significant development in ornamented versions of such compositions for other mediums is the *Fundamentum organisandi* (*Fundamentals of Organ Playing*; Nürnberg, 1452) by Konrad Paumann, organist at the court of Bavaria. By the end of the 15th century, the polyphonic style was establishing itself in an independent form for the organ as a separate and distinct instrument. Pedal notes were ideally suited for a long-note cantus firmus ("fixed song," a basic melody chosen, for example, from a hymn) against manual counterpoint. The great Amsterdam organist Jan Pieterszoon Sweelinck (1562–1621), having studied in Venice (a tradition already established from northern Europe), developed a notable school of organ playing and composition that dominated a significant part of the musical world for almost two centuries, culminating in the genius of J.S. Bach (1685–1750). Among its composers were one of Sweelinck's greatest pupils, Samuel Scheidt of Halle; in the direct line from Sweelinck to Bach, Johann Adam Reinken of Hamburg; and the greatest composer of the high Baroque and one of the chief influences on Bach, Dietrich Buxtehude of Lübeck. In Austria and south Germany, a pupil of Frescobaldi, Johann Jakob Froberger of Vienna, was noted for his improvisational style. Johann Pachelbel of Nürnberg was the agent by which Italian and south German influences were again transported to northern Germany. By the time of Bach, the written *Choral-Vorspiel,* or chorale prelude (as opposed to the improvised prelude to the chorale within the Lutheran service), prelude and fugue, toccata, passacaglia, chaconne, and trio were firmly established forms for the organ—probably never again to be surpassed. A musical critic said of Bach: "He is the spectator of all musical time and existence, to whom it is not of the smallest importance whether a thing be new or old, so long as it is true."

Sweelinck and his successors

France. As far as the manual departments are concerned, French organs differed little from the German type, but the principal choruses were generally larger in scale. The separate, large-scaled Tierce (1⅗ ft) was also universal, and there were many cornet stops. These mixture stops consisted of five pipes to each note: a stopped unison (8 ft) and large-scale open 4 ft, 2⅔ ft, 2 ft, and 1⅗ ft. They extended only from middle C upward and were largely melodic in use. They were never drawn with the principal chorus (Plein Jeu) but generally were used with the reed chorus (Grand Jeu). Apart from this, the Plein Jeu, Grand Jeu, and Jeux de Mutation were seldom or never intermixed in French music.

The cantus firmus pedal

The pedal department of the French organ prior to 1700 was regarded largely as a sort of solo cantus firmus section that consisted usually of only 8- and 4-ft flutes and 8- and 4-ft trumpets. Only in the largest 18th-century organs were 16-ft stops included, although there were often as many as three on the Grand Orgue (the manual analogous to the German Hauptwerk and the English Great Organ). When French organs had more than two manuals (Grand Orgue and Positif), the others (Récit and Écho) were usually of short compass; but if, as sometimes, there was a fifth manual, it was a Clavier de Bombardes, consisting of 16-, 8-, and 4-ft trumpets and a cornet. Unlike its German counterpart, the main case housed all divisions except the Positif, which was in its usual location on the gallery railing.

French organs were notable for their reeds, and the highly stylized French music of the 17th and 18th centuries calls for their frequent use. Surviving specimens in good order are rare; but unaltered, late 18th-century, four-manual organs survive at Poitiers Cathedral (by the noted builder François-Henri Clicquot) and at Saint-Maximin, Provence (by Jean-Esprit Isnard).

Jean Titelouze (1563–1633) of Rouen may be considered the father of organ music in France. Nearly four centuries later the musicologist André Pirro and the composer Alexandre Guilmant say of his *Hymnes de l'église* (*Hymns of the Church*; 1623) in their preface to Guilmant's edition of the works of Titelouze, "He writes continued dissonances in the modes' natural scales and his use of sevenths gives, sometimes, a quite modern character to his modulations." A great tradition of playing and composing developed with a single dynasty presiding at a single church, Saint-Gervais in Paris, for more than 150 years: the Couperin family, including Louis, François, Charles, and culminating in François le Grand (1668–1733), whose two famous masses are repertory staples even today. Contemporaries included the Paris organist Nicolas Lebègue and his pupil Nicolas de Grigny of Reims, whose mass and hymn verses Bach copied in his own hand; Louis Clérambault, known for two modal suites (*i.e.*, using the tonal structure of the old church modes rather than that of major and minor keys); and Louis-Claude Daquin, a great favourite in Paris who played his popular *Noëls* at the royal chapel.

Great Britain. British organs before the Commonwealth (1649–60) seem to have been very immature. Only a very few had two manuals, and none had pedals. Mixtures and reeds seem to have been unknown, and mutations were restricted to a single twelfth.

After 1660 a new school rapidly grew up, and, although the two principal builders had both been abroad during the Commonwealth (Bernard Smith in Germany or Holland and Renatus Harris in France), their British work owed little to foreign influence. Only the Great Organ had a complete diapason chorus, and the Choir, or Chayre, organ usually extended upward only to a single 2 ft. Almost every organ had a Cornet, and the reeds in common use were Trumpet, Vox humana, and Cremona,

or Krummhorn, with half-length, cylindrical resonators. There were no pedals, but the manual compass almost invariably extended to the third G below middle C. If there was a third manual, it consisted of a short-compass Echo department in which all the pipes were shut up in a box to produce the echo effect. In 1712 the builder Abraham Jordan first fitted the echo box with shutters that were controlled by a pedal at the console; this arrangement produced what Jordan described as the swelling organ, but it was not to reach its full development until 150 years later; no 18th-century organ music demands a swell box. There are hardly any surviving examples of British instruments of this period in original condition, and the only one of any size is the 14-stop, two-manual organ at Adlington Hall, near Macclesfield, dating from the last quarter of the 17th century. It is possibly the work of Bernard Smith. It is entirely original and was restored to perfect order in 1959.

Such instruments were adequate for the music of John Lugge, John Blow, Henry Purcell, George Frideric Handel, John Stanley, and even early 19th-century composers, such as Samuel Wesley.

DEVELOPMENTS AFTER 1800

The romantic organ. Because of the increasing interest in orchestral and operatic music, the organ fell out of favour during the 18th century, and by 1800 it survived only as an ecclesiastical drudge. From the middle of the 19th century, however, a revival took place under the leadership of two great builders, Aristide Cavaillé-Coll of France and Henry ("Father") Willis of England. The German Edmund Schulze, who brought to England an organ built by his father's firm in central Germany, was also influential, especially in his flue choruses. In Britain during the first half of the 19th century, the introduction of pedals under the influence of Henry John Gauntlett made it possible for the first time to play the organ music of Bach and his German contemporaries and predecessors. While retaining respectable vestiges of the classical chorus, Cavaillé-Coll and Willis developed the solo stops, especially reeds, and Willis, in particular, provided new aids to registration.

Influence of Cavaillé-Coll

France. The work of Cavaillé-Coll was directly responsible for a new school of organ composition in France: César Franck (1822–90) composed chromatic and grandly Romantic works, culminating in his *Trois Chorals* (*Three Chorales*); also notable, although of less exalted stature, were Camille Saint-Saëns (*Three Rhapsodies on Breton Themes* and an important organ part in his *Symphony No. 3 in C Minor*), Alexandre Guilmant (numerous sonatas and small "service" pieces), and Charles-Marie Widor and Louis Vierne, both of whom wrote a number of large-scale "sonata suites" they entitled *Symphonies.* A successor of Franck at his post at Sainte-Clotilde in Paris was the great improviser Charles Tournemire, who left a highly individual collection of improvisatory-like modal pieces entitled *L'Orgue mystique.* Jean Langlais (born 1907) continued the modal tradition in many descriptive pieces for liturgical use, and Olivier Messiaen (born 1908) has perpetuated the mystical qualities in suites of great originality (*La Nativité du Seigneur, L'Ascension,* and others). Another prominent organist-improviser-composer-teacher in this largely Romantic mold was Marcel Dupré. Francis Poulenc contributed a popular *Concerto in G Minor for Organ, String Orchestra, and Timpani.*

Germany and Great Britain. Parallel to the French movement, German-born Felix Mendelssohn (1809–47), though working primarily in England, revived an interest in the works of Bach and composed sonatas and preludes and fugues for the organ. Franz Liszt and the German Julius Reubke added to the repertory several flamboyant, pianistic pieces. Johannes Brahms wrote chorale preludes and several preludes and fugues. A composer of monumental chromatic fantasies and fugues, as well as simple chorale preludes, was Max Reger (1873–1916).

Organists found that they could play effective arrangements of orchestral music on the new romantic style organ. Since orchestral music was popular and respectable orchestras very rare and other forms of public entertainment even more so, the organ suddenly regained an immense popularity hardly rivalled by that of the 17th and 18th centuries, when it was the acknowledged "king of instruments." Organ builders naturally responded by making their instruments increasingly orchestral in character, culminating at the end of the 19th century in the work of the English builder Robert Hope-Jones, who entirely abandoned the chorus and mutation stops and relied instead upon diapasons of vast scale on heavy-pressure wind, with reeds to match, backed up by huge-scaled flutes, tiny-scaled string stops (with keen-sounding flue pipes), and powerful stops of his own invention called diaphones. Hope-Jones emigrated to the United States, and, although a semblance of classical design returned to England soon after 1900, his influence continued to be felt throughout the first half of the 20th century. This discredited the organ as a musical instrument in the eyes of serious musicians and composers.

First instruments in the Colonies

The United States and Canada. The first organs in America had been imported from England beginning about 1700. This was the period of the English Commonwealth, and the Puritan view of the "unsuitability" of an organ in church was inherited by the colonies. Only parishes of the Church of England (later known as Protestant Episcopal Church) and Lutheran and Moravian churches in Pennsylvania would admit instruments. Another century elapsed before the New England Puritans did likewise. The only builder of note was the German-American David Tannenberg. A U.S. school of builders began to emerge in the early 1800s with such names as Henry Erben, Elias and George Hook, George Jardine, William A. Johnson, J.H. and C.S. Odell, and Hilborne and Frank Roosevelt. Perhaps the inevitable end of the U.S. "romantic" era was reached in Ernest M. Skinner, who lived until the middle of the 20th century. In Canada, Joseph Casavant built his first organ in Quebec province in 1837. Two of his sons visited France in 1878–79 and brought back to North America the Cavaillé-Coll tradition.

Although no significant school of organ composers has emerged in North America, two names, or at least two pieces, stand out: although neglected for years, Charles Ives in 1891 improvised (and later wrote down) *Variations on America*; this piece was remarkably ahead of its time and suits the U.S. organ at the turn of the century most admirably. Healey Willan, though British born, was for many years Canada's leading composer; his greatest work for the organ is probably *Introduction, Passacaglia and Fugue* (published 1919).

Organ revival. *The neoclassical movement.* Albert Schweitzer, organist, philosopher, and later medical missionary, wrote a booklet, *Deutsche und französische Orgelbaukunst und Orgelkunst* ("The Art of German and French Organ Builders and Players"), in 1906 outlining the inadequacies of the 19th-century organ for the performance of Bach and his contemporaries. It was not until 1926, however, with Karl Straube, that the revival began. Straube, organist at Bach's Thomaskirche in Leipzig and noted recitalist, teacher, editor of Baroque organ works, and leading exponent of the very Romantic works of Reger, renounced his whole approach to the organ and called for a return to the instrument of Schnitger and the high Baroque. Since then, the movement has spread among such organ builders as Karl Kemper, Rudolph von Beckerath, and Johannes Klais in Germany; Victor Gonzalez in France; Sybrand J. Zachariassen and Th. Frobenius in Denmark; Dirk A. Flentrop in The Netherlands; Th. Kuhn in Switzerland; and Walter Holtkamp, G. Donald Harrison, and Herman Schlicker in the United States. Many organists interested in fine phrasing and articulation feel that these qualities are only realizable through the medium of tracker action, where there is a direct connection between player and pallet. This neoclassical movement has inspired a few, but significant, composers to write for the organ: Willem Vogel of The Netherlands; Finn Viderø of Denmark; the Germans Paul Hindemith (three sonatas and two concerti), Hugo Distler, Hermann Schroeder, and Helmut Walcha; and the Americans Daniel Pinkham and Alan Stout.

Exemplary modern builders

The eclectic movement. The revival in France, the United States, and Britain strove to produce an instrument that could do equal justice to all legitimate organ music of whatever period. This was not easy, but it was possible. Undoubtedly, the most successful exponent up to about 1950 was G. Donald Harrison (British born but associated with the Aeolian-Skinner Organ Co. in Boston)—*e.g.*, the instrument in the Mormon Tabernacle in Salt Lake City, Utah. In England, successful examples are the London organs of the Royal Festival Hall and St. Giles Cripplegate.

BIBLIOGRAPHY. AUSTIN NILAND, *Introduction to the Organ* (1968), is, as its name implies, a good introduction to the subject from a contemporary British point of view; in a similar vein, very practical, but from a continental approach, is HANS KLOTZ, *Das Buch von der Orgel* (1938; 7th ed., 1965; Eng. trans., *The Organ Handbook*, 1969). The classic work on the subject in English is EDWARD J. HOPKINS and EDWARD F. RIMBAULT, *The Organ*, 3rd ed. (1877, reprinted 1965); less complete, but general, more contemporary coverage is given in WILLIAM LESLIE SUMNER, *The Organ*, 3rd ed. (1962). Primarily historical is an extremely detailed work by JEAN PERROT: *L'Orgue de ses origines hellenistiques à la fin du XIII^e siècle* (1965; Eng. trans., *The Organ from Its Invention in the Hellenistic Period to the End of the Thirteenth Century*, 1971). PETER WILLIAMS, *The European Organ, 1450–1850* (1966), is a thorough history of continental organs. POUL-GERHARD ANDERSEN, *Orgelbogen* (1956; Eng. trans., *Organ Building and Design*, 1969), emphasizes architecture and the organ's relation to it. National schools are discussed in CECIL CLUTTON and AUSTIN NILAND, *The British Organ* (1963), post-revival; NOEL A. BONAVIA-HUNT, *The Modern British Organ* (1947), pre-revival; FENNER DOUGLAS, *The Language of the Classical French Organ* (1969); and WILLIAM HARRISON BARNES, *The Contemporary American Organ*, 8th ed. (1965), heavy on mechanics with drawings. JOSEPH EDWIN BLANTON, *The Organ in Church Design* (1957), very extensive and aimed primarily at architects; and *The Revival of the Organ Case* (1965), are primarily pictorial works on organ cases. See also the classic pen and ink drawings of ARTHUR G. HILL, *The Organ Cases and Organs of the Middle Ages and Renaissance* (1883, reprinted 1966; German trans., *Vierzig Orgelgehäuse-Zeichnungen*, 2nd ed., 1964)—many of these drawings appear in the other books listed. A fascinating book on portatives, positives, and regals is MICHAEL WILSON, *The English Chamber Organ: History and Development, 1650–1850* (1968).

(C.Cl.)

Organic Halogen Compounds

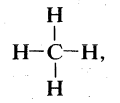
Organic halogen compounds are substances containing atoms of one or more of the so-called halogen elements (fluorine, chlorine, bromine, and iodine) joined to atoms of carbon. In their physical properties and chemical behaviour they are much like other organic compounds (compounds of carbon). Since very few organic halogen compounds occur in nature, most are products of the organic chemist's laboratory. Many organic halogen compounds are used as solvents; carbon tetrachloride, for example, is employed as a cleaning fluid. Other members of the family are used as anesthetics, refrigerants, and propellants for aerosols. The plastic material polyvinyl chloride is an organic halogen compound; so are the insecticide DDT (dichlorodiphenyltrichloroethane) and the herbicide 2,4-D (2,4-dichlorophenoxyacetic acid). Many organic halogen compounds are used in industry or in the laboratory for conversion to other compounds with useful properties, such as dyes and medicinal agents.

GENERAL CONSIDERATIONS

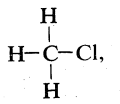
Hydrocarbon derivatives

Chemically, organic halogen compounds may be considered to be derivatives of hydrocarbons (compounds composed exclusively of carbon and hydrogen), in which certain of the hydrogen atoms have been replaced by halogen atoms. In the molecules of hydrocarbons, the carbon atoms form a framework, or skeleton, to which the hydrogen atoms are attached. When the halogen atoms replace hydrogen atoms, they too occupy peripheral or terminal positions, leaving the central framework positions in the molecule to the carbon atoms.

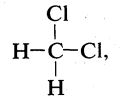
In theory, successive replacement of hydrogen atoms with halogen atoms is possible in any hydrocarbon molecule, until all hydrogen atoms have been replaced. The simplest hydrocarbon, for example, is methane, the molecules of which are composed of one carbon atom and four hydrogen atoms. (A carbon atom usually is able to combine with four other atoms; or, in chemical terminology, it has a valence of four. A hydrogen atom, however, can combine only with one other atom, or has a valence of one.) The structural formula of methane is



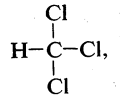
in which the letter C represents the carbon atom, the H's represent hydrogen atoms, and the lines stand for the bonds that hold the atoms together in the molecule. (The methane molecule also may be represented by the simpler, molecular formula CH_4, which simply notes the kind and numbers of the atoms.) Replacement of one of the hydrogen atoms in methane with a chlorine atom (Cl)—all halogen atoms also having valences of one—gives the substance methyl chloride



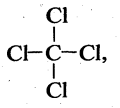
or CH_3Cl. Further replacements of hydrogen with chlorine give methylene dichloride



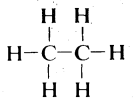
or CH_2Cl_2; chloroform



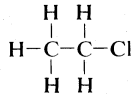
or $CHCl_3$; and carbon tetrachloride



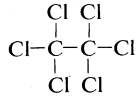
or CCl_4. Similar replacements can be carried out in molecules of the hydrocarbon ethane



(C_2H_6) to give a series of compounds ranging from ethyl chloride



(C_2H_5Cl) to hexachloroethane (C_2Cl_6).



Atoms of each of the other halogen elements—fluorine (F), bromine (Br), and iodine (I)—can similarly be substituted for hydrogen atoms in hydrocarbons (giving compounds containing atoms of more than one halogen element, as well as compounds with multiple atoms of any one element). When the precise nature of the halogen atom is not important, it is customary to use the symbol X, which can stand for an atom of any halogen element. Thus CH_3X could mean methyl fluoride (CH_3F), methyl chloride (CH_3Cl), methyl bromide (CH_3Br), or methyl iodine (CH_3I).

Although organic halogen compounds can be consid-

ered to be derived formally from hydrocarbons by replacement of hydrogen atoms with halogen atoms, this often is not the procedure by which organic halogen compounds are actually prepared in the laboratory. As will be shown, a variety of synthetic procedures is available for preparing organic halogen compounds from other classes of organic compounds.

Nomenclature and classification. Organic halogen compounds, generally, are named according to one of two principles, substitution or the use of organic radicals. In substitution names, the combining form of the name of the halogen element is used as a prefix to the name of the parent hydrocarbon. In this system the compound CH_3Cl is called chloromethane. The analogous combining forms of the other halogen elements are fluoro-, bromo-, and iodo-; halo- is the combining form of the generic term halogen.

Systems of naming

In the "radical" system of nomenclature the organic portion of the molecule (everything but the halogen atom) is designated by a combining form, or radical, which is followed by the name of the halogen in its -ide form (*e.g.*, chloride for chlorine). The organic radicals are derived from the names of the hydrocarbons by substituting the ending -yl for a portion of the hydrocarbon name. Thus methane becomes methyl, and the substance designated chloromethane above is also termed methyl chloride. Often, when it is desired not to specify one particular radical, the letter R— is used. In this way R—Cl represents any organic chlorine compound, and the designation R—X stands for the entire class of organic monohalogen compounds.

Almost any class of organic chemical compound—including alcohols, aldehydes, ketones, and carboxylic acids—can carry halogen atoms in its molecules. The phrase "organic halogen compounds," however, is usually taken to refer simply to halogen derivatives of the various hydrocarbons.

The hydrocarbons themselves fall into various categories depending on the nature of the bonds or linkages between the carbon atoms, and these categories are reflected in the classification of their halogen derivatives—*i.e.*, the organic halogen compounds. Generally hydrocarbons are classified as saturated, or paraffinic, if they contain only single bonds between carbon atoms, and as unsaturated if they contain multiple bonds between carbon atoms (a situation that arises when the molecule does not contain enough hydrogen atoms to satisfy all the valences of the carbon atoms, so that these must form multiple bonds between one another). These multiple bonds may be double or triple bonds, depending upon whether they are the equivalent of two or three single bonds, respectively. A further category of hydrocarbon is called "aromatic"; in their simplest form these are compounds with cyclic systems of six carbon atoms joined by alternating double and single bonds. Saturated hydrocarbons are called alkanes, and the organic halogen compounds derived from them by replacing their hydrogen atoms with halogen atoms are classified as alkyl halides. Hydrocarbons with double bonds are referred to as alkenes, and the halogen compounds derived from them are called alkenyl halides. Triply bonded hydrocarbons are called alkynes, and organic halogen compounds with triple bonds are alkynyl halides; and finally, aromatic hydrocarbons are arenes, and their halogen derivatives are aryl halides.

General chemical properties. The chemical behaviour of chemical compounds is largely determined by the electronic configuration (arrangement of electrons) of their molecules, and this in turn depends upon the electronic configurations of the constituent atoms. The electronic configuration of halogen atoms is quite different from those of carbon and hydrogen atoms, with the result that the incorporation of halogen atoms into hydrocarbon molecules has a marked effect on their chemical behaviour.

Atoms contain varying numbers of negatively charged electrons in what may be defined crudely as concentric shells about the positively charged nucleus. The atoms of the halogen elements, as a group, are characterized by the fact that their outermost electron shells include seven electrons. The halogen elements are differentiated from one another by the number of electron shells, and consequently by the total number of electrons they contain. These numbers increase with the atomic weights of the halogen elements, in the following order: fluorine, chlorine, bromine, and iodine. The seven electrons in the outermost shells, the so-called valence electrons, are farther and farther from the nucleus as the number of shells increases (that is, in the order given above). (The atomic radius of the iodine atom, for example, is rather more than twice that of the fluorine atom.) Consequently the valence electrons are most firmly held by the fluorine nucleus and least firmly held by the iodine nucleus. Because of its small size, fluorine is the most electronegative (electron-attracting) of the halogens, and iodine is the least. In general, less strongly held electrons, such as those of iodine, are more polarizable; *i.e.*, more easily distorted by attractive or repulsive forces near them. Polarizability is an important property that greatly influences the behaviour of halogen atoms with regard to organic molecules, as for example, when free halide ions (halide atoms containing an extra electron, and hence a net negative charge) attack positive centres in organic compounds (as occurs in the synthesis of many organic halogen compounds). In such "nucleophilic" (or positive-charge-seeking) attack, the halide ions attack preferentially in the decreasing order: iodide, bromide, chloride, and fluoride. This explains why hydriodic acid reacts more readily with alcohols to give alkyl halides than do the other halogen acids.

Because carbon is less electronegative than any of the halogen elements, the halogen atom attracts the two electrons that comprise a carbon–halogen bond more strongly than does the carbon atom. As a result, the electrons of the bond are displaced toward the halogen atom, and the bond is polarized. The carbon atom concerned will thus bear a partial positive charge, and will be susceptible to attack by nucleophiles—reagents that seek positive centres. Typical nucleophiles are negatively charged groups, such as the hydroxide ion, a negatively charged group comprised of a linked hydrogen and oxygen atom, OH^-, and molecules having atoms with lone pairs of electrons, such as ammonia, $:NH_3$ (in which the two dots before the N represent a lone pair of electrons). The result of nucleophilic attack on an organic halide is substitution (or replacement) of the halide by the nucleophile. The equation below represents a nucleophilic substitution reaction in which the iodine atom in methyl iodide is replaced by the hydroxide ion acting as a nucleophile:

Nucleophilic substitution

$$HO^- + \overset{\delta+}{C}H_3 - \overset{\delta-}{I} \longrightarrow HO - CH_3 + I^-$$

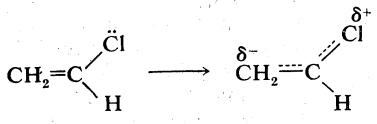
As is usually the case in chemical equations the starting materials are written at the left of the arrow and the products of the reaction are written at the right. In this equation, the polarization of the methyl iodide molecule is indicated by the symbols $\delta+$ and $\delta-$, in which δ (delta) means that partial charges (with signs as shown) appear on the atoms in question.

The readiness with which such nucleophilic substitutions occur depends on two factors: (1) the ease of dissociation of the carbon–halogen bond and (2) the nature of the leaving group (the halide ion). The ease of dissociation of a bond is inversely proportional to the bond energy, which for a carbon–halogen bond increases in the order: iodine, bromine, chlorine, and fluorine. A good leaving group, in general, is the anion of a strong acid, and the strengths of the halogen acids decrease in the order hydrogen iodide, hydrogen bromide, hydrogen chloride, and hydrogen fluoride. The bond dissociation energies and the nature of the leaving groups thus act in the same direction for the halides, with the result that the susceptibility of the various alkyl halides to nucleophilic attack decreases in the order: iodide, bromide, chloride, and fluoride.

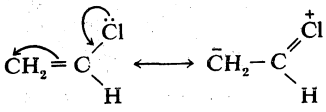
Organic halogen compounds also undergo free-radical reactions, reactions that lead to splitting of a bond, one electron going with each fragment. In such reactions,

only the bond dissociation energies are significant, and, in this case, the order of reactivity of the alkyl halides is the same as it is in nucleophilic attack.

When a halogen atom is attached to an unsaturated carbon atom (one in which not all the valence bonds are saturated), as in certain alkenyl halides, such as vinyl chloride, $CH_2{=}CHCl$, the halogen atom still attracts electrons to it, because of its electronegativity, but another factor must also be considered. In vinyl chloride, for example, the orbital (position in space) of one of the lone pairs of electrons of the chlorine atom overlaps with the orbital of certain of the electrons associated with the double bond. These are the so-called pi electrons, two of which (one from each carbon atom) occupy an orbital covering both carbon atoms and form one of the bonds (called a pi bond) uniting the two carbon atoms. These pi bonds occur only in multiple bonds. As a result of the interaction of the chlorine electrons with the pi electrons of the double bond, carbon–chlorine bonds of this particular type themselves have some double-bond character. Since this involves a partial loss of electrons from chlorine and a gain by the double bond, the molecule becomes polarized as shown in the equation below:



in which the dotted lines indicate partial double bond character. This phenomenon also can be described in a different way as a movement of the lone pair of electrons associated with the halogen atom, as shown in the diagram below by a curved arrow. This shift of electrons causes a polarization of the double bond. The actual state of the molecule is between the two extreme forms shown below, connected by a double-headed arrow:

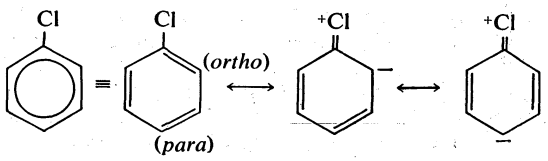


As a result of its interaction with the double bond, the halogen atom of a vinyl halide is much less susceptible to nucleophilic substitution than is an ordinary alkyl halide.

The presence of halogen atoms adjacent to a double bond—the situation in vinyl halides—also has an effect on the chemical reactivity of the double bond. Generally, one of the principal reactions of double bonds is electrophilic addition—a reaction that is initiated by an electron-seeking (electrophilic) reagent and leads to saturation of the double bonds, that is, to production of a molecule with nothing but single bonds. Electrophilic addition is strongly influenced by the polarization of the double bond caused by the halogen atom. As indicated above, a halogen atom on one carbon atom of a double bond leads to a partial negative charge on the other atom of the double bond. This negative charge is the target of an electrophilic reagent, so that the direction of electrophilic addition is dictated by the halogen atom.

When there are several halogen atoms attached to the double bond, their electron-attracting powers become more evident; in fact, they may reduce the negative character of the double bond to such an extent that it adds electrophilic reagents very much less readily than does a double bond without halogen substituents. At the same time, however, it may become more reactive toward nucleophilic reagents (which attack positive centres).

The same situation arises in the aryl halides. In this case, however, there is a more extensive unsaturated system, which can polarize in several different ways, as shown below:



In these diagrams, the hexagon represents a ring of six carbons (carrying single hydrogen atoms except where the chlorine atom is shown); the aromatic nature of the ring system is indicated either by a circle within the hexagon or by three double bonds (the two forms being connected by an identity sign). Forms in which separation of charges occur (as shown by the plus and minus signs) are connected by double headed arrows indicating that they contribute to the overall structure of the molecule. Because this polarization produces partial negative charges at the positions in the ring designated *ortho* and *para* (from Greek roots chosen somewhat arbitrarily before the correct positions were known), electrophilic substitution (*i.e.*, attack by positively charged groups) occurs preferentially at these positions. In aromatic compounds of most varieties, substitution reactions occur more readily than addition reactions because addition destroys the aromaticity of the ring, whereas substitution does not. In polyhalogenated aromatic derivatives, the electronegative halogen atoms reduce the susceptibility of the ring to electrophilic substitution by withdrawing electrons generally from the ring, but, at the same time, they activate the molecule toward nucleophilic attack, of such nature that the halogen atoms themselves are replaced by the attacking nucleophiles.

Electrophilic substitution

General physical properties. Generally in organic halogen compounds, the boiling points increase as the atomic weights of the halogen elements increase and as the molecular weights of the compounds themselves increase (see Table 1). On the other hand, the more highly branched the chain of a given number of carbon atoms is, the lower the boiling point of the compound is.

Table 1: Boiling Points of Alkyl Halides
(°C)

radical	formula	fluoride	chloride	bromide	iodide
Methyl	CH_3—	−78.4	−23.76	3.45	42.5
Ethyl	CH_3CH_2—	−38.0	+12.5	38.4	72.4
n-Propyl	$CH_3CH_2CH_2$—	− 2.5	46.6	71.0	102.5
Isopropyl	$(CH_3)_2CH$—	− 9.4	34.8	59.4	89.5
n-Butyl	$CH_3(CH_2)_3$—	32.5	78.5	101.5	130.4
Isobutyl	$(CH_3)_2CHCH_2$—	...	68.8	91.4	121.0
sec-Butyl	$C_2H_5CH(CH_3)$—	25.1	68.2	91.2	120.0
tert-Butyl	$(CH_3)_3C$—	12.1	50.7	73.2	103.3

Boiling points (all temperatures given in degrees Celsius unless noted otherwise) usually increase with the number of halogen atoms; *e.g.*, methyl chloride (CH_3Cl), −24°; methylene chloride (CH_2Cl_2), 40°; chloroform ($CHCl_3$), 62°; carbon tetrachloride (CCl_4), 77°.

Densities increase with increase in the atomic weight of the halogen and also with the number of halogen atoms in the molecule; *e.g.*, ethyl fluoride (C_2H_5F), 0.818; ethyl chloride (C_2H_5Cl), 0.923; ethyl bromide (C_2H_5Br), 1.47; ethyl iodide (C_2H_5I), 1.98; ethylidene chloride (CH_3CHCl_2), 1.18; ethylene dichloride (CH_2ClCH_2Cl), 1.25; 1,1,1-trichloroethane CH_3CCl_3, 1.35; 1,1,2-trichloroethane $CH_2ClCHCl_2$, 1.44 (the numbers in the names designating the carbon atoms to which the halogens are attached).

Melting and boiling points

Melting points and boiling points of organic halogen compounds, however, do not depend exclusively on the molecular weights of the molecules concerned; they also are influenced by the intermolecular forces involved and hence on the polar (unsymmetrically charged) nature of the molecule (polar molecules being more attracted to one another than nonpolar molecules and hence more resistant to both melting and boiling). For instance, geometrical isomers—that is, compounds with the same structural framework but different spatial arrangements of the substituent groups of atoms—have different melting and boiling points (which also differ from those of any other isomers of the same compounds) because the halogen atoms are differently oriented with respect to one another. An example of such a circumstance is found in the difluoroethylenes: 1,1-difluoroethylene, $CH_2{=}CF_2$, boils at −84° C; whereas the two geometrical isomers of 1,2-difluoroethylene, CHF=CHF, which

Table 2: Melting Points and Boiling Points of Aryl Halides (°C)

compound	fluoro compound		chloro compound		bromo compound		iodo compound	
	melting point	boiling point	melting point	boiling point	melting point	boiling point	melting point	boiling point
Monohalobenzene	−41.9	85	−45.2	132.0	−30.6	156.2	31	188.5
o-Dihalobenzene	−34	91	−17.2	179.2	+ 6.7	225	26.7	286
m-Dihalobenzene	−59.3	83	−26.3	172	− 7	220	35	285
p-Dihalobenzene	−13	89	53.0	174.5	+87.3	220	129	285
1,2,3-Trihalobenzene	−13.5	95	52.4	218	88		116	
1,2,4-Trihalobenzene	−35	88	16.6	213	44		91.5	
1,3,5-Trihalobenzene	− 5.5	75.5	63	203	119	271	184	
1,2,3,4-Tetrahalobenzene	−42	95	47.5	254	47.5		136	
1,2,3,5-Tetrahalobenzene	−48	83	51	246	98		148	
1,2,4,5-Tetrahalobenzene	4	90	138	244	173		254	
Pentahalobenzene	−48	85	87	276	159		172	
Hexahalobenzene	5	80	229	326	326		340–350	

are known as *cis*- and *trans*-1,2-difluoroethylene, boil at −26° C (−15° F) and −53° C (−43° F) respectively. There is a considerable variation in physical properties among polyhalogenated compounds also because of differences in polarity. For example, a nonpolar fully fluorinated compound often has a lower boiling point than less highly fluorinated compounds with the same carbon skeleton, chiefly because the latter are more polar (see Table 2). Boiling points of representative alkyl halides are given in Table 1, and melting and boiling points of aryl halides are presented in Table 2.

The weak intermolecular forces in fully fluorinated compounds (resulting from their low polarity) also are responsible for the low viscosities these substances exhibit—they are used as oils and greases under carefully controlled conditions. (Their viscosities decreased rapidly with increase in temperature, however, and this fact prevents their more general use.)

The bond dissociation energies of carbon-to-halogen bonds, given in the standard units of kilocalories per mole (a mole being equal to the molecular weight expressed in grams), are carbon–fluorine, 108; carbon–chlorine, 81; carbon–bromine, 67; and carbon–iodine, 53. For purposes of comparison, it may be noted that the carbon–carbon and carbon–hydrogen bond dissociation energies are 84 and 102 kilocalories per mole, respectively. The high dissociation energy of the carbon–fluorine bond and the low dissociation energy of the carbon–iodine bond help to explain why the fluorocarbons are thermally stable whereas organic iodine compounds dissociate readily on heating (with liberation of iodine).

ALKYL HALIDES

Monohalides. *Preparation.* Hydrocarbons bearing one halogen substituent are most commonly prepared by two methods: (1) addition of halogen acids to olefins (alkenes) and (2) replacement of hydroxyl (—OH) groups in alcohols. In its simplest form addition of halogen acids to olefins is an electrophilic addition reaction in which the positively charged end of the polarized halogen acid is attracted to the olefinic double bond. The acid then dissociates producing a halide ion and a proton (hydrogen ion) which, with the pi electrons of the double bond, forms a positively charged intermediate known as a pi complex. Finally, the halide ion reacts with the pi complex to give the ultimate product. A typical reaction of this type is shown in chemical formulas below:

$$CH_3CH{=}CH_2 + \overset{\delta^+\ \delta^-}{H{-}X} \longrightarrow H_3C{-}\overset{H}{\overset{|}{C}}{-}CH_2 \quad (H \text{ bridging to } C^+)$$

propylene — halogen acid — pi complex

$$+ X^- \longrightarrow CH_3CHXCH_3 .$$

halide ion — isopropyl halide

The direction of addition to the double bond can be predicted by a consideration of the effects of the alkyl groups (in this case, only methyl, CH_3-) attached to the double bond carbons. The various halogen acids undergo addition to double bonds, in decreasing order of reactivity, as follows: hydrogen iodide, hydrogen bromide, hydrogen chloride, and hydrogen fluoride.

In the presence of traces of peroxides (which can be produced from olefins and traces of oxygen by sunlight), hydrogen bromide reacts with olefins in a different fashion, often to give products in which the addition occurs in the opposite direction to that in the above reaction (that is, with bromine atom appearing on the other double bond carbon atom).

Alkyl halides are produced from alcohols by means of nucleophilic substitution reactions with hydrogen halides (halogen acids), phosphorus halides, or thionyl halides. The reactivities of the halogen acids in this reaction are, in decreasing order: hydrogen iodide, hydrogen bromide, and hydrogen chloride. (Hydrogen fluoride cannot be used.) Tertiary alcohols (alcohols with three carbon atoms attached to the hydroxyl carbon) undergo this reaction readily. Secondary and primary alcohols (alcohols with two and one carbon atom joined to the hydroxyl carbon, respectively) react with less facility. For example, tertiary butyl alcohol reacts with aqueous hydrogen iodide at room temperature, according to the following equation:

Conversion of alcohols to halides

$$H_3C{-}\overset{CH_3}{\overset{|}{C}}{-}OH + HI \longrightarrow H_3C{-}\overset{CH_3}{\overset{|}{C}}{-}I + H_2O .$$
$$\quad\ CH_3 \qquad\qquad\qquad\qquad\quad CH_3$$

tert-butyl alcohol — hydrogen iodide — *tert*-butyl iodide — water

Secondary bromides and iodides (corresponding in structure to secondary alcohols) usually can be prepared in the same way. For primary alkyl chlorides, however, it is necessary to use a catalyst and warm the solution. (Long heating may cause isomerization—rearrangement to another product.)

Phosphorus pentachloride, phosphorus tribromide, red phosphorus and bromine, phosphorus triiodide, and red phosphorus and iodine all react readily with the appropriate alcohols to give primary, secondary, and tertiary halides. Thionyl chloride and thionyl bromide react with primary or secondary alcohols in the presence of an organic base, such as pyridine. Tertiary alcohols need no base.

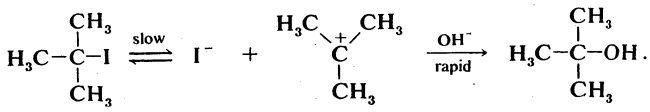
The various alkyl halides can be interconverted, and they also can be prepared from other alkyl compounds. Either process is one of nucleophilic substitution by halide ions, and the choice of solvent for the reaction is important.

Reactions. In most of their reactions, the alkyl iodides are more reactive than bromides, which are more reactive than the chlorides, and these, in turn, are more reactive than the fluorides. This order of reactivity reflects the relative ease with which the respective carbon–halogen bonds are broken. Also, generally speaking, the tertiary halides react most readily, the secondary less so, and the primary least of all, reflecting the fact that alkyl substituents tend to donate electrons to the carbon atom that carries the halogen, causing it to release the halide ion,

and the more alkyl substituents there are (three in tertiary compounds), the more easily is the halide ion lost. The chemical reactions undergone by alkyl halides can be classified under three headings: (1) nucleophilic substitutions, (2) elimination reactions, and (3) free-radical processes.

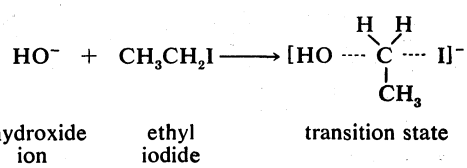
Nucleophilic substitutions

Nucleophilic substitution reactions are classified as unimolecular or bimolecular according to whether the reaction involves one or two molecules. Unimolecular nucleophilic substitutions proceed by way of ionization of the alkyl halide—that is, by cleavage of the molecule to give a positively charged alkyl, or carbonium, ion and a negatively charged halide ion. This type of reaction is undergone most readily by a tertiary alkyl halide in ionizing solvents (aqueous alcohol, for example). Reactions of this type are known to chemists as S_N1 reactions (meaning substitution, nucleophilic, unimolecular). A good example of an S_N1 reaction is the hydrolysis of *tert*-butyl iodide, as shown below:

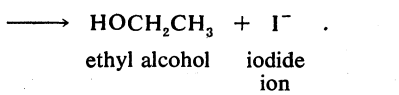


tert-butyl iodide | iodide ion | carbonium ion | *tert*-butyl alcohol

Bimolecular nucleophilic substitutions—S_N2 reactions—proceed through a transition state that includes a nucleophile—for example a hydroxide ion—as well as a molecule of the alkyl halide. They are most common for primary alkyl halides in nonionizing solvents. An example is the reaction of ethyl iodide with a hydroxide ion to give ethyl alcohol and the iodide ion:



hydroxide ion | ethyl iodide | transition state

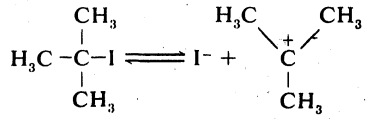


ethyl alcohol | iodide ion

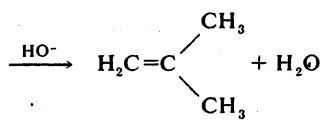
Nucleophiles other than the hydroxide ion that react in this fashion are ammonia and trimethylamine, and the ethoxide, acetate, cyanide, azide, acid sulfide, and hydride ions.

Elimination reactions

Whenever alkyl halides are hydrolyzed, a certain amount of olefin is formed by an elimination process. Elimination sometimes becomes the main reaction, as in the hydrolysis of tertiary halides, in which the carbonium ion formed can easily eliminate a proton. An example is the hydrolysis of *tert*-butyl iodide to give isobutene:



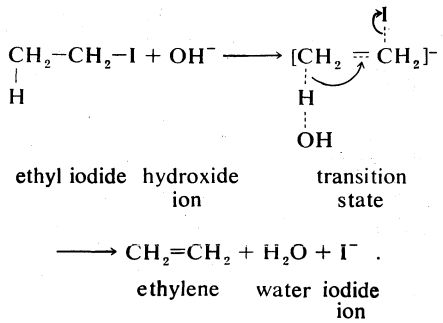
tert-butyl iodide | iodide ion | carbonium ion



isobutene | water

This is a unimolecular elimination—E_1 reaction—so classified because the rate at which it occurs is governed by the rate of formation of the carbonium ion from the alkyl halide.

Biomolecular eliminations—E_2 reactions—occur mainly with primary halides. They occur by removal of a hydrogen ion from the carbon atom adjacent to that carrying the halogen atom. For example, the elimination reaction involving ethyl iodide proceeds as shown (with the movements of the electrons comprising the various bonds indicated by curved arrows):



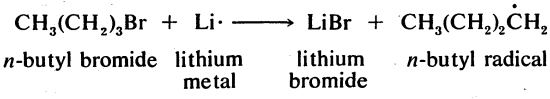
ethyl iodide | hydroxide ion | transition state

ethylene | water | iodide ion

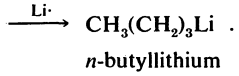
By suitable choice of the reaction conditions (that is, by selecting the right solvent, temperature, and concentration of nucleophile) it is often possible to influence whether a particular reaction proceeds by bimolecular or unimolecular substitution or by an elimination reaction. Because the products of these reactions often are different, the distinction may be vitally important in a synthetic process.

Free-radical reactions

Alkyl halides usually react with metals by a process that generates free radicals—that is, substances with single (unpaired) electrons. The free radical may then react with a second metal atom, resulting, as shown in the example below, in formation of an organometallic compound (that is, an organic compound with a metal substituent):

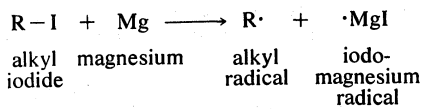


n-butyl bromide | lithium metal | lithium bromide | *n*-butyl radical

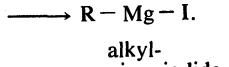


n-butyllithium

(In the names of these compounds *n*, for normal, indicates that the hydrocarbon chain is straight, or unbranched.) With magnesium, the reaction is carried out in an ether as solvent to give an organomagnesium halide:



alkyl iodide | magnesium | alkyl radical | iodomagnesium radical



alkylmagnesium iodide

In these reactions iodides and bromides are generally used because chlorides and fluorides react much less readily. The reduction of alkyl halides by sodium and alcohol, zinc and dilute acid, or similar reducing agents may also be a free-radical process:

alkyl iodide | hydrogen atom | alkyl radical | hydrogen iodide

alkyl radical | hydrogen atom | alkane

Polyhalides. *Preparation.* Alkylidene halides—that is, halides that have two halogen atoms attached to the same carbon atom—can be made from aldehydes and ketones. The chlorides, bromides, and iodides are prepared using phosphorus halides. For example, isopropylidene chloride is produced from acetone and phosphorus pentachloride, which may be illustrated according to the following equation:

$$PCl_5 + CH_3COCH_3$$

phosphorus pentachloride; acetone

$$\longrightarrow POCl_3 + CH_3CCl_2CH_3.$$

phosphorus oxychloride; isopropylidene chloride

To prepare the fluorides, sulfur tetrafluoride or phenyl sulfur trifluoride is used with an aldehyde or ketone. Another general method for preparing alkylidene halides is to add a halogen acid to a vinyl halide or an alkyne. An example is the addition of hydrogen chloride to acetylene, vinyl chloride being produced first:

$$HC \equiv CH \xrightarrow{HCl} CH_2{=}CHCl \xrightarrow{HCl} CH_3CHCl_2.$$

acetylene; vinyl chloride; ethylidene chloride

Alkylene dihalides, in which two halogen atoms are attached to different carbon atoms, are formed from halogens and alkenes by electrophilic addition, or from glycols (compounds with two alcohol groups) by nucleophilic substitution exactly as the alkyl halides are prepared from ordinary alcohols.

The best known trihaloalkanes are those in which all three halogen atoms are on the same carbon atom; these are the haloforms, of which chloroform, $CHCl_3$, is the most familiar. Haloforms generally are made by the halogenation and subsequent alkaline hydrolysis of compounds containing the acetyl group (CH_3CO-) or structures capable of producing it on oxidation. Fluorination of acetophenone, for instance, followed by hydrolysis of the product, gives fluoroform, as shown:

$$C_6H_5COCH_3 \longrightarrow C_6H_5COCF_3$$

acetophenone; α,α,α-trifluoroacetophenone

$$\xrightarrow{H_2O} C_6H_5COOH + HCF_3.$$

benzoic acid; fluoroform

Larger molecules can be made by the free-radical addition of chloroform to olefins, as follows:

$$CH_2{=}CH_2 + \cdot CCl_3 \longrightarrow \cdot CH_2CH_2CCl_3$$

ethylene; trichloromethyl radical (from $CHCl_3$); intermediate radical

$$\cdot CH_2CH_2CCl_3 + HCCl_3$$

intermediate radical; chloroform

$$\longrightarrow CH_3CH_2CCl_3 + \cdot CCl_3.$$

1,1,1-trichloropropane; trichloromethyl radical, regenerated

If the proportion of chloroform present in the reaction mixture is reduced, polymerization (formation of long, chainlike molecules with repeating units) occurs because the intermediate radical reacts with more olefin, giving a series of products of varying chain length, all of which have trichloromethyl end groups. Such products are formed as in the following equations:

$$\cdot CH_2CH_2CCl_3 + nCH_2{=}CH_2 \longrightarrow \cdot CH_2CH_2(CH_2CH_2)_nCCl_3$$

intermediate radical; ethylene; polymer radical

$$\cdot CH_2CH_2(CH_2CH_2)_nCCl_3 + HCCl_3$$

polymer radical; chloroform

$$\longrightarrow CH_3CH_2(CH_2CH_2)_nCCl_3 + \cdot CCl_3,$$

polymer product; trichloromethyl radical

in which n is a variable number that depends on the number of times the first step is repeated.

Compounds more highly halogenated than the above classes of polyhalides result from the direct halogenation of alkanes by elemental fluorine, chlorine, or bromine. This process, too, is considered to involve free radicals. Because the energy liberated in replacing hydrogen atoms by fluorine atoms is more than enough to break a carbon-to-carbon bond, the vapour-phase fluorination of alkanes occurs violently unless the reaction is moderated by dilution of the reactants with gaseous nitrogen and unless the heat produced by the reaction is conducted away by a metal surface. As an alternative, metal fluorides can be used instead of elemental fluorine, or an electrochemical process can be employed. In most instances, but not in the electrochemical method, the amount of partly fluorinated material can be adjusted by varying the reaction conditions, but mixtures are always obtained. Chlorination of alkanes with elemental chlorine in the liquid phase gives mainly polychloro compounds but, in the gas phase, it is possible to arrange conditions so as to give more lightly chlorinated material. Bromination is carried out like chlorination; direct iodination, however, is not feasible. Fluorination is such a vigorous process that there is no discrimination in the attack on the different types of hydrogen atoms; in chlorination and, to a greater extent in bromination, tertiary hydrogen atoms are substituted more readily, followed by secondary and primary hydrogens, in order.

Direct halogenation

Reactions. The reactions of alkylene dihalides are very similar to the reactions of alkyl halides, but, when there are two or more halogen atoms on the same carbon atom, there is a sharp decrease in the reactivity of the halogen atoms. In general, as the atomic weight of the halogen atoms increases the stability of the polyhaloalkanes decreases, not only because the carbon–halogen bonds are weaker, but also because of the crowding caused by the packing together of the larger atoms. Stabilities decrease enormously, therefore, in the series from carbon tetrafluoride, through the chloride and bromide to carbon tetraiodide. Furthermore, 1,1,1-trifluoroethane is resistant to hydrolysis by acids, whereas the trichloro compound is easily hydrolyzed to acetic acid. Because the fluorine atom is not much bigger than the hydrogen atom, it is possible to prepare series of fluorocarbon derivatives entirely analogous to the related hydrocarbons. The sizes of the other halogen atoms, however, prevent the formation of many fully halogenated compounds. Fully fluorinated alkanes (called perfluoroalkanes) are particularly stable—both to heat and to chemical reagents—because of the very strong carbon—fluorine bonds and because the fluorine atoms are of just such size that they give good protection to the carbon chains.

Influences on reactivity

Polyhalogenated compounds mainly undergo elimination reactions. Halogen atoms are eliminated either as molecules of the halogen acid (HX) or as molecules of the free halogen itself (X_2). In both cases iodides are most reactive, and fluorides least. Elimination reactions are widely used in the preparation of halogenated alkenes and alkynes (see below *Alkenyl halides* and *Alkynyl halides*). Exchange of one kind of halogen atom for another occurs when polyhalo-compounds are heated with aluminum halides.

ALKENYL HALIDES

Preparation. Alkenyl halides, halogen derivatives of olefins, differ from one another in their chemical behaviour chiefly because of differences in the relationship of the halogen atom to the carbon–carbon double bond. Vinyl halides are those alkenyl halides in which a halogen atom is attached directly to one of the double-bond carbons; allyl halides are those in which the halogen is attached to one of the carbons adjacent to the double-bond carbons. Only in these classes of alkenyl halides is there interaction between the electrons of the halogen atoms and those of the double bond. Therefore, only these alkenyl halides show unique chemical properties; others of the general class resemble ordinary alkyl halides in their properties and methods of preparation.

Varieties of alkenyl halides

One method that is used to prepare vinyl halides of many different types is the addition of an appropriate simple molecule to an alkyne (triply bonded hydrocarbon). These reactions may occur spontaneously, when a simple molecule like a halogen acid is added, or they may need heating, when more complex molecules are to be added. Examples of both are shown below:

$$CH{\equiv}CH + HCl \longrightarrow CH_2{=}CHCl;$$

acetylene — hydrogen chloride — vinyl chloride

$$CF_3C{\equiv}CH + CCl_3I$$

trifluoromethyl-acetylene — trichloro-iodomethane

$$\xrightarrow{\text{heat}} CF_3Cl{=}CHCCl_3$$

1,1,1-trifluoro-2-iodo-4,4,4-trichloro-2-butylene

The other common methods of preparing vinyl halides are dehydrohalogenation (removal of hydrogen halides) and dehalogenation (removal of halogens) of polyhaloalkanes. Dehydrohalogenation can, in simple cases, be performed by heating with bases, for example:

$$CH_2ClCH_2Cl + NaOH$$

ethylene dichloride — sodium hydroxide

$$\longrightarrow CH_2{=}CHCl + NaCl + H_2O.$$

vinyl chloride — sodium chloride — water

The most common method of dehalogenation is to heat the haloalkane in ethanol solution with zinc dust, as in the following example:

$$CH_2BrCHBrF \xrightarrow[C_2H_5OH]{Zn} CH_2{=}CHF.$$

1-fluoro-1,2-dibromoethane — vinyl fluoride

Allyl halides

Allyl halides are prepared by the action of the appropriate halogen acid on allyl alcohols. Allyl bromide also is made by treating propene with *N*-bromosuccinimide. The bromide can be converted into other halides by halogen exchange.

$$CH_2{=}CHCH_3 + BrN\begin{<}COCH_2\\COCH_2\end{>} \longrightarrow CH_2{=}CHCH_2Br + HN\begin{<}COCH_2\\COCH_2\end{>}$$

propene — *N*-bromo-succinimide — allyl bromide — succinimide

Reactions. In the vinyl halides, because of the interaction of the electrons of the halogen atom with those of the double bond, the carbon to halogen bond is stronger than it is in ordinary alkyl halides. Moreover, the carbon atom to which the halogen is attached does not carry a positive charge, as does the corresponding carbon atom in typical alkyl halides, and as a result nucleophilic replacement of the halogen atom in vinyl halides does not occur. This lack of positive charge, however, does not prevent the formation of organomagnesium halides, nor does it interfere with normal electrophilic and free radical additions to the double bond.

As the number of halogen atoms in a vinyl halide molecule increases, the tendency to undergo electrophilic additions decreases and that to undergo nucleophilic additions increases. Both effects are due to the decrease in electron density of the double bond caused by the electronegative substituents. For polyhalo vinyl compounds, then, the most commonly observed reaction is the addition of nucleophiles, such as alcohols, amines, and thiols. For example, the addition of ethanol to 1,1,2-trichloroethylene gives an ether as an initial reaction product; this is subsequently dehydrohalogenated to dichlorovinyl ethyl ether.

Polyhalo vinyl compounds

$$CCl_2{=}CHCl + C_2H_5OH \longrightarrow C_2H_5OCCl_2CH_2Cl$$

1,1,2-trichloro-ethylene — ethanol — initial product

$$\xrightarrow{NaOC_2H_5} C_2H_5OCCl{=}CHCl$$

dichlorovinyl ethyl ether

Allyl halides, which conform to the structural pattern $CH_2{=}CHCH_2X$, are very much more susceptible to nucleophilic substitution of the halogen atom than are alkyl halides. When a carbonium ion intermediate is formed, (S_N1 reaction) it may be represented by the two formulas:

$$\underset{\gamma}{CH_2}{=}\underset{\alpha}{CH}{-}\overset{+}{\underset{\alpha}{CH_2}} \longleftrightarrow \overset{+}{\underset{\gamma}{CH_2}}{-}\underset{\alpha}{CH}{=}\underset{\gamma}{CH_2}.$$

Attack by the nucleophile occurs at either the alpha (α) or gamma (γ) carbon atoms (as shown). This choice becomes significant for unsymmetrical allyl carbonium ions as the product is different in each case. Bimolecular (S_N2) substitution usually involves direct replacement of the allyl halogen atom, but this reaction also can occur with attack at the gamma position to give an alternate product.

Halogenated alkenes of only two carbon atoms usually polymerize readily, but halogenated alkenes bearing large, halogenated alkyl groups attached to the unsaturated carbon atoms may not do so. Fluorinated olefins easily form cyclic dimers when heated above 200° C (392° F). Halogenated alkenes often can be dehydrohalogenated or dehalogenated to alkynes.

ALKYNYL HALIDES

Preparation. In many cases, compounds containing halogen atoms directly joined to triply bonded carbon atoms are formed by reaction between molecular halogen and a metallic derivative of the alkyne. Various sodium acetylides, for example, react with free iodine to give the corresponding iodo compounds.

$$RC{\equiv}CNa + I_2 \longrightarrow RC{\equiv}CI + NaI$$

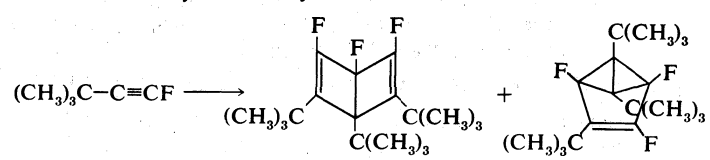
In other instances, alkynyl halides are more easily prepared by dehalogenation or dehydrohalogenation reactions of halogenated alkanes or alkenes. Examples of both reactions, using 1,1,2-trichloroethylene as starting material, are shown below:

$$CCl{\equiv}CH \xleftarrow[\text{alcohol}]{Zn} CCl_2{=}CHCl \xrightarrow[NaOH]{\text{aq alc}} CCl{\equiv}CCl.$$

chloro-acetylene — 1,1,2-trichloro-ethylene — dichloro-acetylene

Reactions. Halogenated acetylenes (alkynes), in which the halogen atom is directly bonded to one of the unsaturated carbon atoms, generally are unstable; the lower the molecular weight, the more likely they are to explode. This instability may be due to spontaneous exothermic (heat-producing) polymerization, which, in some cases, can be regulated so that trimerization to halogenated benzenes occurs. Sometimes isomers of benzene derivatives are formed, as for example, in trimerization of *tert*-butylfluoroacetylene:

Instability of halo-alkynes



tert-butylfluoro-acetylene — isomeric benzene derivatives

In these structures the polygons represent rings of carbon atoms (the carbon atoms at the angles not being shown), with the lines indicating the bonds between atoms.

A halogen atom attached to an unsaturated carbon atom in a halogenated acetylene is resistant to nucleophilic

substitution. Most nucleophiles, therefore, react with haloalkynes first by addition and then by elimination of hydrogen halide. Ammonia, for instance, adds to dichloroacetylene; the initial product then loses hydrogen chloride to give an alkyne, and this in turn isomerizes to a nitrile.

$$ClC{\equiv}CCl + NH_3 \longrightarrow ClCH{=}C(NH_2)Cl$$

dichloroacetylene — ammonia — 1,2-dichloroaminoethylene

$$\longrightarrow HCl + ClC{\equiv}CNH_2 \xrightarrow{\text{isomerization}} CH_2ClC{\equiv}N$$

hydrogen chloride — 1-amino 2-chloroacetylene — chloroacetonitrile

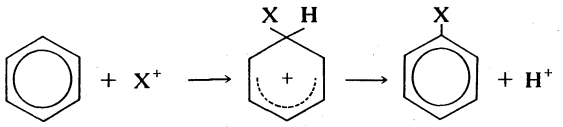
In most solvents, such as carbon tetrachloride, electrophilic additions of halogens and halogen acids to alkynyl halides take place, but the reaction is vigorous and must be controlled carefully. The hydrogen in monohaloacetylenes is acidic, as in acetylene itself, and can be replaced by metals. Haloacetylenes in which the halogen is remote from the triple bond are generally stable and show the separate reactivities of alkynes and alkyl halides. The perfluoroalkylalkynes are less unstable than most other alkynes, and they retain the reactivity of the triple bond, readily undergoing free-radical, electrophilic, and nucleophilic addition reactions.

ARYL HALIDES

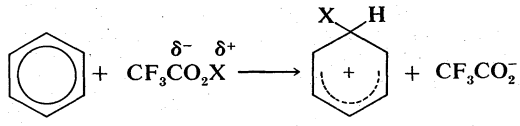
Nuclear-halogenated aromatic compounds. *Preparation.* There are three main methods for producing aromatic compounds that carry halogen atoms on the aromatic ring (or aromatic nucleus, as it is often called). These are (1) replacement of hydrogen by halogen, (2) replacement of an amino group by halogen, and (3) dehydrohalogenation or dehalogenation of polyhalocyclohexanes or polyhalocyclohexenes.

Replacement of hydrogen

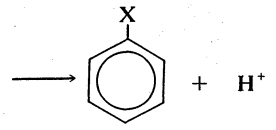
The mechanism of hydrogen replacement is one of electrophilic substitution. It involves, first, the production of either a positively charged halogen ion or a polarized molecule in which the halogen has a partial positive charge (the electrophile). This positive centre then reacts with benzene to form an intermediate from which a proton is eliminated.



benzene — intermediate — halobenzene — proton



benzene — polarized halogen compound — intermediate



halobenzene — proton

Ferric chloride or aluminum chloride are used as catalysts with chlorine or bromine to produce the positively charged halogen ion.

$$Cl_2 + AlCl_3 \rightleftharpoons Cl^+ + AlCl_4^-$$

Iodination requires the presence of an oxidizing agent, such as nitric acid, to remove hydrogen iodide from the reaction as soon as it is produced, as well as to encourage the formation of positively charged iodine. Hypohalous acids, *N*-chloro- or *N*-bromoamides, and acyl hypohalites are useful halogenating agents because they are polarized in such a way that the halogen atom carries a positive charge.

A chlorine, bromine, or iodine atom in the benzene nucleus deactivates it and causes further substitution to occur in the *ortho* and *para* positions (see above *General chemical properties*). Fluorine also causes *ortho* and *para* orientation, but does not deactivate the nucleus. Excellent yields of nuclear halogenated compounds are formed by chlorinating, brominating, or iodinating substituted benzenes.

Replacement of amino groups

Any of the four halogens can be introduced into the nucleus by diazotizing an aromatic amine and then allowing the resulting diazonium salt to decompose in the presence of a suitable salt of the halogen. Chlorine and bromine, for example, are introduced by heating a diazonium salt in dilute acid solution with cuprous chloride or bromide:

$$ArNH_2 \longrightarrow Ar\overset{+}{N}{\equiv}N\ X^- \xrightarrow[HX]{Cu_2X_2} ArX + N_2.$$

aromatic amine — diazonium salt — aryl halide — nitrogen

Ar = any aromatic nucleus

Alternatively, the appropriate diazonium salt can be heated in dilute acid with copper powder:

$$Ar\overset{+}{N}{\equiv}N\ X^- \xrightarrow[HX]{Cu} ArX + N_2.$$

diazonium salt — aryl halide — nitrogen

Iodine is introduced simply by warming a diazonium salt in the presence of aqueous potassium iodide, for example:

$$C_6H_5\overset{+}{N}{\equiv}N\ Cl^- + KI \longrightarrow C_6H_5I + N_2 + KCl.$$

benzenediazonium chloride — potassium iodide — iodobenzene — nitrogen — potassium chloride

The most common method used to introduce fluorine is the dry distillation of a diazonium fluoroborate:

$$Ar\overset{+}{N}{\equiv}NBF_4^- \longrightarrow ArF + N_2 + BF_3.$$

diazonium fluoroborate — aryl fluoride — nitrogen — boron trifluoride

The photochemical (*i.e.*, free-radical) chlorination of benzene causes the addition of chlorine to the double bonds and gives a mixture of hexachlorocyclohexanes. Dehydrohalogenation of this mixture by heating with aqueous alcoholic alkali gives a mixture of trichlorobenzenes.

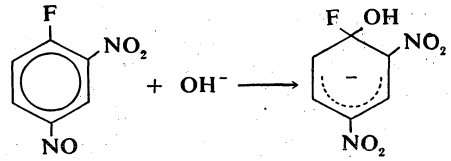
$$C_6H_6 \xrightarrow[\text{ultraviolet light}]{Cl_2} C_6H_6Cl_6 \xrightarrow{\text{alkali}} C_6H_3Cl_3 + 3HCl$$

benzene — hexachlorocyclohexanes — trichlorobenzenes — hydrogen chloride

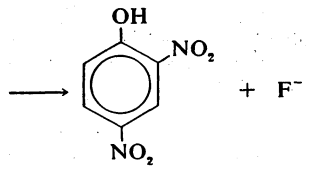
From the mixture obtained by fluorinating benzene with cobalt trifluoride, octa- and nonafluorocyclohexanes can be isolated. Dehydrofluorination of these substances by heating with concentrated aqueous potash gives penta- and hexafluorobenzenes. Deca-, nona-, and octafluorocyclohexanes can be dehydrofluorinated to polyfluorocyclohexenes and -dienes, and these compounds in turn can be defluorinated giving hexa-, penta-, and tetrafluorobenzenes.

Reactions. The main difference between aryl halides and alkyl halides is that the former are much more resistant to nucleophilic attack. If, however, the halogen in an aromatic compound is activated by the presence of other groups in the molecule, or if especially vigorous conditions (such as elevated temperatures and the presence of strong bases) are used, then nucleophilic substitutions or elimination–addition reactions (see below), which give the same end result, can take place. Thus, 2,4-dinitrofluorobenzene on treatment with a nucleophile

such as hydroxide ion undergoes a bimolecular substitution to give a phenol. When the nucleus is not activated either stronger bases or much more vigorous conditions

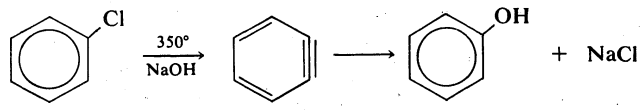


2,4-dinitrofluorobenzene | hydroxide ion | intermediate



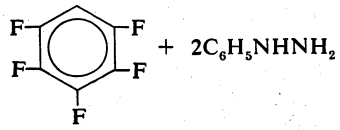
2,4-dinitrophenol | fluoride ion

are needed for nucleophilic attack; in such cases elimination of hydrogen halide gives a benzyne structure, to which the nucleophile then adds.

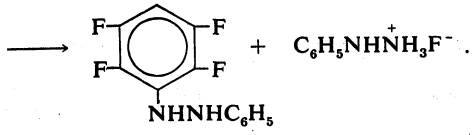


chlorobenzene | benzyne | phenol | sodium chloride

In hexachlorobenzene, the halogen atoms activate the nucleus in the same way as do the nitro groups in dinitrofluorobenzene; and, on heating with potassium fluoride, hexafluoro- and mixed chlorofluorobenzenes are formed by nucleophilic reactions. Pentafluoro- and chlorofluoropyridines are similarly made. Polychloro- and polyfluorobenzenes are highly susceptible to this form of attack. Reagents such as ammonia, sodium methoxide, lithium aluminum hydride, and phenylhydrazine often are used as nucleophiles. An example is given below:



pentafluorobenzene | phenylhydrazine

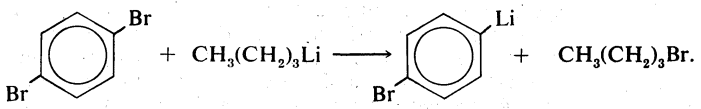


2,3,5,6-tetrafluorohydrazobenzene | phenylhydrazine hydrofluoride

The nuclear hydrogen atoms in aryl halides generally are subject to electrophilic attack and these compounds, therefore, undergo such typical aromatic reactions as halogenation, nitration, and sulfonation. Substitution occurs chiefly in the *para* position, but also in the *ortho* position.

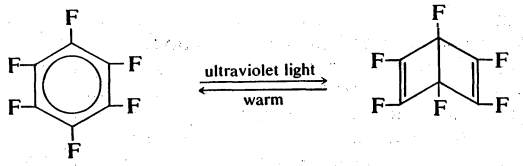
Formation of organometallic compounds

Reactions of aryl halides with metals are similar to those of alkyl halides. Aryl fluorides do not form organomagnesium halides, and chlorides react sluggishly; bromides and iodides, however, react readily. In polyhalo compounds, any hydrogen atoms left in the molecule are acidic because of the presence of the electronegative halogen atoms, and as a result these compounds regularly form organometallic compounds by hydrogen–metal exchange. Organolithium compounds often are formed by halogen–metal exchange in the less halogenated compounds. For example:



p-dibromobenzene | butyllithium | *p*-bromophenyllithium | butyl bromide

In nuclear halogenated compounds, chlorine, bromine, and iodine atoms are replaced by hydrogen atoms when the compounds are heated with hydrogen gas in the presence of a catalyst such as finely divided nickel, platinum, or palladium. Hexafluorobenzene, on ultraviolet irradiation, is converted into the so-called Dewar isomer (an abnormal form of benzene), which reverts to the normal form on gentle heating, but which may explode.

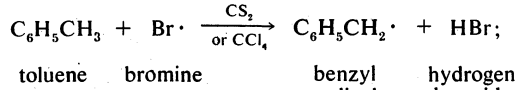


hexafluorobenzene | Dewar isomer

Side-chain-halogenated aromatic compounds. *Preparation.* Direct halogenation of an alkyl group (side chain) attached to an aromatic ring is a free-radical process and, as such, it is helped by exposure to visible or ultraviolet light and by boiling the reaction mixture, which aids dissociation of the halogen molecules to free atoms. After substitution is complete, the reagents effecting halogenation also cause saturation of the nuclear double bonds. In side-chain halogenation it is essential to avoid any trace of catalysts that promote nuclear substitution. Fluorine reacts so vigorously that it cannot be introduced preferentially into the side chain in this way, and iodine requires the presence of an oxidizing agent. The method is ideal for chlorine and bromine.

Side-chain halogenation

molecular bromine | atomic bromine



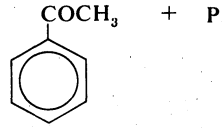
toluene | bromine atom | benzyl radical | hydrogen bromide

and so on.

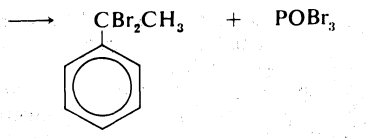
Sulfuryl chloride, with a trace of benzoyl peroxide as a free-radical initiator, can be used as a source of chlorine atoms for side-chain chlorination. Such chlorinations proceed rapidly in the dark. Other reagents that produce halogen atoms and therefore start chain reactions are tertiary butyl hypochlorite and hypoiodite and *N*-bromosuccinimide. The degree of halogenation can be controlled by regulating the amount of reagent used, but mixtures are always produced.

Other methods for preparing compounds halogenated in the side chain are similar to those used to prepare alkyl halides, either from the corresponding alcohol, such as benzyl alcohol ($C_6H_5CH_2OH$), or by the electrophilic addition of hydrogen halides or halogens to aryl olefins.

Aromatic aldehydes and ketones react with phosphorus halides or with sulfur tetrafluoride to give dihalo compounds.



acetophenone | phosphorus pentabromide

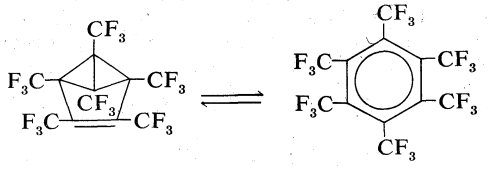


α,α-dibromoethylbenzene — phosphorus oxybromide

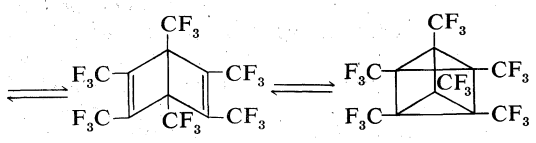
Aromatic acids react with sulfur tetrafluoride to give trifluoromethyl derivatives.

Reactions. Typical examples of aromatic compounds with halogen atoms in their side chains are benzyl chloride ($C_6H_5CH_2Cl$), benzylidene chloride ($C_6H_5CHCl_2$), and benzotrichloride ($C_6H_5CCl_3$). The reactivities of these compounds are intermediate between those of the alkyl and allyl halides with similar halogen atoms. Thus, benzyl halides react readily with nucleophiles; hydrolysis of benzylidene halides gives benzaldehyde, and that of benzotrichloride gives benzoic acid. When halogen atoms are not attached to the carbon atom adjacent to the benzene nucleus, the compounds react almost like similar alkyl halides.

Hexakis(trifluoromethyl)benzene undergoes ready photochemical valence bond isomerization to the benzvalene, "Dewar," and prismane isomers, which are surprisingly stable for compounds of this type.



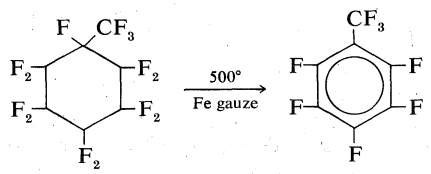
benzvalene isomer — hexakis(trifluoromethyl) benzene



Dewar isomer — prismane isomer

Nuclear- and side-chain-halogenated aromatic compounds. *Preparations.* Compounds that are lightly halogenated in both nucleus and side chain can obviously be prepared by methods already described. Of those that are highly or completely halogenated, only the polychloro and polyfluoro compounds are known, presumably because bromine and iodine atoms are too large. The photochemical chlorination of the side chains of benzene homologues fully chlorinated in the nucleus proceeds, for example, to the dichloromethyl or the trichloroethyl stage, where it stops. It also is difficult to complete the nuclear chlorination of benzene homologues with fully chlorinated side chains. There is one catalyst, aluminum trichloride and sulfur monochloride with sulfuryl chloride, sufficiently active to give perchloroalkaryl compounds (the prefix per- indicating complete substitution) from starting materials with fully halogenated side chains and nonhalogenated nuclei. Of the simple benzene homologues, only *m*-xylene and mesitylene resist complete chlorination by this method. Perfluoro homologues of benzene are prepared by first converting the hydrocarbons (using cobalt trifluoride) to perfluorocyclohexanes. The latter, then, are defluorinated to the fully fluorinated homologue of benzene.

Fully halogenated compounds



perfluoromethyl cyclohexane — octafluorotoluene

Nuclear fluorinated aromatic compounds can be fluoroalkylated by nucleophilic attack with anions generated from fluoride ion and perfluoroalkenes, as shown below:

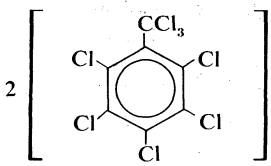
$$CF_3CF{=}CF_2 + F^- \longrightarrow CF_3\bar{C}FCF_3;$$

perfluoropropene — fluoride ion — intermediate anion

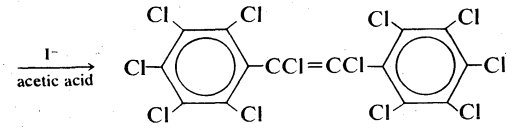
$$C_6F_6 + CF_3\bar{C}FCF_3 \longrightarrow C_6F_5CF(CF_3)_2 + F^-.$$

hexafluorobenzene — anion — perfluorocumene — fluoride ion

The behaviour of alkylbenzenes lightly halogenated in the nucleus and side chain is predictable on the basis of the separate effects of the two classes of halogen atoms. With perhalogenated compounds, new properties appear. For example, prolonged treatment of perchloro compounds with chlorine, in the presence of a catalyst or ultraviolet light, causes chlorinolysis of the side chain to give hexachlorobenzene and the fully chlorinated alkane. Treatment of perchloro compounds with iodide ion in acetic acid causes dechlorination and sometimes coupling (union of two molecules); for example,



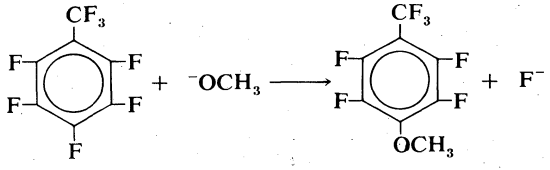
perchlorotoluene



perchlorostilbene

Chlorinated groups adjacent to the chlorinated benzene nucleus are easily hydrolyzed by heating with concentrated sulfuric acid: $C_6Cl_5CCl_2CCl_3 \rightarrow C_6Cl_5COCCl_3$. Trifluoromethyl groups in perfluoro- or chlorofluorobenzene homologues are similarly hydrolyzed to carboxyl groups. In all of these polyhalo compounds, but particularly in the fluorinated ones, the halogen atoms in the nucleus are susceptible to substitution by nucleophiles, such as lithium aluminum hydride, hydrazine, ammonia, methyllithium, and sodium alkoxides. In the perfluoro compounds, substitution occurs *para* to the perfluoroalkyl group (that is, in the position directly across the benzene ring).

Hydrolysis of side-chain halogens



perfluorotoluene — methoxide ion — *p*-methoxyperfluorotoluene — fluoride ion

Polyvalent iodine compounds (preparation and reactions). *Dichloroiodoarenes.* The iodine atom in an aryl iodide can exist in higher states of oxidation; *i.e.*, it can show valencies greater than one. Thus, when chlorine is bubbled into a solution of aryl iodide in cold dry chloroform, a dichloroiodoarene usually crystallizes out as a yellow solid. The formation of dichloroiodobenzene from iodobenzene occurs as follows:

$$C_6H_5I + Cl_2 \longrightarrow C_6H_5ICl_2.$$

These compounds, in which the iodine has a valence of three, are relatively unstable and decompose on heating to about 110° C (230° F). In the case of dichloroiodobenzene the product is *p*-chloroiodobenzene. Dichloro- and difluoroiodoarenes have been used as chlorinating and fluorinating agents.

Iodosyl compounds. When the dichloroiodoarenes are treated with aqueous alkali or aqueous pyridine, compounds containing the iodosyl group (—IO) are formed.

$$C_6H_5ICl_2 + 2NaOH \longrightarrow 2NaCl + H_2O + C_6H_5IO$$

dichloroiodobenzene; sodium hydroxide; sodium chloride; water; iodosylbenzene

Alternatively, these iodosyl compounds can be prepared directly from aryl iodides by oxidation. They behave as though they were anhydrides of the unknown bases, $ArI(OH)_2$, the salts of which can be made by dissolving the neutral iodosyl compounds in the appropriate acids (nitric, hydrochloric, hydrofluoric, and acetic).

Iodosyl compounds are oxidizing agents and liberate iodine quantitatively from acidified potassium iodide solution as follows:

$$C_6H_5IO + 2HI \longrightarrow C_6H_5I + I_2 + H_2O.$$

Iodyl compounds. Disproportionation (spontaneous oxidation and reduction) of iodosyl compounds on boiling with water or, more slowly, on standing, gives iodyl compounds and simple aryl iodides:

$$2C_6H_5IO \longrightarrow C_6H_5I + C_6H_5IO_2.$$

Iodyl compounds also can be made by oxidizing aryl iodides or iodosyl compounds.

Like iodosyl compounds, iodyl compounds are oxidizing agents that are quantitatively reduced by aqueous hydrogen iodide. They must be handled carefully because they explode on impact or on heating.

Iodonium compounds. A mixture of iodyl- and iodosylbenzene, on heating with silver oxide in aqueous suspension, gives a strongly alkaline solution of diphenyliodonium hydroxide:

$$2C_6H_5IO + 2C_6H_5IO_2 + Ag_2O + H_2O \longrightarrow 2(C_6H_5)_2I^+ OH^- + 2AgIO_3 .$$

The addition of a soluble iodide to a solution of a diphenyliodonium hydroxide yields a precipitate of a diphenyliodonium iodide. Stable salts of iodonium hydroxides can be formed by neutralization with acids. Such salts react with a great variety of nucleophiles, to give nuclear substituted products and aryl iodides:

$$(Ar-\overset{+}{I}-Ar)X^- + OH^- \longrightarrow ArOH + ArI + X^-.$$

They also decompose to substituted arenes on heating. For example:

$$(p\text{-}CH_3OC_6H_4-\overset{+}{I}-C_6H_5)Br^- \xrightarrow{180°} p\text{-}CH_3OC_6H_4I + C_6H_5Br.$$

p-methoxyphenylphenyliodonium bromide; *p*-iodomethoxybenzene; bromobenzene

TECHNICAL AND ANALYTICAL ASPECTS OF ORGANIC HALOGEN COMPOUNDS

Commercial uses. The polychloroalkanes and -alkenes are commonly used as solvents for drycleaning, chiefly because of their nonflammability. The most common are carbon tetrachloride and the trichloro- and tetrachloroethylenes. Chloroform is used as a solvent under controlled conditions, but its anesthetic properties make it dangerous. Because of their heavy vapours and their nonflammability some organic halogen compounds (carbon tetrachloride and dibromodifluoromethane, especially) have been used as fire extinguishers. Chloro compounds can be dangerous because under these conditions they give phosgene ($COCl_2$), a poisonous gas. The simple chlorofluoromethanes and -ethanes are used as refrigerants (Freons) and also, because of their great chemical stability, as propellants in aerosols, such as air fresheners and whipped cream.

Use as solvents

Chloroform was used for many years (mixed with acetone and ether) as an anesthetic. It is dangerous, however, because of the low margin between the lethal dose and the anesthetic dose and because the substance can damage the liver. It has now been completely superseded by fluothane ($CF_3CHBrCl$). Ethyl chloride is used as a local anesthetic.

One of the most common polymers is polyvinyl chloride. It is used mainly for electrical insulation and artificial fabrics for rainwear and upholstery. Tetrafluoroethylene and chlorotrifluoroethylene give Teflon (Fluon) and Kel-F polymers, respectively; these have very high thermal stability and electrical resistance. Because of the low intermolecular forces between highly fluorinated compounds, the lower molecular weight Kel-F polymers are used as lubricants, and Teflon is used to pack bearings in motors. Copolymers of hexafluoropropene and vinylidene fluoride (Vitons) are among the most thermally stable elastomers. Electronic apparatus and switchgear are sometimes immersed in fully fluorinated liquid alkanes (Flutec PP5) and cycloalkanes (Flutec PP3), which conduct away the heat developed during operation and act as insulators.

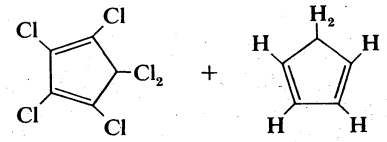
Use as polymers

Polychloro compounds are most important as insecticides. One of the earliest was DDT (dichlorodiphenyltrichloroethane), which is made by condensing together chlorobenzene and chloral:

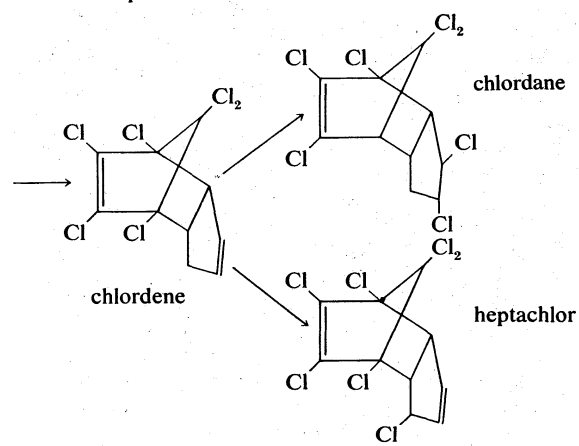
$$2C_6H_5Cl + CCl_3CHO \xrightarrow{H_2SO_4} (p\text{-}ClC_6H_4)_2CHCCl_3 + H_2O.$$

Use as insecticides

Gammexane, the gamma isomer of hexachlorocyclohexane, has properties and uses similar to those of DDT. It is made by the free radical addition of three molecules of chlorine to benzene. Of the nine possible isomers, eight are formed, and—of these—only the gamma form is active. Another important group of insecticides is derived from hexachlorocyclopentadiene. Addition of cyclopentadiene to the hexachloro compound gives chlordene. This substance can be converted either to chlordane by addition of chlorine or to heptachlor by substitution of chlorine for a hydrogen atom:



hexachlorocyclopentadiene; cyclopentadiene



Use of norbornadiene rather than cyclopentadiene in the above reaction gives aldrin, which can be converted to its epoxide dieldrin. Two similar insecticides, prepared by a slightly different route, are isodrin and endrin. The use of these highly chlorinated compounds has been criti-

cized because their stability causes them to accumulate in fish, birds, and animals. Monofluoroacetamide has been used as a systemic insecticide to kill black flies on plants such as roses; sodium monofluoroacetate is used as a rodenticide. Both are dangerous to human beings. Their volatile derivatives (*e.g.*, fluoroacetic acid and ethyl fluoroacetate) were among the first nerve gases.

Use as herbicides

Chlorinated and fluorinated benzenoid and heterocyclic compounds, and also urea derivatives, are used as herbicides. The reaction of chloral and urea gives dichloralurea, which is used as a soil sterilant to prevent the growth of weeds. The heterocyclic compound diquat (1,1′-dimethylene-2,2′-bipyridylium dihalide) and paraquat (1,1′-dimethyl-4,4′-bipyridylium dihalide) are used to destroy grasses and broad-leaved weeds. The substance 3,5-dichloro-4-hydroxydifluoropyridine (Teklon) is used for the control of wild oats and couch grass.

The well-known herbicides 2,4-D and 2,4,5-T (respectively, 2,4-dichloro- and 2,4,5-trichlorophenoxyacetic acids) are used to kill broad-leaved plants and smaller shrubs, respectively.

The compound 5-fluorouracil is thought to replace uracil in nucleic acids and hence interfere with the biochemical operation of living cells. It is used in the treatment of some forms of cancer. The introduction of one or two fluorine atoms into steroid molecules either by replacing hydrogen or by addition across a double bond often enhances the hormonal activity of the steroid. Certain halogenated steroids also are used to reduce skin inflammation.

Separation, identification, and analysis. The introduction of a bromine or iodine atom into a hydrocarbon molecule increases the boiling point of the substance by about 100° to 150° C (180° to 270° F) and creates bonds that are less stable than carbon–hydrogen bonds. In the main, however, alkyl halides, aryl halides, and most polyhalo compounds are stable. The most common are gases or liquids, and the most usual way to purify them is by fractional distillation. Unfortunately, however, polyfluoro compounds have a pronounced tendency to form constant-boiling mixtures, and—as a result—they are often not separable in this way. The technique known as vapour phase chromatography has proved useful in this case, and in fact this method is now used extensively for the separation of mixtures of reasonably volatile halo compounds (with boiling points up to 200° C, 392° F) of all kinds. Fundamentally, vapour phase chromatography is very similar to fractional distillation, the vapour of the mixture in a stream of nitrogen being adsorbed on and desorbed from a column of nonvolatile solvent supported on a substance like kieselguhr. By varying this stationary phase (dinonyl phthalate, silicone oil, and fluorolube are common materials used) it is usually possible to separate any mixture.

Spectroscopic identification

Apart from the use of melting and boiling points, pure organic halogen compounds are identified most often spectroscopically. There are strong characteristic absorptions in the infrared arising from stretching vibrations of the carbon-to-halogen bonds. Because the frequencies at which these absorptions occur are influenced by neighbouring groups, they give valuable information about the molecular structure, revealing, for example, whether the halide is an alkyl or aryl derivative. In the mass spectrometer, which separates materials on the basis of their relative masses, organic halides are usually sufficiently stable to show an ion derived from the intact molecule. As a result, an accurate molecular weight can easily be found. The breakdown pattern of the ions often gives strong clues to the structure of the parent compound.

Nuclear magnetic resonance spectroscopy, which measures the energy required to change the alignment of magnetic nuclei in a magnetic field, is used to determine the structures of compounds containing hydrogen and fluorine atoms. The resonance peaks associated with these atoms appear at different locations in the spectra of various compounds depending on the atoms adjacent to them. By finding the number of atoms in each different environment, the structure of a compound often can be determined.

By measuring another atomic property, the nuclear quadrupole moment, the structures of compounds containing chlorine and bromine can often be deduced. It is probable, however, that in the future the structures of chlorine-, bromine-, and iodine-containing compounds will best be determined by X-ray induced electron emission spectroscopy. This technique is based on the magnetic or electrostatic analysis of the electrons that are emitted from a substance on irradiation with X-rays. The energies of these electrons are characteristic of the atom from which they are emitted and of the environment of that atom. Hence, the results can be used both for elemental analysis and for structure determination. This method, however, was in its infancy in the early 1970s.

Elemental analysis

Conventional elemental analysis of halogens in organic compounds involves, first, fusion of the compound with sodium or potassium, and then estimation of the alkali metal halides. Fluoride can be determined by weight as lead chlorofluoride, and chloride by titrating the alkali liberated by its action on mercuric oxycyanide. Bromide is quantitatively oxidized to bromate by sodium hypochlorite, and this, in turn, is used to liberate iodine from hydrogen iodide. In a similar fashion, iodide is converted to iodate by hypobromite, and this, again, is used to liberate iodine from hydrogen iodide. In both cases the free iodine is titrated with standard sodium thiosulfate.

STOCK, *Aromatic Substitution Reactions* (1968), describe in detail theories concerning nucleophilic and electrophilic substitution in aromatic compounds.

(W.K.R.M.)

Organic Nitrogen Compounds

Since, by definition, organic compounds are compounds containing carbon, organic nitrogen compounds are substances the molecules of which contain at least one carbon and one nitrogen atom. Several hundred thousand such compounds are known, and new ones are being prepared or discovered continually. Organic nitrogen compounds are present in all known living organisms, as essential and often major components. Flesh, hair, horn, milk solids, and blood, for example, are composed largely of organic nitrogen compounds. Many drugs and medicinal agents, both natural and synthetic, including most narcotics, local anesthetics, the sulfa drugs, penicillin; most explosives, such as nitroglycerine and TNT (2,4,6-trinitrotoluene); some rocket fuels; many dyes; and some synthetic polymers (substances of high molecular weight made up of a number of identical or similar groups of atoms bonded together), such as nylons and the melamine resins, belong to this class. For detailed background information see CHEMICAL BONDING; MOLECULAR STRUCTURE; CHEMICAL COMPOUNDS, ORGANIC; CHEMICAL REACTIONS.

No single characterization can be made to apply to the properties of organic nitrogen compounds. Some are gases—*e.g.*, hydrogen cyanide (formula HCN) and methylamine (CH_3NH_2); some liquids—*e.g.*, nitroglycerin

$$[O_2NOCH_2CH(ONO_2)CH_2ONO_2]$$

and aniline ($C_6H_5NH_2$); but most are solids. Some mix completely with water; others are quite insoluble. They may be acidic, basic, or neutral, coloured or colourless, volatile or nonvolatile, intensely poisonous or essential to life.

BONDING IN NITROGEN AND ITS COMPOUNDS

Bonding characteristics of nitrogen. The wide variation in properties of members of the group is directly related to the ability of nitrogen to take part with other elements in a large number and variety of molecular structures. This ability results from the capacity of the nitrogen atom to have a large number of so-called oxidation states (*i.e.*, extents of being joined to more electronegative atoms; see below).

Chemical bonds result from a rearrangement of the electron structures of two or more atoms when they combine to form a molecule or a solid metal or a salt composed of ions (charged atoms). Every atom has a nucleus carrying a number of positive charges (called the atomic number, the largest number known being 105), surrounded by an equal number of negatively charged electrons. The electrons are arranged in orderly fashion in concentric shells and subshells; and their positions are defined by quantum mechanics in terms of energy requirements for the structure. An electron may change position as a result of acquiring or losing energy, and it is then defined by the new position it occupies. Certain configurations of the electron structure are more stable than others, and in the most stable the outermost shell has eight electrons, called the octet. The only neutral atoms with eight outermost electrons are the noble gases. Other atoms, with more or less than eight, lose or acquire one or more electrons, thereby becoming positively or negatively charged ions. Oppositely charged ions attract one another to form electrovalent, or ionic, bonds (as seen, for example, in crystals in which the bonding electrons involved are completely associated with the negative ions). Atoms may also form covalent bonds by sharing one or more pairs of electrons, which hold them together in discrete molecules. In still another form of bonding, the atoms release the electrons of their incomplete outermost shells to the aggregate of atoms, a condition found in metals. Ions may have as many as four positive or negative charges. Bonds of the covalent type may involve one, two, or three pairs of electrons and are termed single, double, or triple bonds; the chemical formula for a compound may show the bonds as a single line for each pair of electrons, thus: H—H, N=O, and N≡N, respectively. In complex molecules, both covalent and ionic bonds may be present.

Nitrogen has atomic number 7; its nucleus thus has a charge of +7 and is surrounded by seven electrons, each having a charge of −1. Two of the electrons fill an inner shell, and the remaining five occupy a second shell, which has a total capacity of eight. Because stable structures generally result when shells are filled, the incomplete second shell of nitrogen is responsible for its chemical combining power. The octet may be filled by electrons that are either shared or acquired.

Oxidation state

The electron pairs of covalent bonds are not shared equally when the bonded atoms are different, a fact that gives rise to the concept of oxidation state (or oxidation number), which is defined as the number of bonds shared with electronegative elements (*i.e.*, those to the right in the periodic table) minus the number of bonds shared with electropositive elements (*i.e.*, those to the left in the periodic table). The oxidation number of nitrogen ranges from −3, as in ammonia (NH_3), through zero, as in elemental nitrogen (N_2), to +5, as in nitric acid (HNO_3), and nitrogen occurs in known organic compounds in these and all intermediate oxidation states (−2, −1, +1, +2, +3, +4).

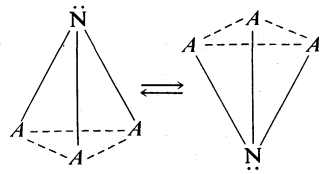
Organic nitrogen compounds are classified on the basis of the inorganic (*i.e.*, not containing carbon) constituent that can be considered the parent compound; *i.e.*, the compound from which the organic compound is produced by removing a hydrogen atom and replacing it with a group of atoms containing carbon. Nitrogen occurs in nature bound to hydrogen, oxygen, carbon, and other nitrogen atoms; it can also form bonds with other elements, including sulfur, phosphorus, fluorine, chlorine, bromine, and iodine.

Nitrogen-compound structures. In almost all organic nitrogen compounds, the three additional electrons required to fill the octet are obtained by sharing an electron pair with another atom, which contributes one electron to the shared pair, thus forming a covalent bond. Three such bonds, adding three electrons to the normal five, result in a filled octet; the fourth pair of electrons of the nitrogen atom is not shared. An example is the reaction shown below (in which *A* represents any atom with one electron available to share, and each electron is represented by a dot); one nitrogen atom combines with three *A* atoms to form a compound in which three pairs of electrons are shared in covalent bonds, and the outer electron shell of the nitrogen atom is filled.

$$\cdot\ddot{N}\cdot + 3A\cdot \longrightarrow A{:}\ddot{\underset{\ddot{A}}{N}}{:}A$$

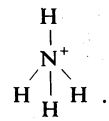
Shapes of nitrogen compounds

It has been shown by experiment and is found consistent with theoretical views that the orbitals (*i.e.*, the regions around the nucleus occupied by the four electron pairs) point to the four corners of a tetrahedron (triangular pyramid). Simple compounds in which three atoms share covalent bonds with nitrogen thus have the shape of a flattened pyramid, with the nitrogen atom at the apex and the unshared electron pair above it. In fact, however, this shape is very mobile and inverts (turns inside out like an umbrella) very rapidly. The interaction between the two forms is represented by an equation in which each bonded pair of electrons is a single line, and each single electron is a dot.



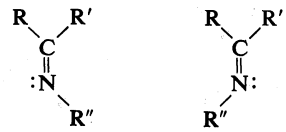
The unshared electron pair is available to form a fourth bond by sharing with another atom having an incomplete outer shell. Such atoms include oxygen (O), hydrogen ion (H^+; an ion is any electrically charged atom or molecule), and carbonium ion (*e.g.*, R_3C^+), a positively charged organic ion in which the outer shell of a carbon atom contains only six electrons shared in covalent bonds to three atoms or groups of atoms, the behaviour of which is explained by assuming that the resulting positive charge is localized on the carbon atom. In the formula, *R* can represent any of a number of groups of atoms bonded to the carbon atom; the symbol *Ar* (for example, ArH_2C^+) often is used to represent an aromatic group; *e.g.*, one having the benzene ring (a six-sided cyclic compound, formula C_6H_6).

The fourth bonding results in the formation of a tetrahedral molecule (or ion) with all four corners occupied by other atoms; an example is ammonium ion, NH_4^+, which can be represented:



Such species of bonded atoms maintain their form more or less rigidly when none of the four surrounding atoms is a hydrogen, and, if all four bonded atoms are different, the same kind of dissymmetry (left- and right-handedness, in reference to the position of the four relative to each other) as is encountered in carbon compounds may arise.

When a nitrogen atom shares two electron pairs with the same atom, a double bond results. The atoms joined by the double bond and the atoms attached directly to them then lie all in the same plane, together with the unshared electron pair on the nitrogen. Such compounds may have two geometrically isomeric forms (*i.e.*, forms differing only in the arrangement in space of the groups about a double bond); for example, many imines (compounds in which nitrogen is doubly bound to carbon) have isomers that may be represented as



The formation of a triple bond by sharing three electron pairs is most commonly encountered between a nitrogen and a carbon atom. Such compounds, called nitriles, have a linear structure (*i.e.*, the atoms lie in a straight line), as in the case of a single radical (*R*) bonded to a carbon atom that also shares a triple bond with a nitrogen atom, expressed as $R—C{\equiv}N$. (Molecular nitrogen and certain less common classes of compounds, the azides and diazonium salts, are considered to have triple bonds between two nitrogen atoms.)

CLASSIFICATION OF ORGANIC NITROGEN COMPOUNDS

Parent compounds

The parent inorganic compounds from which organic nitrogen compounds are obtained include ammonia (NH_3), hydrazine ($H_2N—NH_2$), hydroxylamine ($H_2N—OH$), hydrogen azide (HN_3), nitrous acid (HNO_2), nitric acid (HNO_3), and a few very unstable substances: diazene, or diimide, (HN=NH), nitroxyl (HNO), amino radical ($H_2N\cdot$), aminoxyl ($H_2N—O\cdot$), triazene ($H_2N—N{=}NH$).

Amines. Compounds derived from ammonia by replacement of one or more hydrogen atoms by hydrocarbon groups, which have varying numbers (indicated by *m* and *n*) of carbon and hydrogen atoms, C_mH_n, are known as amines; alkyl (*R*), or aryl (*Ar*). When only one hydrogen atom is replaced, the resulting compounds are called primary amines and are represented as RNH_2; when two hydrogens are replaced, they are secondary (R_2NH), and, when all three hydrogens are replaced, they are tertiary (R_3N). All such compounds resemble ammonia in that they are basic (*i.e.*, they form salts with acids by virtue of the unshared electron pair). As the hydrocarbon portion (the part consisting of groups containing only carbon and hydrogen atoms) of the molecule becomes larger, the amines become less volatile (*i.e.*, have less tendency to vaporize at ordinary temperature), less soluble in water, and generally more like hydrocarbons. Amines have lower melting points than most other classes of nitrogen compounds, and are more strongly basic. Most naturally occurring compounds of nitrogen are amines or derivatives of them.

Amines are named by prefixing the name of the attached groups to the stem amine, as in dimethylamine $(CH_3)_2NH$. If an aryl group such as the phenyl radical, $—C_6H_5$ (from benzene, C_6H_6), is attached, the compound is usually considered to be a derivative of aniline and is named as substituted aniline, as in 4-chloro-*N*-methylaniline ($ClC_6H_4NHCH_3$).

Derivatives of the ammonium (the "-ium" ending indicates, as in carbonium carbon, the presence of a localized positive charge) ion bearing four hydrocarbon groups (R_4N^+) are quaternary ammonium salts. The quaternary ammonium ions themselves are not basic (there being no longer an unshared electron pair), but their hydroxides (compounds in which the positive charge on the nitrogen atom is neutralized by the negative charge of a hydroxide ion, OH^-), $R_4N^+OH^-$, are strong bases that resemble sodium and potassium hydroxides. They are named by prefixing the names of the substituents to the stem ammonium, as in the tetramethylammonium ion ($[CH_3]_4N^+$).

Double bonds

Imines. Compounds in which nitrogen is bound to carbon by a double bond are known as imines (sometimes called Schiff bases). Imines are distinctly weaker bases than the amines. They are most commonly named by following the name of the related carbonyl compound by the word imine, as in diethyl ketone *N*-methylimine, $(C_2H_5)_2C{=}N—CH_3$, related to diethyl ketone, $(C_2H_5)_2C{=}O$.

Carbinolamines. Closely related to the imines, although containing no double bond, are the carbinolamines. They are produced by addition of the elements of water to the double bond and may usually be dehydrated to form imines (providing there is a hydrogen on the carbinolamine nitrogen atom). They are given names on the basis of being amines bearing a 1-hydroxy substituent (OH), as in 1-hydroxyethyldimethylamine,

$$CH_3CH(OH)N(CH_3)_2.$$

Triple bonds

Nitriles. The nitriles have a triple nitrogen-to-carbon bond (which is written $—C{\equiv}N$), generally have low melting points, and are for ordinary considerations totally nonbasic (do not neutralize acids to form salts). They have a close affinity with carboxylic acids—*i.e.*, organic acids containing the carboxylic group, —COOH, such as acetic acid, CH_3COOH, and benzoic acid, C_6H_5COOH; the carbons are in the same oxidation state, having in each case three bonds to an atom having higher affinity for electrons (oxygen or nitrogen). They are named by using the root name of the corresponding acid, with the suffix nitrile, as in acetonitrile, $CH_3C{\equiv}N$ (from acetic acid, CH_3COOH).

Amides. The replacement of an acidic hydroxyl group by an amino group produces the class of nitrogen compounds known as amides. The carboxamides, $RCONH_2$, are the most important group; other substituent groups may be attached to the nitrogen. Amides known as sulfonamides, RSO_2NH_2, are also produced from the sulfonic acids, RSO_3H. Most amides are solids, apt to have high melting points, and are essentially nonbasic and of low volatility. Most are named from the corresponding acid, using the suffix "-amide," as in acetamide, CH_3CONH_2, and *N*-ethylbenzenesulfonamide,

$$C_6H_5SO_2NHC_2H_5.$$

Imides. Compounds of the imide class have two carbonyl (*i.e.*, containing the organic radical $>C=O—$ *e.g.*, acetyl, $CH_3CO—$) groups attached to the same nitrogen, as in acetimide, $(CH_3CO)_2NH$. They are weakly acidic (*i.e.*, neutralize alkalies to form salts) if the nitrogen is not otherwise substituted. If both oxygens of a carboxyl group (—COOH, the radical characteristic of most organic acids) have been replaced by nitrogen, the amidine structure results. Amidines are moderately strong bases. The general formula is $RC(NH_2) = NH$.

Cyanic acid

Carbonic acid derivatives. The compounds derived from carbonic acid are usually considered as a class by themselves. The nitrile of carbonic acid is cyanic acid, $HO—C{\equiv}N$, which in turn can provide two groups of derivatives: the cyanates, $R—O—C{\equiv}N$, and the isocyanates, $R—N{=}C{=}O$. They are named by combining the class name with the name of the substituent, as in ethyl isocyanate, $C_2H_5—N{=}C{=}O$.

The amide of cyanic acid, cyanamide, $H_2N—C{\equiv}N$, and its tautomer (tautomers are compounds of the same chemical formula but different molecular structure that interconvert reversibly) carbodiimide, $HN{=}C{=}NH$, also yield a group of derivatives.

Carbonic acid, HOCOOH, which has two hydroxyl groups, reacts with ammonia to produce amides in two stages, carbamic acid, NH_2COOH, and urea,

$$NH_2CONH_2.$$

Carbamic acids are unstable in the free state but their salts and esters are well known. A salt is the compound other than water formed by reaction of an acid with a base, and an ester is a derivative of an acid in which a hydrocarbon group is attached to an oxygen atom in place of the acidic hydrogen atom. The esters are often called urethans, after the primitive name of the ethyl ester, $C_2H_5O—CO—NH_2$. Urea and its derivatives are almost invariably solids of high melting point and low volatility and are commonly named as substituted ureas, as *N,N'*-dimethylurea, $CH_3—NH—CO—NH—CH_3$. Thiourea is the compound in which a sulfur atom replaces the oxygen atom of urea.

The amidine of carbamic acid goes by the special name guanidine. The guanidines, $H_2NCNHNH_2$, are in general very strong bases, approaching hydroxide ion (OH^-) in strength.

Hydroxylamine compounds. Nearly all the various derivatives of ammonia (NH_3) have their parallel with

hydroxylamine ($H_2N—OH$). Hydroxylamine may carry one, two, or three substituents, which may be bonded to either the nitrogen or the oxygen atom; *e.g.*, *N*,*N*-dimethylhydroxylamine, $(CH_3)_2N—OH$, and ethoxylamine, $C_2H_5—O—NH_2$. Such compounds are similar to amines but are weaker bases. Quaternary compounds corresponding to those of ammonia are of two types: tetrasubstituted salts and amine oxides.

The hydroxylamine compounds analogous to imines are the oximes, $RR'C{=}NOH$, and nitrones,

$$RR'C=\overset{+}{N}RO^-.$$

Nearly all are solids, but the oximes and derivatives have considerably lower melting points than the nitrones.

The most important hydroxylamine derivatives of the carboxyl group are the *N*-acyl compounds, called hydroxamic acids, $RC(=O)NHOH$.

Hydrazine compounds. Hydrazine is also the parent of a family of structures analogous to the organic derivatives of ammonia. There are compounds of from one to four substituents (mono-, di-, tri-, and tetrasubstituted hydrazines); all are weakly basic. Quaternary hydrazinium compounds

$$R_2N-\overset{+}{N}R_3\ X^-$$

(in which X^- represents any negatively charged atom or group of atoms) are also well known. The analogues of imines, $R_2C{=}N—NR_2$, are called hydrazones and may have any of a range of organic groups bonded to the nitrogen atom. Azines, $R_2C{=}N—N{=}CR_2$, have two imine groups joined by an N—N bond. The only important hydrazine derivatives of the carboxyl group are the hydrazides, which are weakly basic.

Diazene compounds. The derivatives of diazene that have two substituted groups (*i.e.*, are disubstituted), $R—N{=}N—R$, are called azo compounds, such as azobenzene, $C_6H_5—N{=}N—C_6H_5$. They are neutral substances, generally coloured and solid. Monosubstituted diazenes are known but are very unstable.

The diazonium compounds,

$$Ar-\overset{+}{N}\equiv N\ X^- \rightleftharpoons Ar-N=N-X,$$

are closely related. The salts of strong acids are truly ionic (*i.e.*, electrically charged) and show the properties to be expected of a triple bond. They are generally rather unstable substances but of great importance as intermediates (chemicals produced as necessary steps between starting material and finished product) in synthesis. The diazo compounds, such as diazomethane,

$$CH_2=\overset{+}{N}=\overset{-}{N} \rightleftharpoons \overset{-}{C}H_2-\overset{+}{N}\equiv N,$$

also show evidence of a triple bond.

Compounds with three or more nitrogens. Triazenes and azides are among the types of compounds having chains of three or more nitrogens. The word triazene denotes three nitrogen atoms and a double bond, $H_2N—N{=}NH$, and, in analogous fashion, names for longer chains and different degrees of unsaturation (that is, capable of combining directly with additional groups of atoms) may be developed.

Azides of various types, such as methyl azide, $CH_3—N_3$, phenyl azide, $C_6H_5—N_3$, and acetyl azide, $CH_3CO—N_3$, all contain the linear (*i.e.*, all the atoms lie in a straight line) azido group

$$-N=\overset{+}{N}=\overset{-}{N} \rightleftharpoons -\overset{-}{N}-\overset{+}{N}\equiv N.$$

The nitroso and nitro compounds, $R—N{=}O$ and $R—NO_2$, represent higher oxidation states. Both are neutral, and the former are all a beautiful blue or green, whereas the latter are colourless to yellow. Most nitroso compounds, such as nitrosobenzene, $C_6H_5—N{=}O$, are in equilibrium with colourless dimers (a dimer is a molecule formed by the union of two simpler molecules), with the nitrogen molecules bonded together. Both classes of compound are invariably named by means of the "nitroso-" or "nitro-" prefix.

Nitrous and nitric acid compounds. The highest oxidation states of nitrogen are represented by the derivatives of nitrous acid (HNO_2) and nitric acid (HNO_3). Among them are the esters, $R—O—N{=}O$ and $R—O—NO_2$, which contain no carbon-to-nitrogen bond. The nitrites that are exceptionally volatile, and the nitrates, such as nitroglycerin (or glyceryl trinitrate), are potentially explosive in proportion as the ratio of oxygen to carbon and hydrogen in the compound approaches the optimum for complete internal combustion to water, oxides of carbon, and molecular nitrogen. Nitrous and nitric acids can give rise to amides, hydroxamic acids, and hydrazides, just as do other acids. All of them are known in the form of organic derivatives.

The volatility of nitrites and nitrates

THE AMINES AND THEIR DERIVATIVES

Physical and chemical properties. The smallest amines are gases, but most amines are liquids, and all of them except the very large have fishy or musty odours. The volatility (*i.e.*, the tendency to vaporize at ordinary temperatures) decreases with increasing molecular weight and increasing number of hydrogens attached to the nitrogen. Primary amines thus have the highest boiling points and tertiary the lowest for comparable molecular weights. The smaller amines are soluble or even completely miscible in water (that is, can be mixed completely without separating into two layers) but, when the size of the molecule exceeds five carbon atoms, the solubility drops rapidly. Nearly all amines are soluble in the common organic solvents. Aliphatic amines (*i.e.*, those in which the nitrogen atom is not attached to a benzene ring) are slightly stronger bases than ammonia and will turn litmus indicator paper blue, but aromatic amines (those in which the nitrogen atom is attached to a carbon atom present in a benzene ring) are considerably weaker, and most of them will not affect litmus.

Aliphatic amines

Salts. Nearly all salts of amines are nonvolatile solids, very soluble in water, to which they give a weak acidic reaction if they are salts of strong acids, such as hydrochloric, nitric, or sulfuric; generally they do not dissolve in nonpolar solvents such as ether and the hydrocarbons. Quaternary ammonium compounds are completely ionic in nature—the hydroxides are alkalies as strong as sodium hydroxide (lye).

Sources and preparation. Some simple aliphatic amines occur naturally, mostly as the products of decay, but there are no practical natural sources. Industrially, aliphatic amines are mostly made from fatty acids (organic acids derived from natural fats and oils), olefins (unsaturated aliphatic compounds whose molecules contain only carbon and hydrogen atoms; *i.e.*, they are hydrocarbons), or alcohols (alcohols are hydroxyl compounds, containing the oxygen–hydrogen radical, OH, bonded to a saturated carbon). The fatty acids (or the fats and oils in which they occur bound) may be reduced to alcohols (one important step in production of detergents), which can then be converted to amines catalytically by reaction with ammonia or by indirect, laboratory methods involving initial conversion to a suitably reactive derivative. Alternatively, the fatty acids may be converted to nitriles (by way of their amides) by reaction with ammonia, followed by hydrogenation (combination of hydrogen with another substance, usually an unsaturated organic compound). These reactions also give rise to secondary and tertiary amines.

A few amines, notably aniline and some of its derivatives, are made by reduction (reduction is an increase in the number of electrons) of nitro compounds, although in recent years it has become more common to produce aniline from chlorobenzene in a continuous process under high pressure.

Reductive alkylation (a process of adding alkyl radicals and hydrogen), whereby an aldehyde or ketone is treated with ammonia and hydrogen in the presence of a catalyst, has both industrial and laboratory utility.

There are three types of reaction by which amines may be prepared on a laboratory scale: displacements on halides or derivatives; reduction of nitriles, amides, oximes, nitro compounds, etc.; and rearrangements (Hofmann,

Curtius, Lossen, Beckmann, Schmidt). Many variations of them are described in specialized works.

Chemical behaviour of amines

The chemical behaviour of amines is dominated by their basicity. Nearly all of them form salts even with moderately weak acids, and the aliphatic amines even extract carbon dioxide from moist air to form salts. Since salts in general are soluble in water, most amines will thus dissolve in dilute solutions of acids. Salts also generally crystallize well, and, by reaction with acids, liquid or gaseous amines can be converted to solid derivatives useful for identification.

Oxidation characteristics. Aliphatic amines are not easily oxidized (oxidation is loss of electrons), but aniline and its derivatives commonly become coloured slowly on prolonged contact with air, owing to oxidation of the activated benzene ring to form complex dyes. Since amines are the lowest oxidation state of nitrogen, they are not ordinarily reducible (except for hydrogenolysis of benzylamines and some quaternary ammonium salts, in which a C—N bond is broken with addition of hydrogen to each fragment).

Chlorine and bromine replace the *N*-hydrogens of amines to form *N*-haloamines. Tertiary amines undergo more deep-seated changes.

The reaction of amines with nitrous acid is an old and important reaction. It appears that all primary amines give a diazonium salt, $R\text{–}N_2^+X^-$, but only with aniline and its derivatives can such products be isolated (or even detected). The observed result with aliphatic primary amines is the formation of mixtures, consisting of olefins, cyclopropanes, and isomeric alcohols, with evolution of nitrogen. The formation of nitrogen gas (effervescence) has been used as a qualitative test for primary amines. From secondary amines, nitrosamines precipitate as nonbasic, yellowish oils, and tertiary amines are degraded to mixtures of nitrosamines with aldehydes or ketones derived from one of the alkyl groups.

Aromatic primary amines are a special case. Cold (about 0° C), they react with dilute nitrous acid to form solutions of diazonium salts, which easily lose nitrogen on warming and form phenols ($ArOH$).

Alkyl halides, sulfates, and related alkylating agents react more or less readily with free amines so as to add an alkyl group to the nitrogen atom. The process may be repetitive, especially if an inorganic base is present, so that most amines are eventually converted to quaternary salts, if bulk does not interfere.

Reactions with other organic compounds. The reactions of amines with other classes of organic compounds form a vast subject. In the most general terms, they do not react with alcohols or olefins except at high temperatures in the presence of surface catalysts, when they may become alkylated on the nitrogen. Aldehydes and ketones will usually react with primary amines to form imines by addition at the carbonyl group (C=O) followed by elimination of water, as shown in the equation

$$R-NH_2+R'_2C=O \longrightarrow R'_2C(OH)-NHR \longrightarrow R'_2C=NR+H_2O.$$

Carboxylic acids form salts, which may lose water when heated very strongly, forming amides, as in the reaction

$$R-NH_2+R'CO_2H \longrightarrow R-NH_3^+RCO_2^- \xrightarrow{\Delta} R'CONH-R+H_2O.$$

Primary and secondary amines react to form amides, vigorously with acid chlorides, slightly less vigorously with acid anhydrides, and extremely sluggishly with esters.

$$RCOX+2R'NH_2 \longrightarrow RCONHR'+R'NH_3^+X^-$$

Amines do not react with other bases, weak or strong, except insofar as amines are liberated from their salts. Quaternary ammonium salts, however, undergo the Hofmann reaction when they are converted to the hydroxides (usually by treating them with moist silver oxide) and then heated strongly. One group is cleaved from the nitrogen as an olefin leaving a tertiary amine.

$$R_3\overset{+}{N}-CH_2CH_2ROH^- \xrightarrow{\Delta} R_3N+CH_2=CHR+H_2O$$

Compounds with amide linkages. *Physical properties.* The carboxamides and imides are mostly solids of low volatility and thus little odour, although they are likely to have flavour. Unsubstituted amides, $RCONH_2$, have the highest melting and boiling points; substitution of hydrogen by alkyl groups (paraffin hydrocarbon radicals) reduces the intermolecular attraction by removing the capability for hydrogen bonding between N—H of one molecule and C=O of another. The small amides and imides (less than six carbon atoms) are soluble in water, and formamide is completely miscible.

Common characteristics of amides

Similar remarks can be made about most of the other types of amides: thionamides, sulfonamides, ureas, urethans (carbamates), amidines, and imidates (imino esters). The last two types, however, which have no carbonyl group, have lower melting points, and the simple imidates are liquid at room temperature.

Amides in general are neutral in water solution, but they show a feeble basicity toward very strong acids, especially in the absence of water. Imidate esters, however, are almost as basic as alkylamines, and amidines are the strongest organic bases short of the quaternary ammonium hydroxides. Sulfonamides show no basic properties, but those having at least one hydrogen on the nitrogen have acidities similar to those of phenols.

Sources and preparation. There are no practical natural sources of simple amides, although polyamides occur in great abundance as the protein of living systems. Simple amides are made industrially from ammonium salts of carboxylic acids by strong heating; some *N*-substituted amides are made analogously. Esters react with ammonia to form amides, but the general laboratory method is to treat an amine with an acid chloride or anhydride. It is usually desirable to add an equivalent of alkali (base, usually having a hydroxyl group that ionizes to hydroxide ion, OH^-, which then combines with the hydrogen ion, H^+, of an acid to form water, a process called neutralization) to neutralize the acid that would otherwise bind a second equivalent of amine (Schotten–Baumann procedure).

Imides do not occur naturally except for some complex heterocyclic compounds. For preparative purposes, imides can generally be prepared from amides by treating them with acid chlorides or anhydrides or with metallic sodium or potassium, but cyclic imides, derived from dicarboxylic acids, can in many instances be prepared by strongly heating the ammonium salt of the acid or the half-amide. Imides can also be prepared by heating nitriles with carboxylic acids.

The derivatives of carbonic acid are a special case. Urea is prepared commercially by heating ammonia with carbon dioxide, but substituted ureas are best prepared by the reaction of an isocyanate with an amine. Urethans are also made from isocyanates, by reaction with alcohols.

The most characteristic reaction of amides is hydrolysis (a chemical reaction with water), by which they are converted to an acid and an amine. Amides are generally inert to pure water and require a mineral acid, alkali, or enzyme to catalyze hydrolysis. Wool and nylon, both of which are polyamides, can thus be dissolved by heating them with strong acid or base such as potassium hydroxide (KOH). The equation is

$$RCONR_2+KOH \longrightarrow RCO_2K+R_2NH.$$

Amides can also be dehydrated, most commonly by heating with phosphorus pentoxide or phosphoryl chloride. Unsubstituted amides give nitriles, and monosubstituted amides give ketenimines, but disubstituted amides are inert. Monosubstituted formamides can be dehydrated to isocyanides.

Amides are not readily oxidized and are inert to most reducing agents. Catalytic hydrogenation will convert amides of aliphatic acids to amines at somewhat high pressures and temperatures, and electrolytic reduction is generally successful with aromatic amides, but the most generally effective reagent is lithium aluminum hydride.

Conditions may generally be chosen so as to favour either amines, alcohols, or aldehydes as the products.

Aldehydes but not ketones generally react with amides that have at least one hydrogen on the nitrogen. The first step is addition to the aldehyde carbonyl group, but this may be followed by reaction with a second molecule of amide and elimination of water. The technique of preserving flesh by immersion in formaldehyde solution makes use of these reactions, and the condensation of formaldehyde with urea (carbamide) produces the industrially important urea–formaldehyde resins.

$$H_2NCONH_2 + H_2C{=}O \longrightarrow H_2NCONHCH_2OH + (-NHCONHCH_2-)_n$$

Amides may react with acid chlorides or anhydrides, especially if a base is present, to form imides.

The halogen elements and the hypohalous acids, HO*X*, replace a hydrogen on the nitrogen in the presence of base. The resulting *N*-haloamides are not very stable and easily undergo the Hofmann rearrangement when warmed with excess base. The overall effect is to convert the amide to a primary amine having one fewer carbon atom.

Amides suffer replacement of the amino group by an aryl or alkyl group, to form ketones (formamides yield aldehydes) in two ways: reaction with Grignard reagents or treatment with an aromatic hydrocarbon, such as benzene, in the presence of phosphoryl chloride (Vilsmeier–Haack reaction).

Compounds with double and triple C—N bonds. *Imines, nitriles, isocyanates, etc.* The simplest members of each class in this section are liquids, although little more can be said about the small imines, for they polymerize so readily. Hydrogen cyanide is actually the smallest nitrile. Acetonitrile has an unusually high dielectric constant and is a polar solvent capable of dissolving many salts as well as most other organic compounds. The isomer methyl isocyanide is a liquid of exceptionally revolting stench; methyl isocyanate has a pungent, biting odour; and methyl isothiocyanate smells somewhat savory as well as pungent. Cyanamide forms transparent crystals. The isomeric (forming isomers) carbodiimides polymerize too rapidly for the simpler ones to have been obtained pure, but in general they are liquids similar to the cyanamides.

The small imines, nitriles, cyanamides, and carbodiimides are miscible or soluble in water, but isocyanides, isocyanates, isothiocyanates, cyanates, and thiocyanates are nearly insoluble.

Imines are most generally prepared either by reaction of a ketone or aldehyde with a primary amine or by the addition of Grignard reagents to nitriles. Oxidation (or catalytic dehydrogenation) of amines can also be made to give imines.

Preparation of isocyanates

Isocyanates are nearly always prepared by the reaction of primary amines with phosgene or by a process called, after its discoverer, the Curtius rearrangement of acyl azides, although other methods exist, such as the addition of cyanic acid to olefins, the reaction of potassium cyanate with alkylating agents, such as methyl sulfate, and the cleavage of certain urethans by heat or salts of silver or mercury. Isothiocyanates, R—N=C=S, can be obtained naturally in some cases; allyl isothiocyanate, for example, comes from mustard seeds, and an old term for isothiocyanates as a class is mustard oils. Laboratory preparation starts with primary amines, which react with carbon disulfide to form dithiocarbamate salts. These can be decomposed to isothiocyanates, sometimes by heating but more generally by treating with salts of silver or of lead. An important source of thiocyanates is the reaction of alkyl thiosulfates with alkali metal cyanides.

Sources of nitriles

The commonest source of nitriles is the reaction of alkyl halides with sodium (or potassium) cyanide, which goes well with primary alkyl halides but fails when they are tertiary. When silver cyanide is used, a complex is formed, which liberates an isocyanide when broken up with excess potassium cyanide. Aryl halides, which are generally inert toward alkali metal cyanides, can be converted to cyanobenzenes by heating with cuprous cyanide. Both nitriles and isocyanides can be made by dehydrating amides.

An industrially important source of nitriles is the catalytic reaction of hydrocarbons bearing methyl groups with ammonia and oxygen at high temperatures (ammoxidation).

Carbodiimides are prepared from thioureas by treating with reagents that extract hydrogen sulfide (*e.g.*, mercuric oxide), as well as by other methods.

Principal reactions. The double and the triple C—N bonds are susceptible to hydrolysis (reaction with water), generally with catalysis by either acid or base (a catalyst alters the speed of reaction enormously, without being itself used up, generally at a much lower temperature than needed to initiate the reaction without a catalyst), with varying degrees of ease. The ultimate result is replacement of all C—N bonds by C—O bonds, such that imines yield aldehydes or ketones, nitriles yield carboxylic acids, isocyanides yield primary amines and formic acid, and cyanates, isocyanates, and their sulfur analogues yield carbon dioxide (or carbon oxysulfide). When conditions are mild enough or the amount of water is limited, hydrolysis may be stopped at the intermediate stage of amides (from nitriles), formamides (from isocyanides,) or ureas (from isocyanates and carbodiimides). Hydrolysis is paralleled by reactions with alcohols, of which the two most important examples are the conversion of nitriles to imidate esters and to ortho esters and of isocyanates to urethans. Ammonia and amines react analogously, particularly with isocyanates or isothiocyanates, and are thereby converted to ureas or thioureas, respectively.

Reduction (a category of reactions, the reverse of oxidation and here usually meaning reaction with hydrogen in the presence of a catalyst) in general saturates the double and triple C—N bonds with hydrogen, converting the compounds to amines of one kind or another.

A class of compounds called Grignard reagents reacts readily with nitriles and isocyanates, converting them to imines and amides, respectively. The same conversion can be accomplished by reaction with aromatic hydrocarbons and a class of catalysts called Friedel–Crafts catalysts; *e.g.*, aluminum chloride.

COMPOUNDS WITH N—N BONDS

Physical properties. The smaller hydrazines are hygroscopic liquids with unpleasant odours and are nearly as strongly basic as amines when they bear only one or two alkyl substituents. Successive substitution lowers the basicity, and the tetraalkylhydrazines, R_2N—NR_2, are only feebly basic. Substitution of methyl groups for hydrogen in hydrazine lowers the boiling point, by reducing hydrogen bonding, but larger substituents add so much weight that their net effect is to raise the boiling point.

Substitution of an acyl group for hydrogen, giving a hydrazide, raises both the melting and boiling point, and such compounds are nearly all solids, basic enough to dissolve in dilute mineral acid but weaker than hydrazine. Hydrazones are intermediate in properties and generally are liquids or low-melting solids (unless there are large substituents on the nitrogen atom) and of feeble basicity. Azines, $R_2C{=}N{-}N{=}CR_2$, may be liquids or solids and are generally yellowish and nonbasic.

The derivatives of azobenzene, a typical azo compound, in general are solids, always coloured, insoluble in water, and nonbasic; the larger aliphatic azo compounds are liquids. Monosubstituted analogues, usually named as diazenes, are of low stability, and much less is known about them.

Azoxy compounds resemble the azo compounds but are of paler colour; they are distinct from the oxadiaziridines, with which they were at one time confused.

Diazonium salts are generally colourless, crystalline, water-soluble substances that decompose slowly at room temperature and are capable of exploding. The salts are neutral in reaction, which implies that the diazonium hydroxides are strong bases. In basic solution, however, diazonium salts become converted to diazotate ions, Ar—N=N—O$^-$, which can exist in stereoisomeric forms

related to those of the imines illustrated previously. Closely related are the diazo compounds, of which diazomethane, $CH_2{=}N_2$, is the best known; they are coloured yellow to purple, generally low-melting, and seldom very stable; they are inert to bases but are destroyed by acids.

The azides are colourless compounds, commonly liquid and insoluble in water. They are neutral but may be destroyed by concentrated acids, and though they are more stable than diazo compounds they may be dangerously explosive, especially if they are small.

The most important of the remaining compounds with N—N bonds are the triazenes, $R_2N{-}N{=}N{-}R$, but all are rarely encountered.

Sources and preparation. Alkyl hydrazines are produced when hydrazine is treated with alkylating agents, and, although mixtures with dialkyl and even trialkyl hydrazines may result, this is usually a satisfactory preparative method. Some alkyl hydrazines are more easily prepared from hydrazides by reduction with lithium aluminum hydride. Reduction of nitrosamines is a good route to *N,N*-disubstituted hydrazines, and reduction of hydrazones has been used to prepare trisubstituted hydrazines. Aryl hydrazines can be obtained in wide variety by reducing diazonium salts; although this is the preferred method, a good alternative is the reaction of azodicarboxylic ester with aromatic hydrocarbons. This reaction produces hydrazine analogues of urethans, which can be hydrolyzed cleanly to aryl hydrazines.

Hydrazones are usually made by the reaction of ketones or aldehydes with hydrazines, although they can also be made by tautomerization of azo compounds. Hydrazides are made by reaction of esters with hydrazine; if acid chlorides are used, diacyl hydrazines are produced.

Aromatic azo compounds can be prepared in great variety by the reaction of diazonium salts with compounds containing reactive benzene rings; this is the method used to prepare azo dyes. Alternatively, an aromatic primary amine and a nitroso compound can be converted to an azo compound by the elimination of water. When the desired azo compound is symmetrical, such as azobenzene, the same effect can be obtained by reducing the corresponding nitrobenzene under suitable conditions. Aliphatic azo compounds are nearly always prepared by oxidizing a hydrazine.

Azoxy compounds are formed by the oxidation of azo compounds with peroxides or by reaction of nitroso compounds with hydroxylamines, with elimination of water. Reduction of a nitrobenzene may be controlled so as to produce the latter two reagents, thereby producing an azoxybenzene.

Diazonium compounds are always prepared by diazotization, the reaction of a primary aromatic amine with cold nitrous acid (although there are some unimportant reactions that also give rise to them).

The most general method among many for preparing diazoalkanes is the treatment of an *N*-nitroso-*N*-alkylamide with a strong base. Oxidation of simple hydrazones is a useful preparative method for larger diazoalkanes.

Aliphatic azides are usually prepared by a simple displacement reaction between an alkyl halide and sodium azide, but aryl azides, which cannot in general be prepared in this way, are easily prepared from diazonium salts and sodium azide. Both aryl and acyl azides can be prepared by the reaction of nitrous acid with the corresponding hydrazine derivative.

Reactions. The most characteristic reactions of alkyl and aryl hydrazines are salt formation and alkylation. Alkyl halides, sulfates, etc., will replace the hydrogens stepwise, usually continuing at the same nitrogen until a quaternary compound is formed. Hydrazones and hydrazides undergo the same type of reaction, although not as readily.

Most organic hydrazine derivatives are reducing agents in some degree, and those that bear no more than one substituent on each nitrogen are especially easily oxidized, forming azo compounds. With two hydrogens on the same nitrogen, oxidation is a little more difficult but can be accomplished with strong oxidizing agents so as to convert disubstituted hydrazines to diazenium salts and hydrazones to diazoalkanes. The N—N bond in hydrazines can be cleaved by reduction to give two molecules of amine; the preferred reagent is hydrogen in the presence of a nickel catalyst.

Nitrous acid attacks most hydrazine derivatives; the initial product in all cases is probably a nitroso (*i.e.*, the molecule contains the —NO group) derivative, but only when the hydrazine is trisubstituted can it usually be isolated. Monoarylhydrazines and simple hydrazides are converted all the way to azides, in an important preparative reaction.

Azo compounds are relatively unreactive. They are inert to alkylating agents, to aldehydes and ketones, and to acylating agents, and are not easily attacked by strong acids or bases. Reduction, their most characteristic reaction, takes place in two stages, first to a hydrazine and then to a pair of amines. Azo compounds having a hydrogen on an adjacent carbon isomerize (*i.e.*, rearrange their molecular structure) rather easily to hydrazones, especially in the presence of a base.

Reaction with acids

The most important general reaction of diazoalkanes is that with acids, which are converted to their esters, usually quantitatively and rapidly. Another important general reaction is the loss of nitrogen to form transient carbenes (electron-deficient species with divalent carbon) when heated or exposed to light. Diazomethane and to a lesser extent other diazoalkanes react with acid chlorides to form diazoalkyl ketones. These undergo the Wolff rearrangement when heated (usually in the presence of a silver catalyst) and form ketenes (or, in the presence of alcohols, water, or ammonia, the corresponding esters, acids, or amides). The overall process thus converts a carboxylic acid through its acid chloride to an acid with one more carbon atom (Arndt–Eistert synthesis).

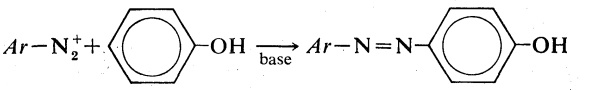
The most important reactions of azides are decomposition by heat, light, or concentrated acids, reduction, and addition of certain very strong bases. Heat or light causes loss of two-thirds of the nitrogen as N_2. In some cases this is accompanied by rearrangement, as in the Curtius rearrangement of acyl azides to isocyanates. In others, a reactive, electron-deficient intermediate, called a nitrene, is produced, which cannot be isolated but reacts very rapidly with itself or the solvent or both.

Many reducing agents, such as hydrogen (with a platinum catalyst) or sodium arsenite, convert azides cleanly to primary amines, for which this process is sometimes a useful preparative method.

The reactions of diazonium salts have been studied intensively since the mid-19th century, and the possibilities are so many and complex that only a small selection can be mentioned here. One important family of reactions involves loss of nitrogen and replacement of the diazonium grouping by another atom or group of atoms. Warming in water solution brings about replacement by OH, giving a phenol. In the presence of inorganic iodides or azides, aryl iodides or azides form rapidly. Replacement by chloride, bromide, or cyanide is brought about with the help of a copper(I) salt as catalyst (Sandmeyer reaction). Replacement by hydrogen may be brought about by alcohol or hypophosphorous acid.

Formation of azo compounds

Another important family of reactions consists of the attachment of another group, usually through a carbon atom, at the end of the diazonium system, to give various types of azo compounds. The most important examples involve reaction with phenols or anilines, forming substituted azobenzenes. When these substances also bear functions that help in binding them to textile fibres, they are azo dyes.



COMPOUNDS WITH N—O BONDS

Classes, sources, and preparation. Hydroxylamines are liquids or low-melting solids, volatile if small, and weakly basic. Oximes are still weaker bases and feeble acids and hydroxamic acids are weak acids similar to phenols. Nearly all hydroxylamine derivatives are soluble

in water if they do not contain more than six carbon atoms.

Compounds with a nitroso group attached to carbon are bright blue or green, low-melting, neutral substances, but few of them are well known, owing to their capacity for rapid dimerization (usually reversible). The dimers are colourless solids having structures analogous to azoxy compounds. With many nitrosobenzenes, the colourless dimer dissociates to the green monomer simply on melting or dissolving in an inert solvent.

Most simple nitro compounds are liquids and are only slightly soluble in water, if at all. Many nitrobenzene derivatives are yellow. Nitro compounds are in general neutral, but those that bear a hydrogen on the same carbon as the nitro group are pseudoacids; that is, although only feebly acidic themselves, they react slowly with bases to form salts derived from tautomeric forms (nitronic acids, or *aci*-nitro compounds), which have acid strengths similar to those of carboxylic acids. Trinitromethane, however, exists entirely in the nitronic acid form and is a strong acid. Nitro compounds are polar, and the smaller nitroalkanes dissolve many salts.

The esters of nitrous and nitric acids are liquids, volatile if small, and insoluble in water. The nitrites are not very stable to storage and are also easily hydrolyzed; the nitrates are considerably more stable, if they are pure, and are difficult to hydrolyze. Nitrate esters are sensitive to heat and shock, especially when impure, and can be violently explosive.

Stable organic derivatives, known as nitrosamines, of the unstable amide of nitrous acid are well known. There is no practical natural source of compounds containing N—O bonds, although some of them occur in nature.

The preparation of organic derivatives of hydroxylamine relies heavily on hydroxylamine itself, which reacts with aldehydes and ketones to form oximes and with esters, anhydrides, or acid chlorides to form hydroxamic acids.

Nitroso compounds are most generally made by oxidation of *N*-substituted hydroxylamines, although many nitrosobenzenes can be made conveniently by oxidizing the corresponding aniline with peroxysulfuric acid, and a few can be made by direct nitrosation (addition of nitroso group, NO) of the benzene ring by nitrous acid (*e.g.*, *p*-nitrosodimethylaniline).

Nitro compounds are prepared in great variety by treating aromatic hydrocarbons with nitric and sulfuric acids; with some severe limitations, nitration of aliphatic hydrocarbons (generally at high temperature in the vapour phase) is also of preparative value, but most aliphatic nitro compounds are made by further reactions of the few commercially available nitroalkanes, such as nitromethane.

Esters of nitrous acid are easily made by reaction between dilute nitrous acid and alcohols, but a mixture of nitric and sulfuric acids is generally required to convert alcohols to alkyl nitrates. Nitrosamines are formed easily when secondary amines are brought into contact with nitrous acid, but nitramines require special methods, such as treating primary amines with α-cyanoisopropyl nitrate or converting an amine to a carbamyl chloride and then treating it with silver nitrate.

Reactions. Although most hydroxylamines are indefinitely stable as their salts, the free bases do not generally store well; *N*-substituted hydroxylamines slowly transform into amines and azoxy compounds, but *O*-alkyl hydroxylamines are more stable. *N*-aryl hydroxylamines differ from the alkyl analogues in that acid easily brings about a rearrangement to form *p*-aminophenols and other ring-substituted anilines.

Both alkylation with alkyl halides and acylation with esters, anhydrides, and acid chlorides take place easily. Aldehydes and ketones react with *O*-substituted hydroxylamines to form oxime derivatives, but *N*-substituted hydroxylamines generally react only with aldehydes, with which they form nitrones.

Hydroxylamines and oximes can be reduced by various reagents, most generally by catalytic hydrogenation, and then form amines.

Hydroxamic acids are hydrolyzed to the parent carboxylic acids by hot aqueous mineral acid. In the form of their alkali metal salts, they can be alkylated or acylated.

The chemistry of nitroso compounds is dominated by their oxidation and reduction. They are active oxidizing reagents, and a wide variety of reducing agents will convert them first to hydroxylamines and then to amines. Because nitroso compounds react with both of these functional groups, the actual products obtained from a reduction may be further transformation products—azo or azoxy compounds, hydrazines, benzidines, etc. Oxidation of nitroso to nitro compounds requires a strong oxidizing agent, such as permanganate or a peroxy acid.

Aliphatic nitroso compounds are generally so tightly bound up as the dimers that reactions specifically of the monomer are not easily observed. If there is a hydrogen on the same carbon as the nitroso group, the monomer easily and irreversibly isomerizes to an oxime. The nitroso group is an effective trap for free radicals, which add to the nitrogen to form a nitroxide, $RR'N{-}O\cdot$. Nitroso compounds react with many other types of compounds under suitable conditions: olefins, aldehydes, Grignard reagents, compounds having active methylene groups, etc.

Reduction of nitro compounds

By far the most important reaction of nitro compounds is their reduction, which, although not so easily accomplished as with nitroso compounds, can still be brought about by a large variety of reducing agents; hydrogen (with catalysts), dissolving metals (iron, tin, zinc, etc.), sulfides, sodium alkoxides, etc. The products may be any of the oxidation states of nitrogen but generally not nitroso compounds, for these are invariably reduced further. If the reducing medium is acidic, reduction almost always goes all the way to an amine. In neutral medium, it is in many cases possible to stop at the hydroxylamine stage. In basic solution, N—N bonds are usually formed, and the products are hydrazo, azo, or azoxy compounds.

The more important part of the chemistry of aliphatic nitro compounds has to do with the reactivity of the hydrogens on the same carbon as the nitro group. Concentrated sulfuric acid isomerizes primary nitroalkanes to hydroxamic acids, which are usually hydrolyzed to carboxylic acids and hydroxylammonium sulfate. Their salts, the nitronates, are not very stable and undergo some unusual reactions. Strong mineral acid cleaves them to aldehydes or ketones and nitrous oxide (Nef reaction). Strong base causes more complex reactions; primary nitroalkanes condense to heterocyclic compounds (isoxazoles) and nitromethane itself is converted in stages to a salt of nitroacetic acid. Heavy-metal salts have distinctive reactions, such as that of the mercuric salt of nitromethane, which loses water to form mercuric fulminate.

Most nitroalkanes decompose above 300° C and form olefins, water, and oxides of nitrogen. With aldehydes (and some ketones), primary nitroalkanes react in a way analogous to the base-catalyzed aldol condensation, adding to the carbonyl group to form a nitro alcohol or its dehydration product, a nitro olefin (Henry reaction).

Alkyl nitrites decompose rather easily under the influence of heat or light to produce mixtures of carbonyl and *C*-nitroso compounds or their further transformation products. The first step is apparently loss of NO to form an alkoxy free radical (*i.e.*, a group of atoms with one unpaired electron), $R{-}O\cdot$. Alkyl nitrites also react as nitrosating agents, similar to nitrous acid.

Alkyl nitrates begin to decompose near 150° C. If the heating is carefully controlled, alkyl nitrites may be formed, along with smaller fragments and oxides of carbon, but otherwise explosion ensues, and the entire molecule may be converted to oxides of carbon, water, and nitrogen. Nitrates are most conveniently converted to the parent alcohol by reduction (zinc and acetic acid, ferrous chloride, etc.), which at the same time converts the nitrogen to nitric oxide or ammonia. Alkyl nitrates can function as alkylating agents or nitrating agents.

Organic Phosphorus Compounds

Organic phosphorus compounds are carbon-containing compounds that also contain one or more atoms of the element phosphorus. Of the several million known organic compounds, several hundred thousand contain phosphorus.

The organic compounds of phosphorus are typically colourless liquids or solids, not physically distinct from other organic compounds of similar molecular size and character. Several types are very toxic, including the phosphines, but they present little danger in normal use because their exceedingly offensive odours generally prevent overexposure. Many toxic phosphorus compounds of other classes, however, are particularly hazardous because they are colourless, almost odourless liquids. Some of them are used as insecticides. Others were developed during World War II as a particularly unpleasant class of chemical warfare agent, the nerve gases.

Organic phosphates

Insecticides and nerve gases belong to the general family of organic phosphates, which are probably the most important of the organic phosphorus compounds. Also included in this category are many biochemical compounds essential to life processes, such as the nucleic acids (control factors in heredity) and nucleotide coenzymes (compounds that permit enzymes to function properly). Other organic phosphates find industrial uses—as solvents and flame-retardation agents, for example. Other classes of organic phosphorus compounds are less useful, but some play important roles in the synthesis of complex chemical compounds of various types, such as pharmaceuticals.

There are many problems connected with the naming of organic phosphorus compounds, largely because the first organic phosphorus compounds were made and named in the early part of the 19th century, before complete knowledge of their structures was obtained. Furthermore, different authors in different countries have frequently used different names for the same compound. This situation was much improved, however, after an international agreement on nomenclature was reached in 1952, but the problem still exists. In this article standard international nomenclature is used.

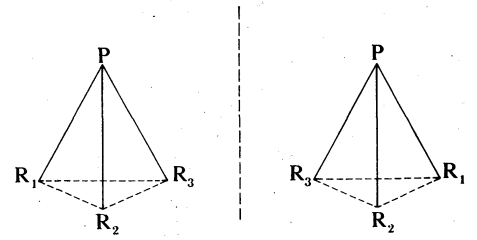
GENERAL PROPERTIES

The chemistry of the organic phosphorus compounds is best understood in terms of the influence of the phosphorus atom on the organic molecule. This influence depends in large measure on the electronic character of that atom.

Electronic configuration. Atoms of phosphorus, like those of other elements, contain a central, positively charged nucleus and, surrounding it, successive concentric rings, or shells, of negatively charged electrons. The electrons of the outermost shell are capable of joining with the electrons of other atoms to form chemical bonds, and they are, therefore, called bonding, or valence, electrons—the term valence referring to the number of other atoms with which a single atom of a given element can combine. In its outermost shell, a phosphorus atom has five electrons in two subshells called—for no important reason—*s* and *p* subshells. Within these subshells the electrons move in particular paths, or orbitals. The five outermost, or valence, electrons of a phosphorus atom occupy one *s* orbital (containing two electrons) and three *p* orbitals. The three *p* electrons are unpaired (each orbital being capable of holding two electrons) and therefore are available to form three single bonds, giving rise to trivalent compounds of phosphorus. Alternatively, however, the two *s* electrons can also become involved in bonding, and this situation leads ultimately to pentavalent phosphorus compounds.

Structure and bonding. Trivalent phosphorus compounds, with the general formula PX_3 (in which P represents a phosphorus atom and X any other atom or group), have pyramidal structures (one atom at each vertex of a three cornered pyramid), that are closely analogous to those of the corresponding and better known nitrogen compounds. One of the main differences between the phosphorus and nitrogen compounds is that the angles between the different P–X bonds are considerably smaller than the corresponding angles between the N–X bonds (in which N is the symbol for nitrogen)—close, in fact, to the 90° expected if bonding involves only the *p* orbitals of phosphorus. Another difference between phosphorus and nitrogen compounds is that the pyramidal configuration in the phosphorus series is much more stable to inversion—that is, to turning inside out, like an umbrella. As a result, trivalent organic phosphorus compounds (phosphines) with three different organic substituents, unlike the corresponding nitrogen compounds (amines), can exist in two separate forms (isomers), which are stable under mild conditions. The two forms are mirror images of one another, as shown by the diagrams below:

Pyramidal structures



In these diagrams, R_1, R_2, and R_3 represent the different organic groups joined to a phosphorus atom. The solid lines represent bonds between the phosphorus atom and the organic groups (and also the edges of the pyramidal structures of the molecules). The dotted lines indicate the bases of the pyramids, and the dashed line is the position of the mirror plane (indicating that each isomer is a mirror image of the other.)

The great majority of phosphorus compounds, however, are not pyramidal but rather have four substituents arranged tetrahedrally about the phosphorus atom. These tetrahedral compounds include salts of the formally trivalent compounds—formed by utilizing the two *s* electrons and based on the phosphonium ion, PH_4^+ (in which H is hydrogen)—as well as the much larger group of truly pentavalent compounds. Pentavalent compounds can be formed because the phosphorus atom has available unused orbitals—called *d* orbitals—which, in the tetrahedral PX_4^+ state, readily accept electrons from other (donor) atoms to form a fifth bond to phosphorus. The donor atom may be in a separate molecule, in which case a pentacovalent species PX_5 results; several scores of compounds with this structure are known. But the utilization of *d* orbitals is most efficient when the donor atom is already bonded to phosphorus. The phosphorus–oxygen bond, for example, is stabilized in compounds such as the phosphine oxides, $R_3P{=}O$ (in which O is an oxygen atom, R represents an organic group, and the double line indicates a double bond), the *p* electrons of oxygen interacting with the vacant *d* orbitals of phosphorus to form a so-called pi bond. This type of multiple bonding stabilizes an adjacent negatively charged centre very effectively in the phosphinimines, $R_3P{=}NR$, and phosphinemethylenes, $R_3P{=}CR_2$ (C representing a carbon atom), as well as being responsible for the great stability of the phosphorus–oxygen double bond (P=O).

Tetrahedral structures

It is also instructive to compare these higher valence compounds of phosphorus to the comparable compounds of nitrogen. Nitrogen atoms, like phosphorus atoms, carry *s* electrons that they are able to use in forming salts—derivatives of the ammonium ion, NH_4^+, just as the related phosphorus compounds are derived from the phos-

phonium ion, PH_4^+. The nitrogen atom, however, does not have vacant *d* orbitals available for sharing donor electrons, so that pi-bonded compounds comparable to those formed by phosphorus do not occur. Thus, the amine oxides, compounds formulated as $R_3N^+–O^-$, cannot form a carbon–nitrogen double bond and are markedly less stable than the comparable phosphorus–oxygen compounds, which do form a phosphorus–oxygen double bond.

This exceptional strength of the phosphorus–oxygen double bond in the phosphoryl compounds has an important influence on much of phosphorus chemistry.

Chemical reactivity. Trivalent phosphorus compounds are readily converted to their oxides and undergo many other reactions that generate products containing the phosphorus–oxygen double bond. Furthermore, the stabilizing effect of pi bonding can be exerted on more than one phosphorus–oxygen bond simultaneously. As a result, anions (negatively charged ions) such as that formulated as $R_2P(=O)(O^-)$ are unusually stable (in having two P–O bonds, both of which can show pi bonding). Indeed, compounds formulated as $R_2P(O)OH$ are strong acids; *i.e.*, they readily give up a hydrogen ion to achieve the stable anionic condition. Even such anions as $RP(=O)(O^-)(OH)$ have acidic properties and in neutral solution are largely dissociated to dianions, RPO_3^{2-}. In these anions, the various oxygen atoms are equivalent and share in the negative charge, while the various phosphorus–oxygen bonds are also equivalent and have equal amounts of partial double bond character.

Importance of the phosphorus–oxygen double bond

Chemically, the phosphorus atom of an organophosphorus compound is a centre of high reactivity. Trivalent phosphorus has a lone pair of nonbonded *s* electrons, which gives it basic (the chemical opposite of acidic) character, as well as nucleophilic character (that is, a tendency to be attracted to positively charged groups). Nucleophilic substitution reactions proceed readily at both trivalent and pentavalent phosphorus centres. The only important exceptions to this generalization are the tertiary phosphine oxides, $R_3P=O$. These have no readily displaced substituent and, therefore, do not undergo substitution reactions of any kind. Furthermore, the doubly bonded phosphorus–oxygen group, P=O, does not undergo the ready addition reactions characteristic of the carbon–oxygen doubly bonded group (C=O, or carbonyl group), the behaviour of which in aldehydes and ketones is an important aspect of general organic chemistry. Thus, the tertiary phosphine oxides, $R_3P=O$, show little or none of the chemical reactivity associated with the ketones, $R_2C=O$.

Analysis of phosphorus in compounds

Phosphorus in organic compounds is usually assayed (measured) as inorganic phosphate. Some compounds, especially those with phosphorus–carbon bonds, are degraded to inorganic phosphate only by powerful oxidizing agents; *e.g.*, concentrated perchloric acid at the boiling point. The inorganic phosphate formed is converted to a substance called phosphomolybdate, which can be determined either gravimetrically (by weight) or colorimetrically (by measurement of colour intensity).

MAJOR CLASSES

Organic derivatives of phosphorus acids. The organic derivatives of the acids based on phosphorus are derived from the six parent acids shown in Table 1. Conversion to organic derivatives can be considered formally to consist of replacement of any or all of the hydrogen atoms by organic groups (R). In addition, one or more of the oxygen atoms may be replaced by sulfur atoms, giving rise to the large family of thioacids of phosphorus.

The free acids themselves exist overwhelmingly in the pentavalent (P=O) forms (shown in the second column of the table), but esters and other derivatives of the trivalent are stable. If this generalization is not appreciated, the nomenclature can be very confusing. Trimethyl phosphite $(CH_3O)_3P$, for example, is a stable liquid that can readily be hydrolyzed (converted by water) to the dimethyl ester. This ester is commonly known, not unreasonably, as dimethyl phosphite, but it exists almost exclusively in the tetrahedral form, $(CH_3O)_2P(=O)H$, and is, therefore, correctly termed dimethyl phosphonate.

Table 1: Trivalent and Pentavalent Forms of the Phosphorus Acids

trivalent form		pentavalent form	
name	formula	name	formula
Phosphinous acid	H_2POH	phosphine oxide	$H_3P=O$
Phosphonous acid	$HP(OH)_2$	phosphinic acid	$H_2P(=O)(OH)$
Phosphorous acid	$(HO)_3P$	phosphonic acid	$(HO)_2P(=O)H$
		phosphoric acid	$(HO)_3P=O$

Most organic compounds of phosphorus formally are derivatives of one of the phosphorus acids—the exceptions being those compounds with three or more phosphorus–carbon or phosphorus–hydrogen bonds. The neutral organic compounds of phosphorus are described below, in sections devoted to the trivalent and pentavalent derivatives, respectively. This section deals specifically with the acid forms, including those acid esters in which the parent acid has more than one acidic group. (Most important by far of these are the esters of phosphoric acid.)

Organic phosphorus acids

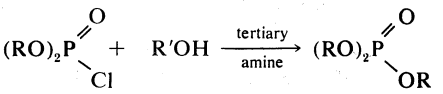
Organic acids of phosphorus are moderately strong acids, with dissociation constants (the standard way of comparing acids) in the region of 10^{-1}–10^{-2}. Acids with two hydroxyl (–OH) groups have a second dissociation constant, usually between 10^{-7} and 10^{-8}. The lower molecular weight compounds are liquids that are soluble in water. The higher molecular weight acids and those containing aromatic groups (a particularly stable organic grouping) become progressively less soluble in cold water. Even these, however, generally dissolve in neutral or alkaline aqueous solution to form anions. As usual, solubility in organic solvents follows almost the reverse trend, being high for nonionized acids and for esters with high molecular weights. In Table 2 is collected a representative selection of acids and their derivatives based on simple organic groups; it illustrates the system of nomenclature now in use, as well as typical physical properties.

Phosphate esters—the esters of phosphoric acid—like other tetrahedral compounds of pentavalent phosphorus, are usually prepared by nucleophilic substitution of

Table 2: Organic Phosphorus Acids and Derivatives

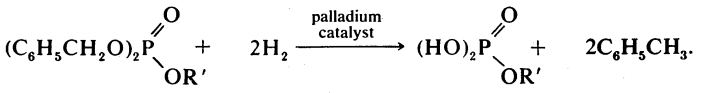
structure	name	melting point (°C)	boiling point (°C)
$(C_2H_5)_2P(=O)OH$	diethylphosphinic acid	19	310
$C_6H_5P(=O)(OH)OC_6H_5$	phenyl hydrogen phenylphosphonate	70–72	...
$(C_2H_5O)_3P=O$	triethyl phosphate	...	215
$C_2H_5OPOCl_2$	ethyl phosphorodichloridate	...	167
$C_6H_5OPO(OH)_2$	phenyl dihydrogen phosphate	97–98	...
$C_2H_5OPO_3^{2-}\ Mg^{2+}$	magnesium ethyl phosphate	...	...
$H_3\overset{+}{N}PO_3^{2-}\ Na^+$	sodium phosphoramidate	...	...
$(C_2H_5O)_2P(O)OPO(OC_2H_5)_2$	tetraethyl pyrophosphate	...	137/1mm
$C_2H_5OP(=O)(O^-)–O–P(=O)(O^-)–O–PO_3^{2-}\ 4\ Na^+$	tetrasodium ethyl tripolyphosphate	...	...

groups located on the phosphorus atom (that is, by attack of a negative group at the positive centre). Syntheses of simple derivatives are based on the readily available substance phosphorus oxychloride, $POCl_3$, which reacts consecutively to lose one, two, or three chloride ions. Triesters are formed when a dialkyl phosphorochloridate (prepared from two molecules of the alcohol to one of phosphorus oxychloride) reacts with an alcohol or phenol in the presence of a tertiary amine, as in the following chemical equation:



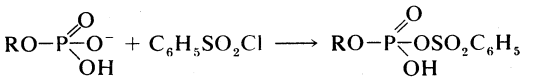
dialkyl phosphorochloridate — alcohol — trialkyl phosphate

This method provides an unambiguous route to unsymmetrical triesters and is readily adapted to the synthesis of monoesters if the first two alkyl groups (R in the above example) can be removed under conditions that leave the third group. The benzyl group ($C_6H_5CH_2-$) is a frequently used blocking group of this kind in the preparation of phosphate esters. It can readily be removed with hydrogen, as in the following example:

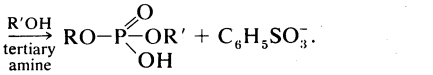


alkyl dibenzyl phosphate — hydrogen — alkyl phosphate — toluene

Important variations of this type of reaction can be carried out with condensing agents, such as acid chlorides or anhydrides, on phosphate anions. These condensing agents convert the negatively charged oxygen atom to a group that is easily displaced. An example of such an easily displaceable group is the benzenesulfonate group (introduced by reaction with benzenesulfonyl chloride). The reactions involved are the following:

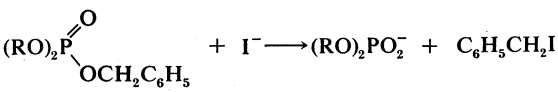


alkyl phosphate anion — benzenesulfonyl chloride



dialkyl phosphate — benzenesulfonate anion

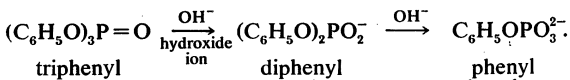
Alternatively, a carbon–oxygen bond may be broken when a powerful but weakly basic nucleophile attacks an ester with a reactive alkyl group, as shown below:



dialkyl benzyl phosphate — iodide ion — dialkyl phosphate anion — benzyl iodide

Beginning in the 1950s the requirement for phosphate esters of known structure in the nucleotide field (see below) greatly stimulated work on methods of phosphorylation.

In their reactions, phosphate esters, especially the triesters, resemble the better known carboxylic esters. Strongly basic nucleophiles, such as hydroxide ions, readily effect nucleophilic displacement of groups on phosphorus atoms in diesters and triesters, as in this example:



triphenyl phosphate — hydroxide ion — diphenyl phosphate anion — phenyl phosphate dianion

Apart from their biochemical importance, organic phosphates play a definite role in the synthesis of organic chemicals containing phosphorus. Organic phosphates and related compounds also find important uses as corrosion and oxidation inhibitors; as plasticizers that confer fire resistance to textiles; as agents for the selective extraction of metals; and as insecticides. Some phosphorylating agents react rapidly and specifically to inhibit certain enzymes, particularly cholinesterase, which is essential for the transmission of nerve impulses. As a result, such compounds are extremely toxic to warm-blooded animals; known as nerve gases, they are particularly hazardous because they can be absorbed through the skin as well as by swallowing or breathing.

Biologically important phosphate esters

Phosphate esters play a vital part in the chemistry of the life process. The genetic code is carried by the deoxyribonucleic acids (DNA), which are high-molecular-weight phosphate esters, built up from four different subunits, called nucleotides. Nucleotides are the phosphate esters of nucleosides (comprised of sugars and organic bases), and in the nucleic-acid structure each nucleotide subunit is joined to the phosphate group of the next by a second ester linkage. The nucleotides themselves also take part in a large number of essential biochemical processes, not only in their monophosphate form but also as diphosphates and triphosphates. Nucleoside triphosphates, especially adenosine triphosphate (ATP), play an important role in the process of phosphate transfer (phosphorylation). This is a key biochemical reaction, because it provides the chemical means by which an organism harnesses the chemical energy available from the degradation of food to do useful work. Phosphorylation is also an important biosynthetic reaction, because a large proportion of the compounds involved in metabolism are present in the organism as their phosphate esters; *e.g.*, the simple-sugar phosphates and phospholipids (compounds structurally similar to fats but containing a phosphate diester linkage).

Several other types of phosphorus compounds are found in nature to a minor extent, including several with phosphorus–nitrogen bonds and a few with phosphorus–carbon bonds (phosphonates).

The acid esters have their own characteristic properties. The monesters, $ROPO(OH)_2$, for example, are stable to alkaline hydrolysis because they are converted to the unreactive dianions, $ROPO_3^{2-}$. At the same time, however, these monoesters are rapidly hydrolyzed under slightly acidic conditions in a unique reaction of the monoanion, which is the predominant ionic form under these conditions. Phosphate diesters are relatively unreactive. They show no special reactivity at any acidity and are hydrolyzed only slowly in alkali—under which conditions, as anions, their reaction with hydroxide ion is inhibited but not completely prevented by electrostatic repulsion; that is, repulsion between electrical charges of the same sign.

Certain structural characteristics confer high reactivity on phosphate esters. Diesters and triesters with their phosphorus atoms contained in a five-membered ring structure, for example, are hydrolyzed some 10^7 times as rapidly as the corresponding open-chain compounds. Also activated toward hydrolysis are many esters with neighbouring ionizable groups close enough to interact with the phosphorus centre. The best known example of this situation occurs in the ribonucleic acids, one of the two principal classes of nucleic acids. Ribonucleic acids are rapidly degraded by alkali under conditions in which the deoxyribonucleic acids, the other principal class, are quite stable. The only structural difference between the two classes of compounds is the presence of an extra hydroxyl group adjacent to the phosphate–ester linkage in the ribonucleic acids.

Trivalent organic phosphorus compounds. Compounds with three substituents bonded to a phosphorus atom have structures resembling those of the corresponding and more familiar nitrogen compounds, but the former group includes a much larger number of stable compounds with bonds to electronegative elements, such as oxygen and the halogens (fluorine, chlorine, bromine

and iodine). Nomenclature of the phosphorus compounds is more complicated than that of the nitrogen derivatives, which are named generally as amines. Naming of phosphorus compounds depends on whether phosphorus is joined solely to carbon or hydrogen atoms or both or whether it is bonded to an electronegative element. Compounds with bonds from phosphorus only to carbon or hydrogen are named as derivatives of phosphine, PH_3, by a system similar to that used for the amines. Thus, methylphosphine, CH_3PH_2, dimethylphosphine, $(CH_3)_2PH$, and trimethylphosphine, $(CH_3)_3P$, are primary, secondary, and tertiary phosphines, respectively. The metal salts are called phosphides, and the protonated forms (compounds to which a hydrogen ion is added) and alkylated forms (compounds to which an organic group is added) are called phosphonium compounds. Compounds with one or more bonds from phosphorus to any element other than carbon or hydrogen are named as derivatives of phosphinous, phosphonous, and phosphorous acids (see Table 1). Compounds with groups formulated as P—OR and P—SR are regarded as esters of the appropriate acid and thio (sulfur-containing) acid, respectively. Amino and halogen compounds are considered to be amides and acyl halides of the respective acids. A representative selection of trivalent phosphorus compounds based on simple organic groups is listed in Table 3. In all, a wide range of compounds is possible, with phosphorus making three bonds to any combination of the following groups: H, R (any organic group), NH_2, NHR, NR_2, OR, SR, SeR (Se being selenium), F, Cl, Br, and I. Compounds belonging to nearly all these categories can be made by nucleophilic substitution reactions at the phosphorus atom, using the readily available phosphorus trihalides, especially phosphorus trichloride, PCl_3. Amines —and alcohols and phenols in the presence of added base—readily displace one or more chloride ions in a phosphorus chloride. Alkyl groups can be introduced by using organic magnesium compounds. A reaction sequence with examples of both reactions is:

Nomenclature of trivalent phosphorus compounds

Table 3: Trivalent Phosphorus Compounds

structure	name	boiling point (°C)
$(C_2H_5)_4P^+\,Br^-$	tetraethylphosphonium bromide	*
$(C_2H_5)_3P^+H\,Cl^-$	triethylphosphonium chloride	
$(C_2H_5)_3P$	triethylphosphine	127
$(C_2H_5)_2P—P(C_2H_5)_2$	tetraethyldiphosphine	
$(C_2H_5)_2PH$	diethylphosphine	85
$C_2H_5PH_2$	ethylphosphine	25
$(C_2H_5)_2P^-\,K^+$	potassium diethylphosphide	
$(C_2H_5)_2PCl$	diethylphosphinous chloride	60–70/15mm
$(C_2H_5)_2PN(C_2H_5)_2$	tetraethylphosphinous amide	181
$C_2H_5P(NH_2)_2$	ethylphosphonous diamide	—
$(C_2H_5)_2POC_2H_5$	ethyl diethylphosphinite	80–85/15mm
$C_2H_5P(OC_2H_5)_2$	diethyl ethylphosphonite	137–9
$(C_2H_5O)_3P$	triethyl phosphite	156–7
$(C_2H_5S)_3P$	triethyl phosphorotrithioite	140–3/18mm

*Decomposes at 300° C.

$$C_2H_5MgCl + PCl_3 \longrightarrow C_2H_5PCl_2 + MgCl_2$$

ethylmagnesium chloride; phosphorus trichloride; ethylphosphonous dichloride; magnesium chloride

$$C_2H_5PCl_2 + 2C_2H_5OH \xrightarrow{\text{base}} C_2H_5P(OC_2H_5)_2 + 2HCl.$$

ethylphosphonous dichloride; ethyl alcohol; diethyl ethylphosphonite; hydrogen chloride

The lower phosphines, with phosphorus–hydrogen bonds, can be converted to metal salts, and these are readily alkylated by alkyl halides, as in the following example:

$$K^+PH_2^- + C_2H_5Br \longrightarrow C_2H_5PH_2 + KBr.$$

potassium phosphide; ethyl bromide; ethylphosphine; potassium bromide

Although the metal salts are easily accessible and useful as synthetic intermediates, the lower phosphines are only very weakly acidic.

The most important class of reactions of trivalent phosphorus compounds is one in which the lone pair of *s* electrons on phosphorus is attacked by electrophilic reagents. The most reactive phosphorus compounds are the phosphines themselves; electronegative substituents on phosphorus and increasing molecular weight both reduce reactivity. Many aliphatic and some aromatic phosphines, for example, are so readily oxidized by atmospheric oxygen that they are spontaneously flammable in air, and these same compounds react explosively with reactive alkylating agents, such as methyl iodide; but triphenyl phosphite, $(C_6H_5O)_3P$, and triphenylphosphine, $(C_6H_5)_3P$, are oxidized and alkylated only relatively slowly and can be handled without special precautions. Similarly, triphenylphosphine is only weakly basic, although aliphatic tertiary phosphines (but not primary or secondary) are bases as strong as the corresponding amines.

Three reactions typical of the phosphines are illustrated by the following equations:

$$(C_2H_5)_3P + C_2H_5I \xrightarrow{\text{cold ether solvent}} (C_2H_5)_4P^+I^-,$$

triethylphosphine; ethyl iodide; tetraethylphosphonium iodide

$$(C_6H_{13})_3P + \tfrac{1}{2}O_2 \xrightarrow{\text{stand in air}} (C_6H_{13})_3P{=}O,$$

tri-*n*-hexylphosphine; oxygen; tri-*n*-hexylphosphine oxide

$$(C_2H_5)_3P + Br_2 \xrightarrow[\text{solvent}]{\text{cold benzene}} (C_2H_5)_3P{-}Br^+\,Br^-.$$

triethylphosphine; bromine; bromotriethylphosphonium bromide

Many trivalent phosphorus compounds remove atoms of oxygen from various molecules, especially when they are attached to nitrogen or sulfur or to another phosphorus centre; for example,

$$(C_2H_5O)_3P + R_3\overset{+}{N}{-}O^- \longrightarrow (C_2H_5O)_3P{=}O + R_3N.$$

triethyl phosphite; tertiary amine oxide; triethyl phosphate; tertiary amine

Many classes of trivalent compounds also form series of complex coordination compounds with metal ions.

As stated above, hydroxyl compounds of trivalent phosphorus exist almost exclusively in the tetrahedral P=O form. Extremely small amounts of the trivalent hydroxyl forms are present in equilibrium, however (often much less than one part per million), and these are thought to be responsible for the observed reactions of the compounds with reactive electrophilic reagents. An example is given below:

diethyl phosphite (tetrahedral form) $(C_2H_5O)_2P(=O)H$

equilibrium

$$(C_2H_5O)_2P{-}OH + Br_2 \longrightarrow (C_2H_5O)_2P^+(OH)(Br)\;Br^-$$

diethyl phosphite (trivalent form); bromine; intermediate

$$\longrightarrow (C_2H_5O)_2P(=O)Br + HBr.$$

diethyl phosphorobromidate; hydrogen bromide

The availability for bonding of the *d* orbitals of phosphorus has a decisive effect on the chemistry of phos-

Phosphonium salts

phonium compounds. Generally, the reactions of phosphonium compounds are more important than those of ammonium compounds, and their chemical behaviour is quite different. Some of these compounds form a fifth bond to phosphorus, as in the following example:

$$(C_6H_5)_4P^+\ Br^- + C_6H_5Li \longrightarrow (C_6H_5)_5P + LiBr.$$

tetraphenylphosphonium bromide — phenyllithium — pentaphenylphosphorane — lithium bromide

Usually, the fifth bond is a pi bond, as in the following:

$$(C_6H_5)_3\overset{+}{P}CH_2C_6H_5\,Br^- + C_6H_5Li$$

benzyltriphenylphosphonium bromide — phenyllithium

$$\longrightarrow (C_6H_5)_3P{=}CHC_6H_5 + LiBr + C_6H_6.$$

triphenylbenzylidenephosphorane — lithium bromide — benzene

Most commonly the multiple bond formed is the very stable P=O bond. Alkoxyphosphonium compounds, for example, are rapidly dealkylated by most nucleophiles to give phosphine oxides:

$$(C_2H_5)_3\overset{+}{P}OC_2H_5\ Br^- \longrightarrow (C_2H_5)_3P{=}O + C_2H_5Br.$$

triethylethoxyphosphonium bromide — triethylphosphine oxide — ethyl bromide

As a result of this reaction, phosphoryl compounds are the final products when any aliphatic esters of trivalent phosphorus acids react with normal alkylating agents, as shown in the following example:

$$(C_2H_5)_2POC_2H_5 + C_2H_5Br \xrightarrow{2\ \text{steps}} (C_2H_5)_3P{=}O + C_2H_5Br.$$

ethyl diethylphosphinite — ethyl bromide — triethylphosphine oxide — ethyl bromide

When the same alkyl group is involved in both ester and alkylating agent, as in the example shown, the alkylating agent is regenerated at the end of the reaction, and only catalytic amounts of it are required. In many instances, the same overall reaction can be brought about simply by strong heating, without the addition of any alkylating agent at all.

Phosphonium compounds are hydrolyzed by strong alkali in an unusual reaction in which an organic group, *R*, is displaced from phosphorus, apparently as the anion R^-. This remarkable result is feasible only because of the great stability of the P=O group of the product and because a mechanism is possible in which two molecules of hydroxide cooperate to break the carbon–phosphorus bond. The steps involved are shown in the equations below:

$$(C_6H_5CH_2)_4P^+ + OH^- \rightleftharpoons (C_6H_5CH_2)_4P{-}OH,$$

tetrabenzylphosphonium ion — hydroxide ion — tetrabenzylhydroxyphosphorane

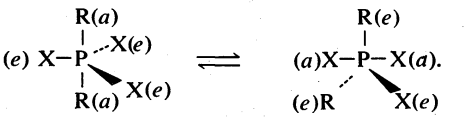
$$(C_6H_5CH_2)_4P{-}OH + OH^- \rightleftharpoons (C_6H_5CH_2)_4P{-}O^- + H_2O,$$

tetrabenzylhydroxyphosphorane — hydroxide ion — anion — water

$$(C_6H_5CH_2)_4P{-}O^- + H_2O \longrightarrow (C_6H_5CH_2)_3P{=}O + OH^- + C_6H_5CH_3.$$

anion — water — tribenzylphosphine oxide — hydroxide ion — toluene

Pentavalent organic phosphorus compounds. The organic compounds of pentavalent phosphorus are of two structural types. A small number have five single bonds to phosphorus and trigonal bipyramidal geometry (that is, a structure formed by two pyramids joined base to base). Examples are pentaphenylphosphorane, $(C_6H_5)_5P$, and pentaethoxyphosphorane, $(C_2H_5O)_5P$. In compounds of this structure, two substituents are in axial (*a*) positions, and three are in equatorial positions (*e*), as shown in the structures below. Compounds with substituents in one position can in some cases be distinguished from those with substituents in the other. Complications arise, however, because axial and equatorial substituents can exchange positions by a process of molecular reorganization known as pseudorotation. An example of pseudoration is shown below:



In this example, the two axial substituents (**R**) become equatorial substituents by changing of the bond positions. In these diagrams, ordinary lines represent bonds in the plane of the paper, dotted lines are bonds extending to the rear, and the wedges indicate bonds extending forward. Compounds with the PX_5 structure are generally very reactive. They readily revert to tetrahedral compounds, usually by way of an initial reversible ionization of the type $PX_5 \rightleftharpoons PX_4^+ + X^-$. An equilibrium of this sort is possible for any phosphonium system, and whether a particular compound exists predominantly as PX_5 or as $PX_4^+X^-$ depends in borderline cases on the environmental conditions (*e.g.*, solvent, temperature, and so on), as well as on the structure of the molecule. Compounds of the PX_5 structure have electrophilic (Lewis-acid) character also, and they may accept electrons from suitable donors to form the rare six-coordinate compounds PX_6^-. One or two organic examples of this class are known.

Compounds with pi bonds

The great majority of pentavalent organophosphorus compounds and, thus, also of all organic phosphorus compounds have four single bonds to phosphorus, one or more of which is reinforced by an additional bond, a pi bond. For purposes of nomenclature these compounds are classified in the same way as the corresponding trivalent derivatives: those with three bonds to carbon or hydrogen have names based on the parent phosphines, and the remainder are named as derivatives of phosphorus acids—in this case phosphinic or phosphonic acids. The range of structures known is essentially that given above for trivalent compounds, with the addition of the fourth bond, which is commonly a phosphorus to oxygen bond, P=O, or phosphorus–sulfur bond, P=S, but may also be a phosphorus–nitrogen or phosphorus–carbon bond, P=NR or $P{=}CR_2$. The selection of compounds listed in Table 4 illustrates the physical properties of these compounds, as well as the ways of naming them.

Tetrahedral compounds of pentavalent phosphorus are generally prepared by reactions involving nucleophilic substitution at phosphorus or oxidation of the appropriate trivalent derivatives. Many reactions of trivalent compounds that give phosphonium compounds as the initial product also lead eventually to phosphoryl derivatives. Several such reactions have been described above. One that is of considerable importance in organic synthesis is the Wittig reaction (named for its discoverer, the German chemist Georg Wittig), in which the oxygen atom of a carbonyl group (carbon and oxygen atoms forming a double bond, C=O) of a ketone or aldehyde is replaced by a doubly bonded carbon atom (methylene group) from a methylenephosphorane, producing an olefin, usually in good yield. The Wittig reagent (the methylenephosphorane) is generated from a phosphonium compound by removing a proton with a strongly basic reagent:

The Wittig reaction

$$(C_6H_5)_3\overset{+}{P}CH_2C_6H_5Cl^- + CH_3(CH_2)_3Li \longrightarrow CH_3(CH_2)_2CH_3 + LiCl$$

triphenylbenzylphosphonium chloride — *n*-butyllithium — butane — lithium chloride

$$+ (C_6H_5)_3P{=}CHC_6H_5\ \{\text{or } (C_6H_5)_3\overset{+}{P}{-}\bar{C}HC_6H_5\}.$$

triphenylbenzylidenephosphorane

Table 4: Pentavalent Phosphorus Compounds

structure	name	melting point (°C)	boiling point (°C)
$(C_6H_5)_5P$	pentaphenylphosphorane	124	—
$(C_2H_5)_3P=O$	triethylphosphine oxide	50	238–40
$(C_2H_5)_3P=S$	triethylphosphine sulfide	94	—
$(C_2H_5)_3P=NC_2H_5$	tetraethylphosphine imine (or imide)	—	—
$(C_2H_5)_3P=C(C_2H_5)_2$	pentaethylmethylenephosphorane	—	—
$(CH_3CH_2CH_2CH_2)_2P(=O)H$	dibutylphosphinous acid (or dibutylphosphine oxide)	58–60	—
$C_8H_{17}P(=O)H_2$	octylphosphine oxide	46–48	—
$(C_2H_5)_2P(=O)Cl$	diethylphosphinic chloride	—	109/16mm
$C_2H_5P(O)Cl_2$	ethylphosphonic dichloride	—	34/3mm
$(C_2H_5)_2P(O)N(C_2H_5)_2$	tetraethylphosphinic amide	—	134/16mm
$(C_2H_5)_2P(O)OC_2H_5$	ethyl diethylphosphinate	—	92/14mm
$(C_2H_5O)_2P(=O)H$	diethyl phosphonate	—	187–88
$C_2H_5PO(OH)_2$	ethylphosphonic acid	61–62	—
$C_2H_5PO(OC_2H_5)_2$	diethyl ethylphosphonate	—	198
$(C_2H_5O)_3P=O$	triethyl phosphate	—	215–16
$(C_2H_5O)_3P=S$	*O,O′,O″*-triethyl phosphorothioate	—	105/20mm
$(C_2H_5S)_3P=S$	triethyl phosphorotetrathioate	—	110/0.2mm

Although the negative charge in the so-called ylide form is largely neutralized by the adjacent positive phosphorus centre (P^+), the unsaturated carbon atom involved remains strongly nucleophilic. In particular, it adds readily to the carbonyl group of aldehydes and ketones, as shown in the example below:

$$(C_6H_5)_3P{=}CHC_6H_5 + (CH_3)_2C{=}O$$

triphenylbenzylidenephosphorane — acetone

$$\longrightarrow (C_6H_5)_3\overset{+}{P}-\underset{\displaystyle (CH_3)_2\overset{|}{C}-O^-}{\underset{|}{CHC_6H_5}}.$$

adduct

The initial adduct rapidly decomposes to the final products, which are the desired olefin and a phosphine oxide, perhaps by way of a cyclic intermediate, as shown below:

$$\underset{\displaystyle (CH_3)_2\overset{|}{C}-O^-}{\overset{H}{\overset{|}{C_6H_5C}}-\overset{+}{P}(C_6H_5)_3} \rightleftharpoons \underset{\displaystyle (CH_3)_2\overset{|}{C}-O}{\overset{H}{\overset{|}{C_6H_5C}}-P(C_6H_5)_3}$$

adduct — intermediate

$$\longrightarrow \overset{H}{C_6H_5C}{=}C(CH_3)_2 + (C_6H_5)_3P{=}O.$$

dimethylphenylethylene (olefin product) — triphenylphosphine oxide

As in earlier examples, the formation of the stable P=O group is an important driving force for this reaction.

The important reactions undergone by the tetrahedral pentavalent organophosphorus compounds have already been described for the phosphate esters and their derivatives. The phosphorus–carbon bond is a strong one, and, with the exception of the Wittig reaction, electronegative substituents on phosphorus are the ones normally involved in chemical reactions.

BIBLIOGRAPHY. R.F. HUDSON, *Structure and Mechanism in Organophosphorus Chemistry* (1965); A.J. KIRBY and S.G. WARREN, *The Organic Chemistry of Phosphorus* (1967), modern mechanistic treatments of the subject, far from comprehensive in their compound coverage; G.M. KOSOLAPOFF, *Organophosphorus Compounds* (1950), deals almost exclusively with compound synthesis, now out of date but the only work of its kind; K. SASSE, *Organische Phosphorverbindungen*, vol. 12/1 and 12/2 of E. MUELLER (gen. ed.), *Methoden der organischen Chemie* (1963–64), a comprehensive and indispensable source book for the preparation and properties of organic phosphorus compounds.

Organic Sulfur Compounds

Organic sulfur compounds constitute a diverse and important subdivision of the class of organic substances. They are widely distributed in nature, often betraying their presence by the strong odours they impart (*e.g.*, to crude petroleum, to certain plants, and to animal secretions). Sulfur-containing amino acids—cysteine, cystine, methionine, and taurine—are important components of biologically important substances, including hormones, enzymes, and coenzymes. Synthetic organic sulfur compounds include numerous insecticides, pharmaceuticals, dyes, solvents, and agents used in flotation processes for refining ores, in improving the performance of lubricating oils, in preparing rubbers, and in making rayon.

Organic compounds make up an enormous class of chemical substances composed of molecules in which atoms of the element carbon are linked to each other and to atoms of other elements, most often hydrogen. Compounds containing only these two elements, the hydrocarbons, undergo characteristic chemical reactions and display distinctive physical properties, but the presence of even one atom of another element in an organic molecule usually has such profound effects upon its chemical and physical properties that organic compounds frequently are classified according to the presence of these additional elements. After carbon and hydrogen, the elements most commonly occurring in organic compounds are oxygen and nitrogen; sulfur is neither extremely common nor extremely rare, but its effects are sufficiently distinctive that organic sulfur compounds comprise a recognized area of specialized study.

The properties of organic sulfur compounds are best understood in the context of knowledge of the composition and transformations of matter, different aspects of which are treated in the articles CHEMICAL COMPOUNDS, ORGANIC; MOLECULAR STRUCTURE; CHEMICAL BONDING; and CHEMICAL REACTIONS.

THE NATURE OF CHEMICAL COMPOUNDS

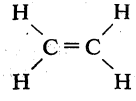
General physical characteristics. *Atoms, nuclei, and electrons.* All matter is made up of one or more of the 100-odd chemical elements, the individual particles of which are called atoms. Each atom is composed of a small nucleus and a surrounding cloud of electrons. In the nucleus, there are particles called protons, each bearing a positive electrical charge, and approximately the same number of uncharged particles, called neutrons. The chemical identity of an atom is determined by the number—the atomic number—of protons in its nucleus; and the chemical behaviour, by the number and arrangement of electrons surrounding it. The electrons are concentrated in well-defined patterns called orbitals, which Orbitals are grouped into sets, or shells, of increasing average distance from the nucleus. Each shell beyond the first is subdivided into subshells, sets of orbitals that differ slightly in energy. The larger the number of the shell, the more numerous are these subshells: the first shell has a single orbital, denoted 1*s*; the second has four, one designated 2*s* and three designated 2*p*; the third has nine, one 3*s*, three 3*p*, and five 3*d*. The approach of other atoms ordinarily affects only the outermost electrons, which therefore determine the kinds of compounds and chemical bonds formed by the atom: that is, its valence.

Particular stability is associated with atoms in which the outermost shell contains eight electrons; an atom that differs from that electron configuration tends to gain, lose, or share electrons with other atoms to attain it. These processes leave the atom with a net electrical charge, and such charged atoms are called ions. Oppositely charged ions attract each other, becoming arranged

in regular geometric patterns in compounds such as calcium sulfide.

Covalent bonds and molecules. In many molecules, particularly those of organic compounds, atoms are held together by the sharing of electrons between pairs of atoms. Each atom shares one, two, or three of its valence electrons to form a single, double, or triple bond with another atom that contributes an equal number. Such bonds are called covalent. A carbon atom shares four electrons in this way, and a hydrogen atom shares one; simple organic compounds composed of carbon and hydrogen are methane, ethylene, and acetylene. The formulas of covalent compounds, like those of ionic substances, indicate the number of atoms present in the compound: the formula of methane is CH_4, denoting the presence of one atom of carbon (C) and four atoms of hydrogen (H); the formulas of ethylene and acetylene are C_2H_4 and C_2H_2, respectively.

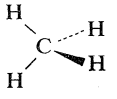
Covalent bonds have specific orientations in space and distances over which they are effective. Often, these directions and distances are indicated in structural formulas, in which each atom is represented by its chemical symbol and each pair of shared electrons by a line:



ethylene

acetylene

The structural formula of methane is often drawn as if the molecule were planar, but a more accurate idea of its true shape is conveyed by a figure in which full lines stand for bonds lying in the plane of the paper, a dotted line stands for a bond projecting away from the viewer, and a wedge for a bond projecting toward the viewer:



methane

Ethylene and acetylene, which have multiple covalent bonds, are classed as unsaturated compounds because they contain carbon atoms bonded to fewer than the maximum possible number, four, of other atoms. Methane, on the other hand, is a saturated compound.

Nomenclature

Structural and functional groups. In this article, many organic compounds are mentioned by name, and it may be helpful to the reader to review briefly some of the salient features of their terminology. In most chemical reactions, only one or two of the covalent bonds in a molecule are affected, while the rest of the structure is unchanged. An unchanged group of atoms, regarded as transferred intact from one compound to another, usually is named after the compound that would be formed by attaching a hydrogen atom to it. For example, methyl bromide and hydrosulfide ion react to produce methanethiol and bromide ion, as represented by the equation:

$$\underset{\text{methyl bromide}}{CH_3Br} + \underset{\text{hydrosulfide ion}}{SH^-} \longrightarrow \underset{\text{methanethiol}}{CH_3SH} + \underset{\text{bromide ion}}{Br^-}.$$

Of the four covalent bonds in each molecule of the starting material, only the one linking the carbon and bromine atoms is broken, while the other three are unaffected. The group CH_3, unchanged in the reaction, is conveniently regarded as a single entity and named methyl to show its structural relationship to methane, CH_4. Such groups derived from saturated hydrocarbons, as methyl from methane, are collectively known as alkyl groups. Analogous groups derived from aromatic hydrocarbons, as phenyl from benzene, are called aryl groups.

A group of atoms that undergoes the same general reactions regardless of the structure of the molecule of which it forms a part is called a functional group: typical examples are hydroxyl (—OH), carbonyl ($>C=O$), carboxyl ($-C\overset{O}{\underset{OH}{<}}$), and amino ($-NH_2$).

The sulfur atom. An uncombined sulfur atom has 16 electrons, 10 of which completely fill the 1*s*, 2*s*, and 2*p* orbitals; of the remaining six (*i.e.*, the valence electrons), two occupy the 3*s* orbital and four are present in 3*p* orbitals: The distribution of electrons in a sulfur atom is abbreviated to $1s^22s^22p^63s^23p^4$. An element closely resembling sulfur in electron configuration is oxygen, which has eight electrons in the configuration $1s^22s^22p^4$. The identical distribution, s^2p^4, of the valence electrons in the two elements leads to many similarities in their chemical behaviour. Important differences, however, arise from the fact that the valence electrons of sulfur interact less strongly with the nucleus than do those of oxygen and that the third electron shell of sulfur includes five *d* orbitals. Although these *d* orbitals are not occupied in the uncombined sulfur atom, their availability makes possible the formation of types of compounds not formed by oxygen. In these compounds, the 3*s* and 3*p* orbitals can, in effect, blend together into a new set of four "hybrid" orbitals that can interact with three or four other atoms, or the 3*s*, the 3*p*, and two of the 3*d* orbitals can hydridize to form a set of orbitals that participate in the formation of hexacovalent compounds.

In Table 1, members of several important groups of organic sulfur compounds are compared with the oxygen

Table 1: Organic Sulfur Compounds and Corresponding Organic Oxygen Compounds

sulfur compounds			oxygen compounds		
group of compounds	characteristic structural unit	example	group of compounds	characteristic structural unit	example
Thiols (aliphatic)	—SH	methanethiol	alcohols	—OH	methanol
Thiols (aromatic)	—SH	benzenethiol (thiophenol)	phenols	—OH	phenol
Sulfides	—S—	dimethyl sulfide	ethers	—O—	dimethyl ether
Disulfides	—S—S—	dimethyl disulfide	peroxides	—O—O—	dimethyl peroxide
Thioaldehydes	S ‖ —C—H	ethanethial (thioacetaldehyde)	aldehydes	O ‖ —C—H	ethanal (acetaldehyde)

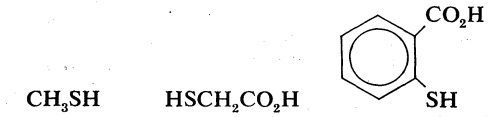
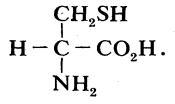
Sulfonic acids		methanesulfonic acid

compounds possessing similar structures. Table 2 lists some of the most important types of sulfur compounds that have no counterparts among oxygen compounds.

ORGANIC COMPOUNDS OF BIVALENT SULFUR

Thiols. The organic sulfur compounds most closely resembling their oxygen analogues are the thiols, also called mercaptans. The functional group of the thiols is the mercapto group (—SH), comparable to the hydroxyl group (—OH) present in alcohols and phenols. In preferred names for thiols, the suffix -thiol is appended to the name of the appropriate hydrocarbon. If another group is designated by a suffix, the prefix mercapto- is used. A few thiols are named by using the prefix thio- to denote the replacement of an oxygen atom of a related compound by a sulfur atom, and a few have names that do not convey structural information. Examples are as follows:



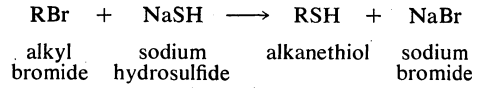


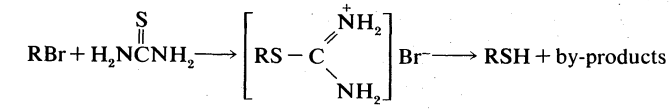
Natural thiols

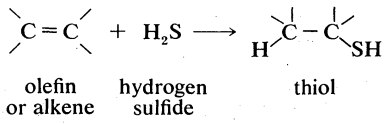
A few thiols are found in nature: crude petroleum contains methanethiol, ethanethiol, and other members of the group. Although they constitute a small fraction of most petroleums, thiols are a serious nuisance. They impart objectionable odours, they are corrosive to the equipment and interfere with the action of catalysts used in refining processes, and their combustion creates the noxious gas sulfur dioxide. Small amounts of thiols are converted into chemical products, but no uses require the amounts that could be recovered from crude oil.

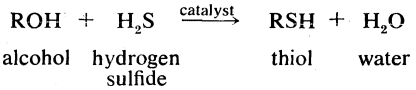
Methanethiol arises from the bacterial decomposition of proteins, such as albumin or gelatin, and butanethiol is present in the defensive secretion of the skunk. A thiol group plays an important role in the natural functions of several proteins and of coenzyme A, which participates in many metabolic reactions.

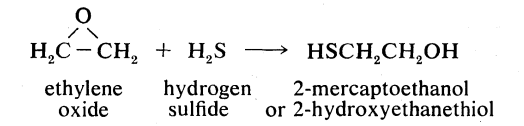
Preparation. Several methods are known for the preparation of thiols. Thiols in which the mercapto group is not attached to an aromatic ring may be made according to the reactions represented by the following equations:

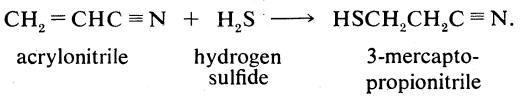




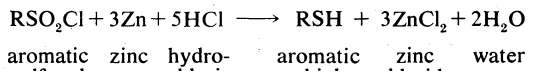


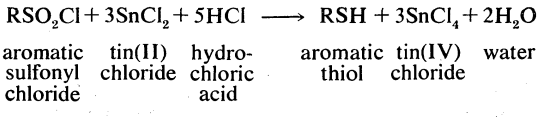


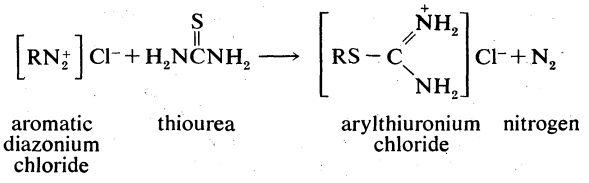


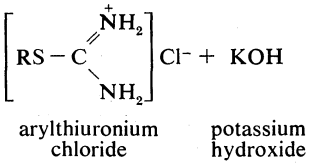


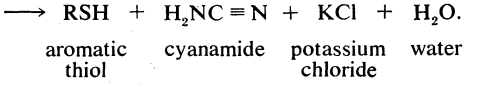
Other methods must be used to make aromatic thiols because of the different nature of reactions typical of aromatic compounds in general (see CHEMICAL REACTIONS). Applicable procedures include those formulated as follows:











Reactions. In most of their reactions, thiols resemble alcohols or phenols, the differences being those of degree rather than kind. Thiols react more completely with alkalies, forming salts, than do the corresponding hydroxyl compounds; that is, the thiols are stronger acids, although very weak in comparison to, say, acetic acid. Aromatic thiols are stronger acids than the aliphatic thiols, just as phenols are stronger acids than alcohols. In the presence of salts of heavy metals (as mercury, lead, zinc, or copper), thiols form mercaptides, soluble in organic solvents (as ether, isopropyl alcohol, benzene, chloroform) but insoluble in water. The characteristic formation of these compounds from mercury salts led to the name mercaptan (Latin *mercurium captans*, "seizing mercury"). The

mercury mercaptide, sodium ethylmercurithiosalicylate (thimerosal, Merthiolate), is a well-known germicide.

Thiols form sulfides (thioethers) and thioesters in reactions similar to those of hydroxyl compounds. They react with aldehydes and ketones to yield thioacetals and thioketals, respectively; sulfur-containing compounds of this type are more readily formed and more stable than the oxygen compounds and are useful in suppressing the reactivity of carbonyl groups while chemical reactions are performed on another part of a molecule. Dithiols are useful for this purpose. Thiols combine with unsaturated compounds, particularly those that have a carbonyl group adjacent to the double bond, forming sulfides.

Thiols differ from hydroxyl compounds in their reactions with oxidizing agents (as oxygen, iodine, hydrogen peroxide). Alcohols usually are converted to aldehydes or ketones, but thiols are transformed into disulfides; further oxidation results in formation of sulfonic acids:

$$2RSH + H_2O_2 \longrightarrow RSSR + 2H_2O$$

thiol; hydrogen peroxide; disulfide; water

$$RSSR + 5H_2O_2 \longrightarrow 2RSO_3H + 4H_2O.$$

disulfide; hydrogen peroxide; sulfonic acid; water

Sulfides and sulfonium salts. Compounds in which two organic groups are bonded to a sulfur atom are called sulfides; the structurally related oxygen compounds are ethers. The organic groups may be both alkyl, both aryl, or one of each. If no other functional group is present in the molecule, sulfides are named as such: dimethyl sulfide is $CH_3—S—CH_3$, methyl phenyl sulfide is $CH_3—S—C_6H_5$, and diphenyl sulfide is $C_6H_5—S—C_6H_5$. If another functional group forms part of the molecule, a sulfide group is designated by the particle -thio-:

thiodiacetic acid; 4-(methylthio)benzoic acid

Properties of sulfides

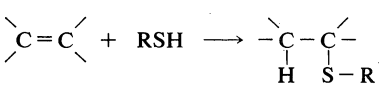
The sulfur atom in sulfides does not cause their physical properties to differ much from those of hydrocarbons of similar molecular size and shape. The sulfides have low solubilities in water, but they are miscible with many organic solvents; they are colourless liquids or solids, many of them possessing odours that are unpleasant, though not as intense as those of the thiols.

Certain sulfides occur in nature: garlic contains diallyl sulfide, and many proteins contain the amino acid methionine, which is a sulfide.

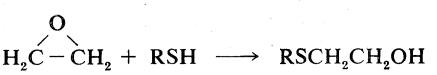
Preparation. Sulfides most often are prepared from thiols; just as preparing a thiol usually involves replacing one of the two hydrogen atoms of hydrogen sulfide, preparation of a sulfide is the replacement of the second, often by similar procedures. Examples are:

$$RSNa + R'Br \longrightarrow RSR' + NaBr$$

thiol sodium salt; alkyl bromide; sulfide; sodium bromide



olefin; thiol; sulfide



ethylene oxide; thiol; alkyl hydroxyethyl sulfide

$$CH_2=CHC\equiv N + RSH \longrightarrow RSCH_2CH_2C\equiv N.$$

acrylonitrile; thiol; 3-alkylthiopropionitrile

The reaction of certain olefins with disulfur dichloride produces chlorine-containing sulfides; the best known example of this process is the manufacture of mustard gas, a blister-forming chemical warfare agent, from ethylene. This reaction is not general, however; the products obtained from other olefins are disulfides or mixtures of monosulfides and disulfides.

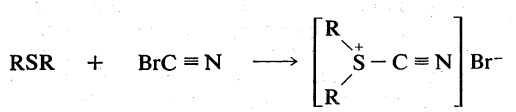
$$2H_2C=CH_2 + S_2Cl_2 \longrightarrow ClCH_2CH_2SCH_2CH_2Cl + S$$

ethylene; disulfur dichloride; mustard gas (bis[2-chloroethyl] sulfide); sulfur

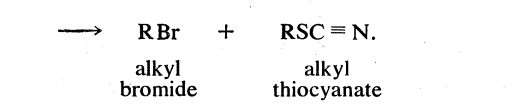
$$2CH_3CH=CH_2 + S_2Cl_2 \longrightarrow ClC_3H_6SSC_3H_6Cl$$

propylene; disulfur dichloride; bis(chloropropyl) disulfide

Reactions. Sulfides combine with chlorine, bromine, iodine, or salts of heavy metals to form crystalline compounds. Cyanogen bromide forms an unstable compound that decomposes by breaking a carbon–sulfur bond:

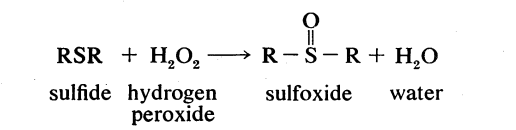


sulfide; cyanogen bromide; unstable sulfonium compound

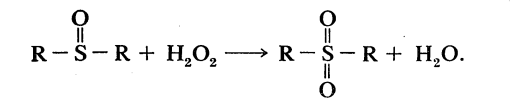


alkyl bromide; alkyl thiocyanate

Oxidizing agents convert sulfides into sulfoxides; if a sufficient amount of the oxidizing agent is present, the sulfoxides undergo oxidation to sulfones:

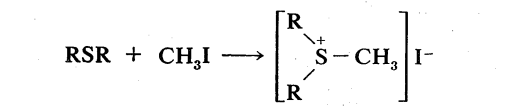


sulfide; hydrogen peroxide; sulfoxide; water



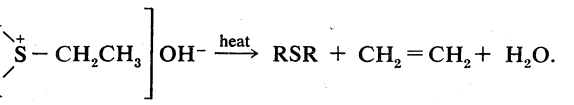
sulfoxide; hydrogen peroxide; sulfone; water

Compounds such as methyl iodide react with sulfides to produce sulfonium salts, in which three organic groups are attached to the positively charged sulfur atom. This process has many parallels in organic chemistry, especially in the reactions of amines and phosphines; it occurs less readily with ethers.



sulfide; methyl iodide; sulfonium iodide

The formation of sulfonium salts from sulfides and alkyl halides can be reversed by heat. The heat-induced decomposition of quaternary ammonium hydroxides (*i.e.*, compounds in which four organic groups are bonded to a positively charged nitrogen atom) is exactly duplicated in the case of sulfonium hydroxides:



sulfonium hydroxide; sulfide; ethylene; water

Disulfides and polysulfides. Disulfides have the structure R—S—S—R′, in which R and R′ represent organic

groups of any kind. They are named by designating the groups attached to the sulfur atoms or by use of the particle -dithio-:

CH_3SSCH_3 — dimethyl disulfide

$CH_3SSCH_2CO_2H$ — methyldithioacetic acid

$HO_2CCH_2SSCH_2CO_2H$ — dithiodiacetic acid

Disulfides. The formation of disulfides by oxidation of thiols or by the reaction of disulfur dichloride and olefins has already been mentioned. A few disulfides have been isolated from natural sources, such as onion, garlic, and asafetida. The amino acid cystine, a disulfide, is an important component of many proteins: the sulfur–sulfur bond is partly responsible for maintaining the molecules in shapes essential for their biological activity. The coenzyme lipoic acid, a disulfide necessary for growth of certain micro-organisms, may also be involved in photosynthesis and other vital processes of plants and animals.

Most important reactions

In the most important reactions of disulfides, the bond between the two sulfur atoms is broken, as by reducing agents, including hydrogen; by strong alkalies; or by alkyl halides:

$$RSSR + H_2 \longrightarrow 2RSH$$

disulfide, hydrogen, a thiol

$$RSSR + KOH \longrightarrow RSH + (RSO)K$$

disulfide, potassium hydroxide, a thiol, alkanesulfenate (salt)

$$RSSR + 4RI \xrightarrow{HgI_2} 2(R_3S^+)I^- + I_2 .$$

disulfide, alkyl iodide, sulfonium iodide, iodine

Chlorine or bromine splits the —S—S— bond of aromatic disulfides but attacks the adjacent carbon atom of an aliphatic disulfide:

$$C_6H_5SSC_6H_5 + Br_2 \longrightarrow 2C_6H_5SBr$$

diphenyl disulfide, bromine, benzenesulfenyl bromide

$$CH_3SSCH_3 + Cl_2 \longrightarrow CH_3SSCH_2Cl + HCl .$$

dimethyl disulfide, chlorine, chloromethyl methyl disulfide, hydrogen chloride

Polysulfides. The tendency to form chains in which atoms of the same element are joined together by covalent bonds, especially pronounced with carbon, is shown to some extent by sulfur. Organic compounds containing such chains of three, four, or more sulfur atoms are called polysulfides. They are less stable than the corresponding carbon compounds, and their properties are not as fully understood. A group of organic polysulfides has received considerable attention as rubbers and as solid propellants for rockets; these are the Thiokols, which are polymeric compounds, having molecules composed of long chains of repeating units built up from simpler compounds. An example is provided by the product made from ethylene dichloride and sodium tetrasulfide:

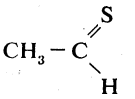
$$nClCH_2CH_2Cl + nNa_2S_4$$

ethylene dichloride, sodium tetrasulfide

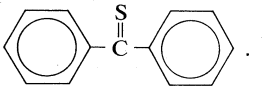
$$\longrightarrow (CH_2CH_2S_4)_n + 2nNaCl .$$

Thiokol A, a polymer; sodium chloride

Thiocarbonyl compounds. The thiocarbonyl functional group ($>C{=}S$), analogous to the carbonyl group, forms part of the structure of thioaldehydes and thioketones. These compounds are named by analogy with the corresponding oxygen compounds:



thioacetaldehyde or ethanethial



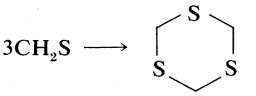
thiobenzophenone or diphenyl thione

The thiocarbonyl compounds have exceptionally repulsive odours. The general method of preparation, from carbonyl compounds and hydrogen sulfide in the presence of acidic catalysts, is not difficult:

$$R-C(=O)-R + H_2S \longrightarrow R-C(=S)-R + H_2O .$$

carbonyl compound, hydrogen sulfide, thiocarbonyl compound, water

The reactions of thiocarbonyl compounds are similar to those of their oxygenated relatives, although they show a greater tendency to undergo cyclotrimerization, in which three molecules unite to form a ring structure:



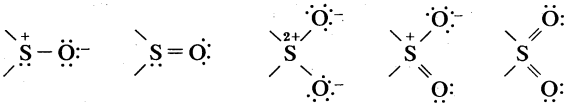
thioformaldehyde, trithiane

Although the monomers are blue, the cyclic trimers (trithianes) are colourless; the latter somewhat resemble the dialkyl sulfides in their reactions.

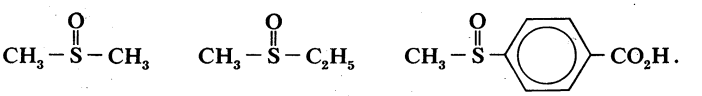
COMPOUNDS CONTAINING POLYVALENT SULFUR

Sulfoxides and sulfones. Two groups of organic sulfur compounds that have no counterparts among organic oxygen compounds are the sulfoxides and the sulfones. In some respects, these compounds resemble carbonyl compounds, containing the group $>C{=}O$, in which the carbon and the oxygen atom each interact with eight electrons, four of which are shared in the double bond. Doubly bonded structures for the sulfinyl ($>SO$) and sulfonyl ($>SO_2$) groups present in sulfoxides and sulfones, respectively, require that the sulfur atom interact with 10 electrons in sulfoxides or with 12 in sulfones. Because these numbers are larger than eight, the number of electrons usually associated with each atom (except hydrogen) in stable covalent compounds, has been the basis of opposition to these formulations. Covalent bond formation by a sulfur atom, however, involves electrons in the third shell, which is larger than the second shell (the one engaged in carbon and oxygen bonding) and has additional orbitals. It is considered that these orbitals (the *d* orbitals) participate in the bonding in sulfoxides and sulfones and that the bonds differ from those of the carbonyl group, showing considerable polarity (separation of electrical charges). Their structures are regarded as intermediate between those with single bonds of high polarity and those with double bonds of low polarity but high electron density on the sulfur atom.

Sulfur–oxygen double bonds

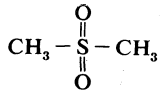


Sulfoxides are named by simply designating the two organic groups attached to the $>SO$ group, with the word sulfoxide, or by forming a prefix from the name of the simpler of the two groups and the particle -sulfinyl-, as shown in the examples:

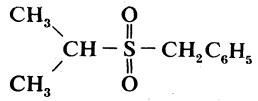


dimethyl sulfoxide; ethyl methyl sulfoxide; 4-(methylsulfinyl) benzoic acid

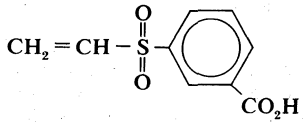
The nomenclature of sulfones is like that of sulfoxides; the particle -sulfonyl- is used in complicated structures:



dimethyl sulfone



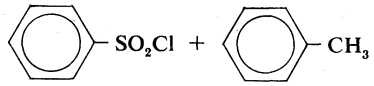
benzyl isopropyl sulfone



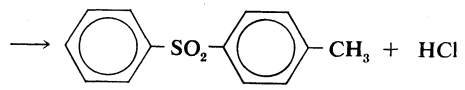
3-(vinylsulfonyl) benzoic acid

Most sulfoxides are colourless liquids or solids with low melting points; they are more soluble in water and possess much higher boiling points than hydrocarbons or carbonyl compounds of similar molecular size. Sulfoxides of low molecular weight have faint odours and tastes described as metallic or garlic-like. In general, sulfones are colourless, crystalline solids at room temperature.

Occurrence and preparation. Several sulfoxides are found in the turnip, garlic, and several species of mustard; another has been isolated from the cockroach. Oxidation of sulfides to sulfoxides and sulfones by hydrogen peroxide has been mentioned; certain aromatic sulfones can be made by the reaction of sulfonyl chlorides (see below *Sulfonic acids*) with aromatic hydrocarbons.



benzenesulfonyl chloride — toluene



phenyl *p*-tolyl sulfone — hydrogen chloride

The reaction of a metal salt of a sulfinic with a halogen compound is sometimes used to make sulfones:

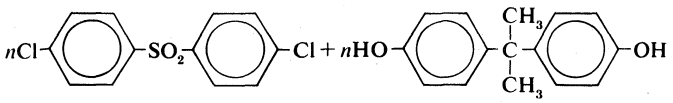
alkanesulfinate (salt) — benzyl chloride — alkyl benzyl sulfone — sodium chloride

A class of polymeric sulfones results from the reaction of sulfur dioxide with olefins:

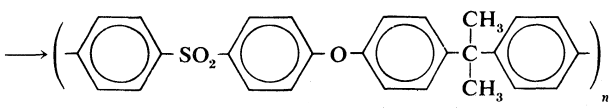
ethylene — sulfur dioxide — polyethylene polysulfone

Polymeric sulfones

These products have not been found useful, although members of a different class of polysulfones have properties that make them valuable as wire coatings. The latter group is made from chlorine-containing aromatic sulfones and a compound (bisphenol A) of two molecules of phenol linked through a hydrocarbon group:



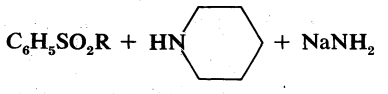
bis(*p*-chlorophenyl) sulfone — bisphenol A



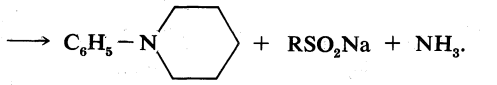
polymer

Reactions. Sulfoxides can be converted to sulfides by powerful reducing agents, such as lithium aluminum hydride, hydriodic acid, or zinc in the presence of sulfuric acid. Sulfoxides are very weak bases, forming salts with strong acids (*e.g.*, hydrochloric acid); they are also very weak acids, giving up a proton only to very strong bases, such as sodium hydride or sodium amide.

Sulfones are generally unreactive compounds and are not attacked by most reducing agents. The bond joining the sulfur atom to an aromatic ring can be cleaved by piperidine in the presence of sodium amide:



alkyl aryl sulfone — piperidine — sodium amide



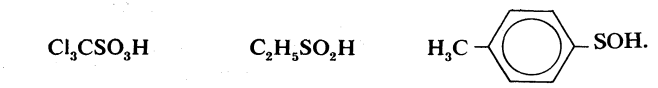
N-phenyl-piperidine — sulfinate (salt) — ammonia

If two or three sulfonyl groups are bonded to the same carbon atom, a hydrogen atom bonded to that atom shows somewhat acidic properties; that is, it can be removed by a base:

trisulfonylmethane — hydroxide ion — trisulfonylmethide ion — water

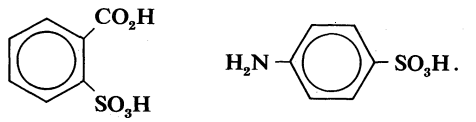
Dimethyl sulfoxide has been investigated as a topical analgesic and as a carrier for drugs (it rapidly penetrates the skin); the disulfones sulfonal, trional, and tetronal have been used in medicine as hypnotics but have been replaced by less toxic compounds.

Sulfonic, sulfinic, and sulfenic acids. Three sulfur-containing functional groups confer acidity upon compounds in which they are present; these compounds are the sulfonic acids, in which the group SO_3H is present; the sulfinic acids, with the group SO_2H; and the sulfenic acids, with the group SOH. All three types of compounds are named by attaching the name of the functional group to the name of the compound in which that group replaces a hydrogen atom:



trichloromethanesulfonic acid — ethanesulfinic acid — *p*-toluenesulfenic acid

Occasionally, sulfonic acids are named using the prefix sulfo- or by arbitrary names:



o-sulfobenzoic acid — sulfanilic acid

The sulfonic acids are very strong—comparable to the mineral acids, hydrochloric, nitric, or sulfuric—and are the most common of the sulfur-containing acids. Most of them are colourless, odourless, crystalline compounds; the characteristic water solubility of these acids and most of their salts has made them useful as detergents that perform well in hard water and as dyes that can be applied to textiles from aqueous solutions.

Sulfinic acids are weaker, less soluble in water, and less stable than sulfonic acids; they are most often prepared in the form of their metal salts, which are more stable.

Sulfenic acids and their salts are unstable compounds, rarely isolated; many substances named as derivatives of sulfenic acids are not actually obtainable from them.

Sulfonic acids. Aromatic sulfonic acids usually are made by the reaction (sulfonation) of an aromatic hydrocarbon with sulfuric acid. Aliphatic hydrocarbons seldom react similarly with sulfuric acid, but aliphatic sulfonic acids may be obtained by oxidation of thiols or other sulfur-containing starting materials or by treatment of certain halogen compounds with sodium sulfite:

$$C_6H_6 + H_2SO_4 \longrightarrow C_6H_5SO_3H + H_2O$$

benzene; sulfuric acid; benzenesulfonic acid; water

$$CH_3SH + 6HNO_3 \longrightarrow CH_3SO_3H + 6NO_2 + 3H_2O$$

methanethiol; nitric acid; methanesulfonic acid; nitrogen dioxide; water

$$ClCH_2CO_2Na + Na_2SO_3 \longrightarrow NaO_3SCH_2CO_2Na + NaCl.$$

sodium chloroacetate; sodium sulfite; disodium sulfoacetate; sodium chloride

The formation of sulfonic acids from sulfuric acid and aromatic compounds can be reversed by reaction with water, although strenuous conditions are sometimes necessary (*e.g.*, use of superheated steam). When aromatic sulfonic acids are heated with caustic alkalies, the sulfo ($-SO_3H$) group is replaced by a hydroxyl ($-OH$) group; this reaction is useful for preparing phenols:

$$C_6H_5SO_3H + NaOH \longrightarrow C_6H_5OH + NaHSO_3.$$

benzenesulfonic acid; sodium hydroxide; phenol; sodium bisulfite

In certain cases, the sulfo group can be replaced by various others, including cyano ($-CN$), nitro ($-NO_2$), formyl ($-CHO$), amino ($-NH_2$), or alkylthio ($-SR$).

Sulfonyl chlorides may be prepared from sulfonic acids by reaction with phosphorus pentachloride, chlorosulfuric acid, or certain other reagents:

$$C_6H_5SO_3H + PCl_5 \longrightarrow C_6H_5SO_2Cl + POCl_3 + HCl.$$

benzenesulfonic acid; phosphorus pentachloride; benzenesulfonyl chloride; phosphoryl chloride; hydrogen chloride

Sulfonyl chlorides are widely employed in preparing sulfonamides, sulfonates (esters of sulfonic acids), and sulfinic acids; their use in making sulfones has already been mentioned. Other sulfonyl halides (fluorides, bromides, or iodides) are less frequently made.

Sulfonamides result from the reaction of sulfonyl chlorides with ammonia or primary or secondary amines, compounds that all have the structure R_2NH, in which R represents a hydrogen atom or an organic group:

$$R'SO_2Cl + 2R_2NH \longrightarrow R'SO_2NR_2 + R_2NH_2^+Cl^-.$$

sulfonyl chloride; primary or secondary amine or ammonia; sulfonamide; hydrochloride

Sulfonates are obtained by treating alcohols or phenols with sulfonyl chlorides in the presence of a tertiary amine:

$$RSO_2Cl + R'-OH + R''_3N \longrightarrow RSO_2OR' + R''_3NH^+Cl^-.$$

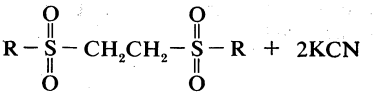
sulfonyl chloride; alcohol; tertiary amine; sulfonate ester; amine hydrochloride

Sulfinic acids. Sulfinic acids usually are made by treating a sulfonyl chloride with finely divided zinc or with sodium sulfite:

$$2RSO_2Cl + 2Zn \longrightarrow (RSO_2)_2Zn + ZnCl_2.$$

sulfonyl chloride; zinc; sulfinic acid (zinc salt); zinc chloride

Aliphatic sulfinic acids can be made by this reaction, but the necessary sulfonyl chlorides are not always available; in such cases, the reaction of ethylene disulfones with potassium cyanide can be employed:



ethylene disulfone; potassium cyanide

$$\longrightarrow 2RSO_2K + N\equiv CCH_2CH_2C\equiv N.$$

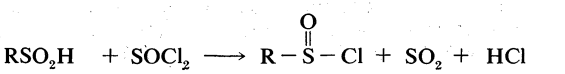
potassium sulfinate; succinonitrile

Several other reactions have been utilized for making sulfinic acids, but they do not have general applicability. One of these reactions is the basis of the manufacture of the sodium salt of hydroxymethanesulfinic acid, sometimes called sodium formaldehydesulfoxylate, used in stripping dyes from textiles and in the discharge printing process for producing dyed designs on fabrics:

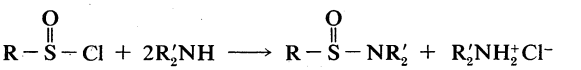
$$Na_2S_2O_4 + CH_2O + H_2O \longrightarrow HOCH_2SO_2Na + NaHSO_3.$$

sodium dithionite; formaldehyde; water; sodium hydroxymethanesulfinate; sodium bisulfite

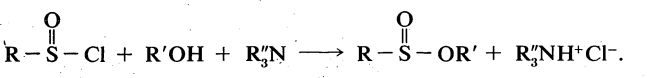
Sulfinic acids are oxidized to sulfonic acids by hydrogen peroxide or by nitric acid but to sulfonyl halides by chlorine, bromine, or iodine. The reaction of a sulfinic acid with thionyl chloride can be used to prepare sulfinyl chlorides, which are useful in the synthesis of sulfinamides and sulfinic esters (sulfinates):



sulfinic acid; thionyl chloride; sulfinyl chloride; sulfur dioxide; hydrogen chloride



sulfinyl chloride; amine; sulfinamide; amine hydrochloride



sulfinyl chloride; alcohol; tertiary amine; sulfinate (ester); tertiary amine hydrochloride

Sulfenic acids. Sulfenic acids or their salts are formed as the initial products in reactions in which the sulfur–sulfur bond of disulfides is broken by the attack of alkalies; the molecules of sulfenic acids react rapidly with one another, producing sulfinic acids and thiols:

$$2RSOK \longrightarrow RSO_2K + RSK.$$

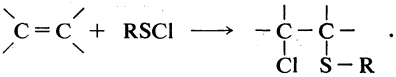
sulfenate (salt); sulfinate (salt); thiol (salt)

The sulfenyl chlorides are more stable than the sulfenic acids; they are formed in the reaction of chlorine with disulfides (see above *Disulfides and polysulfides*). The chlorides can be converted into other derivatives of sulfenic acids, such as amides, esters, or anhydrides:

$$2RSCl + H_2O \longrightarrow RSOSR + 2HCl.$$

sulfenyl chloride; water; sulfenic anhydride; hydrogen chloride

They also react with olefins to produce chlorine-containing sulfides:



olefin; sulfenyl chloride; chloroalkyl sulfide

LESS COMMON ORGANIC SULFUR COMPOUNDS

Organic derivatives of inorganic sulfur-containing acids. Several inorganic acids contain one or more atoms of sul-

fur in their molecules. The most important of these are sulfuric acid, H_2SO_4, and sulfurous acid, H_2SO_3. Most other inorganic acids contain one or more oxygen atoms that can be replaced by sulfur atoms. Nearly all of these acids have organic derivatives, such as esters or amides.

Sulfuric acid. Several esters of sulfuric acid are important industrial chemicals; dimethyl sulfate and diethyl sulfate, made from the alcohols and oleum (a solution of sulfur trioxide in sulfuric acid), are used to introduce methyl and ethyl groups into organic molecules. Certain monoesters of sulfuric acid occur as water-soluble forms in which substances are eliminated from the body.

Thiosulfuric acid. Monoesters of thiosulfuric acid, called Bunte salts, are prepared as intermediates in the synthesis of thiols:

$$RBr + Na_2S_2O_3 \longrightarrow RSSO_3Na + NaBr$$

alkyl bromide; sodium thiosulfate; Bunte salt; sodium bromide

$$RSSO_3Na + NaOH \longrightarrow R-SH + Na_2SO_3.$$

Bunte salt; sodium hydroxide; thiol; sodium sulfite

Sulfurous acid. Esters of sulfurous acid can be made from alcohols and thionyl chloride:

$$2ROH + SOCl_2 \longrightarrow RO-\overset{\overset{O}{\|}}{S}-OR + 2HCl.$$

alcohol; thionyl chloride; dialkyl sulfite; hydrogen chloride

Xanthates, rayon, and cellophane

Carbonic acid. The derivatives of carbonic acid, H_2CO_3, have counterparts in which any or all of the oxygen atoms have been replaced by sulfur atoms. One of the important groups of these compounds is that of the xanthates (Greek *xanthos*, "yellow," from the colour of their copper salts), which are made from hydroxyl compounds and carbon disulfide:

$$ROH + CS_2 + KOH \longrightarrow RO-\overset{\overset{S}{\|}}{C}-SK + H_2O.$$

alcohol; carbon disulfide; potassium hydroxide; xanthate (salt); water

This reaction is used to produce a soluble form of cellulose that can be extruded into an acidic solution, which disrupts the xanthate group, regenerating the cellulose in the form of fibres (rayon) or films (cellophane). Xanthates of simpler alcohols are used as collectors in ore flotation (that is, agents that preferentially attach themselves to the surface of certain minerals, making air bubbles cling to them so that they float to the surface.

Thiourea, the diamide of thiocarbonic acid, is manufactured from hydrogen sulfide and cyanamide or by heating ammonium thiocyanate:

$$H_2S + H_2NC\equiv N \longrightarrow H_2N-\overset{\overset{S}{\|}}{C}-NH_2$$

hydrogen sulfide; cyanamide; thiourea

$$NH_4SCN \xrightarrow{\text{heat}} H_2N-\overset{\overset{S}{\|}}{C}-NH_2.$$

ammonium thiocyanate

It is used as a component of photocopying papers and silver polishes and in a synthesis of thiols that prevents the formation of sulfides as by-products.

Several derivatives of dithiocarbamic acid are used as accelerators of the vulcanization of rubber. The following equations show typical methods of preparing these compounds:

$$2CS_2 + 2R_2NH + ZnO \longrightarrow \left(R_2N-C(=S)-S\right)_2Zn + H_2O$$

carbon disulfide; secondary amine; zinc oxide; zinc dialkyldithiocarbamate; water

$$2R_2N-C(=S)-SNa + H_2O_2 \longrightarrow R_2N-C(=S)-S-S-C(=S)-NR_2 + 2NaOH$$

sodium dialkyldithiocarbamate; hydrogen peroxide; tetraalkylthiuram disulfide; sodium hydroxide

$$R_2N-C(=S)-S-S-C(=S)-NR_2 + KCN$$

potassium cyanide

$$\longrightarrow R_2N-C(=S)-S-C(=S)-NR_2 + KSCN.$$

tetraalkylthiuram sulfide; potassium thiocyanate

Phosphoric acid. Sulfur-containing derivatives of phosphoric acid, H_3PO_4, are useful insecticides, lubricant additives, and ore flotation agents. Some are made from phosphorus pentasulfide or thiophosphoryll chloride:

$$P_4S_{10} + 8ROH \longrightarrow 4(RO)_2PS_2H + 2H_2S$$

tetraphosphorus decasulfide; alcohol; *O,O'*-dialkylphosphorodithioic acid; hydrogen sulfide

$$2(RO)_2PS_2H + ZnO \longrightarrow [(RO)_2PS_2]_2Zn + H_2O$$

zinc oxide; zinc *O,O'*-dialkylphosphorodithioate

$$(CH_3O)_2PS_2H + HC(-CO_2C_2H_5)=HC(-CO_2C_2H_5) \longrightarrow (CH_3O)_2P(=S)-S-CH(CO_2C_2H_5)-CH_2CO_2C_2H_5$$

O,O'-dimethylphosphorodithioic acid; diethyl maleate; Malathion

$$PSCl_3 + 2C_2H_5ONa \longrightarrow (C_2H_5O)_2P(=S)-Cl + 2NaCl$$

thiophosphoryl chloride; sodium ethoxide; *O,O'*-diethyl phosphorochloridothioate

$$(C_2H_5O)_2P(=S)-Cl + O_2N-C_6H_4-ONa$$

sodium *p*-nitrophenoxide

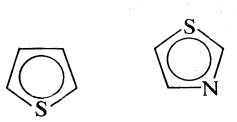
$$\longrightarrow (C_2H_5O)_2P(=S)-O-C_6H_4-NO_2$$

parathion

$$(C_2H_5O)_2P(=S)-Cl + C_2H_5SCH_2CH_2OH \longrightarrow (C_2H_5O)_2P(=S)-OCH_2CH_2SC_2H_5$$

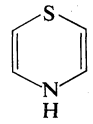
2-ethylthioethanol; Systox

Heterocyclic sulfur compounds. In several groups of organic compounds, sulfur atoms are present in a ring structure (see the article HETEROCYCLIC COMPOUNDS). The most important of these cyclic compounds have the following molecular formulas:

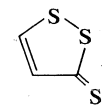


thiophene

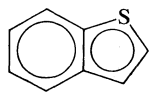
thiazole



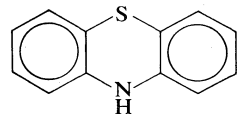
1,4-thiazine



1,2-dithiole-3-thione



thianaphthene or benzothiophene



phenothiazine

BIBLIOGRAPHY. RALPH CONNOR, "Organic Sulfur Compounds," in HENRY GILMAN (ed.), *Organic Chemistry: An Advanced Treatise*, 2nd ed., vol. 1 (1943), is comprehensive but now somewhat dated. W.A. PRYOR, *Mechanisms of Sulfur Reactions* (1962), focusses on reactions of elemental sulfur but contains valuable sections on its organic compounds. NORMAN KHARASCH (ed.), *Organic Sulfur Compounds*, vol. 1 (1961) and NORMAN KHARASCH and C.Y. MEYERS (eds.), *The Chemistry of Organic Sulfur Compounds*, vol. 2 (1966), are collections of chapters on specialized topics. FREDERICK CHALLENGER, *Aspects of the Organic Chemistry of Sulphur* (1959), emphasizes natural products. H. GOLDWHITE treats aliphatic compounds in S. COFFEY (ed.), *Rodd's Chemistry of Carbon Compounds*, 2nd ed., vol. 1, pt. B, ch. 5 (1965); and A.R. FORRESTER and J.L. WARDELL and D.R. HOGG, treat aromatic compounds in the same work, vol. 3, pt. A, ch. 5–6 (1971). Individual groups of organic sulfur compounds are the subject of articles in the 2nd ed. of the *Kirk-Othmer Encyclopedia of Chemical Technology:* M.B. BERENBAUM and R.N. JOHNSON, "Polymers Containing Sulfur," vol. 16, pp. 253–281 (1968); JULIUS FUCHS, "Sulfuric and Sulfurous Esters," vol. 19, pp. 483–498 (1969); W.S. Organometallic Compounds

Organometallic compounds are those substances that contain chemical bonds between carbon atoms and metal atoms, excluding such inorganic salts as the metal carbonates, which show quite different properties. Organometallic compounds constitute an immense group of chemical substances of importance to the history, theory, laboratory practice, and technology of chemistry. In a very general way it may be said that organometallic substances have unique properties that set them apart from both the inorganic and the organic families of compounds. The

The metals in organometallic compounds

metals involved in organometallic compounds may be from any of three categories: (1) the so-called main-group metals of the periodic table of the elements, which include such chemically active metals as lithium and magnesium; (2) the transition series of metals, which include those elements commonly thought of as metallic in character, such as iron, titanium, and platinum; and (3) the metalloids, or partly metal elements, such as silicon and boron. The carbon-containing groups in organometallic compounds also may be of several different varieties, including simple hydrocarbons (groups comprised solely of carbon and hydrogen atoms), unsaturated hydrocarbons (groupings with multiple bonds between carbon atoms), aromatic hydrocarbons (groupings with especially stable multiple bonds), and groups containing atoms other than carbon and hydrogen (oxygen or nitrogen, for example). Metal carbonyls, substances containing metal atoms and units of carbon monoxide, and metal isocyanides, substances containing metals and multiply bonded nitrogen–carbon groups, are classed as organometallic compounds and also as coordination compounds (compounds formed with metal atoms using bonds over and above those normally employed in bonding), revealing the close relationship between organometallic and coordination chemistry.

The carbon–metal bonds in organometallic compounds are of a number of different types: (1) ordinary covalent bonds, or σ-bonds, characterized by pairs of electrons shared between atoms, as, for example, in tetraethyllead, $(C_2H_5)_4Pb$, a gasoline additive; (2) ionic bonds, characterized by complete association of a bonding electron pair with one atom only, resulting in a separation of electrical charge, as in ethylpotassium, $(K^+C_2H_5^-)$; (3) unusual, multicentre covalent bonds, in which bonding extends over a group of atoms (in contrast with the usual two atoms), as in certain polymeric derivatives of light metals, such as ethyllithium, $(C_2H_5Li)_6$; and (4) donor–acceptor bonds, which involve association of a metal atom with an extended system of unsaturation, or overlapping π-orbitals (special electron pathways), as are found in ferrocene, bis(π-cyclopentadienyl)iron, $(\pi\text{-}C_5H_5)_2Fe$.

Physical and chemical properties

A group of compounds as varied as those in the organometallic series naturally includes substances exhibiting a wide range of physical and chemical properties. With regard to stability to heat and to air oxidation they range from alkylpotassium and alkylaluminum compounds, many of which are spontaneously inflammable in air, to ferrocene and the tetraalkyl derivatives of tin, which are very stable. Ferrocene, for example, survives heating to over 470° C in the absence of air. The covalent organometallics vary from crystalline solids, often volatile and usually soluble in organic solvents, to liquids—or even, occasionally, to gases at room temperature; for example, trimethylboron, $(CH_3)_3B$, which boils at −22° C. Many organometallic compounds are highly toxic, particularly those that are volatile.

The first references to organometallic compounds appeared in the early 19th century. In 1827, for example, the Danish chemist W.C. Zeise reported that when platinum chloride was boiled with ethanol, and potassium chloride was added to the solution, a salt was obtained having the composition $KCl\cdot PtCl_2\cdot C_2H_4\cdot H_2O$. More than 100 years later it was realized that Zeise's salt should be formulated as a coordination compound of platinum, viz., $K[C_2H_4PtCl_3]\cdot H_2O$, with carbon–metal bonding. A reasonable theory to account for the bonding of the ethylene molecule (the C_2H_4 unit) to the platinum ion in this compound was not suggested until 1953.

Early historical landmarks in organometallic chemistry were the synthesis of the arsenic compound cacodyl, $(CH_3)_2AsAs(CH_3)_2$, in 1842 by the German chemist Robert Bunsen; the preparation of alkylzinc compounds in 1849 by the English chemist Sir Edward Frankland; the synthesis of nickel carbonyl in 1890 in England by Ludwig Mond, a German-born chemist; and the discovery of organomagnesium compounds in 1900 by the French chemist Victor Grignard. Although organometallic compounds had been studied for over a century, it was not until 1951, when the highly stable substance called ferrocene was discovered and its unusual π-bonded structure became known, that organometallic compounds in themselves became the subject of truly intensive research. Up to that time organometallic compounds had been of importance chiefly as substances that were useful in the synthesis of organic compounds of various types. This situation was particularly true of the organomagnesium compounds which are called, after their discoverer, Grignard reagents.

BONDING IN ORGANOMETALLIC COMPOUNDS

Metals are electropositive elements—that is, their atoms tend to lose electrons to the atoms of other elements with which they combine. The atoms of nonmetals, on the other hand, generally attract electrons in chemical compounds. The concept of electronegativity (the power of an atom in a compound to attract electrons to itself) is useful in understanding the nature of chemical bonds. Thus, all metals have electronegativities less than that of carbon, with the result that in every carbon–metal bond the bonding electrons are attracted somewhat more to the carbon atom than to the metal atom, and the bond is polar (shows a separation of electrical charges) to some degree.

Polar and nonpolar bonding

Differences in electronegativity may be sufficient to produce compounds containing discrete positive and negative ions (atoms that have gained or lost electrons) held together by electrostatic forces. The electronegativity of a carbon atom is enhanced when it is part of an unsaturated system or when halogen atoms, particularly those of fluorine, are joined to it. These charge-transfer, or electrostatic, effects brought about by unsaturation or halogen substitution are responsible for the compound sodium cyclopentadienide having a structure with discrete Na^+ and $C_5H_5^-$ ions, and for the compound bis(trifluoromethyl)mercury, $(CF_3)_2Hg$, resembling more the ionic substance mercuric chloride, $HgCl_2$, than the covalent dimethylmercury, $(CH_3)_2Hg$. The latter substance, unlike its fluorocarbon analogue, is a typically organic, volatile liquid (boiling point 96° C), immiscible with water. More organometallic compounds are covalent in nature than are truly ionic, because electronegativity differences between the organic groups and the metal atoms are not sufficiently pronounced to do other than impart a degree of polarity to a covalent bond. Indeed, with the least electropositive metals, such as tin or lead, their organic derivatives provide excellent examples of covalent compounds, with classical two-electron σ-bonds (bonds formed from ordinary σ-orbitals, as opposed to those from π-orbitals). Consequently, like hydrocarbons (compounds of carbon and hydrogen), these compounds are unaffected by oxygen and water at room temperature.

Organometallic compounds formed from the lighter metals (for example, lithium, beryllium, or aluminum) show somewhat different behaviour. In these compounds the carbon–metal bonds are readily decomposed by oxygen or water, affording metal–oxygen bonds and releasing the organic groups as hydrocarbons. The high reactivity of these covalent carbon–metal bonds is due to their considerable polarity, coupled with the ability of the metals to coordinate (form "secondary" bonds) with reactant molecules as a prelude to decomposition. Indeed, the availability of vacant metal orbitals to accept electron pairs is reflected in the polymeric nature of many of the organic derivatives of lithium, beryllium, and aluminum—*e.g.*, the dimethylberyllium compound, $[(CH_3)_2Be]_x$; the alkyl groups in these compounds link the metal atoms together, and to account for this it is assumed that the electron pairs occupy bonding orbitals embracing more than two atoms. These compounds, in which the number of bonding orbitals exceeds the number of electron pairs, are termed electron-deficient; they represent a bonding akin to that found in the metals, where the electrons are delocalized over many atoms in the structure.

Organometallic compounds of the transition elements

The transition metal–organic compounds include a number of metal alkyls, such as bis(triphenylphosphine)dimethylplatinum $[(C_6H_5)_3P]_2Pt(CH_3)_2$, which contain covalent carbon–metal σ-bonds similar to those found in organometallic compounds of the main-group elements, such as tin. Unless other groups are simultaneously coordinated to the metal atoms, however, this class of compound is usually of low thermal or oxidative stability. Occupation of all coordination sites (typically six) of a metal atom has an important influence on stability. Vacant sites allow coordination of oxygen and water molecules, circumstances that lead to decomposition by paths requiring low activation energies (energies required to initiate reactions). Thus, dimethylmanganese, $Mn(CH_3)_2$, is a bright-yellow powder that readily detonates and reacts instantaneously with air, whereas pentacarbonylmethylmanganese, $CH_3Mn(CO)_5$, is a volatile white solid, mp 95° C, stable to air for long periods in the solid state, and decomposing only slowly in solution.

In addition to the purely σ-complexes, the transition metals also form a large number of coordination compounds in which an unsaturated organic system is associated with the metal. In addition to Zeise's salt and ferrocene (see above), examples include allylpalladium chloride, tricarbonyl(cyclobutadiene)iron, and bis(benzene)-chromium. These compounds are called π-complexes because the π-electrons of the hydrocarbon moieties (combining units) are involved in bonding to the metal atoms. The bonding in these cases is thought to involve reciprocal electron transfers between vacant and occupied π-orbitals of the organic group and filled and unfilled orbitals (electron pathways not involved in ordinary valence bonding) of the metal atom. Generally the metals are in their lower formal valence state—that is, fewer of their *d* electrons are involved in direct bonding—because this condition allows an energetically more favourable interaction of the *d* orbitals with the organic moieties. Many organic derivatives of the transition metals obey the so-called effective-atomic-number rule (a method for determining the degree of electronic saturation), with the result that the final electronic configuration of a fully coordinated metal is that of the next noble gas of higher atomic number. Thus, in the complex π-$C_5H_5Fe(CO)_2CH_3$, the iron atom acquires an additional ten electrons to reach the configuration of the noble gas krypton, which has 18 more electrons than the preceding noble gas, argon; these electrons are supplied by the two CO groups (four electrons), the π-cyclopentadienyl group (five electrons), and the methyl group (one electron).

The effective atomic number rule

Many organic–transition metal complexes show fluxional behaviour—that is, the molecules exist in several chemically equivalent structures and are able to pass from one to another rapidly, a process that may be detected by the technique of nuclear magnetic resonance spectroscopy, which measures certain magnetic phenomena associated with the atomic nuclei.

ORGANOMETALLIC COMPOUNDS OF THE MAIN-GROUP ELEMENTS

Organic compounds of the main-group metals are generally named as a combination of the organic group and the metal; *e.g.*, $Si(C_2H_5)_4$, tetraethylsilicon; C_6H_5HgCl, phenylmercuric chloride; and $Na[B(C_6H_5)_4]$, sodium tetraphenylborate. Occasionally, compounds are named by adapting the name of the metal hydride, in the manner of organic compounds; *e.g.*, $(CH_3)_3SnH$ is called trimethylstannane.

Certain regularities in the trends of properties in the various families of organometallic compounds can be observed. For example, within a family, boiling points increase with increasing atomic weight of the metal atom; thus the boiling points for the tetramethyl derivatives of Group IVa elements (other than carbon) are as follows: silicon, 26.5° C; germanium, 43.4°; tin, 78°; and lead, 110°. Chemical reactivities of organometallic compounds also vary in regular patterns. The small size of the lithium atom results in organolithium compounds having covalent properties, but the other Group Ia organometallics show a steadily increasing reactivity from sodium to cesium.

Methods of preparation. The formation of these compounds may be achieved by three main methods: (1) reaction of a free metal with an organic halide or an unsaturated organic compound; (2) displacement of one metal in an organometallic compound by another, by reaction with a halide of the second metal; and (3) the addition of metal hydrides to unsaturated organic compounds.

1. Reactive main-group metals, such as lithium, sodium, and magnesium, react with organic halides to give either the organometallic compound or an organometallic halide. Examples are:

$$n\text{-}C_4H_9Br + 2Li \longrightarrow n\text{-}C_4H_9Li + LiBr$$

$$(C_6H_5)_3CCl + 2Na \longrightarrow (C_6H_5)_3CNa + NaCl$$

$$CH_3I + Mg \longrightarrow CH_3MgI.$$

Some hydrocarbons—*e.g.*, acetylene and cyclopentadiene—are sufficiently acidic to react directly with a metal, the reaction being accompanied by evolution of hydrogen:

$$C_6H_5C{\equiv}CH + Na \longrightarrow C_6H_5C{\equiv}CNa + \tfrac{1}{2}H_2$$

$$C_5H_6 + K \longrightarrow C_5H_5K + \tfrac{1}{2}H_2.$$

2. Treatment of a metal halide with an organic deriva-

tive of a different metal often leads to the substitution of one metal for the other. This is the most common synthetic method, and it is one of wide scope. A variety of examples are shown:

$$3C_6H_5MgBr + (C_2H_5)_2OBF_3 \longrightarrow (C_6H_5)_3B + 3MgBrF + (C_2H_5)_2O$$

$$(n\text{-}C_3H_7)_3Al + (C_2H_5)_3NBF_3 \longrightarrow (n\text{-}C_3H_7)_3B + (C_2H_5)_3N + AlF_3$$

$$3(C_2H_5)_3Al + GaBr_3 \longrightarrow (C_2H_5)_3Ga + 3(C_2H_5)_2AlBr$$

$$(C_6H_5)_4Sn + 2BCl_3 \longrightarrow 2C_6H_5BCl_2 + (C_6H_5)_2SnCl_2$$

3. The readily available hydrides of metals of Groups IIIa and IVa add across carbon–carbon double and triple bonds, on heating or on exposure to ultraviolet light, often in the presence of a catalyst:

$$(C_6H_5)_3SnH + CH_2{=}CHCN \longrightarrow (C_6H_5)_3SnCH_2CH_2CN$$

$$Cl_3SiH + CH{\equiv}CH \longrightarrow Cl_3SiCH{=}CH_2$$

$$6n\text{-}C_4H_9CH{=}CH_2 + B_2H_6 \longrightarrow 2(C_6H_{13})_3B.$$

In an extensively used industrial process, olefins with terminal methylene, $=CH_2$, groups (1-olefins) react with aluminum and hydrogen under pressure to give the alkyls directly:

$$Al + \tfrac{3}{2}H_2 + 3(\text{l-olefin}) \longrightarrow \text{alkyl}_3Al.$$

Specific synthetic procedures

The syntheses of many specific organometallics are dictated by the particular properties or reactions of a single compound or group of compounds. Thus, cyclopentadienylthallium is insoluble in water, and it may be prepared from cyclopentadiene and thallium hydroxide in aqueous solution because it readily separates from the solution. A large number of organomercury compounds are available by unique reactions: (1) mercuration of aromatic compounds with mercuric acetate, (2) reaction of aryldiazonium salts with mercury, and (3) interaction of arylsulfinic acids with mercuric chloride:

$$C_6H_6 + Hg(O_2CCH_3)_2 \longrightarrow C_6H_5HgO_2CCH_3 + CH_3CO_2H$$

$$ArN_2Cl + Hg \longrightarrow ArHgCl + N_2$$

$$ArSO_2H + HgCl_2 \longrightarrow ArHgCl + SO_2 + HCl,$$

where Ar is an aryl group.

The organosilicon halides, which are technologically important because they are precursors to the silicones, are prepared by a special reaction using copper as catalyst.

$$2CH_3Cl + Si \xrightarrow[300°]{Cu} (CH_3)_2SiCl_2$$

Organogermanium and organotin halides may be prepared similarly.

Many organoboron compounds have compact molecular structures based on cages of boron atoms and carbon atoms ("carboranes"). The most easily prepared carborane is $C_2B_{10}H_{12}$, which has a structure based on an icosahedron (a polyhedron with 20 faces), with ten boron and two adjacent carbon atoms at the apexes and one hydrogen atom attached to each of these. This carborane can be prepared as follows:

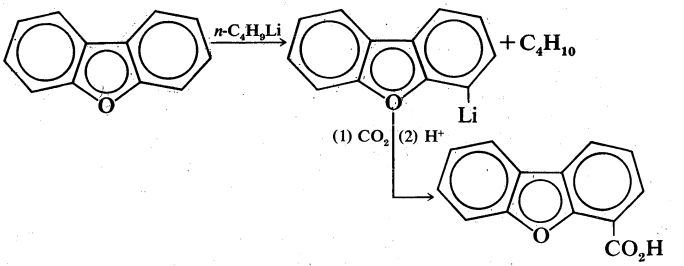
$$B_{10}H_{14} + HC{\equiv}CH \xrightarrow[C_6H_6]{2(C_2H_5)_2S} C_2B_{10}H_{12} + 2H_2.$$

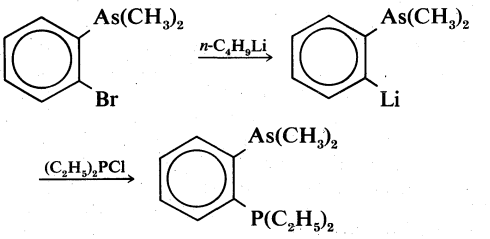
The compound is high melting (294.5–295.5°C) and is very resistant to oxidation and hydrolysis. Substitution at the carbon atoms may be effected by treatment with butyllithium to give $Li_2C_2B_{10}H_{10}$, followed by reaction with reactive halides; *e.g.*,

$$Li_2C_2B_{10}H_{10} + 2(C_6H_5)_2PCl \longrightarrow [(C_6H_5)_2P]_2C_2B_{10}H_{10} + 2LiCl.$$

Principal reactions. The reactions of main-group organometallic compounds are extremely varied, and certain classes of compound—*e.g.*, lithium, boron, and aluminum compounds, and the Grignard reagents—are very useful synthetically.

Organolithium compounds often are not isolated but are used as soon as they are formed, and a frequently employed sequence of reactions is metalation of an organic compound with *n*-butyllithium (a commercially available product) followed by reaction with a selected reagent that reacts with the organometallic intermediate.





A useful reaction occurs with alkyltriphenylphosphonium salts to give phosphinemethylenes. These intermediates react with carbonyl compounds to give olefins, a reaction known as the Wittig reaction.

$$(C_6H_5)_3P \xrightarrow{CH_3Br} (C_6H_5)_3P(CH_3)^+Br^-$$

$$\xrightarrow{C_6H_5Li} (C_6H_5)_3P{=}CH_2 \xrightarrow{R_2CO} (C_6H_5)_3PO + R_2C{=}CH_2$$

Hydroboration

The most important reactions of organoboron compounds, R_3B, are cleavage of the C–B bonds in various ways to give alkanes, alcohols, ketones, and other compounds. The addition of B–H bonds to carbon–carbon double bonds is called hydroboration; the reaction proceeds rapidly in ethers (as solvents) affording diverse species, R_3B, in which the R groups can be complex organic moieties. Many syntheses of purely organic compounds depend on the addition of diborane (B_2H_6), often generated *in situ*, to olefins using a polyether—*e.g.*, diglyme, $(CH_3OCH_2CH_2)_2O$—as solvent.

$$12RCH{=}CH_2 + 3NaBH_4 + 4(C_2H_5)_2OBF_3 \longrightarrow 4(RCH_2CH_2)_3B + 3NaBF_4 + 4(C_2H_5)_2O$$

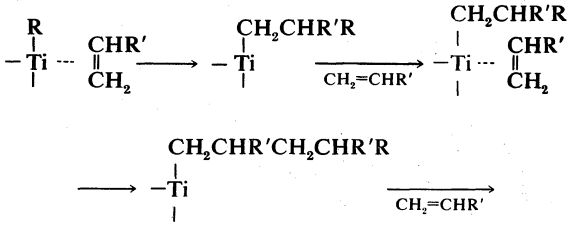
The resulting organoboron compounds are able to undergo a variety of reactions. For example, treatment with alkaline hydrogen peroxide yields an alcohol RCH_2CH_2OH, whereas protonation (addition of a hydrogen ion) with an acid gives RCH_2CH_3; *i.e.*, produces an overall hydrogenation of the starting olefin. Oxidation of $(RCH_2CH_2)_3B$ with chromic acid gives ketones or acids, while treatment with diethylchloramine, $(C_2H_5)_2NCl$, gives RCH_2CH_2Cl (corresponding to an overall addition of hydrogen chloride to the olefin in a reverse manner). Thus, a family of related organic syntheses depends on hydroboration.

The industrial availability of triorganoaluminum compounds has resulted in their becoming reagents of great utility. In the preparation of alkyl derivatives of other metals their use avoids the employment of ethers, which are necessary with Grignard reagents. Aluminum alkyls also cause dimerization, oligomerization, or polymerization of olefins—that is, joining of two olefin molecules, several olefin molecules, or many, respectively. The reactions are of use in the manufacture of detergents, which often are made from long-chain alcohols, as follows:

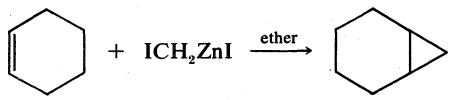
$$(C_2H_5)_3Al \xrightarrow[\sim 100 \text{ atm}]{C_2H_4,\ \sim 100°} [C_2H_5(C_2H_4)_n]_3Al \xrightarrow[\text{oxidation}]{\text{controlled}} H(C_2H_4)_{n+1}OH.$$

Olefin polymerization

If a compound $[CH_3(CH_2)_n]_3Al$ is heated under pressure, the alkyl chain becomes detached in the form of a medium-to-high-molecular-weight linear polyethylene. Such polymers, however, are better obtained by using aluminum–transition metal catalysts (Ziegler–Natta catalysts). For example, treatment of titanium tetrachloride, ($TiCl_4$), with triethylaluminum, $(C_2H_5)_3Al$, in heptane solvent gives a complex that reacts with such olefins as ethylene or propylene. The polymers produced by this reaction are isotactic (sterically regular) solids with desirable properties, as opposed to disordered (atactic) polymers that are oils at room temperature. The mechanism of this industrially important process is a matter of some controversy but probably involves an initial reduction and alkylation of the titanium by the aluminum alkyl, followed by coordination and insertion of olefin molecules in a stereoregular way.



A mixture of zinc and copper reacts with di-iodomethane to give iodomethylzinc iodide (stable in solution only). This compound is useful in reacting with olefins to give cyclopropanes:



norcarane
(bicyclo [4.1.0] heptane)

Organozinc compounds also are formed as transient intermediates in a standard reaction for producing highly substituted esters (the Reformatsky reaction):

$$BrCH_2CO_2C_2H_5 \xrightarrow{Zn} [BrZnCH_2CO_2C_2H_5]$$

$$\xrightarrow[H_2O]{R'_2CO} R'_2C(OH)CH_2CO_2C_2H_5.$$

The most important reaction of organocadmium compounds is the reaction with acid chlorides to give ketones:

$$2RCOCl + R'_2Cd \longrightarrow 2RCOR' + CdCl_2.$$

This method is preferred to the use of Grignard reagents, since the latter react rapidly with the ketone produced.

Analytical chemistry. Organic derivatives of main-group metals may be analyzed by combustion analysis, in which the compound is burned and the carbon and hydrogen present are determined as carbon dioxide and water (the residual metal oxide may be weighed directly). Spectroscopic methods—*e.g.*, infrared and nuclear magnetic resonance spectroscopy—provide a great deal of information, especially about the nature of the organic groups present. Mass spectrometry also is extensively used, often yielding precise molecular-weight measurements.

Industrial applications. Aluminum alkyls are employed industrially in olefin polymerization and in the synthesis of long-chain alcohols (see above). Tetraethyllead is used on a large scale as an additive (antiknock agent) in gasoline, since it is a suitable combustion catalyst, which permits higher compression ratios in the engine. About 1,000,000,000 pounds of tetraethyllead are used each year. The commercial process for manufacture of tetraethyllead is as follows:

Tetraethyllead

$$4NaPb + 4C_2H_5Cl \longrightarrow (C_2H_5)_4Pb + 4NaCl + 3Pb.$$

In gasoline, tetraethyllead is mixed with dibromoethane and dichloroethane; these substances act as "scavengers" within the engine by converting the resulting lead oxide into volatile halides, which are emitted in the exhaust. Volatile lead compounds, however, are highly toxic, and their expulsion into the atmosphere is undesirable. Hence the use of lead alkyls in motor fuels is declining, and other methods are being sought for the production of fuels with superior combustion characteristics (higher "octane number").

Controlled hydrolysis of organosilicon halides produces polymers containing silicon–oxygen and silicon–carbon bonds. The silicones have unusual properties and are widely used for a number of purposes. Organotin compounds are used to stabilize polyvinyl chloride, a polymer used in many common plastic articles. They are also used as fungicides in agriculture and in treating plant diseases that infect potatoes, sugar beets, cacao, groundnuts (peanuts), and other crops. Tricyclohexyltin hydroxide also is used in agriculture, to kill mites. Tributyltin oxide is important as an industrial biocide and surface disinfectant; thus, it is used in preserving wood and in keeping clean the recirculating water of cooling towers.

Certain organomercury compounds have been widely used in pharmacy, for example, as diuretics, but have now been largely replaced by more specific organic compounds. Mercurochrome (2,7-dibromo-4-hydroxymercurifluorescein) is a familiar antiseptic.

ORGANOMETALLIC COMPOUNDS OF THE TRANSITION ELEMENTS

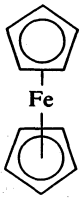
Organic compounds of transition metals are generally named as a combination of the organic group and the metal; *e.g.*, $Mn(CH_3)_2$, dimethylmanganese. When other donor ligands are present, their names precede that of the organic group; *e.g.*, $[(C_6H_5)_3P]_2Pt(C_6H_5)I$ iodobis(triphenylphosphine)phenylplatinum. Similarly, the names of π-bonded organic groups precede those of σ-bonded groups; *e.g.*, $(\pi\text{-}C_5H_5)Fe(CO)_2CH_3$, dicarbonyl-$\pi$-cyclopentadienyl-$\sigma$-methyliron. As these names tend to be cumbersome, many of the commonly encountered compounds have acquired simpler names; *e.g.*, $Fe(\pi\text{-}C_5H_5)_2$, ferrocene or bis(π-cyclopentadienyl)iron; $(\pi\text{-}C_5H_5)Mn(CO)_3$, cymantrene or π-cyclopentadienyltricarbonylmanganese. Organic complexes of the transition elements may be classified according to the number of electrons donated by the organic ligand (that is, the substance complexed with the metal atom; see table). A great many separate compounds are known because many members of each particular class of organic molecule can bond to a given metal. There are, for example, a vast number of complexes of formula diene-$Fe(CO)_3$ because the $Fe(CO)_3$ group shows great affinity for any 4π-electron system based on two conjugated double bonds, of which there are many. Moreover, a particular metal may form complexes with all types of ligand; for example, in the series $CH_3Mn(CO)_5$, $[(\pi\text{-}C_2H_4)Mn(CO)_5]^+$, $(\pi\text{-}C_3H_5)Mn(CO)_4$, $(\pi\text{-}C_6H_8)Mn(CO)_3H$, $(\pi\text{-}C_5H_5)Mn(CO)_3$, and $[(\pi\text{-}C_6H_6)Mn(CO)_3]^+$, manganese is associated with organic groups that donate—in order—from one to six electrons to its valence shell. In each case the effective atomic number rule is obeyed, the manganese atom having 18 electrons in its outermost shell.

Representative Ligands in Organotransition-Metal Complexes

number of electrons	class	examples of complexes
1	yl	$CH_3Re(CO)_5$, white, mp 120°
2	alkene	$[(\pi\text{-}C_2H_4)_2RhCl]_2$, orange red, decomp. > 100°
	carbene	$CH_3(CH_3O)CCr(CO)_5$, white, mp 34°
3	enyl*	$[(\pi\text{-}C_3H_5)PdCl]_2$, yellow, mp 145°
4	diene	$(\pi\text{-}C_4H_6)Fe(CO)_3$,† yellow oil
5	dienyl	$(\pi\text{-}C_5H_5)_2Ni$, green, mp 173°
	ollyl	$[(CH_3)_4N][\{\pi\text{-}1,2\text{-}B_9H_9C_2(CH_3)_2\}_2Fe]$‡, red, mp 247°
6	arene	$(\pi\text{-}C_6H_6)_2W$, green, decomposes 110°
	triene	$(\pi\text{-}C_7H_8)Mo(CO)_3$,§ orange red, mp 101°
7	trienyl	$(\pi\text{-}C_7H_7)V(CO)_3$, dark green, decomposes 134°

*Also called "π-allylic" ligands. †C_4H_6 is buta-1,3-diene. ‡The ligand $\{1,2\text{-}B_9H_9C_2(CH_3)_2\}^{2-}$ is an 11-atom B_9C_2 species (an icosahedron with an apex removed) having a face comprising five atoms (B_3C_2) with π-type molecular orbitals similar to those of π-C_5H_5. In forming the complex the metal atom completes the icosahedron. §C_7H_8 is cycloheptatriene.

Although this rule is very useful, it is not followed invariably; the exceptions may be rationalized by considering the relative energies of the *s*, *p*, and *d* orbitals (designations for electron pathways within the various shells). For metals of the scandium and titanium groups of the periodic table, the 3*d* orbitals have a relatively high energy compared with the other orbitals (4*s* and 4*p*) in the same valence band, and their importance in bonding, therefore, is less. At the other end of the transition series (in the neighbourhood of copper and zinc), the *d* orbitals are of relatively low energy and cannot easily be regarded as valence orbitals. Across the series vanadium, chromium, manganese, iron, cobalt, and nickel, the 3*d* orbitals decrease in energy more rapidly than do the 4*s* and 4*p* orbitals, but all three orbital types are generally sufficiently close in energy to be suitable for metal–ligand bonding. Under these conditions, maximum bonding—with associated stability—occurs when all orbitals are filled with electron pairs. This occurs when the metal atom has an 18-electron configuration; *i.e.*, the five *nd*, one $(n+1)s$, and three $(n+1)p$ orbitals ($n = 3$, 4, or 5) are all occupied by metal and ligand electrons. Nowhere is this better exemplified than in the case of ferrocene, a compound of exceptional stability and one in which the iron atom (eight electrons) is located symmetrically between two π-C_5H_5 groups (ten electrons), forming a classical "sandwich" molecular structure.



Exceptions to the effective-atomic-number rule

It follows from this reasoning that exceptions to the effective-atomic-number rule are found at both ends of the transition series, in which cases the 3*d* orbitals are too high (as with titanium) or too low (copper) in energy. Sixteen-electron environments are prevalent with organotitanium compounds—*e.g.*, $(\pi\text{-}C_5H_5)_2Ti(C_6H_5)_2$—and 14 with the metals of the copper group [*e.g.*, $(C_6H_5)_3PAuCH_3$]. With the latter, not only have the *d* electrons become low-energy (core) electrons but the *p* orbitals have become relatively high in energy compared with the *s* orbitals; consequently only one *p* orbital is used in bonding, in combination with the *s* orbital. A similar effect is responsible for the existence of numerous 16-electron complexes of nickel, palladium, and platinum, in which the relative energies of the *nd*, the $(n+1)s$, and the $(n+1)p$ orbitals are such as to lead to the use of one of the *d*, the *s*, and two of the *p* orbitals in bonding—*e.g.*, $[(C_2H_5)_3P]_2Pd(CH_3)I$.

Methods of preparation. It is convenient to consider separately the methods for preparing the π-complexes and the σ-compounds of the transition metals.

π-Complexes. Treatment of a suitable metal halide with an organic derivative of an alkali metal or a Grignard reagent using an ether (often tetrahydrofuran) as solvent is often a method for preparing π-complexes of transition elements.

$$2CH_2=CHCH_2MgBr + NiCl_2 \longrightarrow (\pi\text{-}C_3H_5)_2Ni + 2MgClBr$$

$$2C_5H_5Na + FeCl_2 \longrightarrow (\pi\text{-}C_5H_5)_2Fe + 2NaCl$$

$$2C_8H_8K_2 + UCl_4 \longrightarrow (\pi\text{-}C_8H_8)_2U + 4KCl$$

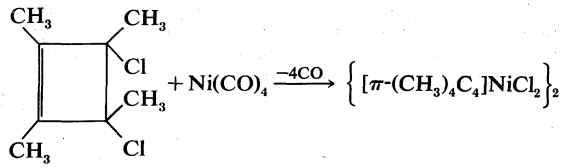
Reactions with olefins

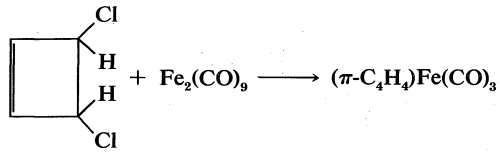
The reaction between a metal complex and an unsaturated hydrocarbon is the most generally useful method of preparing π-complexes; it has several modifications. In one of the simplest forms of this reaction, carbonyls are displaced from metal carbonyl complexes by unsaturated hydrocarbons. The reaction is carried out by heating the reactants together or by exposing them to ultraviolet irradiation in a suitable solvent (often a saturated hydrocarbon).

$$Fe(CO)_5 + CH_2=CHCH=CH_2 \xrightarrow{-2CO} (\pi\text{-}C_4H_6)Fe(CO)_3$$

$$Co_2(CO)_8 + 2C_5H_6 \longrightarrow 2(\pi\text{-}C_5H_5)Co(CO)_2 + 4CO + H_2$$

The more reactive metal carbonyls abstract chlorine atoms from carbon–chlorine bonds with concomitant oxidation of the metal to a metal chloride. This property has been used to isolate organic molecules that are not normally stable in the free state but that can be stabilized by coordination with a metal atom. Cyclobutadiene and its derivatives, sought by chemists for over 80 years, were finally prepared by being stabilized in this way.





Another example of this type of stabilization is found in the preparation of the trimethylenemethane group:

$$CH_2=C(CH_2Cl)_2 + Fe_2(CO)_9 \longrightarrow [\pi\text{-}(CH_2)_3C]Fe(CO)_3.$$

Reactions with acetylenes

Reactions between acetylenes and metal carbonyls (or their derivatives) can be a fruitful source of unusual organometallic compounds. A variety of reactions is possible, including coordination of the triple bond, di- or trimerization of the acetylene, and formation of ligands containing carbonyl groups, with the result that highly complex mixtures of products are obtained. For example, the mixture that results from treatment of iron carbonyls with acetylenes has given complexes of nearly 30 different types, containing such diverse ligands as cyclobutadienes, cyclopentadienones, and quinones.

The preparation of many π-complexes depends upon an initial reduction of a transition-metal compound in the presence of an unsaturated hydrocarbon to serve as the ligand. The synthesis of bis(benzene)chromium depends upon this technique:

$$3CrCl_3 + 2Al + AlCl_3 + 6C_6H_6 \longrightarrow 3[(\pi\text{-}C_6H_6)_2Cr]^+[AlCl_4]^-$$

$$2[(\pi\text{-}C_6H_6)_2Cr]^+ + S_2O_4^{2-} + 4OH^- \longrightarrow 2(\pi\text{-}C_6H_6)_2Cr + 2H_2O + 2SO_3^{2-}.$$

With this procedure, or modifications of it, arene complexes of many of the transition metals have been prepared. Aromatics other than benzene also may be used.

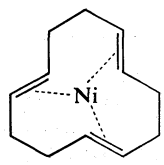
Reduction of nickel acetylacetonate with aluminum alkyls in the presence of triphenylphosphine and ethylene produces a yellow crystalline compound,

$$(\pi\text{-}C_2H_4)\,Ni[P(C_6H_5)_3]_2.$$

With cycloocta-1,5-diene, rather than ethylene and triphenylphosphine, the same method produces

$$(\pi\text{-}C_8H_{12})_2Ni,$$

a yellow solid of melting point 142° C that is unstable in air but is reasonably stable to heat. An unusual complex that is prepared by a similar method is all-*trans*-1,5,9-cyclododecatrienenickel,



in which the metal atom is coordinated only to three double bonds. Many olefin complexes of nickel are used in further syntheses. Thus, $(\pi\text{-}C_{12}H_{18})Ni$ catalyzes the trimerization of butadiene, giving isomers of cyclododecatriene. In some syntheses the hydrocarbon itself functions as the reducing agent. Thus, treatment of rhodium trichloride with butadiene gives bis(butadiene)rhodium(I) chloride, $(\pi\text{-}C_4H_6)_2RhCl$.

Ligand-exchange reactions

Ligand-exchange reactions, those in which an organic group is transferred from one metal to another, also are used to prepare π-complexes. For example, treatment of $(C_6H_5CN)_2PdCl_2$ with diphenylacetylene, followed by reaction with hydrogen halides, gives dimeric tetraphenylcyclobutadienepalladium halides $\{[\pi\text{-}(C_6H_5)_4C_4]PdX_2\}_2$ (X = Cl or Br). The tetraphenylcyclobutadiene group then may be readily transferred to other metals. Thus, reaction of one of the above palladium complexes with $(\pi\text{-}C_5H_5)_2Co$ gives $[\pi\text{-}(C_6H_5)_4C_4]Co(\pi\text{-}C_5H_5)$, and reaction with $Fe(CO)_5$ gives $[\pi\text{-}(C_6H_5)_4C_4]Fe(CO)_3$.

σ-Compounds. Although simple alkyls and aryls of the transition metals are generally very unstable—*e.g.*, $(CH_3)_2Ni$ decomposes above −110° C—derivatives containing such ligands as carbon monoxide, phosphines, and π-bonded hydrocarbons are often reasonably robust chemically. A number of synthetic routes to these compounds are known.

Treatment of transition-metal-complex halides with Grignard reagents or with organolithium compounds frequently leads to replacement of the halogen with alkyl or aryl groups.

$$[(C_6H_5)_3P]_2PdCl_2 + 2C_6H_5MgBr \longrightarrow [(C_6H_5)_3P]_2Pd(C_6H_5)_2 + 2MgBrCl$$

$$CrCl_3(THF)_3 + 3C_6H_5MgBr \longrightarrow (C_6H_5)_3Cr(THF)_3 + 3MgBrCl$$

[THF = tetrahydrofuran, C_4H_8O]

$$(C_6H_5)_3PAuCl + CH_3Li \longrightarrow (C_6H_5)_3PAuCH_3 + LiCl$$

Reactions between complex metal anions and organic halides yield organometallic compounds in which the anion has replaced the halide.

$$Na^+[Mn(CO)_5]^- + CH_3I \longrightarrow CH_3Mn(CO)_5 + NaI$$

$$Na^+[W(CO)_3(\pi\text{-}C_5H_5)]^- + C_2H_5I \longrightarrow C_2H_5W(CO)_3(\pi\text{-}C_5H_5) + NaI$$

The utility of this method is enhanced by the fact that acyl complexes, prepared by reaction of the anions with acid halides, can often be decarbonylated, either thermally or on ultraviolet irradiation, to give the corresponding alkyl compounds:

$$Na^+[Fe(CO)_2(\pi\text{-}C_5H_5)]^- + C_6H_5COCl$$
$$\longrightarrow C_6H_5COFe(CO)_2(\pi\text{-}C_5H_5) + NaCl$$
$$\xrightarrow{h\nu} C_6H_5Fe(CO)_2(\pi\text{-}C_5H_5) + CO.$$

Insertion reactions

Insertion of unsaturated groups into metal–hydrogen or metal–alkyl σ-bonds produces organometallic compounds with more extended alkyl chains.

$$(\pi\text{-}C_5H_5)Fe(CO)_2H + CH_2{=}CHCH{=}CH_2$$
$$\longrightarrow CH_3CH{=}CHCH_2Fe(CO)_2(\pi\text{-}C_5H_5)$$

$$CH_3Mn(CO)_5 + CF_3C{\equiv}CCF_3 \longrightarrow (CH_3)(CF_3)C{=}C(CF_3)Mn(CO)_5$$

A useful synthesis depends on the so-called oxidative-addition or oxidative-elimination reactions. Many transition-metal complexes, in which the metal atom is of low valence and which are not so fully coordinated as they might be, react with electron-acceptor (electrophilic) molecules to form compounds in which the valence state of the metal can be regarded formally as having increased by two units. The reacting molecule, which contains a bond designated A–B, may be cleaved by the metal atom to form in its coordination sphere two separate bonds, M–A and M–B; or, if the bond between A and B is a multiple one, the product may contain an A–B unit coordinated to the metal atom. The following reactions exemplify the utility of these kinds of processes in organometallic syntheses:

$$Fe(CO)_5 + C_3F_7I \longrightarrow C_3F_7Fe(CO)_4I + CO$$

$$[(C_6H_5)_3P]_3RhCl + C_2H_4$$
$$\longrightarrow (\pi\text{-}C_2H_4)Rh[P(C_6H_5)_3]_2Cl + (C_6H_5)_3P$$

$$[(C_6H_5)_3P]_2Ir(CO)Cl + CH_3I$$
$$\longrightarrow CH_3Ir[P(C_6H_5)_3]_2(CO)(Cl)(I)$$

$$[(C_6H_5)_3P]_3Pt + CH_3C{\equiv}CCH_3$$
$$\longrightarrow [\pi\text{-}(CH_3)_2C_2]Pt[P(C_6H_5)_3]_2 + (C_6H_5)_3P.$$

Principal reactions. Each class of organometallic complex (see table) has its own characteristic chemical and physical properties associated with the presence of a particular type of organic group. The degree to which group properties are shown, however, depends on the firmness with which the ligand is attached to the metal atom. Consequently, there are no reactions generally applicable to all those compounds, and even for a particular class large gradations in reactivity are observed.

Many organometallics are endothermic compounds; that is, their formation from the constituent elements involves an increase in free energy. Hence there is an inherent thermal instability with respect to decomposition into the metals and the hydrocarbons that make them up. Nevertheless, many hundreds of these compounds can be prepared, and in some cases they show considerable resistance to thermal decomposition, because it is necessary for a favourable free-energy change to be accompanied by a reaction path of sufficiently low energy if decomposition is to occur at a measurable rate. In many cases, decomposition may be kinetically rather than thermodynamically controlled—that is, it may not be observed normally because the rate is too slow, even though the energy requirements are favourable. The limiting process may be the initial breaking of an M–C bond to form M· and R· radicals (homolytic dissociation) or M^+ and R^- ions (heterolytic dissociation). Such bond dissociations are likely to be facilitated when empty low-lying orbitals are present in the metal atom, since electrons can temporarily reside in these. In both homolytic and heterolytic processes, the carbon fragments are generally reactive and rapidly form stable products; for example, by dimerization. It is the formation of these more stable products that makes the decomposition irreversible; but if there is a high activation energy (energy needed to initiate the process) for the dissociation, decomposition will not occur.

Oxidation

All organometallic compounds are thermodynamically unstable to oxidation because of the large favourable free-energy change in the conversion into metal oxide, carbon dioxide, and water. In this respect organometallic compounds are no different from purely organic compounds except that with the former an additional product (metal oxide) is involved. Again, however, kinetic factors (considerations of reaction rate) are often decisive both in enhancing stability toward oxygen or lowering resistance to oxidative attack. In this case also instability can be associated generally with the presence of empty low-lying orbitals. Similar considerations apply to hydrolytic stability. Hydrolysis often involves an initial bonding with a water molecule, a process facilitated by an empty metal orbital. The M–C bond polarity, however, also is an important factor in hydrolysis because a further step in the process is the elimination of R^- as a hydrocarbon RH.

The existence of a closed-shell (18-electron) configuration has a bearing on the reactivity of a complex (see above). For complexes in which the metal atom already follows the effective-atomic-number rule, reaction may require displacement of one or more ligand molecules in order to provide a vacant coordination site or sites for a reactant molecule. This situation may lead only to the exchange of one ligand for another, but often a molec-

ular rearrangement follows, affording an entirely new structure.

Cleavage and insertion reactions are the hallmark of σ-bonds between transition metals and alkyl or aryl groups. Cleavage reactions are those in which the C–M bond is split, with attendant formation of a new bond to an inorganic atom. Typical reagents that may effect cleavage are acids, hydrogen, halogens, and metal halides.

$$(CH_3)_2Pt[P(C_2H_5)_3]_2 + HCl \longrightarrow CH_3Pt[P(C_2H_5)_3]_2Cl + CH_3Cl$$

$$C_6H_5Pt[P(C_2H_5)_3]_2Cl + H_2 \longrightarrow HPt[P(C_2H_5)_3]_2Cl + C_6H_6$$

$$(C_6H_5)_2Ti(\pi\text{-}C_5H_5)_2 + 2Cl_2 \longrightarrow Cl_2Ti(\pi\text{-}C_5H_5)_2 + 2C_6H_5Cl$$

$$(C_6H_5)_3Cr(THF)_3 + 3HgCl_2 \longrightarrow 3C_6H_5HgCl + CrCl_3 + 3THF$$

The term insertion designates a reaction in which a C–M bond is broken, with the reactant molecule's being placed between the two parts and joined to both. This process is the basis of the Ziegler–Natta olefin polymerizations (see above), but it also is known in many simpler forms.

$$C_2H_5Mo(CO)_3(\pi\text{-}C_5H_5) + CO \longrightarrow C_2H_5COMo(CO)_3(\pi\text{-}C_5H_5)$$

$$C_6H_5Fe(CO)_2(\pi\text{-}C_5H_5) + (C_6H_5)_3P \longrightarrow C_6H_5COFe(CO)[P(C_6H_5)_3](\pi\text{-}C_5H_5)$$

$$CH_3Mn(CO)_5 + SO_2 \longrightarrow CH_3SO_2Mn(CO)_5$$

Conversion of σ- to π-complexes

In many reactions, a σ-bonded organic group is converted into a π-complexed group. A simple example involves the complex $\sigma\text{-}CH_2{=}CHCH_2Mn(CO)_5$, which on heating or exposure to ultraviolet light releases carbon monoxide and forms $(\pi\text{-}C_3H_5)Mn(CO)_4$. Similar decarbonylations (loss of carbonyl groups) have been observed with σ-allyl carbonyl derivatives of cobalt, iron, chromium, molybdenum, and tungsten, in each case π-allyl complexes of these metals being formed.

In 1919 and afterward many polyphenylchromium compounds were prepared by treating chromium chloride ($CrCl_3$) with phenylmagnesium bromide. In 1954 it was shown that several of these compounds were cationic arene–chromium complexes; *e.g.*,

$$[(\pi\text{-}C_6H_6)Cr(\pi\text{-}C_6H_5C_6H_5)]^+,$$

which had been formed by rearrangement of $\sigma\text{-}C_6H_5Cr$ groups either in a hydrolysis step or thermally. Most of these transformations are exceedingly complex, and a multitude of products is formed. The history of the polyphenylchromium complexes is an example of the failure to recognize the true nature of a series of compounds because of the lack of sufficiently sophisticated analytical techniques.

Several σ-alkyl complexes have been converted to cationic olefin π-complexes by hydride abstraction (removal of an H^-) or by protonation (addition of an H^+).

$$\begin{matrix} CH_3CH_2CH_2Fe(CO)_2(\pi\text{-}C_5H_5) \xrightarrow{[(C_6H_5)_3C]^+} \\ CH_2{=}CHCH_2Fe(CO)_2(\pi\text{-}C_5H_5) \xrightarrow{H^+} \end{matrix}$$

$$\left[\begin{matrix} CH_3CH \\ \| \\ CH_2 \end{matrix} \cdots Fe(CO)_2(\pi\text{-}C_5H_5)\right]^+$$

An unusual group of compounds contains a fluorocarbon group (chemical unit of only carbon and fluorine atoms) σ-bonded to a transition metal. These complexes are more stable chemically than their alkyl or aryl counterparts—*e.g.*, $C_2F_5Mn(CO)_5$ decomposes at 150° C, whereas $C_2H_5Mn(CO)_5$ decomposes at 25°; $C_6F_5Mn(CO)_5$ decomposes at 170°, whereas $C_6H_5Mn(CO)_5$ decomposes at 100°. Thermodynamic and kinetic factors both are thought to be responsible for the enhanced stability of the fluorocarbon compounds. The fluorocarbon–metal bonds are more ionic than hydrocarbon–metal bonds; that is, they show more complete association of the shared electron pair with the carbon atom of the bond. This effect is due to the strongly electron-withdrawing character of the fluorocarbon groups, which tend to pull the electron pair farther from the metal atom. Moreover, alkyl–metal bonds frequently decompose by a reaction that is the reverse of an insertion reaction, $M - C_2H_5 \rightarrow M - H + C_2H_4$. The analogous reaction involving elimination of a fluoroolefin and formation of a metal fluoride, although thermodynamically favoured, requires more activation energy in order to proceed at a measurable rate. Because of their stability, bonds between fluorocarbon groups and transition metals show little or no tendency to undergo insertion reactions. More than 500 complexes of this type are known, produced by reactions such as

$$HMn(CO)_5 + CF_2{=}CF_2 \longrightarrow HCF_2CF_2Mn(CO)_5$$

$$NaRe(CO)_5 + C_6F_6 \longrightarrow C_6F_5Re(CO)_5 + NaF$$

$$(\pi\text{-}C_5H_5)_2ZrCl_2 + 2C_6F_5Li \longrightarrow (C_6F_5)_2Zr(\pi\text{-}C_5H_5)_2 + 2LiCl$$

$$(C_4H_9NC)_4Ni + 2CF_2{=}CF_2 \longrightarrow \begin{matrix} CF_2-CF_2 \\ | \qquad \diagdown \\ CF_2-CF_2 \end{matrix} Ni(CNC_4H_9)_2.$$

Reactions of π-complexes

The reactions of π-complexes are extremely extensive; it has been said that the cyclopentadienyl group forms more complexes than any other organic ligand. Whether or not this is strictly true, the range of complexes formed by this five-membered ring is certainly great. Simple cyclopentadienyl derivatives, $(\pi\text{-}C_5H_5)_2M$, of the first row transition elements, from vanadium through nickel, all have the same structure, consisting of a metal atom sandwiched between two five-membered rings. This situation gives rise to a fairly constant melting point (173° C), although the differing electronic configurations result in markedly different reactivities. Thus, in marked contrast with the highly stable ferrocene, chromocene bursts into flame spontaneously in air.

One of the main factors responsible for the many ramifications of coordination chemistry is the ability of a metal atom to bond more than one type of ligand within its coordination sphere at the same time. Moreover, certain ligands stabilize the bonding of others, and this is especially true of the $\pi\text{-}C_5H_5$ group, as illustrated by the existence of the following compounds of metals of the first transition series:

$$(\pi\text{-}C_5H_5)_2Ti(C_6F_5)_2,$$

$$(\pi\text{-}C_5H_5)V(\pi\text{-}C_7H_7),$$

$$(\pi\text{-}C_5H_5)Cr(NO)_2Cl,$$

$$(\pi\text{-}C_5H_5)Mn(\pi\text{-}C_6H_6),$$

$$(\pi\text{-}C_5H_5)Fe(\pi\text{-}C_4H_4N),$$

$$(\pi\text{-}C_5H_5)Co(\pi\text{-}C_5H_6),$$

$$(\pi\text{-}C_5H_5)Ni(CO)CF{=}CFCF{=}CF_2.$$

The cyclopentadienylmetal carbonyls undergo a number of chemical reactions and show several resemblances to the metal carbonyls. For example, the $(\pi\text{-}C_5H_5)M$ group is isoelectronic with (*i.e.*, has the same number of electrons as) the $M'(CO)_3$ group, where M′ is the element preceding M in the periodic table. Many complexes containing the $Fe(CO)_3$ group thus have counterparts containing the $(\pi\text{-}C_5H_5)Co$ group; similarly, the chemistry of $[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$ bears many resemblances to that of $[Mn(CO)_5]_2$, and that of $(\pi\text{-}C_5H_5)Mn(CO)_3$ to

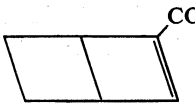
$Cr(CO)_6$. The cyclopentadienylmetal carbonyls also resemble the metal carbonyls in that in both cases there are numerous polynuclear complexes containing metal–metal bonds; *e.g.*, $[(\pi\text{-}C_5H_5)Ni]_3(CO)_2$, $[(\pi\text{-}C_5H_5)RhCO]_3$, or $[(\pi\text{-}C_5H_5)FeCO]_4$.

Aromatic reactions of π-complexes

A striking feature of the chemistry of certain cyclopentadienyl complexes is the ability of the five-membered ring to undergo reactions typical of aromatic systems. Such chemisty was first demonstrated for ferrocene, which can be acylated (substituted with an acyl group) under Friedel-Crafts conditions—that is, with aluminum chloride as catalyst. Furthermore, one of the hydrogen atoms can be replaced by a lithium atom or a mercuriacetate group, using butyllithium or mercuric acetate, respectively. Introduction of these and other functional groups has allowed the synthesis of hundreds of ring-substituted ferrocene compounds. Many other cyclopentadienylmetal compounds, on the other hand, do not undergo substitution reactions for either of several reasons: (1) the metal atom interferes with the reaction—*e.g.*, becomes oxidized; or (2) the complex does not survive the reaction conditions. Aromatic behaviour also has been shown by $(\pi\text{-}C_5H_5)_2M$, M = Ru, Os; $(\pi\text{-}C_5H_5)Mn(CO)_3$, termed "cymantrene"; $(\pi\text{-}C_5H_5)Cr(CO)_2NO$; $(\pi\text{-}C_5H_5)_2ReH$; and certain other compounds.

In tricarbonyl(cyclobutadiene)iron, the metal–ligand bonding is sufficiently strong to allow the cyclobutadiene group to show aromaticity. For example, CH_3CO and HgCl groups may be substituted for H atoms of the ring to give useful intermediates for further syntheses. On the other hand, $(\pi\text{-}C_4H_4)Fe(CO)_3$ can be oxidized, releasing cyclobutadiene, which may be characterized by the reactions it undergoes immediately.

$$(\pi\text{-}C_4H_4)Fe(CO)_3 \xrightarrow[HC{\equiv}CCO_2CH_3]{Ce(IV)}$$



When this reaction is carried out with $C_6H_5C{\equiv}CH$, the organic compound produced is in the unusual situation of having a classical benzene ring bonded to its valence isomer, Dewar benzene (named for the Scottish chemist who proposed this structure for ordinary benzene), the structure shown in the above formula.

Analytical chemistry. Analytical methods for the organic derivatives of the transition metals are generally similar to those for the organic derivatives of the main-group metals. Spectroscopic techniques are an important source of information, and with metal carbonyl derivatives, infrared spectroscopy is extremely valuable in determining the number of carbonyl groups and their arrangement around the metal. Proton magnetic resonance spectra are of help in interpreting the nature of the bonded hydrocarbon groups, although the number of fluxional systems discovered means that care must be exercised in the interpretation of apparently simple spectra. Other spectroscopic methods—*e.g.*, Mössbauer, and electron-spin resonance techniques—have been used where appropriate.

The increasing complexity of the complexes discovered makes X-ray crystallographic methods the final arbiter of structures; about 150 new structures are determined by this method each year. This analytical technique has been greatly facilitated by computer processing of data.

Industrial applications. Relatively few organometallic compounds of the transition metals find direct practical application. On the other hand, their value as reaction intermediates is almost inestimable.

Use in the petroleum industry

As already indicated, organometallics are widely employed in the petroleum-based industries. Certain industrial-scale syntheses depend upon the transient existence of catalysts in the form of metallo-organic complexes, which are constantly regenerated. Hydroformylation, or the conversion of olefins into aldehydes or ketones using carbon monoxide and hydrogen under pressure (100–300° C; 100 atm), is catalyzed by cobalt carbonyl and related complexes, including those of rhodium. The catalytic material in the system is thought to be a hydridocarbonyl—such as $HCo(CO)_3$—derived from $Co_2(CO)_8$, and the various reaction steps include insertion reactions (olefin inserted into metal–hydrogen bonds and CO into metal–alkyl bonds) as well as oxidative-addition and reductive-elimination reactions. The overall process clearly depends upon organometallic intermediates and their cleavage reactions.

$$Co_2(CO)_8 + H_2 \rightleftharpoons 2HCo(CO)_3 + 2CO$$

$$HCo(CO)_3 \xrightarrow[\pi\text{-complex formation}]{RCH{=}CH_2} (\pi\text{-}RCH{=}CH_2)Co(CO)_3H$$

$$(\pi\text{-}RCH{=}CH_2)Co(CO)_3H \xrightarrow{\text{insertion}} RCH_2CH_2Co(CO)_3$$

$$RCH_2CH_2Co(CO)_3 \xrightarrow[\text{insertion}]{CO} RCH_2CH_2COCo(CO)_3 \xrightarrow[\text{oxidative addition}]{H_2} RCH_2CH_2COCo(CO)_3H_2$$

$$RCH_2CH_2COCo(CO)_3H_2 \xrightarrow{\text{reductive elimination}} \underset{\text{product}}{RCH_2CH_2CHO} + \underset{\text{catalyst}}{HCo(CO)_3}$$

The mechanisms of such reactions are related to the mechanisms of catalytic hydrogenation of olefins or acetylenes by certain metal complexes. In both cases, the catalyst carries out three basic reactions: (1) activation of molecular hydrogen by breaking of the H–H bond and generation of two M–H bonds; (2) activation of the olefin by formation of a π-complex; and (3) transfer of hydrogen to the olefin (by insertion to form a σ-metal–alkyl group, followed by cleavage of this group by hydrogen). It is apparent that conversion of a π-complex into a σ-complex represents a key step in the overall process.

Use in hydrolysis reactions

Another useful synthesis depends in part for its success on the fact that coordinated olefins become susceptible to a hydrolysis reaction that leads to oxidation. In this way ethylene is converted to acetaldehyde; propylene, to acetone; and ethylene and acetic acid to vinyl acetate (which serves as a monomer for polymerization). In one variation of this basic reaction, ethylene and oxygen are passed together through an aqueous solution of palladium and cupric salts. The overall reaction ($C_2H_4 + \frac{1}{2}O_2 \rightarrow CH_3CHO$) results from a combination of three steps:

$$(1)\quad C_2H_4 + PdCl_2 + H_2O \longrightarrow CH_3CHO + Pd + 2HCl$$

$$(2)\quad Pd + 2CuCl_2 \longrightarrow PdCl_2 + 2CuCl$$

$$(3)\quad 2CuCl + 2HCl + \tfrac{1}{2}O_2 \longrightarrow 2CuCl_2 + H_2O.$$

Reaction (1), the reaction that forms the product, is itself composed of several steps, including formation of the π-complex anion $[(\pi\text{-}C_2H_4)PdCl_3]^-$ (related to the anion of Zeise's salt) and its rearrangement after hydrolysis to a σ-complex $[CH_2OHCH_2PdCl_3]^{2-}$.

Other industrial reactions catalyzed by transition-metal complexes include the isomerization, dimerization, and polymerization of olefins, the trimerization of acetylenes, the tetramerization of acetylene (to cyclooctatetraene), and the dismutation (conversion to products with both larger and smaller carbon skeletons) of olefins (*e.g.*, the conversion of propene into ethylene and 2-butene). In each of these reactions the making and breaking of carbon–metal bonds are essential steps.

BIBLIOGRAPHY. E.G. ROCHOW, *Organometallic Chemistry* (1964), a highly readable, general introduction to the subject; G.E. COATES, M.L.H. GREEN, and K. WADE, *Organometallic Compounds*, 3rd ed., 2 vol. (1967–68), the most useful general introduction to the subject, with many illustrative examples. These two works treat both main group and transition-metal organometallics. More detailed books on these separate topics are: J.J. EISCH, *The Chemistry of Organometallic Compounds: The Main Group Elements* (1967); and R.B. KING, *Transition-Metal Organometallic Chemistry* (1969). A series of reviews of particular topics may be found in the serial publication *Advances in Organometallic Chemistry*, ed. by F.G.A. STONE and R. WEST (1964–). Volumes appear at approximately yearly intervals.

Organs and Organ Systems, Animal

The bodies of multicellular animals are generally organized on the basis of tissues, organs, and organ systems. Constituting a tissue are many cells, usually similar in both structure and function and bound together by intercellular material. An organ is composed of various tissues, not necessarily similar, grouped together into a structural and functional unit. The bodies of some of the simple multicellular animals generally have few clearly distinct organs. Most larger, more advanced animals, however, characteristically have numerous distinct organs, which, in turn, may be organized into groups of organs that cooperate as a functional complex. Such a complex is called an organ system. Ten highly specialized organ systems make up the bodies of advanced animals; lower forms usually are not as complex in structure.

SPECIALIZED ORGAN SYSTEMS

Integumentary system. The integument, or outer covering of the body, is often called the skin in higher forms. The integument and its derivatives make up the integumentary system, which functions as a protective covering that resists harmful substances and organisms and prevents excessive water loss. All animals have an outer covering, the nature of which varies considerably. In protozoans, the simplest animals, it consists of a fine membrane or a firm, elastic film. In certain more advanced invertebrates, inhabiting an aquatic or moist environment, the integument consists of a single layer of cells; in others, the outer cells secrete a noncellular, waxy substance called a cuticle, which has various degrees of resistance. The cuticle may be hard enough to form a shell, as in the case of snails, or a protective exoskeleton, as in the case of insects. The periodic shedding of this outer layer is known as molting, or ecdysis. In vertebrates, the integument consists of an outer layer, the epidermis, and an underlying layer, the dermis. These layers vary in structure in different parts of the body and give rise to numerous integumentary derivatives (see INTEGUMENTARY SYSTEMS).

Types of integuments

Skeletal system. The framework of the vertebrate body is the skeleton. Vertebrates have a jointed internal skeleton (endoskeleton), composed of cartilage, bone, or both, that supports the rest of the body, serves as an attachment for muscles, and protects delicate vital organs. In a few forms, such as turtles and armadillos, skeletal elements may also be present in the dermis of the skin, making up the dermal skeleton. Among certain lower animals (*e.g.*, many protozoans, coelenterates, flatworms, and slugs), no skeletal system exists. As stated above, the cuticle derived from the integument may, in some animals, form an exoskeleton that provides support and protection and serves for muscle attachment. It may be composed of calcareous (containing calcium carbonate), siliceous (containing silica), or organic substances, and it is either rigid, as in corals and mollusks, or jointed, as in certain echinoderms and arthropods. Deposits of lime salts provide increased protection. Exoskeletons of arthropods must be shed periodically in order to permit growth (see SKELETAL SYSTEMS).

Muscular system. In all but the simplest organisms, specialized muscle cells perform the function of converting chemical energy into mechanical energy. The actual contractile machinery of muscle resides in long, threadlike filaments of molecular dimensions called myofilaments. The combination of muscle cells into large, organized groups—*i.e.*, tissues—that act together is called a muscle. Individual muscles may work together to form part of a muscle system. Two types of muscle tissue are found in animals: striated, or striped, muscle and smooth muscle. Nerves control the action of muscles.

Striated muscle fibres are found in a great variety of both vertebrates and invertebrates. Some coelenterates and rotifers and all arthropods have striated muscle, which is rare in worms and mollusks. All muscles of arthropods, in fact, are striated and thus function as both visceral and skeletal muscles. Striated muscle is found in the heart and in the entire skeletal, or voluntary, muscular system of vertebrates. Striated muscle is capable of rapid motions (*e.g.*, the flight muscles of an insect can contract and relax more than 100 times per second) or slow motion (*e.g.*, the heart muscle of some large mammals may contract only one or two times a second); most striated muscles function between the two extremes.

Smooth muscles vary widely in structure among animals; some have spiral or ribbon-shaped units (myofibrils); others have no recognizable structural units. Smooth muscle is found in all animal phyla. In most worms, the body and visceral movements are dependent on smooth muscle. Smooth muscle is found in the feet of many mollusks and is used when the animal crawls on a surface. Smooth muscle forms the greater part of the visceral musculature of vertebrates and forms coats around the alimentary canal and certain associated structures, such as bile ducts, as well as arteries and veins. In general, smooth muscle fibres act more slowly than do striated ones (see MUSCLE SYSTEMS).

Nervous system. Nervous tissue possesses the properties of irritability (the ability to respond to stimuli) and conductivity (the ability to conduct a signal). In Protozoa with minute hairlike structures called cilia, a specialized region (motorium) serves to coordinate and relay impulses from small filaments (fibrils) connecting the bases of the cilia. Many Protozoa also possess organelles; that is, cell parts analogous to organs specialized for stimulus reception, such as eyespots or sensory bristles. Sponges lack definite nerve cells, but all animal groups above the level of sponges have some form of nervous system. Coelenterates have a diffuse nerve net within the cell layer known as the epithelium but no central ganglion, or nerve cluster. Flatworms have two anterior ganglia with nerves to the head region and two separate nerve cords joined by cross connectives. Mollusks, annelid worms, and arthropods have paired anterior ganglia above and below the esophagus, joined by connecting nervous tissue. The echinoderms possess a radially arranged nervous system. The vertebrate nervous system is divided into two main parts: (1) the central nervous system, composed of brain and spinal cord, and (2) the peripheral nervous system, made up of cranial nerves and spinal nerves. Part of the peripheral system, consisting of portions of cranial nerves and spinal nerves, as well as outlying ganglia, controls involuntary functions, such as muscular contraction of the intestinal wall, and is called the autonomic system (see NERVES AND NERVOUS SYSTEMS).

Components of the vertebrate nervous system

Endocrine system. The endocrine system consists of a number of ductless glands that secrete chemical substances called hormones. These substances are carried by the circulating fluid to all parts of the body and exert highly specific effects on various tissues. In invertebrates, there is evidence of hormones in nematodes, mollusks, annelids, and arthropods. In crustaceans, a substance produced in the sinus gland influences the chromatophores —specialized pigment cells—so that the animal's body colour more closely resembles that of his environment. Endocrine glands in vertebrates include the pituitary, thyroid, parathyroid, adrenals, gonads, islets of Langerhans in the pancreas, and parts of the gastric and intestinal mucosa. In some mammals, the placenta, a structure through which the unborn animal is nourished, functions as an endocrine gland (see ENDOCRINE SYSTEMS; HORMONE).

Digestive system. The function of the digestive system is to procure and process, or metabolize, nutrients. The nutritional requirements and the basic processes of digestion are essentially similar in all animals; however, the body plan of animals varies so greatly that the structures involved are often different. *Amoeba*, a protozoan, lacks a permanent structure for digesting or ingesting food. Pseudopodia, temporary extensions of the body mass, are used to surround the food, which then becomes a bubble-like food vacuole in the body. *Paramecium*, however, another protozoan, has a permanent structure, the ciliated oral groove, into which food passes before forming a food vacuole. Sponges capture food by means of collar cells equipped with flagella, long whiplike structures.

Coelenterates have a central saclike digestive pocket, the gastrovascular cavity, which has only one opening and functions as both mouth and anus. In flatworms, the mouth opens into a muscular pharynx that leads to an extensively branched gastrovascular cavity. Animals above the level of coelenterates and flatworms have a complete digestive system—*i.e.*, one with two openings, a mouth and an anus. Food is passed in one direction through a tubular system that may have distinct sections, each specialized for a different function (see DIGESTION AND DIGESTIVE SYSTEMS).

Respiratory system. If nutrient materials are to be completely metabolized to carbon dioxide and water, oxygen is essential. One of the basic tasks of the organism, then, is the procurement of oxygen and the elimination of carbon dioxide. Gas exchange between a living cell and its environment always takes place by diffusion across a moist membrane. In protozoans, sponges, coelenterates, and flatworms, most of which are aquatic, each cell is in direct contact with the surrounding medium or is only a few cells removed from it. These animals, therefore, have not evolved special respiratory devices.

Mechanisms for gas exchange

With few exceptions, the respiratory systems of higher multicellular aquatic animals involve evaginated (outpocketed) exchange surfaces, usually known as gills. Gills are found in such diverse groups as annelids, mollusks, arthropods, and vertebrates. Most terrestrial animals have evolved invaginated (infolded) respiratory systems. These systems are of two principal types: lungs, found in land snails and the higher vertebrates; and tracheae, found in most terrestrial arthropods (see RESPIRATION AND RESPIRATORY SYSTEMS).

Circulatory system. Since every cell of an animal must obtain nutrients and oxygen and rid itself of carbon dioxide and nitrogen-containing wastes, some mechanism is needed for transporting these substances. In protozoans, such transport occurs by the flow, or streaming, of cytoplasm within the cell. In multicellular types such as sponges, coelenterates, flatworms, and roundworms, these substances are transported by simple diffusion between the external environment and internal organs. In higher metazoans (many-celled animals except sponges), most of the body cells are far removed from the external environment; a circulatory system for internal transport, therefore, has developed. Mollusks and annelids have an open circulatory system with dorsal (back-side) three-chambered hearts; the arthropods have a closed system with dorsal and ventral (belly-side) vessels and cross-connective vessels. In vertebrates, the highly specialized system is composed of integrated vascular networks for the separate transport of blood and lymph, which are carried directly to tissues (see CIRCULATION AND CIRCULATORY SYSTEMS).

Excretory system. Excretion is the process by which waste products of metabolism are removed from an organism. Excretory mechanisms also help to regulate water and salt balance. Special excretory structures are absent in many unicellular and simple multicellular animals, such as sponges and coelenterates. Some protozoans, however, have a special excretory organelle, or organ-like structure, the contractile vacuole. Flatworms possess a primitive, so-called flame-cell excretory system. This consists of two or more long, branching tubules, one end of which opens on the body surface through numerous excretory pores, the other ends of which are ciliated hollow bulbs—the flame cells. The arthropods possess Malpighian tubules, tiny pockets in the walls of the digestive tract. They collect wastes from the body fluids and pass them into the lower end of the gastrovascular cavity (hindgut) for excretion. In the earthworm, an annelid, each body segment has a pair of excretory organs called nephridia that consist of an open ciliated funnel, a coiled tubule, an enlarged bladder, and a pore (nephridiopore) leading to the outside. The excretory organs of vertebrates consist of paired kidneys, each with a separate duct (see EXCRETION AND EXCRETORY SYSTEMS).

Specialized excretory structures

Reproductive system. Reproduction is essential if a species is to survive. Asexual and sexual reproduction occur among animals. Asexual, or agamic, reproduction does not involve transfer of sex cells between individuals and occurs in members of the lower animal phyla. Some protozoans reproduce by dividing into "twin" cells, after which each develops into the original form. Budding, which occurs in coelenterates, is a process by which a new individual arises from an outgrowth, or bud, of an older animal. Some flatworms reproduce by fragmentation of their own bodies; each fragment then develops into a complete animal.

Sexual reproduction is the method of propagation common to all but the lower animal phyla. Gametes—*i.e.*, egg cells, or ova, and sperm cells, or spermatozoa—are formed in the reproductive organs, or gonads—ovaries in the female, testes in the male. If both male and female systems are in one individual, as in flatworms and earthworms, the animal is termed monoecious. In nematodes, arthropods, various other invertebrates, and practically all vertebrates, each individual is either male or female; the sexes thus are separate, and such animals are termed dioecious (see REPRODUCTIVE SYSTEMS, ANIMAL).

INTERRELATIONSHIPS BETWEEN ORGAN SYSTEMS

Functional interdependence. An understanding of the complexity of life functions and of the intricacy with which these functions are interwoven has gradually emerged from investigations of the various aspects of the biology of organisms. This complexity is not restricted to multicellular organisms, with their many cooperating cells, tissues, organs, and organ systems; it also characterizes unicellular organisms, which are known to be far from simple. Each cell of a living organism requires an environment that is dependent upon the interrelationships of cellular structure, metabolism, nutrient procurement, gas exchange, internal transport, regulation of levels of salts and other substances, and excretion. Homeostasis, or the state of equilibrium between the internal and external environments, is brought about by the functional interdependence of organelles, in unicellular animals, and of organ systems, in multicellular animals. This is demonstrated by the inability of one organ system to function without the assistance of another.

That living organisms function in an orderly fashion despite their immense complexity shows clearly that control mechanisms are at work. Coordination of the regulatory functions and all the myriad other functions of an organism depends upon two principal types of control mechanisms: chemical control mechanisms, which are found in all organisms, and nervous control mechanisms, which, in the strict sense, are found only in multicellular animals.

Coordination of regulatory functions

Since the multicellular organism is characterized by a division of labour among its parts, it is not unexpected that evolution has led to specialization of certain cells or tissues as producers of chemical controls, usually hormones. These substances often have important control functions in parts of the body far removed from the sites of synthesis and are transported in higher animals from sites of production to sites of action through the blood circulatory system. Chemical controls are produced by specialized tissues or organs, exert highly specific effects on other tissues of the body, and are effective in very low concentrations. Hormonal control, however, is a relatively slow process, there being an appreciable delay between the release of the hormone and its arrival at the target organ. Slow chemical control is compatible with normal activity when instantaneous response is not needed, as in control of digestion, salt and water balance, metabolism, and growth. When rapid response is required, however, nervous control is essential. A nerve impulse can travel several hundred feet per second, thus reducing the interval between stimulus and response to milliseconds.

In vertebrates, the autonomic nervous system plays a large role in the maintenance of homeostasis and provides a fine control of the visceral, or internal, functions of the body. The autonomic system is generally involuntary and acts on the internal effectors such as smooth muscle, cardiac muscle, exocrine glands (glands with ducts), and endocrine glands (glands without ducts). The

autonomic nervous system is the structural pathway linking the control centres in the brain with the internal organs. Physiological control of visceral functions includes sensors and nerve pathways as well as central control.

Specialized nerve cells, found in both external and internal receptor organs, are the organism's principal means of obtaining information. External sense organs are those stimulated by environmental changes. They include organs for the senses of sight, hearing, smell, taste, touch, pressure, temperature, and pain. Internal sense organs, affected by stimuli arising within the body, include proprioceptors (sensors of body movement and position), deep pain receptors, interoceptors—for such internal sensations as hunger, thirst, and nausea—and sensors of salt balance and carbon dioxide level in the blood plasma. Receptor organs are capable of responding to stimuli by initiating impulses that are transmitted by nerve fibres to the central nervous system for interpretation as sensations. The central nervous system may then send appropriate signals to muscles, glands, or other effector systems for response to the stimuli.

Feedback mechanisms. Since homeostatic mechanisms act to minimize the difference between the actual and optimal response of a system, they may be considered as biological examples of negative feedback control. In systems of this type, the level of the controlled variable is sensed, and action is taken to oppose change from the desired level. If the response increases, a negative, or inhibitory, signal is fed back to an effector mechanism so that the subsequent response is reduced. On the other hand, a decrease in response elicits a subsequent increase.

The interaction between the anterior pituitary gland and the thyroid gland is an example of negative feedback control. Thyrotropic hormone, released by the pituitary when the concentration of thyroxine in the blood is low, stimulates increased production of the thyroxine by the thyroid. When the rising concentration of thyroxine in the blood reaches a certain level, the secretion of more thyrotropic hormone by the pituitary is inhibited. There is thus a feedback of information from the thyroid to the pituitary. The pituitary exerts control over the thyroid, and the thyroid in turn exerts some control over the pituitary. A similar relationship exists between the pituitary and the other endocrine glands.

The nervous control of the rate of the heartbeat provides a good example of autonomic nervous system feedback control. When the heart is engorged with blood, stretch receptors in the wall of the upper right portion (right atrium) send impulses to the accelerating centre in the brain. The impulses from the stretch receptors stimulate the accelerating centre to send, via the autonomic nervous system, excitatory impulses to the S-A (sino-atrial) node, or "pacemaker," thereby causing the heart to beat faster. As the blood pressure rises, however, pressure receptors in the wall of the aorta (the blood vessel that conveys blood to the body) begin sending impulses to the inhibiting centre in the brain, stimulating it to send inhibitory impulses, via the autonomic nervous system, to the S-A node, with the effect of slowing the heart.

DEVELOPMENT OF ORGAN SYSTEMS

Germ-layer concept

The embryonic origins of individual systems. During embryonic development the cells making up the so-called germ layers—ectoderm, endoderm, and mesoderm—are said to be undifferentiated; *i.e.*, they do not possess distinctive or individual characteristics. Further development of an embryo entails, among other things, a differentiation or specialization of various groups of cells to form the several types of tissues and organs that make up an organism. Growth of the embryo and differentiation of organs from germ layers begin even before the germ layers are completely formed. The entire process of development is gradual, and, although the various phases occur in a step-by-step order, they are not in themselves distinct but are merged imperceptibly with each other. In all vertebrates the different germ layers and structures arising from them are considered to be homologous, or similar in origin. The germ-layer concept is of importance chiefly because it furnishes a convenient method of classifying organs according to their embryonic derivation.

The ectoderm gives rise to three main structural groups and their derivatives: (1) the epidermis of the skin and its derivatives, including the skin glands, hair, feathers, nails, claws, hoofs, horns, epidermal scales, and the coverings of external gills; (2) the lining of the mouth and related structures, including enamel of teeth, glands of the mouth, covering of the tongue and lips, and anterior and intermediate lobes of the pituitary gland; (3) the nervous system, consisting of the brain and spinal cord, cranial and spinal nerves, autonomic portion of the peripheral nervous system, sensory parts of all sense organs, inner region (medulla) of the adrenal gland, infundibulum (structure connecting the pituitary gland to the brain), and the posterior lobe of the pituitary gland.

The endoderm develops into the epithelial lining of the following: (1) the alimentary canal, which includes pharynx, esophagus, stomach, intestine, liver, pancreas, and most of the cloaca (a cavity at the posterior end of the body); (2) the pharyngeal derivatives, consisting of the larynx, trachea, lungs, gills of the internal type, middle ear, eustachian tube, tonsils, thyroid, parathyroids, and thymus; (3) miscellaneous structures, including the urinary bladder, its canal to the outside of the body (urethra), and two embryonic structures—allantois and yolk sac.

The mesoderm differentiates into (1) the muscles, including smooth, skeletal, and cardiac; (2) the skeleton, composed of cartilage, bone, and other connective tissue; (3) the excretory organs, including the kidneys and their ducts; (4) the reproductive organs; (5) the circulatory system, composed of the heart, blood vessels, blood, spleen, lymphatics, and blood-forming tissues; and (6) miscellaneous tissues, including dentine of teeth, dermis of skin, outer region (cortex) of the adrenal glands, lining of body cavities, mesenteries (tissues supporting the viscera), and portions of the eye.

Appearance of organ systems during development. Organ systems of the vertebrate body make their appearances at precise stages of embryonic development. The human ovum is normally fertilized in the upper fallopian tube, which leads from the ovary to the uterus. At the end of the first week, it becomes implanted in the uterine wall.

Summary of embryonic development

After two weeks the embryo consists of a flat disk, in the centre of which are the primitive streak, which later becomes the mesoderm, and the first rudiments of the nervous system, the neural plate, and the neural groove. A head process and rudiments of the heart may be present. No endodermal derivatives are yet present.

By the end of the third week the neural groove is complete and closes to form the neural tube; the optic vesicles (rudimentary eyes), auditory placodes (rudimentary ears), and ganglia are present; and the oral membrane may rupture to form the mouth. In addition, the separation of the body from the yolk sac produces the foregut and hindgut, antecedents of the pharynx and lower parts of the digestive tract. The visceral pouches and visceral arches—which both develop into parts of the jaw and throat—and the lung and liver pouches appear. Blood vessels containing blood cells develop and connect with an S-shaped heart, in which pulsations begin. The pronephros, an early stage of the kidney, and its ducts grow posteriorly, or downward.

After four weeks the body has a C shape. The neural tube has entirely closed, the three primary brain sections have formed, and the spinal and cranial nerves are developing. In the endoderm, paired lung buds grow posteriorly; the stomach, liver, pancreas, and intestines are defined. Paired limb buds and primitive vertebral organization are apparent. Abundant blood is forming and circulating, and the heart is tubular. The pronephros degenerates and is replaced by subsequent stages of the embryonic kidney, the mesonephros and the metanephros.

At the end of the fifth week the embryo has a temporary tail. The face is assuming a characteristic appearance with jaws, and the brain has five sections. The trunk and

appendage muscles develop, and bone-forming centres arise. The circulatory system is extensively developed, and the heart begins its final divisions.

After six weeks of development, the heart is the four-chambered organ of the adult; undifferentiated gonad primordia are prominent. By the seventh week, the eye and pituitary gland are well developed, as are the lungs and the components of the digestive system. The body muscles are becoming organized; cartilage formation is extensive; and the jaws, vertebrae, and ribs are becoming bony.

After eight weeks, the embryo, now termed a fetus, has a recognizable form. Muscles of the body are differentiated and innervated to allow movement. The blood-vascular system is complete; the mesonephros degenerates as the metanephros grows; and sex differentiation begins. During the ninth week nails and hair follicles form, and the metanephric kidney becomes functional. By the tenth week, the brain is essentially developed, the lungs are almost complete, and the smooth muscle of the entire gut is organized.

By the 14th week, the head, until now large with respect to the body, and the body approach normal proportions. Most of the bones are present in some degree, allowing spontaneous movements. After 18 weeks, the body proportions approach those of the newborn. The cerebral hemispheres of the brain become convoluted and creased; the retina of the eye becomes sensitive to light, and the sex organs have developed.

EVOLUTION OF ORGAN SYSTEMS

Organelles. Unicellular animals are found only among the Protozoa; all other animals are multicellular. The individual protozoan, however, should not be regarded as equivalent to a single cell of a more complex animal but as a complete organism with the same properties and characteristics of a multicellular animal. Protozoans lack tissues and organs, since such parts are defined as aggregations of differentiated cells, but they do have functionally equivalent subcellular structures called organelles, which are analogous to multicellular organs. Some protozoans digest food in food vacuoles. No special organelles exist for gas exchange, the general cell membrane serving as the gas exchange surface. Many freshwater protozoans possess contractile vacuoles, which function primarily in the regulation of osmotic pressure, thus controlling the internal concentration of salts and water; nitrogen-containing wastes may also be expelled through these vacuoles. Locomotion is performed by formation of pseudopodia or with beating cilia or flagella. Although an individual protozoan has many cilia, cilial action is coordinated by a system of fibrils connecting so-called basal bodies of the cilia.

Multicellularity. Members of the animal kingdom possessing a multicellular plan of structure constitute the subkingdom Metazoa. The body structure of a typical metazoan involves more than just a multicellular condition, however; the specialization of cells for different functions produces an interdependency of cells. Cell specialization has in turn led to the development of tissues consisting of similar cells organized in sheets and layers. In lower metazoans, development of tissues is relatively primitive; in higher groups tissues have become organized to form organs.

Nature of ancestral forms

Zoologists agree that metazoans evolved from unicellular organisms. There are three theories concerning the nature of the ancestral form and the mode of origin. The first is the syncytial theory, which holds that multicellular animals arose from a primitive group of unicellular, ciliated animals having more than one nucleus. The ancestral metazoan, at first syncytial (*i.e.*, with more than one nucleus within a single mass of cytoplasm) in structure, later became compartmented or cellularized by the development of cell membranes, thus producing a typical multicellular condition. Because many ciliates tend toward bilateral symmetry—that is, similar left and right sides comprise the body—proponents of the syncytial theory maintain that the ancestral metazoan was bilaterally symmetrical and gave rise to the acoel flatworms (lacking a digestive cavity with definite walls). The fact that these flatworms, thought to be the most primitive living metazoans, are about the same size as the ciliates, have bilateral symmetry and cilia, and tend towards a syncytial condition is regarded as evidence in support of the syncytial theory. That it requires acoels to be the most primitive living metazoans is regarded as an objection to the theory; a ciliate ancestry, moreover, does not explain the general occurrence of flagellated sperm in metazoans. Opponents of the syncytial theory further point out that the developmental patterns among the lower metazoans are not comparable.

Colonial theory

The second theory of the origin of metazoans is the colonial theory, which states that the origin of multicellular animals is from a spherical, hollow, colonial, flagellated organism. Proponents of the colonial theory regard the following as evidence: (1) flagellated body cells commonly occur among lower metazoans; (2) sperm and eggs as clearly definable entities have evolved in the phytoflagellates, organisms with flagella and the ability to photosynthesize; (3) in some forms of flagellates that live in colonies, a differentiation between reproductive cells and somatic (nonreproductive) cells has occurred. The colonial theory holds that through the migration of cells into the interior of the colony, the originally hollow sphere became a solid, ovoid mass, with similar parts arranged radially around a central axis (radially symmetrical) and with the exterior cells flagellated. Since this hypothetical organism is very similar to an immature coelenterate form called a planuloid larva, it is called the planuloid ancestor of the lower metazoans. The bilateral symmetry of the flatworms would then represent a later modification in symmetry. The principal weakness of the colonial theory is that the extant colonial phytoflagellates are plantlike and possess cellulose walls with chlorophyll. An alternative explanation is that metazoans arose from some group of extinct flagellates that did not have these typical plant features.

The third theory of the origin of metazoans, the theory of polyphyletic origin, proposes that the sponges and coelenterates evolved from colonial flagellates, ctenophores, and flatworms by way of the ciliates.

The colonial theory, despite certain weaknesses, appears to be the most compatible with evidence relating to the subsequent evolution of metazoans. The problem of the planuloid ancestor shifting from a radial to a bilateral symmetry is not difficult if it is assumed that the ancestral planuloid stock lived on the ocean bottom and, as a result, developed a creeping mode of movement over rocks. This type of movement would lead to a differentiation between dorsal and ventral (top and bottom) surfaces; bilateral symmetry would result. The free-living flatworms demonstrate the transition from a bilateral planuloid ancestor to a more complex form.

A hypothetical ancestral flatworm may be described from the various primitive features of living flatworms. A marine animal, it was dorsal-ventrally flattened, with a single layer of ciliated epidermal cells, the bases of which contained contractile extensions that formed a muscle layer. An otocyst, or hearing organ, and a light-sensitive pigment spot may have been present. The otocyst, near the front end, may have been covered by a delicate network of nerve cells. Possibly a midventral mouth opened into a syncytial network of nutritive cells and a meshwork of reproductive cells.

In subsequent evolution of the flatworms, a number of fundamental changes appear that foreshadow the structure exhibited by most higher bilateral animals: (1) the separation of the contractile function from the epidermis to form a distinct muscle layer; (2) the reorganization of a nerve net contiguous with the body surface into a series of deeper, radially arranged, longitudinal nerve cords; (3) the concentration of nervous tissue around the statocyst (an organ of equilibrium) to form a brain; (4) the development of a cup-shaped eye with pigment cells from flattened pigment spots; (5) the formation of a rudimentary digestive system with inturning of the epidermis around the mouth to form a short pharynx; (6) the formation from mesenchyme of a rudimentary reproductive

system with structures for conducting, transmitting, and receiving sperm.

Organs and Organ Systems, Plant

Plant organs include such structures as individual leaves, stems, roots, flowers (or parts of flowers, such as the male or female reproductive structures), fruits, and other units of vegetation depending upon the level of organization chosen to delimit them. Organ systems are groups of mutually functioning organs, such as the aerial shoot system or the entire underground complex of roots, the root system of a plant. Such structures and interrelated systems are the means by which plants exploit the environment; they are the products of successful evolutionary advances over geological time.

The organs and organ systems of plants are most essential to the well-being of man. In fact, man is utterly dependent upon plants for the essentials of his existence. The food of man comes from plants, either directly or via the flesh of animals that feed upon plants. Much of man's clothing and shelter are made from plant products. Paper is made from wood, and many drugs used to cure man's diseases are prepared from plant materials. The coal used to generate electric power is simply fossilized plants that lived millions of years ago. Plants generate oxygen, modify the climate, and aid immensely in the control of erosion and floods. Many kinds of trees, shrubs, and herbs are used as ornamentals in gardens and in landscaping. Plants have exerted enormous influence upon the social and economic life of peoples from earliest times.

IMPORTANCE TO MAN

The shoot system, or portions of it, is used in numerous ways. The leaves of cabbage, lettuce, and watercress are eaten in green salads; those of spinach, kale, collards, and turnips are consumed as a cooked vegetable. Spices such as basil, bay, sage, savory, tarragon, and thyme are leaves, as are spearmint and peppermint used in flavouring drinks, chewing gum, and candies. Sisal fibre used in making twine and rope comes from leaves. Tea, the favourite beverage of millions of people, and tobacco, a popular stimulant, are prepared from leaves. The pain-killer cocaine is made from coca leaves. Celery and rhubarb are leaf petioles (stalks).

Uses of stems

Stems are also utilized in many ways. Gourmets relish the young, juicy, succulent shoots of asparagus; many people enjoy the large, spherical, juicy stems of kohlrabi. Both the spice cinnamon and the medicine quinine come from the bark of certain woody plants. The narcotic peyote, used by certain American Indians in religious ceremonies, comes from the fleshy stem of a small cactus. Wood from trees is used for building material, papermaking, fuel, and furniture. Phloem fibres of flax are used to weave linen cloth; those of hemp and jute are woven into ropes and bags. Both stems and wood strips are made into baskets and matting. The large, hollow stems of bamboo are extensively used in constructing furniture, fishing rods, and many other articles. A favourite vegetable of many people is Brussels sprouts, the axillary (stem) buds of a relative of cabbage.

Inflorescences (flower clusters) consisting of immature flowers and flower stalks comprise the vegetables cauliflower, artichoke, and broccoli. The spices known as cloves and capers are the unopened flower buds of certain flowering plants, and saffron, a flavouring material, is made from flower stigmas and style tips (the upper extremities of the female flower parts). Marijuana is the dried upper portion of female plants; the resinous hairs on the flowers and the flower stalks contain most of the active narcotic principle. The characteristic bitter flavour of beer is caused by the flower buds of the hop plant used during the brewing process.

Underground stems have many food uses. Potato tubers feed millions of people in many parts of the world. In Southeast Asia and Polynesia, the tubers of taro and dasheen are an important starchy food. Onion bulbs also are consumed by millions of people.

Throughout the world, the fleshy storage roots of numerous plants are eaten. Sugar beets constitute an important source of sugar, and radishes add variety to meals. The roots of beets, turnips, parsnips, and rutabagas are cooked and eaten as a starchy food by people in temperate regions. The roots of yams, cassavas, and sweet potatoes provide starch for many people, especially in tropical areas. Gourmets relish the flavours imparted to foods by ginger, turmeric, and horseradish.

Products from fruits and seeds

The reproductive system of plants, including fruits and seeds, provides numerous products of great economic importance to mankind. The entire inflorescence of broomcorn is used in making brooms. The fruits of many species throughout the world are eaten raw or cooked, including such plants as breadfruit, cucumber, eggplant, pumpkins, squash, tomato, apple, pear, watermelon, grape, cranberry, strawberry, orange, date, olive, pineapple, and many others. Spices such as allspice and pepper are fruits, as are the "seeds" (actually one-seeded fruits) of caraway, celery, dill, coriander, and fennel. Two narcotics, opium and heroin, are made from the juice of the unripe ovaries of poppy plants.

There are a multitude of ways in which seeds are utilized. Such beverages as coffee and chocolate are enjoyed by many people. Cereal grains such as rice, wheat, and corn (maize) are staples in the diet of hundreds of millions of people throughout the world. Other cereals such as oats, barley, rye, and millet are important food plants in various regions. Wild rice and buckwheat are delights fancied by many gourmets. Other dietary mainstays of millions of people are the legumes, including beans, peas, soybeans, peanuts, and lentils. Nuts such as pecan, hickory, walnut, pine, almond, and chestnut provide a variable diet for many people. Betel nuts and kola nuts are chewed and enjoyed as mild narcotics.

A fibre obtained from the seed coat of the cotton plant has been used in cloth making for centuries.

DEVELOPMENT OF PLANT ORGANS

Origin of stem, leaf, and root

Very early in its development, the body of a plant exhibits a polarized (*i.e.*, directional with definite shoot and root ends) differentiation into an axis composed of three organs: stem, leaf, and root. This differentiation occurs as the fertilized egg develops into the embryo and, in the seed plants, is evident long before the seed is mature (see DEVELOPMENT, PLANT). Although each of these organs differs significantly in structure and function, all are similar in important ways. They have a common origin in the young embryo. The tissues of each organ merge imperceptibly, an arrangement facilitating the performance of joint functions—*e.g.*, the movement of water, dissolved minerals, and food longitudinally from one part of the plant body to another (see TISSUES AND FLUIDS, PLANT). In addition, the stem and root actually constitute one continuous structure, exhibiting basically a cylindrical or rodlike form. These two organs also possess similarities in their method of growth from the meristems, the regions of cell division in shoot and root tips (see DEVELOPMENT, PLANT). During plant evolution, the stem, leaf, and root have arisen from a common structure.

The stem. *Description.* The stem is normally a cylindrical, rodlike axis that supports the food-producing leaves and connects them with the anchoring and absorbing roots. The stem also produces the cones, flowers, fruits, and other reproductive structures. In addition, the growth pattern and structure of the stem determine the habit or form of the plant.

At its apex, the stem possesses a bud, a juvenile and incompletely developed structure. The bud contains the

microscopically small apical meristem, which gives rise by cell division to new cells and tissues, thereby increasing the height of the stem. During seasons of the year unfavourable to plant growth (winter or dry seasons), the delicate meristem tissue is often protected from desiccation by small modified leaves known as bud scales. During the growing season, the apical meristem is usually protected by a covering of young leaves. Some buds give rise only to new stem and leaves, while others produce only flowers; still others develop leaves and flowers. When the bud develops into a new stem and leaves, the bud scales fall away, leaving several closely crowded bud scale scars on the stem. Embryonic leaves formed by the apical meristem develop at regions of the stem called nodes; the intervening portion of the stem between two nodes is the internode. Depending upon the species, the internodes may be long and distinct or very short and indistinct. In trees and shrubs, the division of the stem into nodes and internodes eventually becomes obscured because of growth in thickness of the stem caused by the cambium, a layer of dividing cells just under the bark. Eventually the leaves are shed from the plant, leaving leaf scars on the stem. Within each leaf scar may be seen one or more vascular-bundle scars produced at the location of the water- and food-conducting tissues (vascular bundles) that enter the leaf from the stem. Each node on the stem, therefore, may have a variety of features: there may be one or more leaves, each usually with a bud in the leaf axil, the upper angle between the leafstalk (petiole) and the stem. After the leaves have been shed, there is left on the stem a leaf scar containing vascular-bundle scars, and a dormant bud is left in the axil.

Structure and contents of buds

Tissue organization. After being produced by the apical meristem, the cells of the young stem differentiate gradually into the three main tissues: protective (epidermis, the outer "skin"), fundamental or ground (cortex, pith), and conducting or vascular (phloem and xylem). There is considerable diversity among plants in the patterns exhibited by these tissues.

Arrangement of vascular tissue

Among the lycopods (club mosses), ferns, and some aquatic angiosperms, the centre of the stem is occupied by a solid rod of xylem, specialized water-conducting tissues made of hollow cells. In most plants, however, the vascular tissue is arranged in a cylinder or as a complex of interconnected strands arranged either as a cylinder or scattered in bundles throughout nearly all of the stem. The region between the vascular tissue and the epidermis is occupied by the cortex, one of the fundamental tissues. The interior of stems in which the vascular tissue is arranged as a cylinder is filled with the pith.

Each strand of the primary (*i.e.*, derived from the apical meristem) vascular tissue is a vascular bundle. Within each vascular bundle, the xylem and phloem are arranged in characteristic patterns. In the collateral pattern, the phloem lies on only one side of the xylem, usually toward the stem exterior, whereas in bicollateral vascular bundles, the phloem is located on both sides of the xylem. In concentric bundles, one type of vascular tissue completely encloses the other, with the phloem surrounding the xylem in some species and the xylem surrounding the phloem in others. All of the vascular bundles and the associated fundamental tissues are interpreted by some plant anatomists as constituting a single unit, the stele.

According to the stele concept, the simplest and most primitive type of stele is the protostele, consisting of a solid column of vascular tissue without a pith. The protostele varies considerably, depending upon the species. Among the earliest known vascular plants and in the stems of young ferns, the protostele consists of a central core of xylem surrounded by a cylinder of phloem. In more complex protosteles, the contour of the xylem core is star shaped (as in many angiosperm roots), or the phloem and xylem may be in the form of separate strands of tissue (as in lycopods).

A type of stele that is more complex and more advanced evolutionarily is the tubular stele, or siphonostele, consisting of a cylinder of vascular tissue enclosing a central column of pith. The siphonostele, with several modifications, is present in most species of vascular plants. In some ferns the xylem cylinder is bounded on both sides by phloem. The xylem cylinder may lack leaf or branch gaps—interruptions evident in cross sections—caused by portions of the vascular cylinder leaving the stem to enter leafstalks. If leaf and branch gaps are present, they may be so large as to dissect the xylem cylinder into a netlike form; the result is a modified siphonostele called a dictyostele. In most plants, however, the phloem is located on the outer side of the xylem cylinder. Dissection of such a stele by the leaf and branch gaps results in a modification termed the eustele. The eustele is present in many seed plants. In monocotyledons, in which the stele consists of a system of scattered vascular strands, the result is the atactostele.

Leaf traces

At each node, one to several vascular bundles depart from the stem vascular system and enter the leaf; each such bundle is a leaf trace. The xylem and phloem of the leaf traces are continuous with the xylem and phloem in the stem. In the region of the vascular cylinder, immediately above the point of departure of the leaf trace out into the leaf, is a gap in the vascular tissue. Within this gap, parenchyma (cells of an undifferentiated, roughly globular form, usually with thin walls) tissue develops instead of vascular tissue, producing a region known as a leaf gap. Leaf gaps are often very conspicuous, especially in the stems of herbaceous plants from which the cortex, phloem, and pith have rotted away. The xylem tissue, more resistant to decay, remains, and the leaf gaps can be seen as holes through the xylem cylinder.

Axillary buds are also served by strands of vascular tissue departing from the vascular system of the stem. The bundles leading to the buds are called bud traces. Just as with the leaf trace, immediately above each bud trace is a region of parenchyma tissue, the bud gap. Bud traces are conspicuous parts of the stem anatomy and also appear as large holes in the vascular cylinder of rotted herbaceous stems.

All plants increase the height of their stems through the production of new cells and tissues, called primary tissues, by the apical meristem. In the young plant, only a small amount of conducting and strengthening tissue is present, the stem and roots being thin and fairly delicate. Many species, especially among the dicotyledons (broad-leaved flowering plants such as roses, woody trees and shrubs, members of the pea family, and others) and gymnosperms, possess the ability to produce additional conductive, fundamental, and protective tissues (secondary tissues) by means of lateral meristems—the vascular cambium and the cork cambium (see TISSUES AND FLUIDS, PLANT). The great bulk of a tree or shrub, therefore, consists of secondary tissues, especially of xylem, produced by the lateral meristems. The xylem formed by the vascular cambium accumulates year after year, with each year's accumulation forming a layer, the annual, or growth, ring. The phloem produced by the vascular cambium usually functions for only one or two seasons and is progressively crushed and destroyed as the new xylem presses outward. The tree does not become devoid of phloem, however, because the cambium is constantly producing new phloem cells during each growing season.

Production of annual growth rings

The vascular cambium in the stems of most gymnosperms and dicotyledons originates as a cylinder between the primary xylem and phloem. As long as the plant is alive, the vascular cambium occupies this same relative position, producing secondary xylem toward the stem centre and secondary phloem toward the stem surface. Secondary growth by the vascular cambium modifies the primary body of the plant in various ways. The secondary tissues usually cover the primary xylem and the pith, and the cells in these tissues eventually die. The primary phloem soon becomes nonfunctional and is destroyed as the stem increases in diameter. The cortex and epidermis are eventually replaced by the development of periderm (bark).

Periderm usually forms in the stems (and roots) of trees and shrubs and may be produced by the older parts of herbaceous dicotyledons. The outer portion of the periderm, the outer bark or cork, may be relatively thin, giving the trunk a smooth surface, or it may be thick, producing a cracked and fissured surface. The bark may develop as wings, projecting from the surface, as large scales or plates, or as long strips. Clearly defined, wartlike lenticels (pores) occur here and there in the cork. Each lenticel is a mass of loosely arranged cells protruding above the stem surface through a crack in the periderm. Each lenticel usually forms just beneath a stoma-guard-cell apparatus in the epidermis. A stoma, or stomate, is a tiny opening or pore in a leaf or stem surface, usually flanked by two liplike cells called guard cells. Like the stomata, lenticels are believed to function in the movement of gases into and out of the stem.

Types of stems. *Life-span categories.* The type of stem is related to the life-span of the plant. Many long-lived plants increase the rigidity of their stems (and often their roots also) by the production in the vascular cambium of hard, mechanically strong xylem tissue; such plants are called either trees or shrubs. Trees are characterized by a stem that grows to become a conspicuous trunk; shrubs usually have several stems, which arise near the ground. Many species of plants are relatively short-lived and consequently possess weak stems, with only a little woody tissue at the base or without any woody tissue at all. Such herbaceous plants are of diverse types. In shrubby herbs, the upper portions of the stems are herbaceous, and the lower parts are woody; the herbaceous portions die during the winter. Perennial herbs possess a very short woody crown stem, which may continue to produce new herbaceous stems for many years. Biennial herbs live only two years, the lower portion of the stem persisting through the winter and giving rise the next spring to an erect stem. After producing flowers and seeds the second year, the entire plant dies. Finally, annual herbs live for only a single growing season, completing their entire life cycle during this brief period.

Perennial, biennial, and annual plants

Woody stems. When the trunk of a tree is sawed in half, the bark and the wood are easily distinguished. The bark, usually much darker in colour than the wood, can be separated fairly easily from the wood, especially in the spring and early summer, because the cells of the vascular cambium have thin delicate walls that are readily broken. Microscopically, the bark can be seen to be composed of all of the tissues outside the vascular cambium, including the phloem and the periderm.

To the interior of the vascular cambium lies the wood or secondary xylem. A conspicuous feature of the wood is the concentric layers, the annual increments, or growth rings, especially in trees of temperate climates. The outer portion of the trunk may be a light-coloured zone of sapwood; the inner part may be differentiated into a generally darker region of heartwood. The sapwood is the younger tissue, and it functions in the conduction of water and dissolved minerals (*i.e.*, "sap") and in the storage of food. As the tree ages, the sapwood is gradually transformed into heartwood. During this process, many by-products of cell metabolism (*e.g.*, oils, tannins, resins, pigments, phenols) are transported away from the living cells of the phloem, cambium, and xylem in the direction of the inner sapwood, where they are stored in the cells. The formation of heartwood in trees is the result of such deposition of the plant's waste products. As the waste materials accumulate in the cells of the inner sapwood, a toxic level is finally reached, the xylem parenchyma cells die, and another cylinder or ring of heartwood is produced. In this manner, the sapwood–heartwood boundary moves outward as the diameter of the tree increases.

Herbaceous stems. The stem anatomy of herbaceous plants varies considerably. Some perennial herbs possess small amounts of secondary growth, especially in the lower portion of the stem and in the root. The stems of many biennial and annual herbs may lack secondary growth entirely because of the absence of a vascular cambium. Externally, the stems of these herbs resemble closely those of the young twigs of a woody plant, except that typical winter buds are not formed. Apical growth, nodes, internodes, and lateral branches are usually present in herbaceous stems. Internally, the vascular bundles are usually arranged in a single ring. This basic pattern of stem anatomy may be variously modified, especially in those stems functioning as food- and water-storing organs. In such stems, extensive parenchyma is often present.

Plants without secondary growth

The stems of most monocotyledons (flowering plants with parallel-veined leaves, such as grasses, orchids, and palms) lack a vascular cambium and do not have secondary growth. Palms and other treelike monocotyledons do, however, possess a means of thickening the trunk through the activity of a primary thickening meristem located beneath the embryonic leaves at the stem apex. In herbaceous monocotyledons such as the grasses, the stem-tissue arrangement features numerous vascular bundles scattered throughout the stem, as in corn (maize), or in two circles near the periphery, as in wheat. Just beneath the epidermis is (usually) a continuous cylinder of sclerenchyma (thick-walled cells) that functions in support of the stem. In some grasses, the stem centre is occupied by a pith, which may break down in the internodes during growth, leaving a hollow pith cavity. At the base of each internode in grasses is a region of cell division called the intercalary meristem, which adds new cells to the internode.

The leaf. The leaf is the principal photosynthetic (food-producing) organ of the plant. Although the leaf normally differs significantly, especially in form, from the stem, both of these organs are actually part of the same unit, the shoot. Both the stem and the leaf arise in the bud from the apical meristem. When fully developed, the tissues of the stem merge with those of the leaf. The leaf possesses basically the same tissues as the stem, with an epidermis forming the outermost layer, vascular tissues arranged in veins, and photosynthetic tissue occupying the same region as does the cortex in the stem.

Form and structure. The leaf is highly variable in its form and internal structure, and, accordingly, several kinds of leaves can be distinguished. The most familiar type is the foliage leaf, usually consisting of a thin, flat-

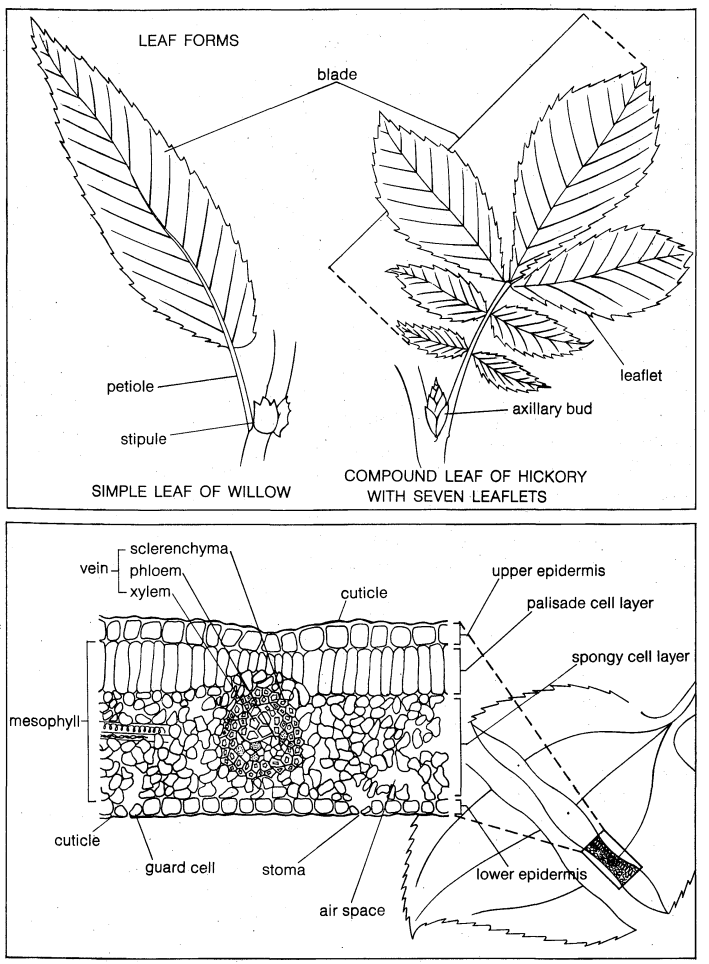

Figure 2: (Top) Leaf forms. (Bottom) Internal organization of a leaf shown in cross section.
From (top) Adams, Baker, and Allen, *The Study of Botany* (1970), Addison-Wesley, Reading, Massachusetts; (bottom) Kimball, *Biology*, 2nd ed. (1968), Addison-Wesley

tened, green blade, which, in many species, is attached to the stem by a stalk, the petiole. The base of the leaf in many monocotyledons and some dicotyledons is differentiated into a sheath, which encircles the stem. The leaf base of some species possesses leaflike outgrowths, the stipules, which function in protecting the young leaf before it unfolds. The stipules are often inconspicuous and fall away early in leaf development. If only a single leaf blade is present, the leaf is simple. The simple leaves of species such as maples may be deeply lobed. A compound leaf has two or more blades, the leaflets. The leaf margins of some species are smooth, or entire, while the margins of others may be finely or coarsely indented. Only one vascular bundle or vein may be present, as in conifers, but leaves of most ferns and angiosperms have numerous veins. In many dicotyledons, the veins form a reticulate, or netted, pattern. The leaves of many monocotyledons have veins that run essentially parallel throughout most of the blade. In both types of venation, the veins join with one another at intervals, forming a closed system. The venation of many ferns, *Ginkgo*, and a few dicotyledons consists of repeatedly forked, or dichotomous, veins.

Leaf venation

Internal structure. Internally, foliage leaves are constructed of three main tissues: epidermis, mesophyll, and vascular tissue. The epidermis, a single layer of living cells, forms a protective layer on both surfaces of the leaf. The outer walls of the epidermal cells are covered by a delicate film, the cuticle, composed of a waxy material, cutin, which enables the leaf to resist excessive evaporation of water. In many plants the waxy cuticle forms a light-gray "bloom" that can be easily wiped off, as in the leaves of red cabbage. A distinctive feature of the epidermis is the conspicuous pairs of usually bean-shaped cells with a small opening between them. Since the size of the opening can vary through changes in the shape of the pair of cells, they are known as guard cells. The pair of guard cells and the opening between them constitutes a stoma (plural: stomata). The stomata provide a connection between the external atmosphere and the system of intercellular spaces inside the leaf, thereby facilitating the exchange of gases between the atmosphere and the leaf interior. The stomata are usually much more abundant on the lower surface of the leaf than on the upper. Many woody plants typically lack stomata on the upper surface of the leaf. The floating leaves of aquatic plants, however, usually have stomata only on the upper surface.

Arrangement of cells inside leaves

Enclosed within the epidermis is the mesophyll, a tissue composed of parenchyma cells rich in chloroplasts (small structures containing chlorophyll, the photosynthetic pigment). This is the principal photosynthetic tissue of the plant. In many species, the mesophyll is differentiated into regions called the palisade parenchyma and spongy parenchyma. The palisade cells are more elongated at right angles to the epidermis and are separated from each other by spaces that facilitate the aeration of these photosynthetic cells. The spongy parenchyma occupies the lower half of the mesophyll and possesses a conspicuous system of air spaces that connect with the stomata, thus facilitating the movement of gases. The leaf, therefore, possesses an aerating system of impressive proportions, the spaces between the mesophyll cells making possible a thorough exchange of water vapour, carbon dioxide, and oxygen between the photosynthetic cells and the outside atmosphere.

The vascular tissues of the leaf are contained within the veins, which form either a network or a parallel system coursing throughout the mesophyll. Each of the larger veins is enclosed within a layer of tightly packed parenchyma cells, the bundle sheath, which extends to the ends of the veins, completely enclosing each one. The bundle-sheath cells participate in the movement of materials between the vascular tissue inside the veins and the mesophyll cells. In addition to containing the conducting xylem and phloem tissues, the veins serve as a strengthening framework for the leaf. Additional support for the leaf blade is provided by the pressure of the water inside the mesophyll cells. The epidermis also affords much support for the leaf because of the compact arrangement of its cells and the strength of the cuticle layer. Collenchyma cells (cells with thickened walls) and sclerenchyma fibres may also be present beneath the epidermis or in close association with the veins, an arrangement that provides additional support for the leaf blade.

Appearance and behaviour of cotyledons

Kinds of leaves. In addition to the more familiar foliage leaves, plants usually possess one or more of the following kinds of leaves: cotyledons, scale leaves, and bracts. Cotyledons are the first leaves to be formed, arising early in the development of the embryo inside the seed. During germination the cotyledons in some species remain enclosed within the seed coat and hidden beneath the soil surface. In other species the cotyledons break through the seed coat and appear on the young seedling above the ground surface, where they become green and carry on photosynthesis for a time, just as do foliage leaves. Scale leaves occur as bud scales, where they function in protecting the young developing leaves and apical meristem inside the bud. Scale leaves are the only type of leaf produced by underground stems, or rhizomes; they are usually small and short-lived. Bracts are often associated with the flowers, where they serve to protect the young developing flower. Sometimes the bracts are brightly coloured (as in the poinsettia) and function as petals in the attraction of prospective pollinators (bees, butterflies, birds, etc.; see POLLINATION).

Leaf fall. Leaves are relatively short-lived organs and sooner or later are shed from the plant, leaving leaf scars on the stem marking their former locations at the nodes. In evergreen species, such as conifers, and many broad-leaved angiosperms, the leaves may be retained on the tree for two or three years, after which they fall irregularly. In deciduous plants, the leaves function for only a single growing season and fall completely, usually in the autumn or at the beginning of the dry season. The fall of leaves of perennial and woody plants is a complex phe-

nomenon involving the separation of the leaf from the stem without undue damage to the newly exposed living tissues. Preceding the fall of the leaves from the tree, a special group of cells known as the abscission layer differentiates across the petiole near its base. Through chemical changes in their walls, the cells in this abscission layer become softened until the leaf finally breaks away and falls to the ground. On the stem side of the abscission layer, a healing layer develops, closing the wound with a corky tissue, which forms the leaf scar. The abscission process involves complex biochemical processes that are, in turn, influenced by various environmental factors such as day length, temperature, availability of oxygen, water, and mineral nutrients, and even attacks by insects or fungi. Various chemical sprays are often used in agriculture and in warfare to promote leaf abscission.

Leaf modifications. Leaves of many species have undergone various modifications during the course of evolution. Their form and structure have become conspicuously adapted in varying degrees to their environment. The leaves of plants in very dry habitats may be very small in blade area, or they may quickly die and in such plants the photosynthetic function is performed mainly by the stem, as in the cacti. In species such as *Acacia*, the leaf blade has disappeared, and the petiole has become flattened and leaflike (a phyllode). Many plants of deserts and other dry habitats possess pointed, awl-shaped spines, which are, in many cases, evolutionary derivatives of leaves. The leaves of other desert plants are very thick and fleshy, with abundant water-storage capacity; such plants are known as succulents.

Adaptations to dry habitats

Climbing plants often possess elongated, threadlike, branched or unbranched organs known as tendrils, which wrap themselves around nearby stems, thereby anchoring the plant. In many species tendrils are evolutionary modifications of leaves or leaf parts. In cucumbers and melons, for example, the tendrils have evolved from the midribs of leaves, whereas in peas the tendrils originated from a leaflet of a compound leaf.

Highly bizarre leaf modifications are present in carnivorous plants. The leaf of the sundew plant (*Drosera*) has tentacles resembling the "horns" of a snail. These tentacles excrete a sticky fluid attractive to insects, which become firmly caught and are eventually digested by the leaf. The leaves of the Venus's-flytrap function as mechanical traps, capturing insects with amazing rapidity. The leaves of *Sarracenia* and *Nepenthes* are modified into hollow, trumpet- or jug-shaped, brightly coloured structures containing a watery fluid attractive to animals. Upon entering the leaf, the animals (usually insects) slide into the fluid and are unable to escape. Subsequently, their bodies are digested and the dissolved materials used in the plant's own nutrition.

The root. *Form and growth.* The root is generally the underground portion of the plant body and functions primarily as an anchoring and absorbing organ. Some subterranean structures are actually modified stems. The root, however, differs from such underground stems by always lacking leaves and buds and by having its growing tip protected by a root cap. The root cap consists of short-lived parenchyma cells. A short distance behind the root tip, where the cells have reached their maximum length, root hairs occur. Each root hair, a tubular outgrowth of a single epidermal cell, greatly increases the surface area of the root, thereby facilitating absorption of water and dissolved minerals from the soil. Root hairs usually live only a few days but are rapidly replaced by new ones, which form just back of the growing root apex. Root hairs are usually lacking in plants living in aquatic habitats.

Primary roots

The first root of a plant, the primary root, develops from the root end of the embryo (the radicle) during seed germination. In gymnosperms and dicotyledons, the primary root usually develops into the root system of the plant through the formation of branch or secondary roots from the pericycle tissue, a special layer of cells surrounding the vascular bundle, or stele, in the interior of the root. In monocotyledons, however, the primary root commonly dies while the plant is still very small. In these plants adventitious roots, roots that grow in other than the usual place on a plant, develop from the stem, usually close to the nodes. Adventitious roots are also produced on the creeping and underground stems (rhizomes) of many dicotyledons.

Internal structure. Internally, the root possesses a definite pattern of tissues. Three main regions are discernible: epidermis, cortex, and vascular cylinder. The epidermis is composed of tightly packed cells and typically lacks a cuticle. Root hairs occur in the region near the root tip. The cortex consists mostly of parenchyma cells that are characteristically separated from each other by spaces of various sizes. The cortex functions in the movement of water and dissolved minerals across the root from the epidermis to the xylem and also stores food molecules transported downward from the leaves. The innermost layer of the cortex usually differentiates as an endodermis, composed of a cylinder of cells, each of which develops a narrow, waterproof band, the Casparian strip, around all but the innermost- and outermost-facing cell walls. The Casparian strip serves as a barrier to the free movement of water and minerals between the cells, thus requiring all such materials to enter the central stele through the membranes of the living endodermis cells.

Interior to the endodermis is the vascular cylinder, which begins with one or more layers of parenchyma cells, the pericycle, immediately inside the endodermis. Cells of the pericycle retain the ability to undergo cell division, thereby giving rise to branch or secondary roots. On the inner surface of the pericycle are the vascular tissues, which, in many species, are arranged in a star-shaped pattern. Comprising the core of this star is the xylem tissue. The phloem tissue is located in small groups between the points of the star. Usually the phloem is separated from the xylem by a cambium layer, which, in those species whose roots undergo an increase in thickness, produces both secondary xylem and phloem. In most monocotyledons and some herbaceous dicotyledons, the central core of the stem consists of pith tissue.

Secondary growth in roots

In many plants the roots undergo increase in thickness through the production of secondary growth by the vascular cambium, just as does the stem. In fact, the old roots of trees may reach several inches in diameter and exhibit numerous annual rings similar to those in the wood of the stem. As the root increases in thickness, a secondary covering of periderm (bark or cork) similar to that of the stem replaces the epidermis as a protective covering. Externally, therefore, the older root can hardly be distinguished from an older stem, especially when erosion has removed the soil cover, exposing the root to weathering. Internally, the woody root can hardly be distinguished from the woody stem.

Modifications of the root. During the course of evolution, roots of many species have become modified and specialized with reference to particular functions. The root may function as a food-storage organ, becoming enlarged and swollen, as in the carrot, turnip, radish, or sweet potato. Roots may serve as supporting structures, as in mangrove and corn (maize) plants. In plants of swamps and marshes, branch roots may grow above the mud into the atmosphere and function as aerating organs (pneumatophores) for the entrance of oxygen into the root system. In some palms the roots become modified into thorns. Many species of vines and epiphytes (plants that are supported on the branches of trees rather than being rooted in soil) form aerial roots that hang freely in the air. In many trees and shrubs, the absorptive roots are short and thick and are enclosed within a dense network of fungus hyphae (filaments). The fungus enters the root cortex, producing a condition known as mycorrhiza. The mycorrhizal association of root and fungus takes the place of root hairs in the absorption of water and dissolved minerals. The roots of the mistletoe plant, a partial parasite on trees, enter the stem cortex of the host, where they absorb water and dissolved minerals (see SANTALALES). In Spanish moss, an epiphyte, roots are absent, and the leaves function in the absorption of water and minerals by means of special absorptive hairs.

Mycorrhizal fungi

PHYSIOLOGY OF THE PLANT ORGANS

The external and internal morphology of the organs of the plant body can be understood simply by viewing them as adaptations facilitating the way the green plant makes its living as an autotrophic (*i.e.*, self-feeding—plants manufacture their own food by photosynthesis) organism. Although it is convenient for botanists to describe the plant in terms of three organs (stem, leaf, root), the plant must be viewed as a whole functional organism in which the cells, tissues, and organs work together to carry out an integrated series of activities. Only when the individual organs of the plant body are viewed in relation to the whole can the intricate mechanisms by which the living plant maintains itself begin to be understood.

During the course of plant evolution, there has been considerable selective value in the development by the green plant of light-accessible surfaces: the erect stem with many branches carrying numerous flattened leaves. It has also been of great selective value for the green plant to develop an underground portion highly efficient in both anchoring the plant and in absorbing water and dissolved minerals from the soil; hence, the root with its many branches and numerous root hairs has developed.

Green plants require three classes of materials from their environment: water, minerals, and the gases carbon dioxide and oxygen. To be used by the plant, however, these materials must be moved from the environment into the plant body.

Water absorption by roots

Nearly all of the water for the plant is absorbed by the roots, especially through the root hairs. In the soil surrounding the root hairs, water is usually present in high concentration. Inside the root cells, water is generally in much lower concentration because of the dissolved sugars, salts, and other substances present in living cells. Water molecules, therefore, move into the root cells by the process of osmotic diffusion, the movement of water across cell membranes (which prevent the passage of sugars, salts, and many other substances) from regions of high water concentration to regions of lower water concentration. There is also evidence suggesting that some of the water absorption by the root requires the expenditure of energy by the root cells.

Considerable amounts of water may enter the root and move across the epidermis and cortex by diffusing through the cell walls, never actually entering the living cells. To move into the vascular cylinder, however, the water molecules must move across the membranes of the endodermis cell layer. The water is channelled in its movement through the endodermal-cell membranes by the bandlike layer of waxy thickening (Casparian strip) in some of the walls of the endodermis.

In addition to water entering the root through the root-hair region of young roots, considerable absorption of water has been found to take place in roots old enough to possess a corky bark. Since as much as 95 percent of the root surface of a tree or shrub consists of bark-covered roots, it is most likely that the major portion of the water and mineral absorption occurs not through the root hairs but through lenticels and cracks in these older roots.

Roots also absorb the mineral elements necessary for plant growth. These elements enter the root cells as ions; *i.e.*, atoms or groups of atoms bearing an electric charge. Phosphorus, for example, is absorbed as phosphate ions (PO_4^{-3}), nitrogen as nitrate ions (NO_3^-) or ammonium ions (NH_4^+), and potassium in the form of potassium ions (K^+). There is good evidence that the root cells must expend energy to absorb mineral ions from the soil; that is, the absorption process is an active transport phenomenon. Water and minerals may also be absorbed through the stems and leaves. It is common practice, for example, to apply iron and other minerals to shrubs and trees by spraying them on the leaves.

Gaseous exchange in leaves

The gases, carbon dioxide and oxygen, enter the plant by diffusion whenever the stomata of the leaves are open. Experiments have demonstrated that, while the open stomata constitute only 1 to 2 percent of the epidermal surface, they possess, nonetheless, the capacity to permit the passage of gases from the atmosphere into the interior of the leaf to a degree far greater than that required by the plant. It seems very likely that the stomatal complex of guard cell, stoma, and intercellular-space system of the leaf evolved primarily as an adaptive device facilitating the absorption of the carbon dioxide required for photosynthesis and the oxygen necessary for respiration. Once inside the intercellular-space system of the leaf mesophyll, carbon dioxide and oxygen become dissolved in the thin film of water that encloses the mesophyll cells and then diffuse into the interior of the cells.

It has been known at least since the late 17th century that plants not only absorb but also lose large amounts of water from their leaves. The corn plants on a single acre, for example, have been shown to lose some 324,000 gallons of water during one growing season. When glass containers are placed over a leafy shoot, water will soon condense on the container walls. The process of water loss involves evaporation from the mesophyll cells into the intercellular spaces. The diffusion of this water vapour to the exterior of the leaf is controlled by the behaviour of the guard cells enclosing the stomata. Since the loss of water in gaseous form from the leaves differs in this respect from ordinary evaporation, the term transpiration is used for this process.

Transpiration, the loss of water from the leaf in vapour form, is, therefore, one of the normal functional processes of plants. The plant can do little to stop this water loss. The stomata are an adaptation for the movement of carbon dioxide and oxygen from the atmosphere into the leaf. Both gases are absolutely necessary for the continued life of the plant. A structure that is an excellent adaptation for the entrance of gases is also an efficient device for the loss of water vapour from the leaf interior. In fact, the entire leaf structure is highly favourable for the loss of water by transpiration. Whenever the stomata are open, there is a direct pathway from the surface of the mesophyll cells in the leaf interior out through the stomata into the atmosphere. There is some evidence that the loss of water from the leaf by transpiration is of some value in cooling the plant. On the other hand, when plants are transpiring rapidly, as in the middle of a hot, dry summer day, they may lose so much water that the cells of the leaves and young stems lose turgor (internal water pressure), causing these structures to wilt. If the wilting is severe, the leaves and young stems may droop, and the leaves become rolled. Little harm is done to the plant if these tissues recover their turgidity at night, but, if the loss of water has been too great, the plant may not recover and may eventually die from dehydration.

Causes of plant wilting

If water is being lost from the plants by transpiration from the leaves and if water is being absorbed from the soil by the roots, then there must be some mechanism for the transportation of water from the root tissues upward through the xylem of the stem into the veins of the leaves. Many explanations have been proposed to account for this water movement upward in plants; none is completely satisfactory. Various experiments have clearly demonstrated that the water is actually being pulled upward in the plant by forces acting in the leaves. It has been shown that the water in the xylem cells is actually under tension; *i.e.*, it is being pulled much in the way a rubber band is stretched.

In addition to the transport of water and dissolved minerals in the xylem, there is also movement through the phloem of sugars, hormones, and vitamins. Much is known about the phloem-transport process, yet no single explanation yet proposed has been able to account for all the various observations about conduction of materials through the phloem. It is known that the phloem cells are alive, unlike the cells of the xylem, which are dead at functional maturity. The rate of movement of materials through the phloem is relatively rapid, although much slower than movement through the xylem.

THE ORGAN SYSTEMS OF VASCULAR PLANTS

Variability of growth forms. The body of a vascular plant consists basically of the three organs: stem, leaf, root. Any individual plant, however, may possess several to many stems (and stem branches), numerous leaves, and many roots. It is convenient for descriptive purposes

to speak of the stem with its many branches and numerous leaves as comprising the shoot system and all of the roots as the root system. The shoot system and the root system form one continuous structure and function together in a remarkably integrated, harmoniously interacting organization, the whole plant body.

Extremes of plant size

Vascular plants exist in a remarkable array of diverse forms and sizes. Among the angiosperms, the plant body ranges from giant *Eucalyptus* trees of over 300 feet in height to the minute floating aquatic herb *Wolffia*, with a body so tiny that it can be more easily felt between the fingers than seen with the unaided eye. This amazing diversity presented by vascular plants is the result of the working-out in detail during evolution of a scheme of construction that is in itself unlimited. Any plant has the fundamental architectural potential to attain indefinite size, even the smallest herbs (through the activity of the meristems).

The unlimited scheme of growth exhibited by plants becomes evident very early in the development of the embryo. As the embryo grows, the production of new cells and tissues gradually becomes limited to certain regions of the embryonic axis, the meristems. The meristems remain permanently embryonic. Thus, unlike an animal, which usually completes the construction of all its tissues and organs during an early period of embryonic development, a plant body is partially embryonic and partially adult throughout its entire life. In a plant body, therefore, additional organs (*e.g.*, leaves) are formed throughout the life-span of the individual, while, in the animal body, the number of organs is fixed at a certain definite number early in embryo development.

The shoot system. *Branching habits.* The shoot system consists of the stem, its branches, and the leaves. During its development, the shoot system may attain considerable complexity due to branching. In lycopods and some ferns, the growing shoot subdivides or dichotomizes into two more or less equal apices. Each of these sister apices grows individually for a time and then may dichotomize once again. Dichotomous branching is considered to be the most primitive type of ramification in the vascular plants.

The shoot system in the vast majority of vascular plants consists of a main shoot axis or stem from which lateral branches develop from buds in the leaf axils; this is monopodial or lateral branching. The lateral branches may themselves branch and rebranch, producing an intricate shoot system. In some species, one of the axillary buds near the apex of the main stem may grow vigorously, soon overtopping the main stem, producing an apparent monopodial condition that actually consists of a series of lateral branches. This is sympodial branching.

The lateral branches of the main stem may grow into long shoots with widely spaced internodes and numerous leaves. In some species, however, most of the lateral branches are short shoots with crowded internodes and only a few leaves. In pines, most of the leaves are borne on short shoots. The flowers and fruits in many plants occur only on short shoots. Short shoots are apparently caused by growth-inhibiting hormones produced by the long-shoot tissues.

The tree—a model shoot system. Perhaps the tree is the most familiar type of shoot system. Trees vary considerably in both external form and in internal construction. In the tree ferns, much of the trunk thickness is caused by a thick sheath of intertangled adventitious roots that arise close to the shoot apex and grow downward through the trunk. At the base of the trunk, a dense mat of these roots forms a buttress that aids in supporting the tree trunk. Another type of tree construction occurs in palms and other, arborescent (treelike) monocotyledons. In these plants, the stem apex of the seedling enlarges rapidly just below the apical meristem. Cells in the region below the embryonic leaves function as a primary thickening meristem, which enlarges the stem of the young palm to almost the full diameter it is destined to have. Only after this dramatic increase in thickness does the stem begin to increase markedly in length. Thus the stout trunk is a primary construction of the stem apex and involves no secondary tissues of the kind produced by the vascular cambium of dicotyledons.

Increase in stem thickness among palms

The most common type of tree construction is that characteristic of the conifers and angiosperms. In these plants the original stem is produced by the apical meristem. Later, the stem becomes thicker by the activity of a lateral meristem, the vascular cambium. The vast bulk of a coniferous or angiospermous tree, therefore, is a secondary construction of the cambium, not the apical meristem.

In addition to variations in their internal anatomy, trees also exhibit a wide range of external forms. At one extreme is the short, unbranched or sparsely branched tree with a stout trunk supporting an umbrella-like crown, or rosette, of large compound leaves. Some of these umbrella, or rosette, trees have soft trunks with only weak secondary thickening; *e.g.*, the papaya (*Carica*). Other species—*e.g.*, the cycads and palms—exhibit the same general form but possess much more secondary thickening and much stouter trunks. At the other extreme is the lofty canopy tree with an immense crown consisting of thousands of small leaves borne on hundreds of twigs on the lateral branches. The canopy tree is well developed in the tropical rain forests. Between these extremes are various types of trees with diverse combinations of branching pattern, leaf types, sizes, and wood and bark development.

The shrub and other shoot systems. Another familiar type of shoot system is the shrub. The shoot system of a shrub is characterized by extensive branching, usually from or near the ground level. The buds in the lower portion of the main stem tend to develop instead of those higher up the principal axis. The shrubby shoot system generally is much shorter than that of the tree, and the life-span of the shrub is usually much less than that of the tree.

The shoot system of some species is well adapted for climbing up on other plants, thereby bringing the leaves into the sunlight. Such climbing plants are called vines or lianas and are very abundant in the tropical rain forests, often weaving the canopy into a continuous web. The stem of many species of vines is a long, flexible woody structure resembling a rope or cable. Internally, the secondary xylem is often arranged in bands, furrows, or discrete cylinders or bundles. Many species possess special structures that facilitate climbing. The shoots of roses (*Rosa*) and blackberries (*Rubus*) possess sharp, curved epidermal outgrowths called prickles. Other plants (*e.g.*, *Bougainvillea*) have hooklike thorns. Climbing plants such as grape (*Vitis*) have tendrils that wrap around the stems of other plants.

Lianas

Shoot adaptations. The shoot systems of many species exhibit various modifications enabling the plant to be better adapted to its environment. Perennial herbs, for example, may have slender stems that grow horizontally along the soil surface or just beneath the ground level; these horizontal stems are known as stolons or runners. In other plants the underground horizontal stem may be a thick structure with short internodes and much-reduced, colourless scale leaves. These are rhizomes, the "root" of *Iris* being a familiar example. Adventitious roots usually arise from the nodes. These subterranean stems or rhizomes function as food-storage organs. Rhizomes usually continue growth for several years, giving rise each growing season to new, aboveground portions of the shoot. Other plants produce short thick stems or parts of stems in which food is stored but that persist only from one growing season to the next. These structures, known as stem tubers, may be formed entirely from the hypocotyl (the root end of the embryo), as in the radish and beet, or they may arise at the tips of underground stolons, as in the potato. The depressions ("eyes") on a potato tuber are the locations of lateral buds and small scalelike leaves (visible in the young potato tuber). After the tubers are produced, the parent plant dies. In such species as crocus and gladiolus, the lower portion of the main shoot itself may develop into another kind of thickened underground stem known as the corm. Thin, membraneous scale leaves cover the solid, essentially round stem. Another

Stem tubers

type of shoot modification is the bulb, consisting of an underground, very short stem from which arise thick, fleshy scale leaves in which food is stored. Bulbs are characteristic of onions, tulips, hyacinths, and leeks.

The root system. Just as the shoot system becomes more complex through the production of lateral branches, the root system increases in surface area by branching. In the lycopods, dichotomous branching of the root occurs. In most vascular plants, root branching is lateral. Unlike the lateral branches of the shoot, however, the lateral roots arise at some distance back of the growing apex in a region where the tissues are fully matured. In addition, lateral roots originate from tissues deep within the parent root, usually the pericycle of the vascular cylinder in the seed plants, and they must penetrate the cortex tissue of the parent root in their growth outward into the soil. Usually the lateral roots are more slender than the parent root, and they are usually arranged more or less at right angles to the main root. Most trees and shrubs and many herbs have a root system consisting of a radially symmetrical taproot that grows straight downward into the soil. From this taproot, lateral or branch roots develop in sequence, the youngest near the growing root tip, and spread out horizontally or obliquely into the soil. In turn, these branch roots give rise to smaller lateral roots. The result is an extensively branched root system that is especially effective in both the absorption of water and dissolved minerals and in anchoring the plant. The taproots of many species may be especially adapted for the storage of food; *e.g.*, the carrot. The lateral roots of some species (*e.g.*, *Dahlia*) develop into thick, fleshy tubers, which, like the stem tubers they resemble, serve as food-storage structures. The root system of grasses, sedges, and most ferns is a fibrous system composed of numerous roots arising from the stem, all of about the same size. Although fibrous root systems do not anchor plants in the ground as well as do taproot systems, they are well adapted for absorbing water near the surface. In ferns and in many monocotyledons, most of the root system is adventitious, with the roots developing from the stem nodes. This type of root system is well illustrated by corn and grasses.

Root systems of grasses

Transition between the root and shoot systems. Usually there is a transition between the root system and the shoot system near the soil level. This transition is marked externally in the young plant by a rapid abrupt change in coloration from the pale colour of the root to the green colour of the stem. In woody plants with secondary growth, the change in external appearance is less pronounced since the bark extends over both the stem and older roots. In the embryo, the connection between the root and shoot systems is accomplished by the embryo axis or hypocotyl. Internally, the transition between the two parts of the plant body involves changes in the arrangement of the primary vascular tissues. The vascular tissue, which in the root is essentially a single central core or bundle with discrete strands of phloem lying adjacent to the central core of xylem, is gradually changed so that, in the stem, the xylem and phloem tissues assume characteristic positions within the several vascular bundles. Once cambial activity begins, however, the secondary xylem and phloem form continuous tissues between the root and the stem, thus obscuring the initial differences in the structure of the root–shoot transition region.

The reproductive system. Both the shoot and the root systems of the plant may participate in reproduction. The shoot system is involved in the formation of flower clusters or inflorescences; the inflorescence is a part of the branching system of the stem with flowers at the tips. Inflorescences vary greatly in size, form, and in flower number; various types have been distinguished. For more information on flowers, see REPRODUCTIVE SYSTEMS, PLANT; for seeds and fruit, see SEED AND FRUIT.

Asexual reproduction.

Both the shoot and the root systems are involved in vegetative or asexual reproduction. The shoot system exhibits diverse modifications facilitating reproduction. Some plants—*e.g.*, the aquatic plant *Anacharis canadensis* (elodea)—multiply largely by fragmentation of the plant body. Gardeners and horticulturists propagate plants by inducing cuttings from the parent plant to produce adventitious roots. In many plants, specialized portions of the plant body known as propagules are produced. The propagule may be a stolon or runner, which gives rise to new plants at the nodes, as in the strawberry. In species such as iris and canna, the propagule is a rhizome, which forms a new plant at the growing tip. The corm is utilized as a propagule in species such as crocus and gladiolus, while bulbs serve the same function in onions, tulips, and many other plants. Stem tubers are used to propagate potatoes; the tuber is cut into pieces, each of which gives rise to a new plant. Many aquatic plants, such as *Utricularia*, develop special buds called turions that overwinter in the bottom mud and germinate the following spring to produce new plants. Small, fully formed plantlets are formed on the leaf margins of many ferns and angiosperms such as *Bryophyllum*. These eventually fall to the ground and grow into new plants.

Like the shoot system, the root system also participates in asexual reproduction through the production of a diversity of structures. Species of *Cyrilla* and *Hypericum* develop new plants at irregular intervals along roots that grow just beneath the soil surface; these are "root sprouts." Many perennial and biennial herbs form root tubers; *e.g.*, *Dahlia* and many terrestrial orchids. See also REPRODUCTIVE SYSTEMS, PLANT.

THE ORGANS OF NONVASCULAR PLANTS

Differentiation of the plant body into organs has occurred also in various kinds of multicellular nonvascular plants, including mosses, liverworts, and algae. Much of the vegetative body of mosses and most liverworts is constructed very similarly to that of the vascular plants; that is, there is an aerial, shootlike portion attached to a subterranean rootlike portion. The leafy shootlike gametophyte (*i.e.*, one of the two main phases in the life cycle of lower plants—in mosses and liverworts it is the conspicuous leafy growth form) of mosses exhibits differentiation into three tissue regions: epidermis, cortex, and central conducting strand. While the conducting tissue is composed of phloemlike cells, there are no tracheids (elongate overlapping water-conducting cells that communicate by lateral pores) or vessel elements (more advanced tubular hollow cells with open ends) such as those of vascular plants. The leaves are usually one-cell-layer thick, except over the midrib, and typical mesophyll is lacking. The rootlike underground portion has filamentous structures called rhizoids, but these serve mainly to anchor the plant in the soil. The gametophyte body of some liverworts consists of a flat, ribbonlike, often dichotomously branched, green structure with filamentous rhizoids on its lower surface. Both mosses and liverworts are largely restricted to moist habitats.

Lower plant structures compared to vascular plants

Among the algae are many species that exhibit bodies remarkably similar to those of vascular plants, at least in external appearance. The stoneworts *Chara* and *Nitella* have an upright, green, shootlike portion with whorls of branches at the nodes and very long internodes. The plants are anchored to the mud in the bottom of ponds and streams by colourless, branched filamentous rhizoids that arise from the nodes near the base. Among the brown algae (Phaeophyta) are many species with bodies composed of leafy shootlike portions anchored to the rocks by means of rootlike holdfasts; *e.g.*, the giant kelps *Nereocystis* and *Macrocystis*. Some of these large brown algae even have food-conducting cells remarkably similar in structure and function to the sieve cells (a type of phloem cell) of vascular plants. Various members of the red algae (Rhodophyta) also display leaflike and stemlike bodies very similar in external appearance to the leaves and stems of vascular plants. The internal anatomy of these highly organized algal bodies is much less complex than that of the vascular plants, however. See ALGAE. Among the green algae (Chlorophyta), the genus *Fritschiella* has a multicellular body consisting largely of parenchyma tissue differentiated into an erect, aerial system anchored to the mud by a prostrate system of rhizoids. In fact, these features make *Fritschiella* an attractive model for a possible ancestor of green land plants.

EVOLUTION OF PLANT ORGANS AND ORGAN SYSTEMS

Functional evolution. The great diversity of organs and organ systems among the numerous species of plants is the result of evolution by natural selection. These structures enable the plant to be better adapted to its environment. The origin and diversification of multicellular plants with complex organs and organ systems have long been a subject of intense interest among plant evolutionists. The fossil record indicates that simpler plants originated earlier in geological time than the more complex plants. It is consistent with the concept of evolution by natural selection to assume that plants received some selective advantage in becoming more complex.

Advantages of complex multicellular structure

What advantages may have accrued to plants by the adoption of the more complex multicellular state? The multicellular condition enables cell and tissue specialization, a division of labour among the parts of the whole plant body. Some cells and tissues can become specialized for capturing sunlight and synthesizing food, others anchor the plant body, while still others play a role in reproduction. The result is a corresponding increase in the ability of the plant to exploit its environment and increase its chances for survival.

The fossil record. The time of origin of the multicellular plant body can be estimated from the earliest occurring fossils presently known. Filamentous structures identified as blue-green algae have been discovered in rocks calculated as being about 2,000,000,000 years in age. Multicellular bodies differentiated into organs had evolved among the green algae and possibly also among the red algae and brown algae by the beginning of the Ordovician Period, some 500,000,000 years ago.

Proposed conditions leading to land-plant evolution

The earliest known fossil land plants (*i.e.*, vascular plants with an erect aerial photosynthesizing system and a horizontal underground anchoring and absorbing system) are found in rocks formed during the Upper Silurian and Early Devonian periods, around 395,000,000 years ago. Geological evidence suggests that, during this time, many regions of the Earth's surface may have been subjected to prolonged seasonal droughts. During some portions of the year, rainfall would be abundant (as today in some tropical regions); at other times, the rains would cease, and the water level in the larger bodies of water would decrease drastically, while that of many smaller ponds and lakes might dry up altogether. Under these conditions of intermittent drought, the evolutionary migration of plants to the land is thought to have occurred.

Once the transition to full-time land existence had been accomplished, the stage was then set for the relatively rapid adaptive radiation of plants into all suitable habitats. This radiation produced several evolutionary lines of vascular plants as well as of the mosses and liverworts. The invasion of the land by photosynthetic plants also created a new environment—one in which fungi and animals could compete successfully for the necessities of life. Indeed, clear evidence that fungi were in existence during the Early Devonian Period is provided by the discovery of fungal hyphae in the fossilized remains of vascular plants that lived during that time. Fossil remains of land-dwelling invertebrate animals, which lived during this time, have also been discovered.

(P.Ad.)

Origen

Origen (Origenes Adamantius), the most influential and seminal theologian and biblical scholar of the early Greek Church, provoked questions and controversies that for centuries were to absorb the attention of churchmen.

Early life and education. He was born *c.* 185, probably in Alexandria, Egypt, of pagan parents, according to the Neoplatonist philosopher Porphyry, but of Christian parents, according to the ecclesiastical historian Eusebius of Caesarea, whose account is probably more accurate. Eusebius stated that Origen's father Leonides, was martyred in the persecution of 202, so that Origen had to provide for his mother and six younger brothers. At first he lived in the house of a wealthy lady. He then earned money by teaching grammar and lived a life of strenuous asceticism. Eusebius added that he was a pupil of Clement of Alexandria, whom he succeeded as head of the Catechetical school under the authority of the bishop Demetrius. Eusebius also alleged, without supporting documents, that Origen, as a young man, castrated himself so as to work freely in instructing female catechumens; but this was not the only story told by the malicious about his extraordinary chastity, and thus it may merely have been hostile gossip. Writing in 248, Origen deplored the fanaticism of those who literally interpreted Matt. 19:12 ("... there are eunuchs who have made themselves eunuchs for the sake of the kingdom of heaven"). Eusebius' account of Origen's life, moreover, bears the marks and embellishments of legends of saints and thus needs to be treated with this in mind.

Head of the Catechetical school

According to Porphyry, Origen attended lectures given by Ammonius Saccas, the founder of Neoplatonism. A letter of Origen mentions his "teacher of philosophy," at whose lectures he met Heraclas, who was to become his junior colleague, then his rival, and end as bishop of Alexandria refusing to hold communion with him.

Career as an educator and polemicist. Origen invited Heraclas to assist him with the elementary teaching at the Catechetical school, leaving himself free for advanced teaching and study. During this period (from *c.* 212), Origen learned Hebrew and began to compile his *Hexapla.*

A wealthy Christian named Ambrose, whom Origen converted from the teachings of the heretical Valentinus (who, as a Gnostic, advocated the dualism of spirit and matter) and to whom he dedicated many of his works, provided him with shorthand writers. A stream of treatises and commentaries began to pour from Origen's pen. At Alexandria he wrote his lost *Miscellanies* (*Stromateis*), *On the Resurrection* (*Peri anastaseos*) and, above all, *On First Principles* (*De principiis*). He also began his im-

mense commentary on St. John, written to refute the commentary of the Gnostic follower of Valentinus, Heracleon. His studies were interrupted by visits to Rome (where he met the theologian Hippolytus), Arabia, Antioch, and Palestine. Because of his reputation, he was much in demand as a preacher, a circumstance that provoked the disapproval of Demetrius, bishop of Alexandria, who was anxious to control this free lay teacher and especially angry when Origen was allowed to preach at Caesarea Palestinae. In about 229–230 Origen went to Greece to dispute with another follower of Valentinus, Candidus. On the way he was ordained presbyter at Caesarea. The Valentinian doctrine that salvation and damnation are predestinate, independent of volition, was defended by Candidus on the ground that Satan is beyond repentance; Origen replied that if Satan fell by will, even he can repent. Demetrius, incensed at Origen's ordination, was appalled by such a doctrinal view and instigated a synodical condemnation, which, however, was not accepted in Greece and Palestine. Thenceforth, Origen lived at Caesarea, where he attracted many pupils. One of his most notable students was Gregory Thaumaturgus, later bishop of Neocaesarea, who praised his master according to the contemporary fashion by writing a eulogy and claimed for Origen a position equal to that of the great pagan philosophers.

Ordination as a presbyter

From Caesarea, Origen continued his travels. In 235 the persecution of Maximinus found him in Cappadocia, from which he addressed to Ambrose his *Exhortation to Martyrdom*. During this period falls the "Discussion with Heracleides," a papyrus partially transcribing a debate at a church council (probably in Arabia) where a local bishop was suspected of denying the pre-existence of the divine Word and where obscure controversies raged over Christological issues and whether the soul is, in actuality, blood. During the persecution under the emperor Decius (250), Origen was imprisoned and tortured but survived to die in about 254 at Tyre. His tomb there was held in honour, and its long survival is attested by historians of the period of the Crusades.

Writings. Origen's main lifework was on the text of the Greek Old Testament and on the exposition of the whole Bible. The *Hexapla* was a synopsis of Old Testament versions: the Hebrew and a transliteration were followed by the Septuagint (an authoritative Greek version of the Old Testament), the versions of Aquila, Symmachus, and Theodotion and, for the Psalms, two further translations (one being discovered by him in a jar in the Jordan Valley). The purpose of the *Hexapla* was to provide a secure basis for debate with rabbis to whom the Hebrew alone was authoritative. The Greek churches generally accepted the Septuagint text and canon. Origen frequently mentioned textual variants among New Testament manuscripts but undertook no study of them comparable to the *Hexapla*, which is extant only in parts.

The *Hexapla*

Exegetical writings. His exegetical writings consist of commentaries (scholarly expositions for instructed Christians), homilies for mixed congregations, and scholia (detached comments on particular passages or books) which are almost entirely lost. None of his commentaries survives complete; quite apart from doubt about his orthodoxy, their length militated against preservation in that they were too long to copy. All extant manuscripts of the commentary on St. John, which extended to 32 books, depend on a codex preserved in Munich (Germany) containing only a few of the books. This codex and a related manuscript at Trinity College, Cambridge (England), are the sole witnesses for the Greek original of books 10–17 of his commentary on St. Matthew. Greek fragments of this, as of most of Origen's exegetical works, survive in writings known as *catenae* ("chains"; *i.e.*, anthologies of comments by early Church Fathers on biblical books). Commentaries on the Song of Solomon and on Romans survive in a drastically abbreviated Latin paraphrase by the Christian writer Tyrannius Rufinus (*c.* 365–410/411). The homilies on Genesis through the Book of Judges (except Deuteronomy) and Psalms 36–38 survive in a Latin translation by Rufinus. Jerome, the great Christian scholar (*c.* 347–*c.* 420), translated homilies on the Song of Solomon, Isaiah, Jeremiah, Ezekiel, and Luke. These Latin homilies were widely read in medieval monasteries and have a rich manuscript tradition. The Greek original of homilies on Jeremiah survives in a single manuscript in the Escorial (Spain), and that of a homily on the witch of Endor (which provoked early criticism for its thesis that Samuel really was conjured up) in a manuscript in Munich and on papyrus.

Doctrinal writings. Prior to 231 Origen wrote *De principiis*, an ordered statement of Christian doctrine on an ambitious scale, based on the presupposition that every Christian is committed to the rule of faith laid down by the Apostles (the Creator as God of both Old and New Testaments, the incarnation of the pre-existent Lord, the Holy Spirit as one of the divine Triad, the freedom of rational souls, discarnate spirits, the noneternity of the world, judgment to come) but that outside this restriction the educated believer is free to speculate. Origen was writing long before the conciliar definitions of Chalcedon (451) concerning the Trinity and the Person of Christ and at a period when a far larger area of doctrine could be regarded as open for discussion and argument than was the case by 400. *De principiis* diverged in its speculations from later standards of orthodoxy. The original was consequently lost and can only be reconstructed from the *Philocalia* (an anthology compiled by Basil the Great and Gregory of Nazianzus illustrating Origen's biblical interpretation), from Rufinus' Latin paraphrase (which avowedly rewrites heterodox-sounding passages), and from later writers, notably Jerome and Justinian I (who quote especially compromising passages to prove Origen a heretic). The polemical anti-Origenists, however, need to be read with care since they were not above misquoting Origen and ascribing to him the words of later Origenists.

Speculative theology

Polemical writings. Origen's great vindication of Christianity against pagan attack, *Contra Celsum*, written (probably in 248) at Ambrose's request, survives in its entirety in one Vatican manuscript, with fragments in the *Philocalia* and on papyruses. Paragraph by paragraph it answers the *Alēthēs logos* ("The True Doctrine" or "Discourse") of the 2nd-century anti-Christian philosopher Celsus and is therefore a principal source for the pagan intelligentsia's view of 2nd-century Christianity as well as a classic formulation of early Christian reply. Both protagonists agree in their basic Platonic presuppositions, but beside this agreement, serious differences are argued. Celsus' brusque dismissal of Christianity as a crude and bucolic onslaught on the religious traditions and intellectual values of classical culture provoked Origen to a sustained rejoinder in which he claimed that a philosophic mind has a right to think within a Christian framework and that the Christian faith is neither a prejudice of the unreasoning masses nor a crutch for social outcasts or noncomformists.

Devotional writings. The tract *On Prayer*, preserved in one manuscript at Cambridge, was written about 233; it expounds the Lord's Prayer and discusses some of the philosophical problems of petition, arguing that petition can only be excluded by a determinism false to the experience of personality, while the highest prayer is an elevation of the soul beyond material things to a passive inward union with Christ, mediator between men and the Father.

Theological system. Origen's experience as a teacher is reflected in his continual emphasis upon a scale of spiritual apprehension. Christianity to him was a ladder of divine ascent, and the beginner must learn to mount it with the saints in a never-ceasing advance. Uneducated and elementary Christians may entertain strange misunderstandings and may even believe things of God that would not be believed of the most savage and cruel men. But the truth at the higher level is plain: that God's nature is essentially goodness and that he desires of his creatures a love that is free. Everything in Origen's theology ultimately turns upon the goodness of God and the freedom of the creature. The transcendent God is the source of all existence and is good, just, and omnipotent. This omnipotence is never mere power emptied of moral quality; one cannot appeal to it to rationalize absurdity or the merely extraordinary. In overflowing love, God created rational and spiritual beings through the Logos (Word); this creative act involves a degree of self-limitation on God's part.

Nature of God

The cosmos. In relation to the created order, God is both conditioned and unconditioned, free and under necessity, since he is both transcendent to and immanently active. In one sense, the cosmos is eternally necessary to God since one cannot conceive such goodness and power as inactive at any time. Yet in another sense, the cosmos is not necessary to God but is dependent on his will, to which it also owes its continued existence. Origen was aware that there is no solution of this dilemma. The rational beings, however, neglected to adore God and fell. The material world was created by God as a means of discipline (and its natural catastrophes such as earthquakes and plagues remind man that this world is not his ultimate destiny). Origen speculated that souls fell varying distances, some to be angels, some descending into human bodies, and the most wicked becoming devils. (Origen believed in the pre-existence of souls, but not in transmigration nor in the incorporation of rational souls in animal bodies.) Redemption is a grand education by providence, restoring all souls to their original blessedness. For none, not even Satan, is so depraved and has so lost rationality and freedom as to be beyond redemption. God never coerces, though with reformative intention he may punish. His punishments are remedial; even if simple believers may need to think of them as retributive, this is pedagogic accommodation to inferior capacity, not the truth.

The role and work of Christ. The climax of redemption is the incarnation of the pre-existent Son. One soul had not fallen but had remained in adoring union with the Father. Uniting himself with this soul, the divine Logos, who is the second *hypostasis* (Person) of the Triad of Father, Son, and Spirit (subordinate to the Father but on the divine side of the gulf between infinite Creator and finite creation), became incarnate in a body derived from the Virgin Mary. So intense was the union between Christ's soul and the Logos that it is like the union of body and soul, of white-hot iron and fire. Like all souls Christ's had free will, but the intensity of union destroyed all inclination for change, and the Logos united to himself not only soul but also body, as was apparent when Jesus was transfigured. Origen, influenced by a semi-Gnostic writing, the *Acts of John*, thought that Jesus' body appeared differently to different observers according to their spiritual capacities. Some saw nothing remarkable in him, others recognized in him their Lord and God. In his commentary on St. John, Origen collected titles of Christ, such as Lamb, Redeemer, Wisdom, Truth, Light, Life. Though the Father is One, the Son is many and has many grades, like rungs in a ladder of mystical ascent, steps up to the Holy of Holies, the beatific vision.

The Logos and revelation

The union of God and man in Christ is pattern for that of Christ and the believer. The individual soul, as well as the church, is the bride of the Logos, and the mystery of that union is portrayed in the Song of Solomon, Origen's commentary on which was regarded by Jerome (in the period of his enthusiasm for Origen) as his masterpiece. Thus redemption restores fallen souls from matter to spirit, from image to reality, a principle directly exemplified both in the sacraments and in the inspired biblical writings, in which the inward spirit is veiled under the letter of law, history, myth, and parable. The commentator's task is to penetrate the allegory, to perceive within the material body of Scripture its soul and spirit, to discover its existential reference for the individual Christian. Correct exegesis (critical interpretation) is the gift of grace to those spiritually worthy.

Destiny of man and the world. Both the biblical revelation and the spiritual life of the believer are progressive. The church is the great "school of souls" in which erring pupils are disciplined: elementary education in this life, higher education in the world to come, where the atoning and sanctifying process will continue in a purging baptism of fire, burning up the wood, hay, and stubble. Hell cannot be an absolute since God cannot abandon any creature; because of his respect for freedom it may take time, but God's love will ultimately triumph. Christ's work remains unfinished until he has subdued all to himself. Heaven is not necessarily absolute because freedom is an inalienable characteristic of the rational creature. "If you remove free will from virtue, you destroy its essence." Because the redeemed remain free, when all souls have been restored the whole drama may begin again. The Stoics believed in world cycles determined by fate. Origen thought them possible for the opposite reason, because freedom means that there is no ultimate finality.

Hell and heaven

Influence. If orthodoxy were a matter of intention, no theologian could be more orthodox than Origen, none more devoted to the cause of Christian faith. His natural temper is world denying and even illiberal. The saintliness of his life is reflected in the insight of his commentaries and the sometimes quite passionate devotion of his homilies. The influence of his biblical exegesis and ascetic ideals is hard to overestimate; his commentaries were freely plagiarized by later exegetes, both Eastern and Western, and he is a seminal mind for the beginnings of monasticism. Through the writings of the monk Evagrius Ponticus (346–399), his ideas passed not only into the Greek ascetic tradition but also to John Cassian (360–435), a Semi-Pelagian monk (who emphasized the worth of man's moral effort), and the West. Yet he has been charged with many heresies. In his lifetime he was often attacked, suspected of adulterating the Gospel with pagan philosophy. After his death, opposition steadily mounted, respectful in the Greek Christian Methodius of Olympus' criticism of his spiritualizing doctrine of the Resurrection (*c.* 300), offensive in Epiphanius' (375), a refuter of Christian heresies, violent in Jerome's anti-Origenist quarrel with Rufinus (*c.* 393–402). Origen had his defenders, especially in the East (Eusebius of Caesarea; Didymus the Blind, the head of Catechetical School of Alexandria [*c.* 313–398], Athanasius, bishop of Alexandria [*c.* 293–373], to some degree; and especially the Cappadocian Fathers—*i.e.*, Basil the Great, Gregory of Nazianzus, and Gregory of Nyssa); but in the west Rufinus' translation of *De principiis* (398) caused scandal, and in the East the cause of Origen suffered by the permanent influence of Epiphanius' attack. In the 6th century the "New Laura" (monastic community) in Palestine became a centre for an Origenist movement among the monastic intelligentsia, hospitable to speculations about pre-existent souls, universal salvation, and spherical resurrection bodies (a belief not countenanced by Origen himself). The resultant controversy led Justinian I to issue a long edict denouncing Origen (543); the condemnation was extended also to Didymus and Evagrius by the fifth ecumenical council at Constantinople (553). Nevertheless, Origen's influence persisted, such as in the writings of the Byzantine monk Maximus the Confessor (*c.* 550–662) and the Irish theologian John Scotus Erigena (*c.* 810–877); and since Renaissance times, controversy has continued concerning his orthodoxy, Western writers being generally more favourable than Eastern Orthodox.

Ecclesiastical opposition

The chief accusations against Origen's teaching are the following: making the Son inferior to the Father and thus being a precursor of Arianism, a 4th-century heresy that denied that the Father and the Son were of the same substance; spiritualizing away the resurrection of the body; denying hell, a morally enervating universalism; speculating about pre-existent souls and world cycles; dissolving redemptive history into timeless myth by using allegorical interpretation, thus turning Christianity into a kind of Gnosticism, a heretical movement that held that matter was evil and the spirit good. None of these charges is altogether groundless. At the same time there is much reason to justify Jerome's first judgment that Origen was the greatest teacher of the Early Church after the Apostles.

Orinoco River

The Orinoco River (Río Orinoco) and its tributaries constitute the northernmost of South America's three major river systems. Bordered by the Andes mountains to the west and the north, the Guiana Highlands to the east, and the Amazon watershed to the south, the river basin covers an area of about 366,000 square miles (948,000 square kilometres). It encompasses approximately four-fifths of Venezuela and one-fourth of Colombia. The Orinoco River itself flows in a giant arc for 1,337 miles (2,151 kilometres) from its source in the Guiana Highlands to its mouth on the Atlantic Ocean. Throughout most of its course it flows through Venezuela, except for a section where it forms part of the frontier between Venezuela and Colombia. The name "Orinoco" is derived from Guarauno words meaning "a place to paddle"—*i.e.*, a navigable place.

For most of its length, the Orinoco flows through impenetrable rain forest or undeveloped grasslands; however, the cities of Ciudad Bolívar (Bolívar City) and Ciudad Guayana (also known as Santo Tomé de Guayana or Guayana City) are located on its lower course, and this region is fast developing into one of the most industrialized areas of South America. The river forms a waterway used in the exploitation of the vast mineral wealth of the Venezuelan interior. (For an associated physical feature, see LLANOS.)

The natural environment. *The course of the river.* The western slopes of the Sierra Parima (Parima Mountains), which form part of the boundary between Venezuela and Brazil, are drained by spring-fed streams that give rise to the Orinoco River. The source is placed in Venezuela at 63°21′ W and 2°19′ N, at an elevation of 3,523 feet (1,074 metres). From its headwaters the river flows west–northwest, leaving the mountains to meander through level plains known as the Llanos. The volume of its waters increases as the river receives numerous mountain tributaries, including the Río Mavaca on the left bank and the Manaviche, Ocamo, Padamo, and Cunucunuma rivers on the right.

The Brazo Casiquiare

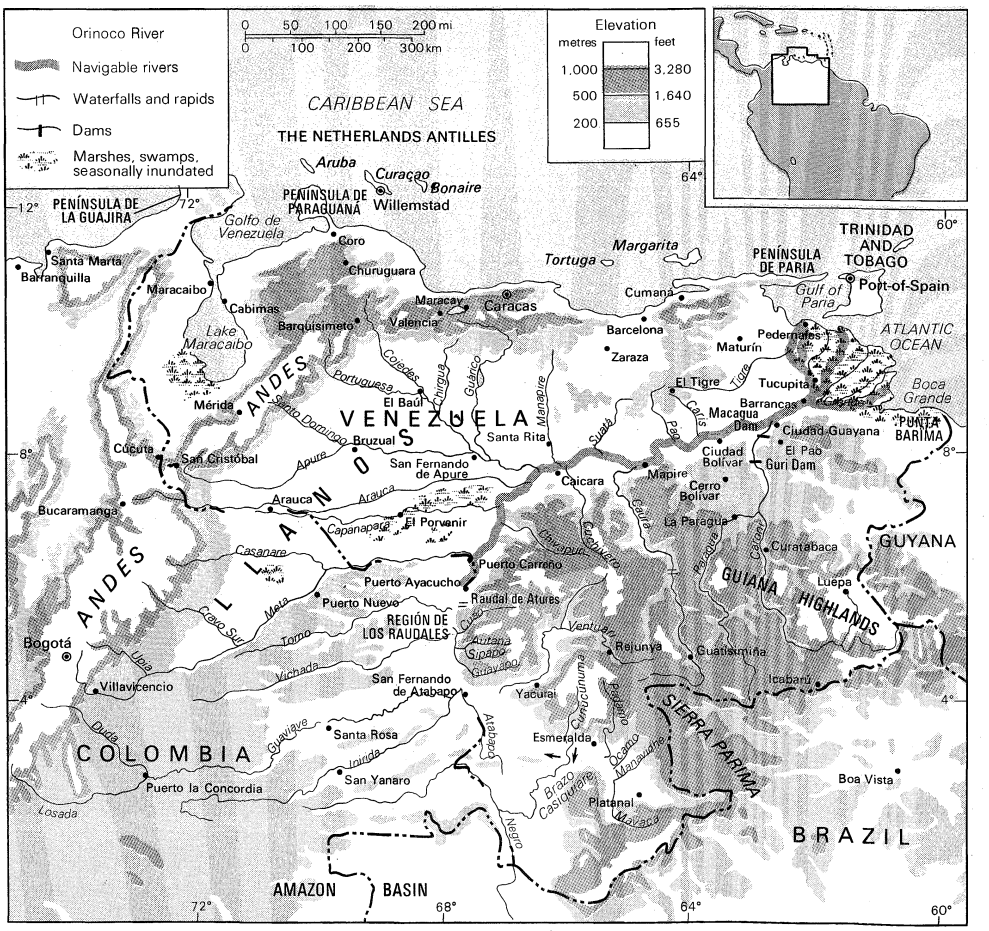
Below the town of Esmeralda some of the waters of the Orinoco flow south into the Brazo Casiquiare (Casiquiare Channel). This channel, a feature peculiar to the Orinoco River system, is a natural passage that flows for more than 220 miles to the Río Negro (Black River), linking the Orinoco and Amazon river systems.

After its bifurcation in the Casiquiare, the river bends to the northwest and flows in great meandering curves to its confluence with the Río Ventuari. There the river turns to the west to run between high alluvial banks; its course is marked by numerous extensive sandbars. Near San Fernando de Atabapo, the Atabapo and Guaviare rivers join join the Orinoco, marking the end of the Upper Orinoco.

Downstream from San Fernando de Atabapo, the river flows northward and forms part of the border between Venezuela and Colombia. It passes through a transitional zone, the Región de los Raudales (Region of the Rapids), where the Orinoco forces its way through a series of narrow passes among enormous granite boulders. The waters fall in a succession of rapids, ending with the Raudal de Atures (Atures Rapids). In this region, the main tributaries are the Vichada and Tomo rivers from the Colombian plains, and the Guayapo, Sipapo, Autana, and Cuao rivers from the Guiana Highlands.

The Raudal de Atures marks the beginning of the Lower Orinoco Basin, in which the river makes its great bend to the east. In this section, the river flows slowly through the lowest level of the plains and increases to about five miles in width. Along the bend, it receives the largest number of affluents of its entire course, including the Meta, Arauca, and Capanaparo rivers. The Río Apure contributes waters from numerous Andean streams, which form a swampy maze in their lower courses.

From its junction with the Río Apure, the Orinoco meanders eastward over gently sloping plains. Shoals and alluvial islands are abundant; some of the islands are



The Orinoco River Basin and its drainage network.

large enough to divide the channel into narrow passages. Tributaries include the Guárico, Manapire, Suatá, Pao, and Caris rivers, which enter on the left bank, and the Río Cuchivero and the Río Caura, which join the main stream on the right. So much sediment is carried by these rivers that they often form islands at their mouths. The Río Caroní, one of the Orinoco's largest tributaries, joins the river on its right bank after plunging over the Saltos del Caroní (Caroní Falls) above Ciudad Guayana. Many lagoons, including the Mamo, Amana, and Colorada, are located on the banks of the Orinoco west of its confluence with the Río Caroní and east of Ciudad Bolívar. At the town of Barrancas, the river begins to form its great delta.

The delta region

The delta extends for about 275 miles along the Atlantic coast, from Pedernales on the Gulf of Paria in the north to Punta Barima in the south on the Boca Grande (literally the "Great Mouth"). Scores of islands are connected by innumerable *caños*, or canals, which constitute an intricate network. The main channel of the Orinoco, known in the delta as the Río Grande, flows eastward from Barrancas to discharge into the Boca Grande.

Climate. The climate is tropical, with the seasons marked by differences in rainfall rather than in temperature. The year is divided into two seasons, the rainy and the dry (locally known as winter and summer), the former extending from April to October or November, the latter most marked from November through March or April. Temperature differences, on the other hand, are slight throughout the year; and no month averages more than 69° F (21° C) or less than 64° F (18° C). Whatever the average temperature, there is little difference from month to month. The only marked variation is from day to night, being greater than that from month to month.

Rainfall varies considerably from district to district. The northeast trade winds blow across the coastal districts without losing much precipitation, in some places leaving less than 20 inches per year. Areas lying behind topographic barriers also get little rain, while windward slopes are generally well watered. In some areas enough rain falls to support a lush jungle growth and, in others, enough for a true selva (rain forest). The Llanos suffer severely from drought from about January to April, and then suffer equally from flooding of the whole countryside from June to October.

Hydrology. The river basin, as a geomorphological feature, dates from the Quaternary Period (from 2,500,000 years ago to the present). The enormous quantities of material produced by highlands are carried down by torrential rains to the rivers. The rivers, unable to hold the excessive material, overflow or break their banks, producing periodic floods that submerge the lowlands.

The drainage pattern

Under these conditions, drainage presents an unstable and indefinite pattern, marked by the shifting of rivers, lagoons, and swamps over the lower lands. The Orinoco Delta is rapidly extending into the ocean, but the tremendous amounts of sediment that accumulate are accelerating the subsidence occurring in the entire delta region.

Wide fluctuations in the river's flow reflect the seasonal rainfall regime. During the dry season or "low-water" period from October to March, the average river depth is about 49 feet in the lower basin near Ciudad Bolívar. The rise of the Orinoco begins with manifest regularity in April at the beginning of the rainy season. The "high water" period from April to October reaches its maximum in July. The depth of the river at this period is about 165 feet at Ciudad Bolívar. From June to August the lowlands of the basin are flooded and in some places are 65 feet under water. At the end of August the waters gradually recede and reach their lowest point in October.

Vegetation. The Llanos are grass-covered plains with isolated stands of palms and chaparro (scrub oak). The tributary streams that cross the plains have deposited alluvial soils, and strips of forests line their banks. Some of this natural tree cover, however, has been reduced by deforestation. The Guiana Highlands are covered with high, dense forest that is interrupted by small patches of savanna (grassy parklands). The tropical rain forest of the Upper Orinoco Valley contains hundreds of species of trees. Rain forest also covers the delta region.

Animal life. More than a thousand species of birds frequent the Orinoco region; among the more spectacular are the scarlet ibis, the bell bird, the umbrella bird, and numerous parrots. The numerous fish include the voracious caribe (piranha) and the *laulao*, a catfish that often weighs more than 200 pounds. The Orinoco crocodile is the longest of its kind in the world, reaching a length of more than 20 feet. The array, or side-necked turtle, which grows to a shell-length of about 30 inches, nests on the sandy islands of the river.

The human imprint. *The population.* Except for the Guajiros of Lake Maracaibo, all of the Venezuelan aboriginal population lives within the Orinoco Basin. The most important indigenous groups include the Guaicas (Waicas), also known as the Guaharibos, and the Maquiritares (Makiritares) of the southern uplands, the Guarauno (Warrau) of the delta region, and the Guahibos and the Yaruros of the western Llanos. These peoples live in intimate relationship with the rivers of the basin, using them as a source of food as well as for purposes of communication.

Indigenous peoples of the basin

The important towns, with the exception of Ciudad Bolívar, are built on high ground to avoid recurrent flooding. Town plans reflect Spanish influence: streets are arranged in a chequered pattern with a central plaza. Most of the original colonial buildings have vanished, although some old homes still remain. In the small villages, thatched huts are the usual dwellings.

History of exploration. European exploration of the Orinoco River Basin began in the 16th century. A series of expeditions sponsored by the banking house of Welser of Augsburg penetrated the Llanos southward across the Apure and Meta rivers. From the east, several Spanish expeditions ascended the river from its mouth without much success. In 1531 the Spanish explorer Diego de Ordaz voyaged up the river, and that same year another Spanish explorer, Antonio de Berrio, descended the Casanare and Meta rivers and then descended the Orinoco to its mouth.

In 1744 Jesuit missionaries discovered the Brazo Casiquiare. Alexander von Humboldt, the German naturalist, travelled over 1,700 miles of the river basin in 1800. By 1860 steamships were navigating the Orinoco. The source of the river remained in dispute, however, until a Venezuelan expedition finally identified it in 1951.

Navigation and river crossings. The Orinoco and its tributaries have long served as vast waterways for the indigenous inhabitants of the Venezuelan interior. Especially during the floods of the rainy season, the canoe with outboard motors is the only means of communication throughout large areas of the river basin. Large river steamers travel upriver for about 700 miles from the delta to the Raudal de Atures. Dredging has allowed large oceangoing vessels to navigate the Orinoco from its mouth to its confluence with the Río Caroní—a distance of 226 miles—in order to tap the iron-ore deposits of the Guiana Highlands. The Llanos and the Guiana region were connected in 1967 with the completion of the 5,507-foot bridge across the Orinoco at Ciudad Bolívar. In 1961, the Venezuelan government bridged the mouth of the Río Caroní to connect the new industrial town of Puerto Ordaz with the old Orinoco port of San Félix, thereby creating the urban unit of Ciudad Guayana.

Economic development. The Guiana Highlands are rich in mineral deposits. Iron ore, which is more than 60 percent pure, is mined at Cerro Bolívar and El Pao. Numerous other mountain deposits constitute proved reserves totalling about 1,567,000,000 tons.

Other minerals include deposits of manganese, nickel, vanadium (a metallic element used to form alloys), and chrome. There are also deposits of gold and diamonds. Petroleum and natural gas are exploited in the northern and northwestern parts of the basin.

The Saltos del Caroní has the largest hydroelectric potential in South America, amounting to 10,000,000 kilowatts. A vast project to tap this power source includes the Macagua Dam, in use since 1960, and the Guri Dam, planned as one of the world's largest hydroelectric plants, with a capacity of 6,000,000 kilowatts.

The Llanos, along the great bend of the Orinoco, have long formed one of Venezuela's major cattle-raising areas. Seasonal subsistence farming is carried out along the river from the confluence with the Apure to Ciudad Bolívar. West of the Apure junction, cotton is grown on a commercial scale. Land reclamation and flood control projects in the delta region are planned in order to open vast agricultural lands.

The Ciudad Guayana complex

Industrial development of the river basin is concentrated at Ciudad Guayana. The semi-autonomous government body Corporación Venezolana de Guayana (Venezuelan Guiana Corporation) is conducting a careful development plan based on the resources of the nearby Guiana Highlands and the Río Caroní. The dams at Saltos del Caroní supply power for industry, including a steel mill, an aluminum plant, and a paper factory. Power is also supplied by natural gas, which is piped from the oil fields north of the Orinoco River. There are plans for a timber and furniture industry, as well as for other industries that would make use of electrochemical processes.

(Me.F.G.)

Orissa

Orissa, a state of the Indian Union, is situated in eastern India. It is bounded by the Bay of Bengal in the southeast; by West Bengal in the northeast; by Bihār in the north; by Madhya Pradesh in the west; and by Andhra Pradesh in the south. Its area of 60,178 square miles (155,860 square kilometres) and population of about 22,000,000 (1971), represent about 5 percent of the area and about 4 percent of the population of India, respectively. Many people speaking Oriya (the language of Orissa) also live in the adjoining areas of neighbouring states. Before India became independent in 1947 Orissa's capital was at Cuttack. The present capital was subsequently built at Bhubaneswar, in the vicinity of its historic temples.

The land corresponding roughly with modern Orissa, but at times much larger in area, passed under the names of Utkala, Kaliṅga, and Oḍra Deśa in ancient and medieval times. In origin, these names were associated with peoples. The Okkalā or Utkala, the Kaliṅgā, and the Oḍra or Oḍḍakā were mentioned in literature as tribes. Ancient Greeks knew the latter two as Kalingai and Oretes. Ultimately the names became identified with territories. For centuries before and after the birth of Christ, Kaliṅga was a formidable political power, extending from the Ganges River to the Godāvari. The great war of the Indian emperor Aśoka (*c.* 265–238 BC) was called the Kaliṅga War; Khāravela's extensive empire (1st century BC) was known as the Kaliṅga Empire; and even the ancient Hindu colonies in Malaya and the East Indies were named Kaliṅga. Approximately between the 11th and 16th centuries the name fell into disuse; instead, the name Oḍra Deśa was gradually transformed into Uḍḍiśa, Uḍisā, or Oḍisā, which in English became Orissa. The language of Oḍisā came to be known as Oriya or Oria.

The British did not conquer the entire Oriya-speaking area at the same time; nor did they administer the whole area, when conquered (1803), as one unit. Consequently, there arose a demand for unification on a linguistic basis, and as a result Orissa was constituted a separate province on April 1, 1936. Even then 26 Oriya princely states remained outside the provincial administration, but after 1947 all those states, except Saraikela and Kharsāwān (which merged with Bihār), were included in Orissa. The Constitution of India (1950) recognized Orissa's statehood.

Linguistic basis of unification

History. At the dawn of Indian history Kaliṅga was already famous. Buddhist sources refer to the rule of King Brahmadatta in Kaliṅga at the time of Buddha's death. In the 4th century BC the first Indian empire builder, Mahāpadma Nanda, conquered Kaliṅga, but the Nanda rule was short-lived. In 261 BC Aśoka invaded Kaliṅga and fought one of the greatest wars of ancient history. He then renounced war, became a Buddhist, and preached peace and nonviolence in and outside India. In the 1st century BC the Kaliṅga emperor Khāravela conquered vast territories. In the early centuries of the Christian Era Kaliṅga was a maritime power. Its overseas activities culminated in the 8th century AD with the establishment of the Śailendra Empire in Java. During the 8th, 9th, and 10th centuries Orissa was ruled by the powerful Bhauma-Kara dynasty, and in the 10th and 11th centuries by the Soma dynasty. The Temple of Liṅgarāja at Bhubaneswar, the greatest Śaiva monument of India, was begun by the Soma King Yayāti.

The Gaṅga dynasty

Medieval Orissa enjoyed a golden age under the Gaṅga dynasty. Its founder, Anantavarma Cōḍagaṅgadeva (1078–1147), ruled from the Ganges to the Godāvari with Cuttack as his capital. He began the construction of the Temple of Jagannātha (Lord of the Universe) at Puri. Narasiṃhadeva I (1238–1264) built the Sun Temple of Konārak, widely acknowledged as the finest specimen of Hindu architecture. In the 13th and 14th centuries, when the whole of India was overrun by the Muslims, independent Orissa remained a citadel of Hindu religion, philosophy, art, and architecture. The Gaṅgas were succeeded by the Sūrya dynasty. Its first king, Kapilendradeva (1435–1466), won territories from his Muslim neighbours and greatly expanded the Orissan kingdom. His successor, Puruṣottamdeva, maintained these gains with difficulty. The next and the last Sūrya king, Pratāprudradeva, became a disciple of Caitanya, the great medieval saint, and became a pacifist. After his death (1540) Orissa declined, and 1568, when King Mukundadeva was killed by his own countrymen, Orissa lost its independence to the Afghān rulers of Bengal.

The Mughal emperor Akbar conquered Orissa from the Afghāns. When the Mughal Empire fell, part of Orissa remained under the Bengal Nawabs, but the greater part passed to the Marāthās. The Bengal sector came under British rule in 1757 after the Battle of Plassey; The Marāthā sector was conquered by the British in 1803. Meanwhile, the inaccessible areas of Orissa remained under princely rulers. Orissa assumed its present form with the inclusion of the princely states after 1947.

The landscape. Physiographically, Orissa is of a heterogeneous character. Its geological formations vary from the oldest rocks of the Earth's crust in the stable landmass of the Indian Peninsula to deltaic alluvium or littoral deposits and ridges of windblown sand on the seaboard.

The four geographic regions

Broadly, the state can be divided into four natural divisions: (1) the Northern Plateau, (2) the Eastern Ghāts, (3) the Central Tract, and (4) the Coastal Plains. The Northern Plateau is an extension of the Chota Nāgpur plateau covering the Mayūrbhanj, Keonjhar, and eastern Sundargarh areas. The upper reaches of the rivers Subarnarekha, Baitarani, and Brāhmani lie in the area. Its central portion contains many small hills and forests. The Eastern Ghāts form an undulating plateau that extends over Koraput, parts of Kalāhāndi, Phulbāni, and Ganjām. The Central Tract covers the districts of Sambalpur, Bolāngir, and Dhenkānāl, and parts of Kalāhāndi, Sundargarh, and Phulbāni. The rivers Mahānadi, Brāhmani, and Baitarani and their tributaries flow through the area. The landscape consists of a succession of plateaus, hills, uplands, and valleys. The coastal plains comprise the Balasore, Cuttack, and Puri districts, and parts of Ganjam. This fertile area runs parallel to the coast and contains the river deltas; it is formed of alluvium and silt.

The main rivers are the Subarnarekhā, Burābalang, Baitarani, Brāhmani, Mahānadi, Rushikulya, and Vansadhara. Notable mountain ranges are the Mahendra Giri (rising to 5,000 feet), the Malyagiri (3,896 feet), and the Meghasana (3,823 feet). Orissa's Chilka Lake is the biggest saltwater lagoon in India.

Climate. Orissa is situated in the hot climatic belt where the monsoon winds blow. The main seasons are summer from mid-February to June, the rainy season from July to October, and winter from November to mid-February. Places in Sambalpur and Mayūrbhanj districts have an extreme climate, whereas in places like Puri and Gopālpur the climate is equable. The average rainfall is about 60 inches.

Vegetation. The vegetation is of a tropophilous character—that is to say it is able to adapt itself to a rapidly

changing environment. Forests cover about 40 percent of the total land area. In forest wealth, Orissa occupies the third place in India. The forests are of three broad types: northern tropical semievergreen; northern tropical moist deciduous; and northern tropical dry deciduous. The first group includes the mango; the second group includes, for example, teak; while the third includes bamboo.

Animal life. Orissa has the same animal life as the rest of peninsular India. Monkeys are common. Carnivores include different types of tigers. The elephant, the wild buffalo, the blackbuck, and the four-horned antelope are found in some districts. The peafowl is one of the features of the Orissa forests. Lake Chilka is noted for its marine fauna.

Population. The population includes the Australoid, the Alpinoid, and the Mediterranean racial groups. The Australoids are represented mainly by the Saora, Santāl, Khond, Gond, Munda, Ho, Juang, Gadaba, Bhuiyan, Koya, and Oraon tribes. These tribes are divided into three linguistic groups: the Munda-speaking (the Santāl, Saora, Juang, and others); the Dravidian-speaking (the Khond, Gond, Oraon, and others); and the Oriya-speaking (the Bhuiyan, and others). Most tribes live in the hill areas, but they are also found in the plains. The Alpinoid and Mediterranean groups are represented among the nontribal population, which is mainly Oriya-speaking and Hindu.

The tribes have for a long time been going through the process of Hinduization. Tribal chieftains have claimed Kṣatriya (warrior) status, while many of the Khonds, who constitute the largest tribe, have abandoned their Kui language (Dravidian) and speak Oriya. Many tribes are bilingual. Some have become almost indistinguishable from the Hindus and have lost their original language. The Oriya language does not vary in its written form, but it differs in the spoken form from place to place. The purest Oriya is spoken in the Cuttack and Puri districts. The Balasore, Sambalpur, and Ganjam districts have distinct local accents.

The caste structure

More than 97 percent of the people are Hindus. The caste structure is the same as in other states of eastern India, with some regional variations. Next to the Brahmins are the Karaṇas (the writer class), who claim Kṣatriya status (with the pen as their weapon rather than the sword). The Khandayats (literally, "swordsmen") are mostly cultivators but call themselves "Khandayat-Kṣatriyas." All castes look to Jagannātha (one of the forms of the Hindu god Viṣṇu) as the centre of their religious faith. For centuries Puri, the abode of Jagannātha, has been the only place in India where all castes, including the so-called untouchables, eat together.

Orissa has a predominantly rural population. In 1971, only 9 percent of its people lived in towns. The building of the new capital at Bhubaneswar, of a steel town at Raurkela, of a port at Paradip, of a dam at Hirākud, and of a power-generating station at Tālcher have necessitated new urban settlements, and a number of industrial towns are under construction. There were 79 towns including four cities—Cuttack, Raurkela, Bhubaneswar, and Berhampur—in 1971, and the number of villages exceeded 46,000

Administration. The head of the state is a governor appointed by the president of India. The actual administration is conducted by a council of ministers, headed by a chief minister and responsible to the elected legislature, which consists of only one chamber of 140 members elected at intervals of not more than five years through universal adult suffrage.

The districts of Orissa

There are 13 districts: Bālāsore, Bolāngir, Cuttack, Dhenkānāl, Ganjām, Kalāhāndi, Keonjhar, Koraput, Mayūrbhanj, Phulbāni, Puri, Sambalpur, and Sundargarh—grouped into three revenue divisions, each under a divisional commissioner. A board of revenue is in charge of revenue administration. The district administration is conducted by a deputy commissioner who is also the district magistrate. Each district has a superintendent of police. The districts are divided into *tahsils*, each having a *tahsildar* as its revenue officer. *Tahsils* comprise groups of villages, administered by *pañcāyats* (village committees), to which villagers elect their representatives. A *sarpañc* (elected president) heads the *pañcāyat*. The system represents a democratic decentralization of power for the benefit of the rural population. The towns are administered by municipalities.

Social conditions. *Health.* At one time the coastal belt was highly malarious and the whole state was subject to epidemics of cholera and smallpox. The incidence of filariasis (a disease caused by the presence of filarial worms in the blood and glands), leprosy, and tuberculosis was high. The high rate of mortality even led to a decrease of population in certain places. During the first three Indian five-year plans (1951–66) much attention was paid to health services, and excellent results were achieved by various programs.

By 1971, rural Orissa possessed 314 primary health centres; the number of hospitals and dispensaries had increased; and the three medical colleges, at Cuttack Berhampur, and Burla, had expanded considerably. For an estimated 22,000,000 population in 1970, the number of doctors in government service was 1,550, and the number of registered doctors about 3,400.

Education. The number of educational institutions increased considerably after 1947. In 1970 there were four universities and 73 colleges for general education, with an enrollment of 33,000 students; 5,200 secondary schools with 451,000 students; and 26,208 primary schools with 1,898,000 students. About 26 percent of the population was literate in 1971.

Welfare. Orissa has a Tribal Welfare Department. Schemes have been devised to promote the educational, cultural, economic, and social advancement of the tribes. The state Social Welfare Advisory Board, instituted in 1954, cares for the welfare of women and children through courses of instruction, urban-welfare-extension projects, and holiday camps for children.

Economy. About 80 percent of the rural population depends on agriculture, even though some areas are unproductive and some others are unsuitable for more than a single annual crop. The nonagricultural classes live by handicrafts, by trade, and by the rendering of services. About 6 percent of the rural families depend on village or cottage industries, including weaving.

More than 15 percent of the agricultural families engage in nonagricultural pursuits by way of subsidiary employment. Whatever their occupation, most rural people do not get continuous employment the year around. The amount of agricultural land available per person has been declining because of the growth of population. The per capita area under cultivation was only 0.83 acres in 1950. By 1970, it was further reduced, and consequently the search for new lands for cultivation, the partial abolition of large landholdings, and the distribution of available land among landless families became acute problems for the government.

Mineral deposits

The industrial resources of Orissa are considerable. As most mineral deposits are in the former feudatory states, their exploitation began only after 1947. In the early 1970s Orissa was ahead of all other Indian states in the production and export of iron ore and chromite and took second place in the production of manganese. It was producing annually nearly 4,000,000 tons of iron ore, 350,000 tons of manganese ore, 90,000 tons of chromite, 850,000 tons of coal, and more than 2,200,000 tons of limestone and dolomite. It also had rich deposits of graphite and bauxite. The reserves of Orissa iron ore were estimated at 5,900,000,000 tons, while an additional 4,000,000,000 tons also probably existed.

Large-scale industries in the early 1970s included: a steel plant at Raurkela with an annual production capacity of 1,000,000 tons of ingots; a ferromanganese plant at Joda in Keonjhar, with a capacity of 30,000 tons; a ferromanganese plant at Rāyagada (capacity 12,000 tons); a refractory at Rajgāngpur (capacity 80,000 tons); another refractory at Belpahar (capacity 124,000 tons); a tube works at Chowdwar (capacity 36,000 tons); a low-shaft furnace at Barbil, Keonjhar, and Chowdwar (capacity 100 tons per day each), for production of pig iron and ferroalloys; a cement factory at Rajgāngpur (capacity

725,000 tons); and an aluminum smelter at Hīrākud (capacity 10,000 tons).

Other industries included: paper mills at Brajrajnagar Chowdwar, and Singhpur; a fertilizer plant at Raurkela; a socket-manufacturing plant at Cuttack; a textile mill at Chowdwar; sugar factories at Rayagada and Aska; a chlorine and caustic soda factory at Brajrajnagar; and a glass and ceramic factory at Bārang. The Hīrākud dam project for the supply of electric power envisages an ultimate effective capacity of 200,000 kilowatts. The Machkund hydroelectric system is another source of power.

Transportation and communications. Communication facilities were undeveloped before 1947, but the merger of the feudatory states with Orissa and the discovery of mineral resources necessitated the construction of a network of good roads. During the five-year plans, bold construction programs were undertaken and bridges were built over most of the major rivers, but the state still lacks adequate railway communications. It has only 14 miles of rail track for every 1,000 square miles, against an all-India average of 33.

The port of Paradip

An all-weather, sheltered, deep-draft port has been constructed at Paradip at the mouth of Mahānadi River, whence it is intended to export annually 5,000,000 tons of iron ore. The port has an extensive hinterland with mineral deposits and a developing industrial belt.

Cultural life. Orissa has a rich artistic heritage and has produced some of the best examples of Indian art and architecture. Artistic traditions are maintained through mural paintings, stone carving, wood carving, icon paintings (known as *patta* paintings), and paintings on palm leaves. Handicraft workers are famous for their exquisite silver filigree ornamentation and decorative work.

In tribal areas Orissa has a wide variety of folk dances. The music of the *madal* and flute is common in the countryside. The classical dance of Orissa, known as the *orissi* dance, has survived for more than 700 years. Originally it was a temple dance, performed before gods. The modes, movements, gestures, and poses of the dance are depicted on the walls of the great temples, especially at Konārak, in the form of sculpture and in relief carvings. Modern exponents of the dance have made it popular outside the state. The *chhau* dance (performed by groups of masked dancers) of Mayūrbhanj and Saraikela regions is another feature of Oriya culture. For the promotion of dancing and music, the Kala Vikash Kendra centre was founded at Cuttack in 1952 with a six-year teaching course. The National Music Association serves a similar purpose. Other notable dance and music centres in Cuttack are the Utkal Sangit Samaj, the Utkal Smruti Kala Mandapa, and the Mukti Kala Mandir.

The Boita-Bandana ceremony

There are many traditional festivals. A unique festival is the ceremony of Boita-Bandana (worshipping of ships). In October–November for five consecutive days before the full moon, people gather near riverbanks or the seashore and float miniature boats, as a symbolic gesture that they will leave for the faraway lands (Malaysia and the East Indies) to which their ancestors once sailed. The greatest religious festival of Orissa is the Car Festival of Jagannātha at Puri, which attracts hundreds of thousands of people from all parts of India.

(1965), which contain detailed statistics relating to economic conditions, agriculture, administration, and education; and the *Techno-Economic Survey of Orissa* (1961), a publication of the government of India that includes socio-economic data.

(M.N.D.)

Orozco, José Clemente

Considered by many to have been the pre-eminent artist of modern Mexico, José Clemente Orozco was also one of the most powerful modern exponents of public-scale art. He helped found the mural movement in 20th-century Mexico and used that form of painting as an instrument of his social conscience. Orozco's art constituted a rare combination of intense, personal expressionism with simplified synthetic forms. His artistic style, as well as his aesthetic philosophy, influenced many artists of the Americas throughout the second quarter of the 20th century.

"Self-Portrait," tempera on cardboard, by Orozco, 1940. In the Museum of Modern Art, New York.
By courtesy of the Museum of Modern Art, New York

Early life and training. Orozco was born on November 23, 1883, in Ciudad Guzmán, also known as Zapotlán el Grande, in the state of Jalisco, Mexico. Believing themselves to be descendants of leading *conquistadores* of western Mexico, his family was prominent in Jalisco. Orozco first became obsessed with art in 1890, when his family moved to Mexico City. Going to and from school each day, he paused in the open workshop of José Guadalupe Posada, Mexico's first great printmaker, whose grotesque caricatures and illustrations appeared in sensational news sheets devoted to reporting lurid crimes and political scandals. Orozco was captivated by Posada's strong images and vivid style and for the rest of his life acknowledged the early influence of the master engraver.

Orozco's prodigious skill was immediately recognized, and he began night classes in drawing at the Academia de San Carlos. The future social critic tolerated no censure of his work, and his mother frequently had to defend him against charges of sacrilege and anticlericism. Toward the end of the decade, his pursuit of art was interrupted when he was forced to study for careers as an agronomist and, later, as an architectural draftsman. When he was 17, however, he lost his left hand in a laboratory accident, and he abandoned his architectural studies for painting. He re-entered the Academia de San Carlos in 1905 with a renewed passion for painting and set about assiduously to become a competent painter. Unlike many of his fellow students, he enjoyed the academy's rigorous discipline, which demanded that students draw a model repeatedly from the same view until a drawing was produced realistic enough to be favourably compared to a photograph of the subject.

Influence of Gerardo Murillo

More important to the ultimate meaning of Orozco's art was his acquaintance with a radical student named Gerardo Murillo. Violently opposed to the cultural anti-Mexicanism in vogue, Murillo assumed the Aztec name of Doctor Atl and urged artists to reject the cultural domination of Europe and to cultivate in their work Mexican traits. Accordingly, Orozco began conscientiously to explore Mexican themes and to draw more directly from scenes of daily life. In 1910 Orozco and other young artists working with Atl organized Mexico's first exhibition of Mexican artists, and the same year they formed an association called the Artistic Centre, which proposed to get permission to paint murals on the walls of government buildings. The organization was dissolved the same year, however, after disorders of the Madero Revolt made large-scale artistic activity impossible. With

the academy closed by student strikes, Orozco became a caricaturist for an opposition paper and haunted the barrios, or slums, of Mexico City, painting a series of watercolours dealing with the lives of prostitutes. The series, collectively titled "House of Tears," showed the mordant colours of his early Expressionist style and marked his initial use of the prostitute as a symbol of human degradation. When the academy reopened, it was dominated by would-be Impressionists, and Orozco left in disgust to continue developing his own style.

Again, in 1914, civil war broke out in Mexico. Orozco did not take an active part in the fighting but supported the forces of Gen. Venustiano Carranza as a satirical artist on the revolutionary paper *La Vanguardia* ("The Vanguard"), which was edited by Atl. Though a noncombatant, Orozco witnessed all the bestiality and excess that accompanies war, an experience that indelibly stamped his mind and art.

Mature work and later years. In 1917 the reaction of critics and moralists to the exhibition of his "House of Tears" paintings forced Orozco to leave Mexico for the United States, where he lived for several unhappy years in San Francisco and New York City. On his return to Mexico in 1920, he found the new government of Pres. Alvaro Obregón eager to sponsor his work, and, along with his colleagues Diego Rivera, David Alfaro Siqueiros, and others, he was commissioned to paint murals on the walls of the Escuela Nacional Preparatoria, initiating the so-called Mexican muralist movement. Orozco's early (1923–27) murals there, such as "Maternity" and "Christ Destroying His Cross," were derivative, and Orozco himself destroyed many of them. Those dating from 1926 however, show him coming into his own style, achieving in such works as "Cortés and Malinche" and "The Trench" (both in the Escuela Nacional Preparatoria) a monumentality unprecedented in Mexican art.

In 1927 government patronage and protection were withdrawn from Orozco and his fellow muralists, and the subsequent attacks of critics and moralists or conservatives again forced him to flee to the United States. Humiliated in his own country, he consciously strove, after settling in New York City, to forge an international reputation that would force his countrymen to recognize his value as an artist. By frequenting the salon of a prominent Manhattan art patron (whose circle included the poet Khalil Gibran), he slowly became known in American art circles and finally was commissioned in 1930 to paint a major mural in the refectory of Pomona College, Claremont, California. In choosing to do a mural of Prometheus, Orozco temporarily abandoned social criticism and historical subjects in favour of a more universal theme: the self-sacrificing titan from ancient Greek mythology, bringing man fire, which enlightens, liberates, and purifies but also consumes. Orozco also turned away from the relative stylistic repose of the Escuela Nacional Preparatoria murals. Recalling Atl's drawings and enthusiastic descriptions of the tortured figures in Michelangelo's "Last Judgment" in the Sistine Chapel, he portrayed Prometheus as a monumental pseudo-Michelangelesque giant, straining his powerful muscles against the burden of his fate. By contrast, his murals at the New School for Social Research in New York City, dealing with the themes of universal brotherhood and social revolution, suffer by the slavish use of "dynamic symmetry," a theory fashionable in the 1920s, which purported to represent the ancient Greek system of proportions.

Work in the United States

In 1932 Orozco made a brief trip to Europe, where he viewed the art of England, France, Spain, and Italy. Although he was impressed with the paintings of Picasso, his even deeper admiration of the Byzantine mosaics of Rome and Ravenna is reflected in his great series of murals at Dartmouth College, Hanover, New Hampshire. Just as the Byzantine mosaics illustrate the Christian concept of history, Orozco illustrated his world view in a vast scheme divided into two series of murals correlated to the two main scenes, "The Coming of Quetzalcoatl" and "The Return of Quetzalcoatl." This dichotomy contrasted the stages of man's progression from a primeval, non-Christian paradise to a Christian, capitalist hell. Byzantine mosaics also clearly influenced the pictorial style of "Modern Migration of the Spirit," but such scenes as "Stillborn Education" and the Quetzalcoatl murals achieve unique levels, respectively, of grotesqueness and of sweeping force.

Return to Mexico

His art enriched and matured and his reputation firmly established, in 1934 Orozco returned triumphantly to Mexico, where he completed the illustration of his view of history in the mural "Catharsis." This eschatological work displayed a laughing prostitute lying among the debris of civilization's last cataclysm, showing the constantly increasing pessimism that culminated in his Guadalajara murals. Murals painted in the lecture hall of the Universidad de Guadalajara, the Palacio de Gobierno (1937), and the chapel of the orphanage of Hospicio Cabañas (1938–39) recapitulate the historical themes developed at Dartmouth and in "Catharsis" but with an intensity of anguish and despair he never again attempted. Here, history is blindly careening toward Armageddon. The only hope for salvation is the self-sacrificing creative man, the "Man of Fire," painted in the Hospicio dome.

Orozco's subsequent murals, such as those in the Gabino Ortíz Library, in the Palacio de Justicia, and in his last great work, "National Allegory" (1947–48; Escuela Normal, Mexico City), neglect universal themes and dwell almost exclusively on nationalism. Canvases such as "Metaphysical Landscape" (1948; estate of Orozco, Mexico City), however, hint at a growing mysticism, and its abstract style indicates that Orozco may have been on the brink of nonfigurative painting when he died. His easel paintings, such as "Zapatistas" (1931; Museum of Modern Art, New York City), often attain the grandeur of his murals, which remain his definitive vehicles of expression, the touchstones of his genius.

Orozco, whose childhood and youth were filled with struggle and persecution, became a national hero in his later years, honoured as the leader among those who raised Mexican art to a position of international eminence. In 1947 the President of the Republic of Mexico awarded him a prize as the outstanding Mexican figure in the arts and sciences during the preceding five years. He died September 7, 1949.

MAJOR WORKS

Murals (1923–27; Escuela Nacional Preparatoria, Mexico City); murals (1926; Casa de los Azulejos, Mexico City); murals (1926; Escuela Industrial, Orizaba, Mexico); murals (1930; Pomona College, Claremont, California); murals (1930–31; New School for Social Research, New York); murals (1932–34; Dartmouth College, Hanover, New Hampshire); mural, "Catharsis" (1934; Palacio de Bellas Artes, Mexico City); murals (1936–39; Universidad de Guadalajara, Palacio de Gobierno, Hospicio Cabañas); murals (1940; Gabino Ortíz Library, Jiquilpan, Mexico); fresco panels, "Dive Bomber and Tank" (1940; Museum of Modern Art, New York); murals (1941; Palacio de Justicia, Mexico City); murals (1942–44; Hospital de Jesús Nazareno, Mexico City); murals (1947; Escuela Normal, Mexico City); mural (1948; "Juárez" Museo Nacional de Historia, Mexico City); murals (1949; Cámara Legislativa, Guadalajara, Mexico).

BIBLIOGRAPHY. JOSE CLEMENTE OROZCO, *Autobiografía* (1945; Eng. trans., 1962), essential to an understanding of Orozco; JUSTINO FERNANDEZ, *José Clemente Orozco: forma e idea* (1942), especially important for its insights into Orozco's art and aesthetic; MACKINELY HELM, *Man of Fire: J.C. Orozco* (1953, reprinted 1971), the earliest major work in English—still considered a classic; ALMA REED, *Orozco* (1956), a biographical account written by an American who had known the artist for many years.

(Ed.)

Orthopteran

Orthopteran has come to be regarded as a common name for several related groups of insects that exhibit considerable morphological, physiological, and paleontological diversity. Although sometimes these insects are combined into the order Orthoptera, generally, several orders are implied in the term orthopteran. Among the orthopterans, cockroaches and mantids are placed in the order Dictyoptera; the grylloblattids (order Grylloblattodea) and walking sticks (order Phasmida) are given ordinal

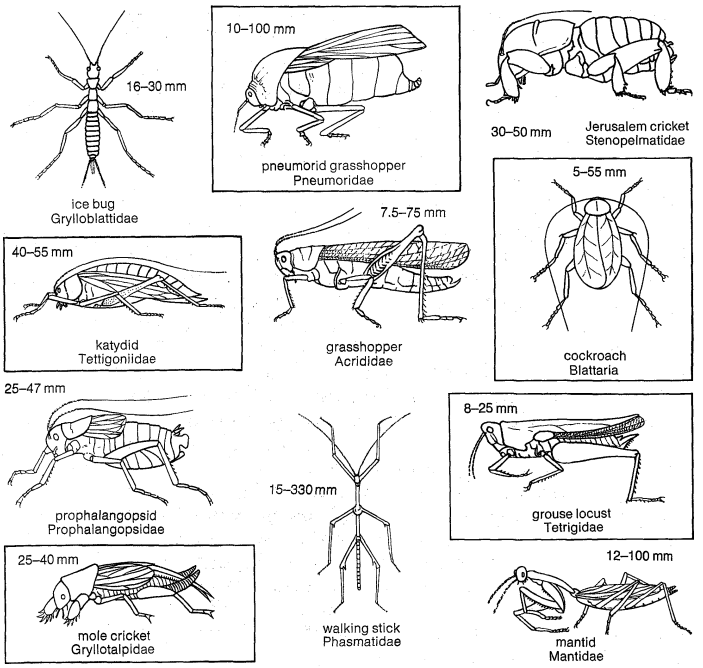


Figure 1: Diversity among orthopterans.

rank also. On the other hand, members of the suborders Ensifera (katydids, crickets, and camel crickets) and Caelifera (pygmy sand crickets, grasshoppers, and locusts) are considered to comprise the order Orthoptera. For completeness of discussion, all of these groups, handled here as four separate orders, are included in this article.

Orthopterans, abundant in tropical regions throughout the world in both numbers of species and individuals, are common in the summer months in temperate regions, when their relatively large size and chirping sounds attract considerable attention. Zoologists have long been interested in cockroaches, one of the oldest insect groups known. Most of the 24,000 species of orthopterans are plant feeders, with mouthparts adapted for chewing. Locusts, known as pests since biblical times, are very destructive to agricultural products.

GENERAL FEATURES

Orthopterans may be bizarre in appearance, unusually large in size, or show peculiar behaviour. They range in size from a few millimetres to more than 30 centimetres. Some tropical walking sticks resembling tree twigs are more than 30 centimetres long, and others, much smaller, resemble leaves of plants. The size range of present-day cockroaches is typical of the diversity of body size among orthopterans: tiny flightless cockroaches (*Attaphila*), living as commensals in the nests of ants, are only two millimetres long when mature, whereas a species of *Megaloblatta* found in South America reaches 10 centimetres in length with a wing span of almost 19 centimetres.

Distribution and abundance

Approximately 24,000 species of orthopterans have been identified. Throughout the U.S. there are about 1,300 species; not all of them inhabit any one place. There are more species (*e.g.*, 282 in Arizona) in southern and southwestern sections of the U.S. than in the North (*e.g.*, 103 in all the New England states). Of the 600 species found in Europe, Great Britain has only 35, including four established, introduced species (adventives).

The largest families of orthopterans are worldwide in range, although all have decreased numbers of species in cold temperate zones. Few mantids or walking sticks, for example, occur outside tropical or subtropical areas. There are about 20 mantid species and 27 walking stick species in the southern U.S., compared with 400 mantid species and 600 walking stick species in Central and South America. A few northern groups include the gryllobla ttids and several genera of grasshoppers.

Importance. Among the orthopterans are many species that are either harmful to agricultural products or are pests. Grasshoppers are capable of causing widespread devastation of the agricultural crops grown in many countries throughout the world. In cattle-growing regions there often is competition between grasshoppers and livestock for available forage. Mormon crickets (a common name for species of the genus *Anabrus* that originated during the early years of the Mormon settlement in Utah) are major pests of both crops and open rangeland in the western part of the U.S. during seasons that are favourable for their development. Cockroaches, known throughout the world as domestic pests, are a frequent nuisance, especially in warm-temperate to tropical areas. Although cockroaches occasionally carry organisms such as bacteria or parasites that produce intestinal diseases, they are more generally considered to be mechanical carriers of contaminating filth.

Mantids, predators on other insects, have become adapted to resemble the flowers, tree trunks, or grass stems on which they await their prey. Crickets, katydids, and grasshoppers are known for the songs they produce using stridulatory mechanisms, and research concerned with song production is an active field. The biology of migratory grasshoppers or locusts involves hormones that promote transformation of nonmigratory, solitary, shorthorned grasshoppers into gregarious hordes of locusts capable of causing great destruction. This transformation has been studied in attempts to control these pests.

NATURAL HISTORY

Life cycle. *General features.* Since orthopterans undergo simple metamorphosis and have externally developing wings, they are known as hemimetabolous insects. The grylloblattids are wingless, and all large orthopteran groups contain a few wingless species, even though the basic structure of the orthopteran thorax proves their relationship to winged insects. A typical orthopteran life cycle has three stages: egg, nymph, and adult. Usually eggs are deposited outside the body on the ground or on vegetation; however, in some cases (*e.g.*, viviparous cockroaches), eggs are incubated in a brood chamber within the body of the female, and nymphs are born alive. Nymphs resemble adults except for their smaller size and lack of development of reproductive organs and wings; there is no pupa, or resting stage. In most orthopteran groups, the hatching insect that wriggles from the egg is not a fully formed nymph with freely moving legs; actually it is little more than an active embryo and is still enclosed in a thin membrane. This stage is called a vermiform larva; shed-

Simple metamorphosis

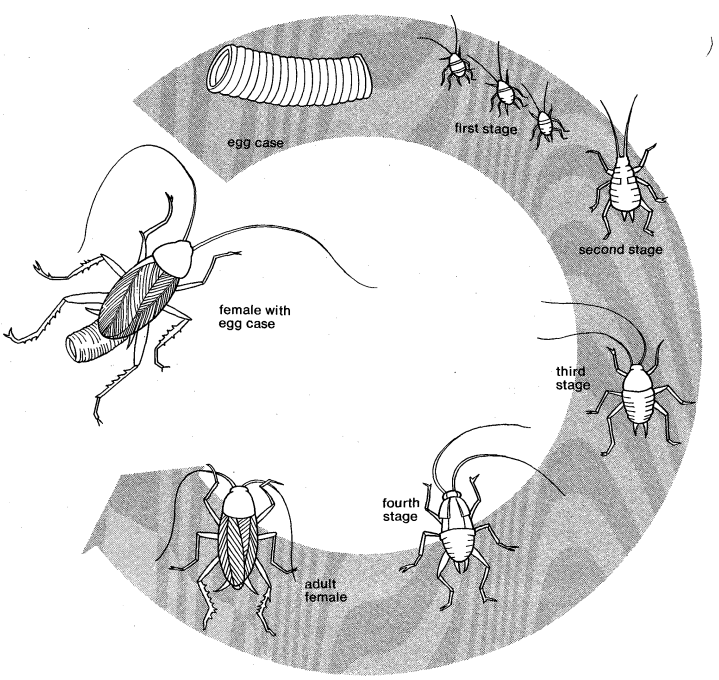

Figure 2: Orthopteran life cycle.
Courtesy of the U.S. Department of Agriculture

ding of the enclosing membrane occurs at the intermediate molt. The shapeless skins shed by young grasshoppers crawling from egg pods or by mantids leaving an egg case are examples of such exuviae (cast skins).

The number of nymphal stages between the intermediate molt and adulthood varies from about 4 to 13. Generalizations are approximately as follows: cockroaches, 5–13; mantids, 4–9; grylloblattids, about 8; crickets and katydids, 5–9; walking sticks, 4–6; and grasshoppers, 4–9, most often 5–7.

Egg cases

Egg laying. Egg-laying habits are distinctive in many orthopteran species. Among cockroaches, only one family (Blaberidae) is viviparous; the other four families contain species that have well formed egg cases (oothecae). Among these families, some species carry the oothecae protruding from the body until hatching time is near; others, however, deposit their egg cases within several days of formation. Usually oothecae contain from a few to more than 30 eggs arranged in two rows. Along one edge of the ootheca is a seam that bears a keel, or ridge; the shape of the ridge varies in species that carry the ootheca externally. Minute openings from the base of the keel to the interior of the ootheca are known to be a ventilating device in some species. The ootheca is first carried in the body with the keel uppermost; in certain groups, however, it is rotated prior to deposition so that the keel is on one side. Details concerning positioning of the ootheca and other aspects of egg laying were not correlated with behaviour patterns or group affinities until a basis for understanding their significance was established.

Mantids lay eggs in clusters of less than ten to more than 300. Usually they are laid in regular layers surrounded by a viscous quick-drying liquid that provides a light but tough protective covering. The egg masses of most mantids have a distinctive shape and size. Although most mantid species attach oothecae to vegetation, these egg cases may be attached to rocks in some environments or placed in grooves in the sand and covered over in the desert.

Grylloblattid eggs are laid in damp moss, decaying logs, or in pockets between broken rocks and wet soil. The eggs, about 3 mm long and usually black in colour, are laid loosely or inserted into the hatching site with the ovipositor.

Of the walking stick species studied, most have eggs that look like small seeds and are dropped loosely on the ground. At least one species, however, attaches its eggs to foliage, and a large, heavily bodied species of the southeastern U.S. (*Anisomorpha buprestoides*) scratches a depression in sandy soil with its front and middle legs, deposits eggs in it, and covers them with sand.

Crickets and katydids utilize their ovipositors to insert eggs into soil or plant material. The eggs of tree crickets (*Oecanthus*), for example, are inserted in rows in the canes of blackberries and various other stems; the eggs of field crickets (*Gryllus*) are laid in soil; the flattened eggs of certain katydids (*Scudderia*) are forced between the upper and lower epidermis layers at the margin of tree leaves; and the eggs of other katydids (*Microcentrum*) are laid in overlapping rows lengthwise on twigs of trees.

Most grasshoppers lay their eggs in soil; a few drill holes in dead wood or place their eggs at the bases of grass clumps or on the surfaces of leaves. Before laying the eggs, the female manipulates the valves of her ovipositor to make a hole in suitable soil (the type varies with the species). During the digging process, the abdomen is greatly extended, and the female manipulates the ovipositor valves to open and close and rotate on the long axis. Then she deposits several dozen eggs in the hole. The eggs are surrounded by a mucilaginous mass (the egg pod) that dries in a cylindrical shape. The number of egg pods laid by one female and the number of eggs in each pod vary according to the species and local conditions. The egg pods are laid over an interval of several weeks.

Parthenogenesis

A few orthopteran species have females only; therefore, reproduction occurs without fertilization (parthenogenesis). Only rarely are species that normally reproduce bisexually parthenogenetic; and when parthenogenesis does occur in bisexual species, it is usually only partially successful because the few nymphs that do hatch often are deformed and fail to reach maturity. In the laboratory, however, there have been a few cases in which several generations have been produced parthenogenetically, proving that there is an inherent capability in these bisexual groups for reproduction without males.

Growth and life span. Increases in the number of antennal segments occur during the development of some orthopterans. The German cockroach, *Blattella germanica*, has been studied in detail in this regard, and it has been shown that a newly hatched nymph has about 24 segments in each antenna. Each of the succeeding nymphal stages (there are usually six in this species) shows an increase in the number of segments until, by the time the adult stage is reached, the average number is 94. The two basal segments do not divide; the third segment, as well as certain other ones, is a growth centre that divides during molting. It is customary for grasshoppers to have 20–30 antennal segments when mature; this is about twice the number present in the first-stage nymph.

The life span of orthopterans depends in part upon whether or not there are long periods during winter or at other times (*e.g.*, a dry season) when the insects are quiescent. Some species habitually spend several months resting during unfavourable periods; such species have one generation per year, and the life span of an individual is approximately one year. The portion of the life span spent as an adult varies, but is likely to be about one or two months. In some species egg maturation is delayed several months after the final molt, and the females do not lay the eggs until they have matured. In other species eggs are not hatched until one or more years after they are laid; therefore, more than one winter or dry season is passed in the egg stage, and a single life cycle can occupy two or more full years. For instance, a walking stick commonly found in the U.S., *Diapheromera femorata*, often has some eggs that hatch the year following deposition and others that hatch after two winters have been passed amid dead leaves on the ground. There are some orthopterans that develop very slowly, and their life cycles require several years for completion; an example is a North American cockroach (*Cryptocercus punctulatus*) that inhabits rotting logs, feeds on decaying wood, and attains maturity after six or seven years. Grylloblattids live for five to seven years. The time required for domestic cockroaches to reach maturity varies with species and environmental conditions. The German cockroach completes nymphal growth in about 95 days, but the American cockroach (*Periplaneta americana*) needs about 225 days. Similarly, adults live from a month or two to several years, depending on conditions and species.

Reproduction. *General features.* Typically each female has paired ovaries consisting of tubes in which eggs develop, moving posteriorly into a single oviduct as they "ripen." The oviduct leads to a vagina and then to the exterior where there is either a simple or specialized ovipositor consisting of paired appendages called ovipositor valves. Attached to the oviduct or vagina is a sac (called the spermatheca) for storage of male sperm; as eggs move down the oviduct, they are fertilized by the sperm. The typical male contains paired testes that produce vast numbers of slender active sperm; these are stored in enlargements of the tubes leading posteriorly from the testes. Accessory gland secretions provide not only the medium for carrying the sperm but also a material that solidifies to form a thin-walled sac, or reservoir, containing some sperm and fluid. This reservoir, called the spermatophore, is almost universally found among orthopterans.

Spermatophores

Grasshopper spermatophores consist of a bladderlike reservoir and a spermatophore tube. The spermatophore is formed during the first two minutes or so of copulation, after which the tube extends from the male genital organs to the spermathecal duct of the female. The spermathecal duct opens at the base of the ovipositor valves. Sperm pass to the female during copulation; after sperm transfer is complete, parts of the spermatophore may remain attached to both male and female. In some orthopterans, particularly crickets and katydids, the entire spermatophore is attached to the female.

Courtship behaviour. All orthopteran groups have species that show definite courtship behaviour prior to actual mating. Male cockroaches are attracted particularly by females that are virgin and in a receptive condition. Such females frequently secrete pheromones. Pheromones, chemical substances secreted by certain insects, influence the behaviour of other individuals of the same species. Antennae of males of a domestic roach, *Periplaneta americana*, have specialized sense organs that detect the odour of female *P. americana* pheromones; upon detection of the odour, the male initiates searching movements, first with the antennae, then with the palpi. Finally, the male, with folded wings raised and fluttering, actively searches out the female. If the female is still receptive when he finds her, the male protrudes his posterior abdominal segments, pushes under the end of the female, and grasps the terminal ventral segments of the female with his genital hooks; then he expels the spermatophore, which becomes attached to the spermathecal opening of the female. The entire process lasts up to an hour.

Mating calls

Among the grasshoppers, species with coloured hind wings and the habit of making sounds during flight use hovering and other special flight patterns to attract the attention of females. Crickets and katydids have the most dramatic courtship displays because "songs" enter into the precopulatory behaviour. Females of some species are receptive only to the specific song of a male of the same species; in others, however, mating calls are not necessary, and a female will mate with a male who is unable to sing because his wings have been removed. Here, as in grasshoppers, a variety of mating positions are assumed.

A striking sequel to mating occurs frequently in mantids when the female eats the male. There is a popular opinion that mantid males always are eaten, but many escape under natural conditions. But in the close confines of a small cage cannibalism of the male is more common.

Ecology. In a broad sense, ecology represents the sum total of interrelations between organisms and their environment. In the case of orthopterans, the basic requirements of food and moisture; shelter, including protection from weather and from enemies; favourable habitats, involving special niches such as caves or deserts; as well as preferred seasons and conditions conducive to successful reproduction, are involved.

Food. Mantids are the only orthopteran group that feeds almost entirely on insects, but some members of primarily plant-feeding groups also capture and devour insects. For instance, tree crickets (*Oecanthus*) regularly eat flowers, leaves, and other plant parts, in addition to many aphids and other weak insects. Some katydids are active predators of insects. Most cockroaches are typical scavengers, but some are specialized feeders. *Cryptocercus*, for example, digests cellulose in decaying logs with the aid of symbiotic protozoans in its intestines. All walking sticks and a majority of grasshoppers are plant feeders. Although many grasshoppers feed on a wide variety of plant species, some are restricted to a single plant species or one group of plants. Some orthopterans consume only certain parts of plants; for example, coneheaded katydids of the genus *Neoconocephalus* feed mainly on seeds of grasses. Plant preferences among some leaf-eating orthopterans change with the seasons of the year; in other leaf-eating groups feeding habits are dependent on the stage of the life cycle—*i.e.*, nymphs do not eat the same plants as adults of the same species. Moisture requirements of orthopterans vary, as evidenced by the habitats they occupy. Some can absorb water from a drop on the cuticle (skin); others obtain it from water vapour in the air if the relative humidity is sufficiently high.

Predators, plant feeders, scavengers

Habitat. Shelter utilized by orthopterans ranges from general hiding places amid living plant foliage or dead leaves on the ground to special structures such as subterranean galleries in soil or the recesses in caves occupied by various crickets. Some Gryllacrididae are leaf rollers and produce silk to maintain the rolled shape of their hiding places. The loose bark of trees and logs and the water-filled leaf bases of bromeliads often shelter certain genera of cockroaches, some of which are semi-aquatic in their habits. In Africa a few cockroaches (*Cyrtotria*), of elongated and cylindrical body shape, are adapted to enter round holes in hollow plant stems where they sometimes live. With the exception of cockroaches, most conspicuous orthopterans are active by day (diurnal), although there are nocturnal species in every group. Although grylloblattids are essentially nocturnal, they are sometimes active on cloudy days or in winter. The majority of crickets and katydids are nocturnal, as are many walking sticks and some mantids; however, many mantids prey on insects that visit flowers by day.

The degree of moisture, types of vegetation, and altitude above sea level influence the location of orthopteran communities. Grasshoppers breed in the Himalayan Mountains at altitudes as high as 6,000 metres (about 18,000 feet), and each mountain altitudinal zone has distinctive species; fully winged, actively flying species are usually not restricted to a single zone but are found in adjacent ones. On the other hand, at high altitudes there are proportionately greater numbers of grasshoppers with short, nonfunctional wings or none at all.

Caves as habitats

Caves are a special habitat occupied by orthopterans on all continents. The long-horned grasshoppers and the crickets are the principal orthopteran representatives; nearly 200 species of these two groups have been found in caves. In addition, more than 30 cockroach species inhabit caves; and a third group, the grylloblattids, has at least one cavernicolous species in Japan and three in the U.S. Some of these orthopterans inhabit lava tubes and fissures resulting from past volcanic action. Air currents and high humidity in these tubes and fissures produce an "ice cave" condition. In the U.S., the grylloblattids and a few dozen cave crickets (Gryllacrididae) are the principal cavernicoles. It is noteworthy that a bone from a bison skeleton, found in a French cave in the 1920s, bore a prehistoric carving that depicted *Troglophilus*, a European cave cricket.

Usually the orthopteran species found on a given continent are distinct from those of other continents, especially if the land masses are well separated. For example, there are about 2,000 species and 500 genera of grasshoppers in Africa; although several of the genera are found in North America, none of the species is. Some species in North Africa, however, also inhabit southern Europe and western Asia. Explanations for distinct continental species are found not only in the far, overwater distances involved but also in the long periods of isolation that have occurred and in the different conditions that have prevailed in past geologic periods.

Oceanic islands have been populated, in part, by species that were transported by hurricanes, floating debris, birds, and in recent centuries by human activities. The 85 species of Hawaiian orthopterans include four distinct genera of crickets and katydids comprising about 45 of the 85 species. Evidently some of these evolved following the establishment of a few parent species. The remainder are believed to have been established as a result of the activities of man. Since cockroaches are scavengers, they are often found where man is found; *i.e.*, in his buildings and campsites. Early man probably spread cockroaches as he moved about seeking food. Modern commerce has been even more helpful to these unwelcome travellers. An analysis of the distribution of 11 domiciliary species found in the U.S. and related species found elsewhere suggested that five reached America in shipping from West Africa; another African species might not have reached America directly; two probably came from Europe; two might have come from the Orient; and one was native to the West Indies. Thus man has played an important role in spreading cockroaches throughout the world.

Taxonomic significance of ecology

The familiar, large, black field crickets of the U.S. are good examples of ecological differences among similar species. There are six native species in the eastern U.S.; several others occur in the western states, and at least two introduced species have become established in the Gulf States. Using the general appearance of dead specimens, the native eastern species are very similar and difficult to distinguish. For many years, the taxonomy of these species was unsettled. Entomologists using behaviour rather than morphology as a major taxonomic criterion

have found that five of the six species have distinct songs; that four of them overwinter as nymphs, the other two chiefly as eggs; and that, to a considerable extent, the habitat preferences are different—*i.e.*, one species lives in abandoned fields, another in leaf litter of open woodland. Laboratory attempts to crossbreed males and females of different species have been unsuccessful; the pair either failed to copulate or, if they did, produced unhealthy hybrids. Ecological differences also are important for other groups of closely related orthopterans.

FORM AND FUNCTION

Adaptive features. *Movement.* Orthopterans exhibit various adaptations for movement; some are present in an entire family or suborder, others are peculiar to certain genera. The head of mantids is borne by the prothorax in such a way that it is easily turned to face in different directions. Since the mantid diet consists almost entirely of insects, vision is critically important and is unusually well developed. The best known orthopterans with specialized front legs are mantids; the principal leg segments are hinged and spined for seizing and holding prey. Some Orthoptera, especially certain groups of Tettigonioidea, also have front legs with long spines that enable them to hold other insects, although the hinging is not comparable to that in mantids.

Burrowers

Although some cockroaches burrow in soil, sand, or decomposing wood, the principal burrowers are found among the Orthoptera. In both groups the legs, especially the front tibiae, are short and strong, with heavy spurs. Mole crickets, false mole crickets, and sand crickets are accomplished burrowers. Small tunnels serve as shelter and as egg-laying locations, and roots or tubers encountered while burrowing are sometimes used as food. Several genera of camel crickets (Gryllacrididae) in the southwestern U.S. have conspicuous, sometimes basket-shaped, clusters of spurs on the hind legs. They often live on sand dunes and burrow chiefly for shelter. A few desert-living grasshoppers, some in the southwestern U.S., others in Africa, exhibit what has been called "self-burial." Instead of making an elongated cylindrical burrow, the grasshopper rests on the surface of the sand or moves forward and backward, manoeuvring its legs until it has submerged itself and covered its body with sand. The apparent purpose is protection.

Hind legs of Orthoptera, though useful in walking, are used primarily for leaping. Particularly important are the large muscle in the femur, the hinged attachment of tibia to femur, and the tendon extending within the leg from the femur to the end of the tarsus. In a few semi-aquatic Orthoptera, the hind tibia is broadened as a paddle or equipped with fringed spurs to permit effective swimming strokes in water. The ability to run swiftly is common among cockroaches and some mantids. Cockroaches escape enemies by running; mantids utilize their running ability both to escape predators and to catch prey. Some mantids that live on the ground, in deserts, or on tree trunks in the tropics are active runners; however, the majority of mantids stalk their prey slowly or wait quietly until an unsuspecting insect moves nearby.

Body shape is important to many orthopterans, either allowing them to live in places where adequate shelter from weather and enemies is provided or affording them concealment through camouflage. Most cockroaches have flat bodies that enable them to hide beneath stones, under other objects on the ground, or under the loose bark of logs. Examples of orthopterans whose camouflages resemble parts of plants are members of the Phasmida; some of them resemble leaves, others look like twigs or rough pieces of small limbs from trees. Several katydids and grasshoppers resemble leaves; some are green or brown, others have spots that resemble leaves affected by plant diseases. There are some slender grasshoppers that live among grasses, where they conceal themselves by clinging lengthwise to stems and remaining motionless or by quickly sidling around behind stems.

Colour

Camouflage. There are two basic types of insect colours. Structural colours occur when irregular cuticle or scale surfaces break up and reflect certain wave lengths of light. Metallic lustres of some orthopterans (*e.g.*, silvery patches on some grasshoppers) are examples. Most orthopteran colours are due to pigments; often they are located in the cuticle, but sometimes they occur in some deeper body layer. The pigments may be naturally occurring ones or, like melanin, dependent on an oxidation process or a hormonal balance that influences metabolism; these latter pigments are present in varying amounts in different individuals of the same species.

Among some orthopterans, especially grasshoppers, body colours tend to simulate the colour of the habitat background. This is particularly true of species inhabiting rocky or sandy environments. In some cases, colour changes occur rapidly; this was demonstrated by certain light gray African grasshoppers that became black after being caged a few days on dark burnt-over ground. In other cases more time is required. Colour changes usually involve the effect of bright light on integumentary pigments. Among some orthopterans, however, light must enter the eyes, and a rhythm related to some nervous-endocrine mechanism is apparently involved.

An unusual and rapid colour change occurs in an Australian alpine grasshopper (*Kosciuscola tristis*), which lives at above 5,000 feet elevation. The adult male, bright greenish blue on the upper part of its body at temperatures above 25° C, is dull and blackish below 15° C. At intermediate temperatures, correspondingly intermediate shades of colour occur. Detailed experiments by Australian entomologists prove that temperature, not light intensity, relative humidity, or degree of crowding is the controlling factor. The epidermal cells of the integument contain brown and blue granules; at warmer temperatures on sunny days the blue granules, in a discrete layer uppermost in the epidermal cells, are near the surface of the integument. At night or on cloudy days, the brown granules migrate from the bottom of the epidermal cells and change places with the blue granules. Thirty minutes is sufficient time for a colour change to take place.

Glandular secretions

Defense. There are no known stinging orthopterans but many have chemical mechanisms in the form of glands that produce irritating fluids or repugnant odours. The disagreeable smell of some cockroaches, especially when disturbed, is well known. Examples are several species of *Eurycotis* in Florida and tropical America; both sexes have a large gland in the hind part of the abdomen between the sixth and seventh segments. An acidic, milky fluid consisting of several chemical constituents is emitted either as an oozing liquid or as a three-foot spray. Another cockroach (*Diploptera*) has a defense gland that ejects a mixture of quinones from the second abdominal spiracles. Ants, beetles, and other predators become confused and avoid these cockroaches when they release their secretions; however, certain mantid predators are not affected.

Man may handle most walking sticks safely, but a large, heavily bodied species in the southeastern U.S. (*Anisomorpha buprestoides*) sometimes forcibly ejects a milky fluid that is extremely irritating if introduced into the human eye. This species has a pair of circular pores on the thorax leading to reservoirs of the fluid; each reservoir has circular muscles that permit ejection of fluid without the general body contraction characteristic of some grasshoppers. When handled, most grasshoppers and some other orthopterans regurgitate from the mouth a brown fluid that superficially resembles molasses. Release of the fluid from the forward part of the alimentary canal is triggered by a response of the nervous system to pressure on certain parts of the body, especially the sides of the thorax or the femurs. Some grasshoppers have other defense mechanisms (*e.g.*, some exude fluid through spiracles or from special glands opening on the body or even leg joints). Sometimes hissing sounds and blowing of bubbles from spiracles accompany secretion.

Physiology and biochemistry. *Body composition.* Several grasshopper species have been analyzed chemically. They consist of (by dry weight) roughly 50% to 75% crude protein, 4% to 18% fats, 4% to 16% carbohydrates, and 3% to 19% ash.

The tough and usually hard outer body wall (exoskele-

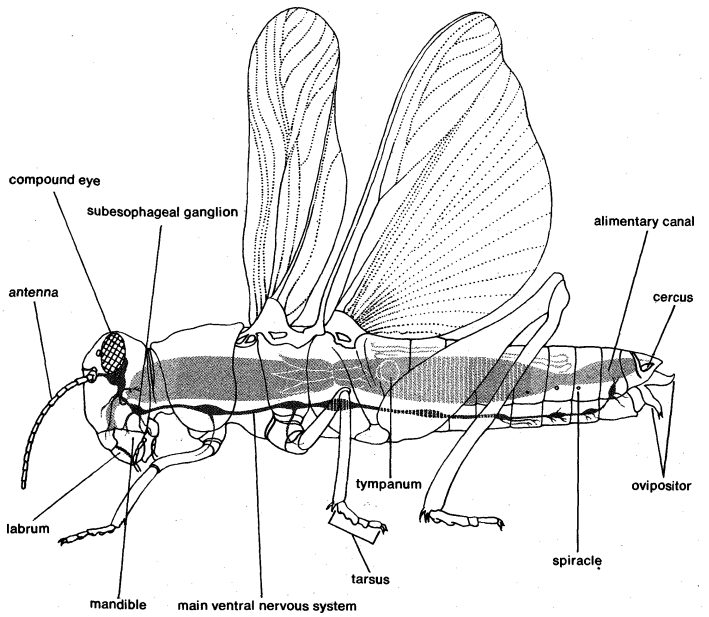

Figure 3: Internal and external body plan of adult orthopteran.
From H. Weber, *Grundriss der Insektenkunde* (1966); Gustav Fischer Verlag, Stuttgart

ton) of orthopterans is called the integument or cuticle; its most important component is chitin, a stable polysaccharide chemically similar to plant cellulose. Chitin makes the cuticle strong and flexible but does not provide rigidity. Sclerotin, the horny substance of the cuticle formed by a tanning-like process involving protein produced in the exoskeleton, is found in hard body plates (sclerites), leg spurs, and sharp tubercles; sclerotin is responsible for the rigidity of these structures. A heavily "sclerotized" cuticle is one that is hard and usually dark coloured.

Hormones. The importance of hormones in the biology of orthopterans has been revealed by research. Together with the related pheromones, which tend to coordinate individuals within the population of a species instead of regulating function within an individual, hormones are important in many activities of orthopterans related to mating and reproduction. Other activities involving hormones in grasshoppers include control of fat accumulation in metabolism, control of peristalsis in the malpighian tubules (excretory organs attached to the posterior part of the alimentary canal), secretion of an enzyme at hatching time for dissolving the cuticle that encloses the embryo, and control of the number of molts in nymphal growth.

Activities involving hormones

Detailed studies on the reproduction of cockroaches have disclosed an interrelated series of neurological and glandular functions that combine to control mating and egg production. Frequently, dorsal abdominal glands of the male aid in attracting the female to a mating position. In several cases, once a female has mated and an ootheca is being carried, mechanical pressure of the ootheca causes a stimulation to be transmitted to glandular bodies closely associated with the cerebral ganglia and called corpora allata; this in turn inhibits development of additional eggs in the ovarioles until laying and subsequent removal of pressure occur. In other cases, virgin females are receptive to mating just when yolk deposition is occurring in the first oocytes of developing eggs. Following mating, the mechanical stimulation of the inserted spermatophore inhibits further attraction of the female to the male abdominal glands until after the first group of eggs is deposited.

Phase polymorphism in locusts

Locust is a common name for several species of short-horned grasshoppers that often increase suddenly in numbers and undertake mass migration. Thus, a locust has both solitary and gregarious phases. Gregarious locusts outnumber solitary ones, migrate both as nymphs and adults, and travel in swarms. Swarming adults are tremendously destructive to crops. Typically, gregarious locusts have darker bodies and longer wings compared with solitary forms. Colour changes in adults are correlated with maturation of reproductive organs.

Hormones and pheromones are involved in many stages of locust development. Solitary locusts can transform into gregarious ones as a result of hormonal changes induced by crowding. The presence of mature male locusts under conditions of crowding stimulates a maturation hormone that causes females to mature rapidly. Head glands in the female are stimulated to release another hormone that speeds egg maturation. A favourable season followed by an unfavourable one may cause gregarious locusts to develop. In a favourable season with enough food, the population of solitary locusts increases. If the next season is a poor one, the solitary locusts are forced to crowd together where food is available. Crowding exposes the females to male secretions, females and their eggs respond by maturing rapidly, a population explosion occurs, and a locust horde results. In *Schistocerca gregaria*, the attainment of reproductive activity is sometimes synchronized with environmental contact with certain aromatic shrubs that produce terpenoids in season.

Sound production and hearing. Some orthopterans make conspicuous sounds, while others produce sounds that are outside the range of human hearing. In both cases sound production is important to behaviour necessary for success of the species concerned. Except for Grylloblattodea, in which sound production is unknown, all major groups of orthopterans produce some sort of sound, though sound production is widespread only in crickets, katydids, and grasshoppers.

Stridulation

The stridulatory mechanism of grasshoppers involves moving the hindleg across the folded front wing (tegmen). Serrations, or pegs, which vary in shape, number, and location among different species, are located on the inner surface of the femur and rub across special raised veins of the tegmen, creating a characteristic lisp; sometimes the serrations are on the tegminal veins. In the hindwings of other grasshoppers are stiff veins that make a crackling sound (crepitation) in flight.

Among male crickets and katydids, a front wing with an enlarged transverse vein near its base bears teeth that rasp when shuffled across a scraper on the other front wing. The row of teeth is called the file, and the membrane to which it is attached vibrates when the teeth move over the scraper. During stridulation the tegmina are lifted at an angle of 15° to 40° to the surface of the abdomen, then rapidly opened and closed (shuffled); sound is produced during the closure.

The best known auditory organs of orthopterans, the tympanic organs on each side of the abdomen, are found in both sexes of grasshoppers and on the front tibiae of most crickets and katydids. There are auditory nerves running from special cells beneath a tympanic membrane (a thin area of cuticle, backed by an air sac and free to vibrate) to a ganglion of the central nervous system. In addition to these evident tympanic structures, other less evident auditory organs occur in the orthopterans. Many orthopterans, however, have no conspicuous tympana and are entirely dependent for sound reception on sensory hairs located on cerci, the head, other parts of the body, and an auditory organ called Johnston's organ, which is widespread in the second segment of the antenna.

EVOLUTION AND PALEONTOLOGY

Cockroach fossils

Cockroaches are the most abundant and the earliest fossilized orthopterans found; fossils have been discovered at various localities in North America, France, and the U.S.S.R. Several hundred Carboniferous Period (about 280,000,000 to 345,000,000 years old) and at least a hundred Triassic cockroach species (about 190,000,000 to 225,000,000 years old) have been described; they differ from present Blattaria chiefly in details of wing venation. In addition, some early species had long ovipositors, unknown in recent species. Only a few fossil mantids are known, the oldest in Baltic amber of the Oligocene (about 26,000,000 to 38,000,000 years ago). Some phasmatid-like Jurassic species (about 136,000,000 to 190,000,000 years old) are believed to be primitive walking sticks.

Although fewer in number than the Blattaria, fossil Orthoptera have contributed to orthopteran classification. Ensifera occur from the Triassic to the present; apparently Ensifera and Caelifera separated as distinct evolutionary lines as early as the Carboniferous. The earliest fossils in the acrididoid line had long antennae. Shorter antennae, reduction of tarsal segments to three, and reduction in length of the ovipositor occurred by the Eocene Period (about 38,000,000 to 54,000,000 years ago).

By the late 19th century, all principal groups of orthopterans except Grylloblattodea were represented in collections; however, the order Orthoptera, broader in scope than it is at the present time, included earwigs and other groups. Gryllacridids were not placed in a separate family, and Phasmida were considered a family closely related to Mantidae because both are walking rather than jumping in habit. By the 20th century, however, basic morphological studies, as well as extensive reports on fossils, contributed new insights into fundamental relationships. The Grylloblattids were first reported in 1914, and numerous publications since then have analyzed their phylogenetic significance. In the late 1930s extensive studies of fossils were correlated with important work on current species, especially concerning the Orthoptera (restricted sense). Meanwhile, comparative studies of wing venation, the proventriculus, reproductive organs, and behaviour have steadily advanced the knowledge of group relationships. Additional details and supporting data, for example, were given in an extensive phylogenetic study in 1968. The rank of a suborder (Acridomorpha) for grasshoppers alone (Eumastacoidea through Acridoidea of this article), has not been evaluated sufficiently. Many of the earliest fossil orthopterans were different enough from any present ones to justify the recognition of separate though extinct families.

CLASSIFICATION

Distinguishing taxonomic features. Among the distinctive features of orthopterans are their wings, which, when present, usually number four. The two forewings, generally long and narrow, are many-veined and somewhat thickened. Among the Orthoptera, Dictyoptera, and Phasmida the forewings, hardened and of a leathery consistency, are known as tegmina. The hindwings, broad with many veins, usually are folded fanlike beneath the forewings when at rest. The females have ovipositors. Some are concealed by ventral abdominal segments; others are as long as the body. Orthopterans have mandibulate mouthparts adapted for chewing and undergo simple metamorphosis.

The classification of orthopterans into orders and families is based chiefly on comparative morphology, on indications of ancestry derived from fossils, and on relationships suggested by patterns of behaviour and the physiology of body systems. Similar anatomical structures that have been significant in deducing orthopteran relationships include: tarsal segments; hindlegs; wings; stridulatory and auditory organs; head capsule; thoracic sclerites; ovipositor; male genitalia; and proventriculus. In recent years correlations between behaviour and mating and reproduction, especially in cockroaches and crickets, have been used widely to support classification of families and subfamilies as well as distinctions between species.

In the grylloblattids, cockroaches, and mantids, the cerci are segmented; segments are lacking in katydids, crickets, grasshoppers, and walking sticks. The external male genitalia are sometimes concealed; in Grylloblattodea (grylloblattids), Dictyoptera (cockroaches and mantids), and Phasmida (walking sticks), the genitalia are asymmetric; in the Orthoptera (katydids, crickets, grasshoppers, and locusts) they are symmetrical. The Orthoptera have the femur of the hindleg enlarged for jumping; other groups have hindlegs similar in size to the middle legs. In mantids the front legs are modified for seizing prey, in mole crickets for digging. The tarsus consists of five segments in grylloblattids, mantids, and cockroaches; there are usually five segments in walking sticks, usually only three or four in Orthoptera. The antennal segments vary from fewer than seven to many long and setaceous ones.

Annotated classification.

ORTHOPTERAN

Common name for several orders of related insects; wings, when present, number 4; chewing mouthparts; mostly plant feeders; size range from 2 mm to 30 cm; more than 24,000 species; worldwide distribution.

Order Dictyoptera

Hindlegs similar to middle ones, adapted for running; tarsi 5-segmented; wing pads not reversed during nymphal stages (front wings remain above hindwings); antennae usually filiform, with more than 30 segments; cerci many-segmented; without auditory tympanum.

Suborder Blattaria (cockroaches)

Head usually concealed from above by shieldlike pronotum; two ocelli represented by pale areas (fenestrae); front legs adapted for running; proventriculus (gizzard) heavily armed on inner lining, with longitudinal folds between the teeth; members from Carboniferous to present; worldwide distribution; sizes 2 to 100 mm, average about 15 mm; more than 3,000 species.

Family Cryptocercidae. Wingless; blackish; cerci (sensory appendages) concealed by apical segments of abdomen; eyes small; size usually at least 15 mm; found in China, Manchuria, U.S.; 3 species.

Family Blattidae. Middle and hindfemurs with numerous strong spines similarly arranged on both ventral margins; ovipositor a plowlike (vavular) modification of apical ventral segment of abdomen; male subgenital plate symmetrical with widely spaced styli; size range about 10 to 35 mm; worldwide distribution; about 550 species.

Family Polyphagidae. Middle and hindfemurs mostly with few strong spines ventrally; spines on front and back ventral margins arranged differently; anal area of folded hindwing not plaited fanlike; postclypeus usually enlarged; range in size about 3 to 35 mm; worldwide distribution; about 200 species.

Family Blattellidae. Variable, mostly small species; mostly with numerous similar spines on ventral margins of middle and hindfemurs; ranging in size from 3 to 100 mm, with an average of about 12 mm; worldwide distribution; about 1,700 species.

Family Blaberidae. Mostly large species; spines of middle and hindfemurs variable; male subgenital plate asymmetrical; viviparous or ovoviparous; from 10 to 60 mm in size; worldwide in distribution; about 650 species.

Suborder Mantodea (mantids)

Head usually conspicuous anterior to a narrow pronotum, seldom concealed by a broad pronotum; 3 distinct ocelli; front legs adapted for seizing prey; proventriculus not heavily armed, inner lining with fine anastomosing ridges between teeth of moderate size.

Family Mantidae. Oligocene to present (fossils rare); size from 20 to 155 mm, average about 60 mm, worldwide distribution; about 2,000 species.

Order Grylloblattodea (Notoptera)

Legs similar, adapted for running; 5-segmented tarsi; wingless; eyes small or absent; no ocelli; antennae fairly long, filiform, about 25–40 segments; female with well-developed ovipositor, resembling Tettigoniidae (see below under *Orthoptera*); cerci long, with 8 to 9 segments.

Family Grylloblattidae (ice bugs). Recent (no fossils); size about 20–25 mm; found in northwestern North America, eastern Siberia, Japan; about 15 species.

Order Phasmida (Cheleutoptera or Phasmatoptera)

Legs similar, adapted for walking; tarsi nearly always 5-segmented; often wingless; when winged, tegmina often shorter than wings; wing pads not reversed as nymphs; ovipositor short, often concealed; male genitalia asymmetrical; cerci short, unsegmented; no tympanum or conspicuous stridulatory organs; usually very slender, elongated, sometimes broadened, even leaflike.

Family Phasmatidae (walking sticks, stick insects). Variable, rarely less than an inch long; a broadly conceived family; Triassic to present; 15 to 325 mm in size with average about 70 mm; worldwide distribution centred in warm countries; about 2,000 species.

Family Phylliidae (leaf insects). Depressed, leaflike, winged; tegmina short in males, covering most of abdomen in females; antennae long, pubescent in males, very short in females; all members recent; about 60 mm in size; Indo-Malayan distribution from Ceylon to Fiji; about 25 species.

Order Orthoptera

Hindlegs almost always enlarged and adapted for jumping; tarsi usually 3- or 4-segmented, occasionally fewer than 3 or as many as 5 segments; front wings more or less thickened; wing pads reversed (hindwing partly covering front wing)

during late nymphal stages; cerci nearly always unsegmented; specialized auditory and stridulatory organs often present.

Suborder Ensifera

Antennae usually long, with more than 30 segments; auditory organs, if present, consist of tympanum at base of front tibia; many species with stridulatory mechanism at base of tegmen; ovipositor usually present as rounded or flattened bladelike, or elongated cylindrical spearlike, structure.

Superfamily Prophalangopsoidea. Tarsi compressed or cylindrical, 3- or 4-segmented; tympanum present; simple stridulatory vein on each male tegmen.

Family Prophalangopsidae. Triassic to present. 25–47 mm in size; recent species found in India and northwestern North America; 3 species.

Superfamily Tettigonioidea. Tarsi usually depressed, 4-segmented, at least on middle and hindlegs; tympanum present; stridulatory organ specialized, with left tegmen uppermost and scraper (at edge of lower tegmen) often better developed on right tegmen.

Family Tettigoniidae (katydids, bush crickets). Jurassic to present; size range from 15 to 120 mm, average about 35 mm; distribution worldwide; about 3,000 species.

Family Phasmodidae (phasmodids). Very slender, resembling Phasmatidae (see above); head prognathous (*i.e.*, mouth directed forward instead of downward); hindfemurs not enlarged; all members recent; found in Australia; size range from 25 to 85 mm; 2 species.

Superfamily Gryllacridoidea. Tarsi depressed, usually 4-segmented; front wings without stridulatory mechanism; usually no tympanum; ovipositor usually flattened, bladelike; 12 to 50 mm in size with average 25 mm.

Family Stenopelmatidae (stenopelmatids, Jerusalem crickets). Heavy body, often wingless; front legs usually strongly armed for digging; ovipositor inconspicuous; members from Miocene to present; found in southeastern Asia, South Africa, North America, and Central America; about 35 species.

Family Gryllacrididae (gryllacridids). Usually winged, with folded wings surrounding abdomen at rest; found from Jurassic to present; chiefly tropical, most nocturnal, in trees and shrubs; one species in U.S.; about 550 species.

Family Schizodactylidae (schizodactylids). Winged or wingless; when winged, wing tips very long, rolled in a coil at rest; tarsal segments 2 and 3 with conspicuous lateral lobes; all members recent, found in southern Asia, South Africa; about 8 species.

Family Rhaphidophoridae (camel crickets and allies). Wingless; usually of humpback appearance; tarsi compressed; legs often very long and slender; found from Oligocene to present; worldwide distribution; about 300 species.

Family Lezinidae. Wingless; cerci with apical segmentation; found in Asia and Africa; about 10 species.

Family Henicidae. Usually wingless; front tibia with 1 or more dorsal spurs; front coxa usually with spine; represented in Old and New World tropics; about 150 species.

Superfamily Grylloidea. Tarsi 3-segmented; tegmina of males usually highly developed for stridulation; tympanum usually at base of front tibia; ovipositor most often round in cross section, spearlike, other times somewhat flattened or reduced; 2 to 50 mm in size with average 18 mm.

Family Gryllidae (crickets). Front legs usually not for digging; ovipositor usually elongated; species from Triassic to present; worldwide distribution; about 2,400 species.

Family Gryllotalpidae (mole crickets). Front legs highly modified for digging, with tibiae expanded and with fingerlike dactyls; ovipositor vestigial; represented from Oligocene to present; distribution worldwide; about 65 species.

Suborder Caelifera

Antennae short, with less than 30 segments; auditory organs, if present, at base of abdomen in form of tympanum; ovipositor usually consists of paired valvular appendages adapted for digging.

Superfamily Tridactyloidea. Tarsi 1- or 2-segmented; antennae short, with 12 or fewer segments.

Family Tridactylidae (pygmy sand crickets). Front tarsi 2-segmented; hindtibiae with unsegmented tarsus, no "claws," 2 long "paddles"; usually winged; 3 to 18 mm in size; worldwide distribution; about 60 species.

Family Cylindrachaetidae (false mole crickets). Body elongated, cylindrical, wingless; antennae 7- to 8-segmented; eyes reduced; ocelli absent; front tibia with 4 or 5 dactyls; cerci very short. All members recent; inhabit Australia and southern South America; size 40–60 mm; about 8 species.

Superfamily Tetrigoidea. Pronotum strongly elongated, extending backward over most or all of abdomen; tegmina short, scalelike; hindwings usually fully developed; no tympanum; front and middle tarsi 2-segmented; hindtarsus 3-segmented.

Family Tetrigidae (pygmy grasshoppers or grouse locusts). Miocene to present; 8–25 mm in size with average about 14 mm; worldwide distribution; about 700 species.

Superfamily Eumastacoidea. Abdominal spiracles situated in lateral membrane between terga and sternums; basal abdominal terga without auditory tympanum; basal segment of hindtarsus with serrated margins or at least with an external tubercle (all U.S. species wingless).

Family Eumastacidae (eumastacids or monkey grasshoppers). Sides of abdomen without stridulatory organ; antennae relatively short; frontal costa forked below median ocellus; represented from Miocene to present; worldwide in warm countries; about 200 species.

Family Tanaoceridae (tanaocerids). Specialized stridulatory organ on side of 3rd abdominal tergum, rubbed by hindfemur; antennae very long; frontal costa not forked; found in southwestern U.S.; 3 species.

Superfamily Pneumoroidea. Body robust; male fully winged, female short winged; hindlegs short; tympanum absent; male with stridulatory ridges on side of 3rd abdominal tergum.

Family Pneumoridae (pneumorids). All members recent; restricted to southern Africa; 11 mm to 107 mm in size; about 18 species.

Superfamily Proscopioidea. Body sticklike, superficially like Phasmatidae (see above under *order Phasmida*); head elongate, conical, usually oblique or vertical; wings rarely present, tympanum absent; no stridulatory organ.

Family Proscopiidae (proscopiids). All representatives recent; from Costa Rica to southern South America; size 30 to 180 mm with average about 60 mm; about 100 species.

Superfamily Acridoidea. Typically robust, with both pairs of wings and tympanum present, but very variable; pronotum not or briefly prolonged over abdomen; abdominal spiracles located in terga; tarsi 3-segmented, basal segment without serrated margins; size 8 to 120 mm with average about 28 mm.

Family Acrididae (grasshoppers). Many of unusual appearance; stridulatory mechanism often present, but not with organ on abdomen; vertex without a definite longitudinal furrow; tympanum normally present (absent in some, especially wingless genera); ocelli small; hindtibiae usually not expanded apically for swimming; Eocene to present; worldwide distribution; more than 5,000 species.

Family Pamphagidae (pamphagids). Usually large; wings variable; many wingless bulky species in arid regions; vertex of head with longitudinal furrow; lower basal lobe of hindfemur longer than upper lobe; members recent; in Africa and southern parts of Europe and Asia; about 300 species.

Family Pyrgomorphidae (pyrgomorphids). Head conical; longitudinal furrow of vertex present; lower basal lobe of femur longer than upper lobe; tympanum usually present; no stridulatory mechanism; recent; worldwide in tropical and subtropical areas, unknown in U.S.; about 350 species.

Each of the following 7 families contains only a few species: Pauliniidae, Xyronotidae, Ommexechidae, Trigonopterygidae, Charilaidae, Lathiceridae, Lentulidae. The Xyronotidae includes 1 Mexican species only; the other families are not represented in North America.

Critical appraisal. The arrangement of orders, suborders, superfamilies, and families presented above is a consensus of current opinion; however, some entomologists recognize different relationships and additional families too minor or too little understood to be included here. In most large groups, there are a few peculiar species that vary slightly from the characteristics described. Although an attempt was made in this classification to indicate the earliest geological period in which major groups were found, available information is not always clear as to whether the insect found belongs to a modern family or an ancestral one with more primitive features and a different name. The known species shown for each group represent living ones that have been named; it does not include fossils. In some cases modern catalog and monographs supply accurate counts; for others, estimates are given.

Several other orders of insects are orthopteroid in their general relationships. Among them, the Dermaptera (earwigs) differ from orthopterans by having short leathery front wings devoid of veins, hindwings with veins radiating from a central point midway of the anterior margin, and most cerci modified into pincer-like structures. Isop-

tera (termites) have similar front and hindwings; although in many ways they resemble some cockroaches, they differ in their elaborate caste system and their habits (*i.e.*, living in complex colonies consisting of reproductive individuals, sterile workers, and soldiers). Zorapterans show some morphological relationship to cockroaches but have two-segmented tarsi, peculiar wing venation, a primitive caste system, and other differences. Embiopterans (web spinners) are also orthopteroid in basic morphology, but are notably distinct from orthopterans by the much enlarged silk-producing basal segment of the front tarsus. Plecoptera (stoneflies) are also orthopteroid, but their front and hindwings are of a similar texture (unlike orthopterans), and their immature stages are specialized for an aquatic life.

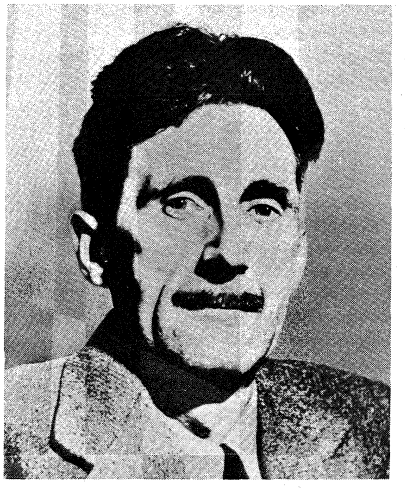
(A.B.G.)

Orwell, George

Journalist, satirist, autobiographer, and influential prophet of the evil shape of things to come, George Orwell, in his social and intellectual unorthodoxy, exemplifies an attractive recurrent strain in the British character.

Born Eric Arthur Blair, he never entirely abandoned his original name, but his first book (*Down and Out in Paris and London*, 1933) appeared as the work of George Orwell (the surname he derived from the beautiful River Orwell in East Anglia). In time his nom de plume became so closely attached to him in his daily life that eventually few people but relatives and his bank manager knew his real name was Blair.

By courtesy of the British Broadcasting Corporation



Orwell.

The change in name corresponded to a profound shift in Orwell's life-style, in which he changed from a pillar of the British imperial establishment into a literary and political rebel. He was born in 1903 at Motihāri, Bengal, into the class of sahibs. His father was a minor official in the Indian civil service; his mother, of French extraction, was the daughter of an unsuccessful teak merchant in Burma. Their attitudes were those of the "landless gentry," as Orwell later called people whose pretensions to social status had little relation to their income.

Early life

Orwell was thus brought up in an atmosphere of impoverished snobbery. After returning to England, he was sent in 1911 to a preparatory boarding school on the Sussex coast, where he was distinguished among the other boys by his poverty and his brilliance. The miseries of those years he told in his autobiographical essay, *Such, Such Were the Joys* (1953). He grew up a morose, withdrawn eccentric boy; but even then, as his schoolfellow Cyril Connolly remembered him, "Orwell . . . was a true rebel."

Orwell won scholarships to two of England's leading schools, Winchester and Eton, and chose the latter. He stayed from 1917 to 1921. Aldous Huxley was one of his masters, and it was at Eton that he published his first writing in college periodicals.

Instead of accepting a scholarship to a university, Orwell decided to follow family tradition and, in 1922, went to Burma as assistant district superintendent in the Indian Imperial Police. He served in a number of country stations, and at first appeared to be a model imperial servant. Yet from boyhood he had wanted to become a writer, and when he realized how much against their will the Burmese were ruled by the British, he felt increasingly ashamed of his role as an alien police officer. Later he was to recount his experiences and his reactions to imperial rule in his novel *Burmese Days* (1935) and in two brilliant autobiographical sketches, "Shooting an Elephant" and "A Hanging," classics of expository prose.

In 1927 Orwell, on leave to England, decided not to return to Burma, and on January 1, 1928, he took the decisive step of resigning from the imperial police. Already, in the autumn of 1927, he had started on a course of action that was to shape his character as a writer. Having felt guilty that the barriers of race and caste had prevented his mingling with the Burmese, he thought he could expiate some of his guilt by immersing himself in the life of the poor and outcast people of Europe. Donning ragged clothes he went into the East End of London to live in cheap lodging houses among labourers and beggars; he spent a period in the slums of Paris and worked as dishwasher in French hotels and restaurants; he tramped the roads of England with professional vagrants and joined the people of the London slums in their annual exodus to work in the Kentish hopfields.

Down and Out in Paris and London

These experiences gave Orwell the material for *Down and Out in Paris and London* (in which actual incidents are rearranged into something like fiction). Later experiences, teaching in private schools and working in bookshops, expanded his scope and contributed to his early novels, *A Clergyman's Daughter* (1935) and *Keep the Aspidistra Flying* (1936).

Orwell's revulsion against imperialism led not only to his personal rejection of the bourgeois life-style but to a political reorientation as well. Immediately after returning from Burma he called himself an anarchist and continued to do so for several years; during the '30s, however, he began to consider himself a Socialist, though he was too libertarian in his thinking ever to take the further step—so common in the period—of declaring himself a Communist.

Orwell's first Socialist book was an original and unorthodox political treatise, *The Road to Wigan Pier* (1937). It began by describing his experiences when he went to live among the unemployed miners of northern England, sharing and observing their lives; it ended in a series of sharp criticisms of existing Socialist movements. It combined mordant reporting with a tone of generous anger that from that time onward was to characterize Orwell's writing.

Role in the Spanish Civil War

By the time *The Road to Wigan Pier* was in print, Orwell was in Spain; he went to report on the Civil War and stayed to join the Republican militia, serving on the Aragon and Teruel fronts and rising to the rank of second lieutenant. He was seriously wounded at Teruel, damage to his throat permanently affecting his voice and endowing his talk with a strange, compelling quietness. Later, in May, 1937, after having fought in Barcelona against Communists who were trying to suppress their political opponents, he was forced to flee Spain in fear of his life. The experience gave him a lifelong dread of Communism, first expressed in the vivid account of his Spanish experiences, *Homage to Catalonia* (1938), which many consider one of his best books.

Returning to England, Orwell showed a paradoxically conservative strain in writing a novel (*Coming Up for Air*, 1939), full of nostalgia for the decency of a past England and fears for a future threatened by war and fascism. When war did come, Orwell was rejected for military service. For a time he headed the Indian service of the British Broadcasting Corporation, until in 1943 he became literary editor of *Tribune*, a left-wing Socialist paper associated with the British Labour leader Aneurin Bevan. At this period Orwell was a prolific journalist, writing many newspaper articles and reviews, together with serious criticism, like his classic essays on Dickens and on boys' weeklies and a number of books about England (notably *The Lion and the Unicorn*, 1941) that combined patriotic sentiment with the advocacy of a libertarian, decentralist socialism very much unlike that practiced by the British Labour Party.

In 1944 Orwell finished *Animal Farm*, a political fable based on the story of the Russian Revolution and its betrayal. At first he had difficulty finding a publisher for this small masterpiece, but when it appeared in 1945 *Animal Farm* made him famous and, for the first time, prosperous.

Animal Farm was probably Orwell's finest work, full of wit and fantasy and admirably written. It has, however, been overshadowed by the repute of his last book, *Nineteen Eighty-Four* (1949), a novel he wrote as a warning after years of brooding on its subject. In it he portrays the kind of society he believed could evolve if man allowed the state to assume more power and permitted politicians to establish and perpetuate totalitarian rule by a systematic distortion of the truth and a continuous rewriting of history.

Orwell wrote the last pages of *Nineteen Eighty-Four* in a remote house on the Hebridean island of Jura, which he had bought from the proceeds of *Animal Farm*. He worked between bouts of hospitalization for tuberculosis, of which he died in a London hospital in January 1950.

Orwell's ideal was to write "prose like a window pane," and he often succeeded. He recognized that he was not at his best as a novelist, and his best works of fiction are really fables. As a journalist and a writer of autobiography he was superb. He had little power of invention; it was life that moved him to his indignations and his finest writing.

MAJOR WORKS

NOVELS: *Burmese Days*, 1934; *A Clergyman's Daughter*, 1935; *Keep the Aspidistra Flying*, 1936; *Coming Up for Air*, 1939; *Animal Farm*, 1945; *Nineteen Eighty-Four*, 1949.

ESSAYS: *Inside the Whale*, 1940 (including also "Charles Dickens" and "Boys' Weeklies"); *Critical Essays*, 1946 (reprinting "Charles Dickens" and "Boys' Weeklies" and including also "The Art of Donald McGill," "Rudyard Kipling," and "In Defence of P.G. Wodehouse"); *Shooting an Elephant and Other Essays*, 1950 (including also "A Hanging," "How the Poor Die," "The Prevention of Literature," "Politics and the English Language," "Politics vs. Literature: An Examination of Gulliver's Travels," "Lear, Tolstoy and the Fool," and "I Write as I Please," articles from the *Tribune*); *England Your England and Other Essays*, posthumously published 1953 (including also "Inside the Whale" and the essays on Dickens and boys' weeklies, with "Looking Back on the Spanish War," "Anti-Semitism in Britain," "Poetry and the Microphone," "Why I Write," and part of *The Lion and the Unicorn* and *The Road to Wigan Pier*); *Such, Such Were the Joys*, posthumously published 1953 (except for the title essay, first published in this collection, and omission of extracts from *The Lion and the Unicorn* and *The Road to Wigan Pier*, containing the same essays as are collected in *England Your England*); *Collected Essays*, posthumously published 1961 (including most of the essays in *Shooting an Elephant*, *Critical Essays*, and *England Your England*).

OTHER PROSE (AUTOBIOGRAPHICAL): *Down and Out in Paris and London*, 1933; *The Road to Wigan Pier*, 1937 (account of conditions in the depressed areas of the north of England, observed on a tour commissioned by Victor Gollancz for the Left Book Club); *Homage to Catalonia*, 1938 (on his experiences in the Spanish Civil War). (POLITICAL): *The Lion and the Unicorn: Socialism and the English Genius*, 1941 (pamphlet); contributions to *Betrayal of the Left*, 1941; *Victory or Vested Interests?*, 1942; *Talking to India*, 1943 (broadcast talks). (MISCELLANEOUS): *The English People*, 1947 (text of volume in the "Britain in Pictures" series); introduction to vol. 1 of *British Pamphleteers*, 1948.

BIBLIOGRAPHY. The main cache of primary material is the Orwell Archive at University College, London; there are smaller collections at the University of Texas and the New York Public Library. All these archives are strong in letters and weak in other material since Orwell kept few papers. In accordance with a request in Orwell's will, no biography exists. The nearest thing, full of information about his life, with notes and a chronology, is SONIA ORWELL and IAN ANGUS (eds.), *Collected Essays, Journalism and Letters of George Orwell* (1968). Critical studies include: GEORGE WOODCOCK, *The Crystal Spirit* (1966); JOHN ATKINS, *George Orwell: A Literary Study* (1954); RICHARD REES, *George Orwell: Fugitive from the Camp of Victory* (1961); ROBERT A. LEE, *Orwell's Fiction* (1969); and KEITH ALLDRITT, *The Making of George Orwell: An Essay in Literary History* (1969).

(G.W.)

Ōsaka–Kōbe Metropolitan Area

The Ōsaka–Kōbe metropolitan area is the second largest urban and industrial agglomeration in Japan. Located on Ōsaka-wan (Ōsaka Bay) at the eastern end of the Inland Sea, it is usually defined to include the ancient city of Kyōto, once the national capital, which is located 25 miles northeast of Ōsaka.

Ōsaka, a city of 3,000,000, is the capital of Ōsaka Urban

Prefecture (Ōsaka-fu), an administrative division that includes Ōsaka City (Ōsaka-shi) and a large rural area. Kōbe, with a population of 1,300,000, is the capital of Hyōgo Prefecture (Hyōgo-ken) and one of Japan's chief ports. There are many satellite industrial and residential cities around the two central cities. The total population of Kyōto, Ōsaka, Kōbe, and their contiguous districts was 9,553,000 in 1965 and had increased to 14,886,000 at the 1970 census.

Ōsaka's ancient origins

History. The plain of Ōsaka was settled in prehistoric days and early became a political centre. The national capital was situated at nearby Nara in 710 AD. Among many ancient burial mounds in the vicinity of Ōsaka is that of the Emperor Ōjin (died AD 310?). The palace and town were built in 645, 651, and again in 724.

When Kyōto became the capital of Japan in 794, the road and water routes between Ōsaka and Kyōto were improved. The reclamation of the delta of the Yodo-gawa (Yodo River) allowed the building of new settlements, including Watanabe, which became a provincial capital and port during the Middle Ages. South of Ōsaka, on the eastern shore of the bay, is the port of Sakai founded in the 13th century. Like some of the medieval European towns, it was run by merchant guilds, and the accounts of Christian missionaries tell of the great houses of its wealthy men. In the 15th century, when Kyōto was destroyed in a war, Sakai became a centre of the arts.

In 1496, Buddhist priests built a temple in the uplands near Ōsaka, called Ishiyama Jinaimachi ("temple town with fortifications"). In 1580 it fell to the conqueror Oda Nobunaga after a siege of many years. His successor, Toyotomi Hideyoshi (1537–98), built a great castle on the site with massive stone walls and broad moats, and until 1596 it was the seat of the government of Japan. Destroyed by fire in 1868, the castle has been partly reconstructed, and it towers above the modern city. During the Tokugawa era (1603–1867) Ōsaka became the country's largest commercial city; feudal lords from all Japan established their warehouses along the canals, where they traded the rice of their villagers. Many other goods were traded in Ōsaka, and the city became an expanding industrial centre. In the 17th century the towns of Nada (now part of Kōbe), Nishinomiya, and Itami became famous for their sake (rice wine).

As its economic prosperity grew, Ōsaka became a centre of culture. It had schools of art, music, Kabuki, classical studies, and modern science. In the mid-19th century, when Japan was still closed to most Westerners, the Dutch language and Western science were studied by Japanese in Ōsaka.

Lawrence Smith—Photo Researchers

Ōsaka Castle.

Ōsaka remained pre-eminent both as a port and as a centre of industry until after World War II, when the Tokyo–Yokohama area underwent a great expansion. The revolution in China deprived Ōsaka of its important China trade, while the increasing economic role of the national government tended to encourage industrial location in the Tokyo–Yokohama area.

The contemporary city. *The city site.* The city of Ōsaka is situated on the delta of the Yodo-gawa. To the east of the central city, Hideyoshi's castle stands on the upland, which is the northern extension of the upland that rises in the southern part of Ōsaka Urban Prefecture and is about 65 feet above sea level. The metropolitan area spreads over the deltas of the Yodo, Yamato, and other rivers, and into their diluvial uplands. The area is bounded by the Ikoma-sanchi (Ikoma Mountains) in the east, the Izumi-sanchi in the south, and the Rokkō-sanchi in the northwest. The southwestern boundary of Ōsaka-wan is formed by Awaji-shima (Awaji Island). On the northwestern shore of the bay is Kōbe, above which rises the granite peak of the Rokkō-zan (Mt. Rokkō; 3,057 feet, or 932 metres). The coastline here has been altered by reclamation for port facilities and industries. Along the coast and in the uplands are the best residential areas of Kōbe and the cities of Ashiya, Nishinomiya, Ikeda, Itami, and Toyonaka. On the delta of the Kanzaki-gawa, just west of Ōsaka, is the city of Amagasaki, a centre of heavy industry. To the north of Ōsaka are the cities of Toyonaka, Suita, and Ibaraki. Above them, on Senriyama (Senri Mountain), are new towns developed after 1967. Northeast of Ōsaka, along the Yodo-gawa, are the industrial and residential cities of Takatsuki, Moriguchi, Neyagawa, and Hirakata. To the east of Ōsaka are the cities of Kadoma, Higashiōsaka, and Yao. To the southeast are Fujiidera, Tondabayashi, Matsubara, and others, most of them old historical towns. To the southwest, on the coastal plain, are Sakai, Izumi-Ōtsu, Kaizuka, Kishiwada, and Izumi-Sano, some of them industrial and others residential. Urbanization extends to Nara, 25 miles east of Ōsaka, and to Kyōto 25 miles northeast. A dense network of railways winds throughout the area.

River deltas and uplands

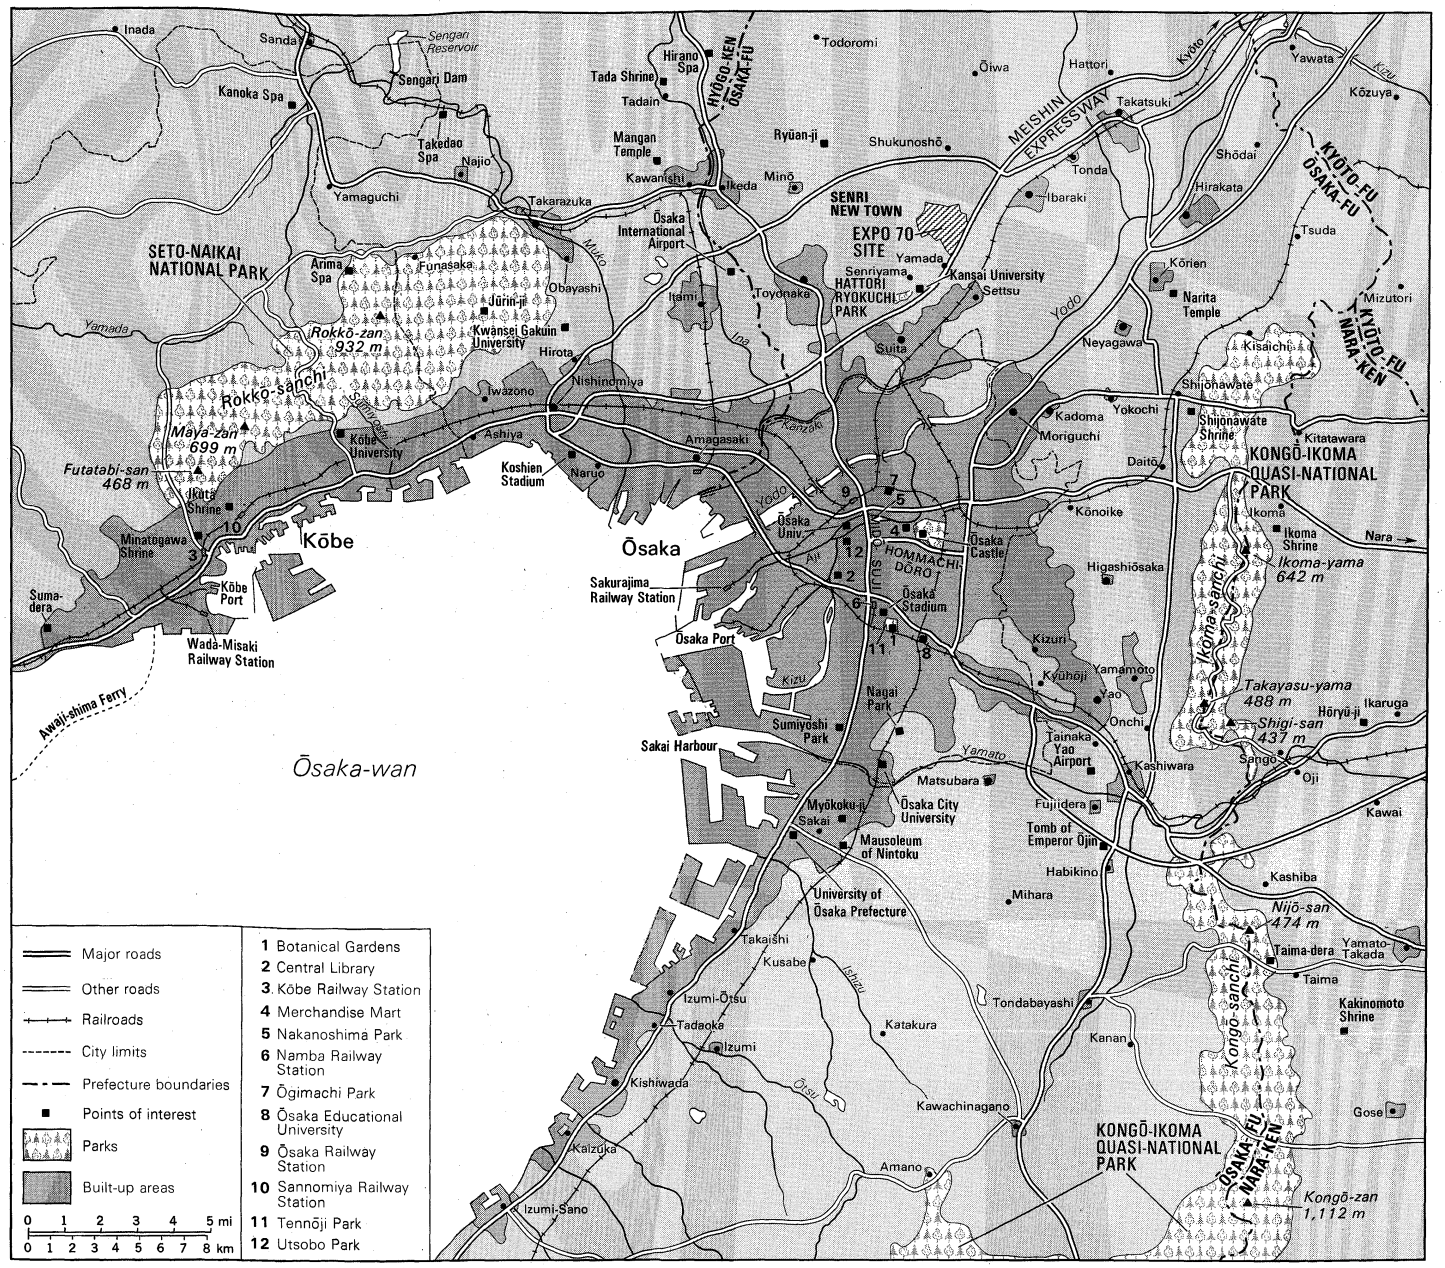
The physical environment. Ōsaka has a temperate climate. The annual mean temperature is 59.9° F (15.5° C), and the annual rainfall averages 53.5 inches (1,359 millimetres). The temperature in August is often 86° F or more (above 30° C), with no breeze from the sea at night. The January mean is 40.1° F (4.5° C), and snow falls several times in winter. The rainy seasons are in June–July and September–October. In September the region will usually be struck by one or two typhoons. The greatest typhoon disaster in the Ōsaka–Kōbe area's history occurred in 1934, when 3,000 persons were killed and 476,000 houses damaged. During the rainy season of June–July 1938, huge landslides from the Rokkō-sanchi buried wide areas of Kōbe.

The citizens of Ōsaka once took pride in its smoky atmosphere as a mark of industrial progress, but by the mid-1970s its smog and air pollution were seen as harmful. Other environmental problems were water pollution and subsidence (sinking) of the earth in the Amagasaki region caused by overuse of water beneath the ground.

Street patterns

City plan. Ōsaka's streets are laid out in checkerboard style. The north–south axis is Midō-suji (Mido Street), connecting Ōsaka railroad station in the north and Namba station in the south. The east–west axis is Hommachi-dōri (Hommachi Street), running east to the castle. Parallel to Midō-suji is the narrow Shinsaibashi-suji, the southern part of which is the central shopping district. Dotombori, at the south end of Shinsaibashi-suji, is a crowded theatre and cabaret area.

The central business district is the northern part of the downtown area. Nakanoshima, situated on an island formed by arms of the Yodo-gawa, contains the city offices, Ōsaka University, the Sumitomo Bank, and the headquarters of a number of large businesses. The traditional commercial centres were Semba and Shimanouchi



The Ōsaka–Kōbe metropolitan area.

streets, where the old-style white-walled shops with family quarters behind them continued for centuries, until World War II. Ōsaka's industrial areas are on the lower Yodo delta and in the eastern and northeastern parts of the city.

The street pattern of Kōbe is governed by its location between the mountains and the shore. Main streets run east and west, crossed by short north–south streets and occasional longer streets going up into the hills. The central shopping street, Motomachi, runs between the Sannomiya and Kōbe railroad stations. The central business district is near the harbour.

Transportation. Ōsaka is a junction point for the Japanese National Railways, feeding traffic from the north and east to the west and south. The JNR also runs local and interurban rapid transit lines, but the best service for suburban commuting and for regional passenger traffic is provided by the private electric lines, of which there are two between Ōsaka and Kōbe and two between Ōsaka and Kyōto. Nonstop electric trains run between Ōsaka and the city of Nagoya. Rail lines run from Kōbe to the Arima Spa on the north side of Rokkō-zan, to other northern mountain areas, and westward to Himeji, the third largest city of Hyōgo Prefecture.

There were 40 miles of subway lines in Ōsaka in 1970, and the system was being expanded. Because of heavy automobile traffic, the city's main streets were one-way. Elevated expressways ran through the central parts of Ōsaka and Kōbe and out to Ōsaka International Airport, near Itami. An express highway extends from Nagoya to Kōbe, and ordinary highways span the whole region. Kōbe and Ōsaka are both international and domestic ports; passenger ships, freighters, and car ferries sail to the islands of Shikoku and Kyūshū and to various ports of the Inland Sea.

Population. The population of Ōsaka declined from 3,156,000 in 1965 to 2,980,000 in 1970 because of migration to the suburbs. The density of the population in 1970 was 5,636 persons per square mile. The highest density is not in the centre of the city but in the peripheral wards, because the population decrease has been greatest in the central wards, while the outer wards were still growing. The population of Ōsaka Urban Prefecture in 1970 was 7,620,000 as compared with 6,637,000 in 1965. The increase was partly natural and partly the result of migration; on the average, the prefecture receives about 390,000 persons from other prefectures each year and sends out 310,000.

The city of Kōbe had a population of 1,289,000 in 1970 and of 1,217,000 in 1965; there was a slight decrease in the central ward and high increases in peripheral wards. Hyōgo Prefecture, of which Kōbe is the centre, had 4,668,000 in 1970 and 4,310,000 in 1965.

There were 27 cities of more than 100,000 population in the Ōsaka–Kōbe metropolitan area in 1970.

Burial mounds and housing developments

Housing and buildings. The Ōsaka area has been settled and built upon since prehistoric times. There are many ancient burial mounds and relics of Korean settlers, who introduced pottery and weaving to the Japanese. The ancient villages of the rice farmers were on the marshy plains, while the palaces, shrines, and temples were located on higher ground. Medieval settlements were in the uplands. Some of the present residential areas have been built on the sites of several former settlements. Thus, Tezukayama, a middle class residential development in Ōsaka south of the old castle, formerly an upper class area, is built over a number of ancient mounds.

The central part of Ōsaka is now primarily commercial; since 1920 there has been a migration from the city to the suburbs, helped along by the suburban railways that have made building land available along their rights-of-way. The Hankyu Electric Railway was particularly active in developing the city of Toyonaka (population 369,000) northwest of Ōsaka. Two of the large postwar housing developments are Koori Danchi, accommodating 22,000, and Senri New Town built in 1967–70, with 150,000.

Ōsaka Urban Prefecture had 1,830,000 dwelling units in 1968, and Hyōgo Prefecture had 1,124,000. About two-thirds of Ōsaka Urban Prefecture's dwellings were apartment houses. Inner-city areas were occupied mostly by Western-style multistoried buildings. Nineteenth-century architectural styles can be seen in the Public Hall of Ōsaka and in many residential houses in Kōbe. The redevelopment of Ōsaka's central business district in the 1960s produced some large new buildings: the Merchandise Mart, rising 256 feet above ground level and descending 66 feet below, and the Senba building under an elevated expressway—only four floors in height but about six-tenths of a mile in length.

The economy. Ōsaka was once known as the Lancashire of the Orient because of its great textile industry. At the beginning of the present decade its leading industry was the manufacture of machinery. The relative importance of its various industries was as follows (in percentages of the total production of Ōsaka Urban Prefecture in 1968): electric machinery, 12.6%; ordinary machinery, 12%; iron and steel, 11.2%; fabricated metals, 8.3%; textiles, 8.3%; chemicals, 8.2%; food, 6.3%; nonferrous metals, 5.7%; transportation machinery, 5.7%; printing and publishing, 3.9%; pulp and paper, 3.3%; other, 14.4%. Nearly 2,000,000 workers were employed in manufacturing in Ōsaka Urban Prefecture in 1968, 535,000 in the city itself.

Major industries

Between Ōsaka and Kōbe are several other industrial cities. The largest, Amagasaki, employed 100,000 workers; it is a centre of machinery, metallurgy, chemicals, cement, and paper production. Kōbe is pre-eminent in shipbuilding and steel production. Heavy industry and chemical plants are situated along the shore of Ōsaka-wan, while light industry and assembly plants are inland.

The merchants of Ōsaka greet one another in the mornings with the query, "Are you making money?" The city had 27,000 wholesale establishments in 1969, or about one-fifth of the country's total. The wholesale area is in the central part of Ōsaka, where the streets are named after commodities: Medicine Street, Textile Street, and so on.

Ōsaka is Japan's second largest financial centre. Together with Kōbe it is the leading port for foreign trade, handling about 30 percent of all exports.

Administration and social conditions. Ōsaka is the capital of Ōsaka Urban Prefecture, consisting of 31 cities and 15 towns and villages. It is also the centre of the Kinki-chiho (Kinki District), which consists of the seven prefectures of Ōsaka, Kyōto, Hyōgo, Nara, Wakayama, Shiga, and Mie. Various prefectural and regional institutions have their main offices in Ōsaka. Kōbe is the capital of Hyōgo Prefecture.

Public utilities. Ōsaka's main source of water is the Yodo-gawa. Kōbe has several reservoirs on the slope of the Rokkō-sanchi. Sewage services in the metropolitan area are generally inadequate, but most central city sections have flush toilets. Electricity is available everywhere, and gas is available in most city areas.

Health and education. Medical care in Ōsaka hinges on the hospitals of Ōsaka University and of the Ōsaka City University. Other hospitals and health centres are distributed throughout the metropolitan area. Ōsaka Urban Prefecture had 113 persons per hospital bed in 1969. The number of physicians per 100,000 persons was 132.6, which was higher than the national average. In general, the medical services compared favourably with those of other industrially developed countries.

The educational system

Ōsaka has the Japanese six–three–three–four educational system—six years of elementary schooling, three of junior high, three of high school, and four years of college. In 1969 the prefecture had 696 primary schools, 321 junior high schools, and 191 high schools, most of them run by public authorities. In Ōsaka and Hyōgo prefectures there were 55 universities with 177,000 students and 63 junior colleges with 38,000 students. There are four national universities: Ōsaka University, Ōsaka University of Foreign Studies, Ōsaka Educational University, and Kōbe University. Some of the public universities are Ōsaka City University and the University of Ōsaka Prefecture. Kansai University and Kwansei Gakuin University were the oldest and largest private universities located in the area.

Cultural life. Ōsaka and Kyōto have long been leading centres of culture—Ōsaka, famous for its restaurants, has a more bustling, democratic tone than Kyōto, which is one of the great centres of Japanese culture, and the difference is expressed in the popular sayings: "The Kyōto people spend too much money on clothes," and "The Ōsaka people eat too much rich food" (*Kyō no kidaore, Ōsaka no kuidaore*).

Traditional and modern Japanese drama and music are performed at theatres and halls in the metropolitan area, as are Western music, operas, and plays. There are numerous science and art museums, art galleries, and libraries.

Ōsaka is the place of publication of the national newspapers *Ōsaka Asahi* and *Ōsaka Mainichi*. There are also several local newspapers and many specialized publications. The national radio and television system has stations in Ōsaka, as do four commercial radio stations and four commercial television stations.

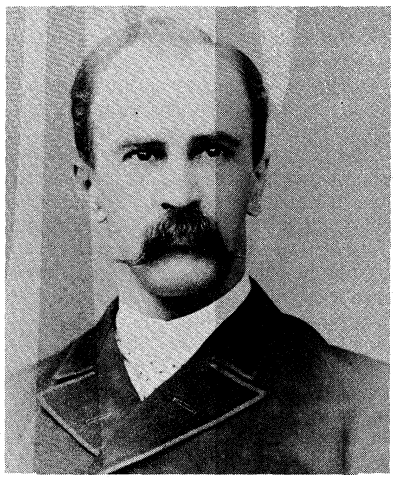
Green space in the city of Ōsaka is scarce. Two important parks are Nakanoshima and Tenno-ji, the latter with a zoo and botanical gardens. The suburbs have many historical sites and large recreation areas. Besides the large man-made Hattori Ryokuchi Park, there are the Kii-hantō (Kii Peninsula) on the Pacific, the beaches of the Inland Sea, the historical towns of Nara and Kyōto, and beautiful Biwa-ko (Lake Biwa)—a little larger than Switzerland's Lake Geneva—near Kyōto. At Kōbe, Rokkō-zan can be ascended by motor road or by cable car; there is a golf course at the top and ponds for swimming. There are four professional baseball teams in the metropolitan area, and the national high school baseball championships are played in the summer at Koshien Stadium. The town of Takarazuka in the northwest has been developed as an amusement centre; it houses the renowned Girls Opera and Dancing Theatre. In 1970 the Japan World Exposition (Expo 70) was held near Senriyama; the site is now used as a university campus and recreation area. (S.K.)

Osler, Sir William

When William Osler died in 1919, he was probably the most famous and beloved physician in the English-speaking and perhaps the whole world. He remains so more than 50 years later. His renown was not due to his contributions to science, which were small, or his contributions

to medicine, though these were sizable. He adored and fascinated the young, and he transformed medical education in the United States and elsewhere. Before Osler, the relations between teacher and student, teacher and teacher, and teacher and patient had been cold and formal. After him, the relations were warm and friendly. He personified the learned, scholarly, skillful physician who was also a warm human being. Osler thought his epitaph should be that he took the teaching of medicine into the wards.

By courtesy of the National Library of Medicine, Bethesda, Md.



Osler, 1886.

Early life

William Osler was born at Bond Head in western Ontario on July 12, 1849. He was the youngest of the nine children of the Rev. Featherstone Osler, who had gone to Canada as an Anglican missionary, and his wife, Ellen. William, like his father, was intended for the church. But while at school he read *Religio Medici* and became fascinated by natural history. He began to study arts at Trinity College, Toronto, but decided that the church was not for him and entered the Toronto Medical School in 1868. He subsequently transferred to McGill, where he took his medical degree in 1872. During the following two years he visited medical centres in Europe, spending the longest period at University College, London, in the physiology laboratory of John Burdon-Sanderson, who was making experimental physiology pre-eminent in medical education.

In 1873 Osler demonstrated that hitherto unidentified bodies in the blood were in fact the third kind of blood corpuscles, which were later named the blood platelets. These corpuscles had been observed before, but no one before Osler had studied them so thoroughly. Thus began what he called his periods of "brain dusting"—travel and studies that made him almost as much a part of Europe as of America.

Osler returned to Canada and began general practice in Dundas but was soon appointed lecturer in the institutes of medicine at McGill. He became professor there in 1875. A year later he became pathologist to the Montreal General Hospital and in 1878 physician to that hospital. At McGill he taught physiology, pathology, and medicine. His research was conducted largely in the postmortem room. In 1884, while in Leipzig, he was invited to occupy the chair of clinical medicine in Philadelphia. He decided to do so on the toss of a coin. While in Philadelphia he became a founder member of the Association of American Physicians.

Work at Johns Hopkins

In 1888 Osler accepted an invitation to be the first professor of medicine in the new Johns Hopkins University Medical School in Baltimore. There he joined William H. Welch, chief of pathology, Howard A. Kelley, chief of gynecology and obstetrics, and William S. Halsted, chief of surgery. Together, the four transformed the organization and curriculum of clinical teaching and made Johns Hopkins the most famous medical school in the world. Students studied their patients in the wards and presented the results to the "Chief." They were also encouraged to take their problems to the laboratory. Finally, the experts pooled their knowledge for the benefit of the patient and the student in public teaching sessions. Thus was born the pattern of clinical teaching that spread throughout the United States. Osler was not only professor of medicine but physician in chief to the hospital, an office first devised by the president of the university on the basis of his experience of running a large department store, and later to spread to most of the medical centres of the United States. For the first four years there were no students at Hopkins, and Osler used the time to write *The Principles and Practice of Medicine*, first published in 1892. In the same year he married Mrs. Grace Gross, widow of a surgical colleague at Philadelphia and great-granddaughter of Paul Revere.

Osler's textbook was lucid, comprehensive, interesting, and scholarly. It quickly became the most popular textbook of its day and has continued to be published since under a succession of editors, though never regaining the quality with which Osler endowed it. The textbook had an unexpected sequel. In the summer of 1897 it was read word by word by F.T. Gates, who had been engaged by John D. Rockefeller to advise him in his philanthropic endeavours. As a result of his reading, Gates inspired Rockefeller to direct his foundation toward medical research and to establish the Rockefeller Institute of Medical Research in New York.

Years at Oxford

In 1904, while visiting in England, Osler was invited to succeed Sir John Burdon-Sanderson in the Regius Chair of Medicine in Oxford. Osler's practice and teaching had for many years imposed enormous demands on his time and energy. His forceful wife telegraphed him from America: "Do not procrastinate. Accept at once." Osler did. The Regius Chair at Oxford is a crown appointment for which only citizens of the crown are eligible, but Osler had kept his Canadian nationality. He took up his chair in the autumn of 1905, becoming a student, roughly a lifetime fellow, of Christ Church, one of the Oxford colleges, a member of its Hebdomadal (weekly) Council, and curator of the Bodleian Library. In Oxford he taught only once a week, did a small amount of practice, and spent most of his time on his books. His library became one of the best of its kind, and after his death it passed intact to McGill, where it is specially housed. His scholarship was recognized by his election as president of the Classical Association. He was also active in medical affairs and inspired the formation of the Association of Physicians of Great Britain and Ireland and the establishment of the *Quarterly Journal of Medicine*. He was elected a fellow of the Royal College of Physicians of London in 1884 and a fellow of the Royal Society of London in 1898; he became a baronet in 1911. He and his wife were immensely hospitable, especially to visiting Americans, among whom their house was known as the "Open Arms."

Osler gave many lectures, mostly on the subjects of medical history and literature, some of which were collected and published. *Aequanimitas*, which he regarded as the most desirable quality for doctors, was the title of the most famous of these. Osler had a puckish wit and wrote some admirable medical nonsense under the pseudonym of Egerton Yorrick Davis, a retired surgeon captain of the U.S. army.

In medical terminology, Osler is immortalized in Osler's nodes (red, tender swellings in the palm or palmar surface of the fingers and hands in subacute bacterial endocarditis), Osler-Vaquez disease (polycythaemia vera or rubra), and Rendu-Osler-Weber disease (a familial form of recurring nose bleeds with multiple teliangectases of the skin and mucous membranes).

The Oslers had one son, Revere, named after his great-great-grandfather, Paul Revere. His death in action during World War I took the spirit out of his father, who died of pneumonia on December 29, 1919. His funeral was in the cathedral and chapel of Christ Church at Oxford on January 1, 1920. Lady Osler died in 1928. Her ashes, and those of Sir William, are now in the Bibliotheca Osleriana at McGill.

(G.Pi.)

Oslo

Occupying a site of rare natural beauty, the city of Oslo has grown into the capital of the kingdom of Norway and the centre of national economic, political, and cultural life. It is also the most important Norwegian port and the leading road, rail, and air junction; car ferries connect with Germany and Denmark, and there are regular passenger connections with Britain and the United States. Oslo is situated in southeastern Norway, at latitude 60° N, longitude 10° E, at the northern end of the 60-mile-long Oslo Fjord. The city covers over 175 square miles (453 square kilometres) and is, in area, one of the largest cities in the world. The built-up area, however, comprises only 60 square miles (155 square kilometres). Outside this historic waterside core, the greater part of the city area has been kept in a natural state. This region, which includes the areas known as Østmarka, Lillomarka, Nordmarka, Krokskogen, and Vestmarka, consists of extensive pine- or spruce-clad hills, interspersed with lakes (totalling 9 square miles), and marshes. It has been preserved primarily for recreational purposes, and a network of marked paths and trails threads the whole region, which is a popular destination for hiking and skiing trips on the part of Oslo citizens and their families.

The people of Oslo are in fact often prouder and fonder of the outlying regions than of central Oslo, even though the city centre has much to commend it: attractive parks; handsome public buildings; and the renowned thoroughfare of Karl Johansgate, which links the parliament building, the old university, the National Theatre, and the royal palace, which is surrounded by a park.

History. The *Snorres kongesagaer* ("Snorr's King's Sagas"), a historic Norse chronicle, records that

> King Harald established a town in the east, in Oslo, and spent a great deal of his time there, as supplies were easily obtained and the countryside thriving. Here he was in a good position to protect the country against the Danes, and also to make raids on Denmark.

The reference is to King Harald Hardraade, who lived around the year 1050, and illustrates the strategic advantages of Oslo's original site.

This lay close to the Oslo Fjord, to the east of the Aker River at the foot of the Ekeberg Heights. The old city district, as it is now known, contains only a few archaeological traces of this early settlement, which once contained a bishop's residence and several church and monastery buildings, some of them built on Hovedøya, an island in the fjord.

Original foundation

To the west of the old city, a rocky cliff juts out into the fjord, and it was on this commanding site that the Akershus Fortress was established (*c.* 1300). Rebuilt and extended, it dominates the centre of Oslo Harbour to this day, is still used for state occasions, and has lent its name to the county (*fylke*) encircling the city. It was under the walls of this castle that, following a disastrous fire in 1624, one of several which ravaged the young city, King Christian IV of Denmark–Norway built a new town laid out with a regular rectangular street system. This replaced the Ekeberg site. A famous statue, standing in the marketplace in front of the Cathedral, together with the names—Christiania 1624–1877, Kristiania 1877–1925—by which Oslo was formerly known, commemorate the modern city's founder.

During the 19th century, the growing city gradually grew beyond its old limits; its population grew from a mere 11,000 in 1814 to 225,000 in 1910; and it replaced its rival, the west coast port of Bergen, as Norway's largest and most influential city. A university was founded in 1811, while at midcentury, to the west of the then built-up area, an impressive royal palace was constructed. This was erected at the behest of Karl Johan (Charles XIV) the joint king of Norway and Sweden, who was to give his name to the city's main thoroughfare, Karl Johansgate. The Norwegian monarch still maintains his residence at the palace.

The 19-century expansion of the city initially took place along roads leading out from the old city centre, notably Grønlandsleiret and Strømsvein. The latter connected the city and its harbour with the hinterland, primarily the sawmills at Strømmen. Traffic in lumber was heavy, and the road was crowded with horse-drawn vehicles. In 1854, the nation's first railway line, connecting Oslo and Eidsvoll, was opened: this took over much of the lumber and freight traffic and, by stimulating the urban economy, made an important contribution to the growth of the city. Within the city itself, the turbulent Aker River became a focus for sawmills and other industrial development; and outlying settlements, consisting of the wooden dwellings of the new working class, soon sprang up, while the western sections of the city developed more as residential areas for the prosperous elements of society. By the 1970s much of the physical legacy of this period of growth was in a state of deterioration and extensive programs of urban renewal were under way. The Vika area around the city hall, has been the scene of an ambitious program of new construction since World War II.

Nineteenth-century growth

In the 20th century the most rapid period of growth for the city also occurred after World War II. In 1948 Oslo incorporated the nearby township of Aker, and in the following decades a number of satellite towns and residential areas—notably Grorud, Veitvet, Bøler, and Lambertseter—grew up to the east of the city.

The contemporary city. The geological conditions underlying Oslo are varied and interesting. At the end of the Ice Age, about 10,000–12,000 years ago, the sea level in the Oslo Fjord was nearly 700 feet higher than it is today. As a result the ancient rocks underlying much of the Oslo region have been covered by a thick layer of marine clay. Consequently, variations in the subsoil of the city have created problems during the construction of modern buildings, roads, and railways. Parts of the centre of Oslo had to be built on large rafts laid on top of the clay deposits, while subway construction has been a complicated and costly affair.

The hills surrounding the city offer magnificent views, with the highest points—Grefsenåsen, Vettakollen, Holmenkollen, and Tryvasshøgda—lying to the north of the city. A television tower 393 feet high rises from the top of Tryvasshøgda (1,760 feet [536 metres] above sea level). The Maridalen and Sørkedalen valleys, also on the outskirts of the city, have been maintained as agricultural areas: no residential building is allowed, except on the part of the local farmers. The nearby Maridalsvatn Lake is Oslo's largest lake and forms the most important reservoir for the city's supply of drinking water.

The perimeter of the city is some 73 miles long, with the Lysaker River forming the boundary line of the municipality of Bærum, the most highly populated of the suburban municipalities in Akershus County. In addition to Akershus, the city of Oslo also adjoins the counties of Buskerud and Oppland.

Demography. In 1801 Oslo proper had 9,500 inhabitants: in 1875, 76,800; in 1948, 429,500; and in 1971, 481,000, together with a steadily increasing suburban population. Newcomers from other parts of the country made up over half of Oslo's population in the early 1970s, and Oslo also has many more foreigners than other Norwegian cities, although it is not as cosmopolitan in character as other western European capitals. In the central parts of the city the population is decreasing, and the average age of the inhabitants there is fairly high. In the developing suburban districts, the population is younger, and there is an increasing need for more schools; in the inner city, on the other hand, schools are being closed down and used for other purposes.

The expansion of industry in Oslo and a housing shortage within the city have caused a steadily increasing flow of commuters. New housing areas are being opened constantly in the outlying municipalities to assist families who are affected by this trend. As a result the population of greater Oslo reached 700,000 by 1970, while the Oslo region as a whole had in excess of 850,000 inhabitants.

Development of outlying areas

Economic life. Oslo is the focus of Norwegian trade, banking, industry, and shipping. The value of the city's imports in 1971 was 12,600,000,000 kroner, while exports amounted to 2,860,000,000 kroner (7.12 kroner = U.S. $1; 17.09 kroner = £1 sterling). Oslo Harbour is the largest, as well as the busiest, in the country, with a waterfront extending for eight miles. The city has over 130 shipping firms, which command a merchant fleet of around 7,000,000 gross tons, of which 4,300,000 gross tons are dry cargo tonnage and 2,800,000 gross tons are tank tonnage.

Industry in Oslo is primarily concerned with the domestic market, with industrial production constituting about a quarter of the total value of output for the entire country. In addition, Oslo firms pay out nearly 30 percent of the national industrial wages. The leading industries are the production of consumer goods, shipbuilding, and the electrotechnical and graphic industries. The most important national daily newspapers—including the *Aftenposten, Dagbladet,* and *Arbeiderbladet*—are also published in the city. Industrial districts have been sited along the Loelva and Akerselva from an early stage in the city's growth, while smaller industrial districts are to be found near the outlying communities of Bislett, Majorstna, and Skøyen.

Around 50 percent of Norway's wholesale trade, together with 25 percent of all retail business, is transacted in Oslo. The Norwegian Trade Fair exhibition hall is located in Skløyen, to the west of the city. The important Norwegian fur auctions are held at Økern, in the northeast of Oslo.

Administration. Oslo, as the capital city of Norway, contains numerous government offices and other public institutions. These include the parliament, the supreme court, the Bank of Norway, and the Norwegian broadcasting corporation.

The city council is made up of 84 representatives and a mayor, who is elected for two years. The city hall, which contains a number of municipal offices, is an impressive building with two massive towers. Situated near the harbour in the Vika district, it dominates the seaward approach to the city. A modern building, it has been richly decorated by 28 Norwegian artists.

Services. Oslo has two main railway centres. From the east station, main lines radiate to Bergen, Fagernes, Trondheim, Stockholm, and Gøteborg, while from the west station, the Sørland line leads to Stavanger. Freight is transported by rail along the harbour partly through tunnels alongside the Akershus Fortress. Electric suburban trains connect the city centre with the east, north, and west suburbs, with some of the suburban lines running in tunnels under the central section of the city.

Transportation improvements

The network of roads around Oslo is being extended rapidly, with major new stretches of modern highways opened every year, although, as in all parts of Norway, the difficult terrain makes road construction costly and arduous.

Automobile traffic in Oslo itself had also become a problem by the 1970s, especially in rush-hour periods. Some of the traffic is channelled along roads encircling the centre, but there is a growing need for a new motor road through the city. Such a road, in the planning stage in the early 1970s, would alter radically the face of the city.

Oslo's electrical energy requirements are set by deliveries from water-powered stations, the most important of which are located in Numedal, Hallingdal, Gudbrandsdalen, and at Glomma (or Glåma).

Cultural life and recreation. The leading Norwegian cultural institutions are located in Oslo. The city centre contains the National Theatre, the Norwegian Theatre, the Oslo Nye Teater, and Den Norske Opera. Near the oldest part of the university are found the Historial Museum (with the Ethnographic Museum) and the National Gallery, the latter containing an excellent collection of paintings. At Tøyen, in the east of the city, are the botanical gardens and several museums. At Bygdøy, the Norwegian Folk Museum, a Viking ship hall, the Framhuset (containing a famous polar exploration vessel), the Kon-Tiki Museum (commemorating the Pacific expedition of Thor Heyerdahl), and the Norwegian shipping museum serve as reminders of Oslo's maritime connections. Frogner Park, in the west section of the city, is justly famous for its impressive display of works by the modern sculptor Gustav Vigeland.

A number of scientific institutions are attached to the university, which had around 16,000 students by the 1970s; the university library is the main library in the country. The majority of university departments are located at Blindern, in the northwest of the city, while apartment buildings for students have been built just outside the university centre, at Sogn and Kringsjå. These students' apartments are used by tourists during the summer months. The city's most distinguished auditorium is the university's Aula (Hall), decorated by the painter Edvard Munch, and it is here that the Philharmonic Society's concerts are held. Oslo also has a number of other national centres of higher learning.

Winter sports

Oslo has exceptional natural advantages for winter sports, especially cross-country skiing; the annual Holmenkollen competitions bring together participants from all the leading ski nations, and the site also houses an interesting ski museum. The Bislett arena, located in the city centre, is an internationally famous speed-skating rink.

Oslo Fjord is used extensively for swimming, although water pollution has become a serious problem in the innermost portions. Boating and sailing are also popular sports on the fjord in summer. The freshwater lakes of Bogstad and Sognsvatn are also frequently visited by swimming enthusiasts, and popular camping-grounds for tourists are to be found at Ekeberg and Bogstad.

Considerable care has been taken by city planners to safeguard the recreational facilities surrounding Oslo: green belts or park areas have been kept free of development, and it is still possible to ski almost to the city centre from outlying regions.

(Öi.R.)

Ostariophysi

The fishes of the superorder Ostariophysi include the majority of freshwater fishes throughout the world. Familiar representatives of this group are the minnows, suckers, characins, loaches, gymnotid "eels," and innumerable catfishes. The 31 recognized families of catfishes constitute the order Siluriformes, the remaining 26 families the order Cypriniformes. Man consumes huge quantities of these fishes for food and derives pleasure from the beauty of tropical aquarium fishes. A few harmful species can inflict painful injuries; some others serve as intermediate hosts for parasites of man. Strange and fascinating

behaviour is exhibited by many of these fishes—nest building, oral incubation, egg laying in mollusk shells, walking and flying, air breathing, production of sound and electricity, and communication by chemical secretions.

GENERAL FEATURES

Size range and diversity of structure. Most ostariophysians are small to moderate in size, from two to 30 centimetres (about one to 12 inches) long; others rank among the giants of the freshwater world. The elegant mahseer (Cyprinidae) of Asia grows to two metres (6½ feet) and 90 kilograms (200 pounds); the wels, a Eurasian catfish (Siluridae), attains 4.5 metres (15 feet) and 30 kilograms (660 pounds). The extent of morphological diversity is at least as great as that in any other group of living vertebrates.

Ostariophysians abound in nearly all freshwater habitats, including subterranean caverns and those on all major land masses and continental islands of the world except for Greenland and Antarctica. A few invade brackish waters, and two families consist largely of marine species. Approximately 6,000 species are recognized, about one-fourth of all known species of fish. Their undisputed success may be attributed at least in part to two remarkable features: a sense of hearing more acute than that in any other group of fish and a warning system by chemical communication unique among fishes.

Importance to man. Many moderate to large ostariophysians are utilized for food, and commercial fisheries harvest huge quantities of marketable species. The common carp (*Cyprinus carpio*), originally from China, has been introduced nearly worldwide and is extensively cultured in the warmer regions. Other Chinese carp under cultivation include the grass carp (*Ctenopharyngodon*), silver carp (*Hypothalmichthys*), snail carp (*Mylopharyngodon*), and bighead carp (*Aristichthys*). Culture of the channel catfish (*Ictalurus punctatus*) is an important industry in the southern United States. Numerous ostariophysians provide sport fishermen with recreation and food; several rank among the world's prized game fish; *e.g.*, mahseers (several species of *Barbus*) of Asia and the dorado (*Salminus maxillosus*) of South America.

Ostariophysians as aquarium fish

The tropical-fish industry has multiplied phenomenally since World War II. In 1968 more than 60,000,000 tropical fishes were imported into the United States. Among the most popular are the characins, tetras, rasboras, danios, barbs, loaches, and innumerable catfishes. Adaptability of many ostariophysians to aquarium life has resulted in their widespread use as experimental animals in scientific research. Foremost among these are the goldfish (*Carassius auratus*) and the common carp.

In eastern Asia and parts of Europe, humans frequently become infected with liver flukes acquired by eating raw or imperfectly cooked fish. The carps, especially *Ctenopharyngodon idellus*, are the second intermediate host of the Chinese liver fluke (*Clonorchis sinensis*). Many cyprinids serve as intermediate hosts for the cat liver fluke (*Opisthorchis felineus*). Domestic animals similarly become infected with flukes and tapeworms.

Some ostariophysians are pests or are potentially dangerous to man. The common carp is a nuisance in many localities in the U.S. Introduced species such as the walking catfish (*Clarias batrachus*) pose a serious threat to the native fauna. In South America, on occasion, the piranha (*Serrasalmus*) voraciously attacks man and domestic animals, and the diminutive candiru (*Vandellia cirrhosa*) can penetrate the urogenital openings of human bathers and cause intense pain and hemorrhaging.

NATURAL HISTORY

Behaviour. *Reproductive cycle.* Like most fishes, ostariophysians are bisexual; eggs develop in the ovaries of the female and spermatozoa (milt) in the testes of the male. In temperate zones most species breed in the spring, when water temperatures are rising and day lengths (photoperiods) are increasing. In tropical regions many fishes spawn the year round. All ostariophysians lay eggs; none give birth to living young. Eggs are fertilized externally in the water in all species except a few auchenipteriod catfishes and the South American characins of the subfamily Glandulocaudinae in which fertilization is internal. Development is direct; newly hatched individuals do not pass through morphological changes (metamorphosis) but instead are miniature replicas of their parents. The age at sexual maturity depends on the species and relative body size. Many small species reproduce when only a few months old and rarely live more than one to a few years. Large species attain sexual maturity when several years old, and, in captivity, the common carp has been known to live more than 50 years.

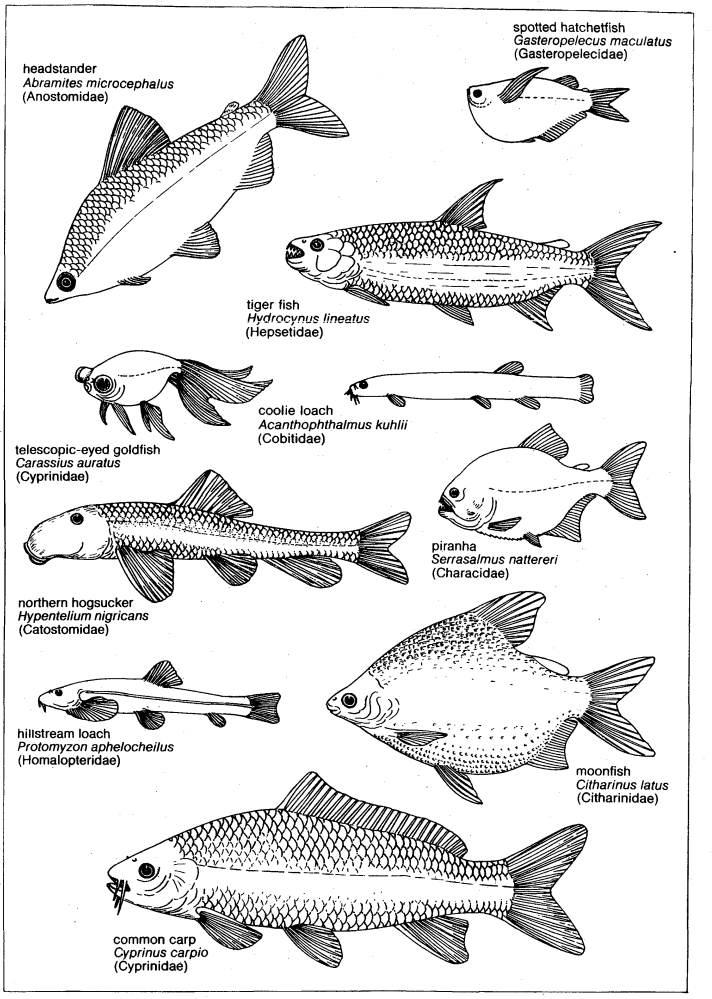

Figure 1: Body plans of representative ostariophysian fishes.
Drawing by D.P. Janson

Breeding. Distinct pairing occurs in most ostariophysians, and courtship behaviour in characoids and cyprinoids often consists of elaborate displays by males in brilliant nuptial coloration. The eggs are heavier than water (demersal) and sink; most are sticky and adhere to the surface or to various objects. Characins and cyprinids generally deposit their eggs among aquatic plants, under stones and logs, or in shallow pits in gravel and sand. Among the many exceptions is the characin *Copeina arnoldi*; the female actually leaps out of the water to lay her eggs on the undersides of overhanging leaves (or, in captivity, of aquarium covers), to which she clings, joined by the male, during egg deposition. The parents then splash water on the eggs during development. The female bitterling (*Rhodeus sericeus*) deposits its eggs in the gill cavity of freshwater mussels by means of an elongated ovipositor, which she inserts into the mussel's incurrent siphon. Catfishes choose breeding sites in streams and ponds, generally in quiet water among plants or on mud, sand, gravel, or debris. The nest may be a simple circular depression (as in bullheads) or a tunnel-like affair in the bank (as in the channel catfish). Migrations comparable

Egg laying on leaves out of water

to those of salmon and eels are unknown among the ostariophysians, but the tendency to migrate occurs among suckers (Catostomidae), which swarm upstream into small tributaries and spawn over gravel or sand bottoms, and in other riverine species, as the mahseer (*Barbus tor*) and the African tiger fish (*Hydrocynus*).

Parental care. Although many species exhibit no parental care, nest building and egg guarding are widespread among this group of fishes. Some cyprinids, such as the chubs (*Nocomis*), build massive pyramidal nests of stones; they desert the nests once spawning is completed. Other species of breeding minnows often swarm over these nests, and hybrids frequently are produced by the mixing of eggs and sperm from different species. The eggs of characids are commonly guarded by the male. Catfishes provide their eggs with considerable protection, either by guarding nests or by carrying the eggs with them. Oral incubation is practiced in sea catfishes (Ariidae); the male carries from ten to 50 marble-sized eggs in the mouth cavity until hatching. The male continues to protect the hatchlings in his mouth even after the young have begun to feed independently. In certain species of banjo catfishes (Aspredinidae), the eggs are anchored to spongy tentacles on the underside of the female's abdomen. Some female callichthyid catfish carry eggs on the abdomen only for fertilization; others deposit their adhesive eggs in froth nests and guard them. The loricariid catfishes employ various methods; some lay adhesive eggs in cavities, others carry them under the lower lip, and a few deposit them on rocks, where they are cleaned, fanned, and guarded by the male.

Defense. Ostariophysians with bright colours and gaudy patterns are popular among tropical-fish fanciers; however, many other small species are somberly coloured, relying on this protective coloration for passive defense from enemies. Large carnivorous forms such as the African tiger fish and the South American piranhas have powerful jaws and strong teeth, extremely effective weapons for defense as well as for offense. Most catfishes and some Old World cyprinids possess spines (hardened fin rays) in the dorsal and pectoral fins. The spines alone afford a considerable degree of protection; in addition, venom glands develop at the base of the spines in some bullheads and madtoms of North America (Ictaluridae), labyrinthic catfishes (Clariidae), and sea catfishes (Ariidae and Plotosidae). Painful but rarely fatal injuries result when the skin of a victim is punctured and venom injected.

Protection by poisonous spines

Although a variety of freshwater fishes can generate an electrical charge, only two develop sufficient voltage to stun other animals, including man—the electric eel (*Electrophorus electricus*) and the electric catfish (*Malapterurus electricus*).

Ecology. *Habitat and distribution.* Ostariophysians are the dominant fishes in virtually all types of freshwater habitats throughout the tropical, temperate, and sub-Arctic regions of the world. Only a few species of the families Cyprinidae and Aspredinidae are known to invade low-saline or brackish waters. The only truly marine members of this superorder are the sea catfishes (Ariidae and Plotosidae), which inhabit tropical coasts. Some plotosids, however, live in freshwater.

The upper regions of small mountain streams are characterized by steep gradients, waterfalls and rapids, and torrential currents. Here occurs a variety of ostariophysians (Homalopteridae, Sisoridae, Akysidae, Loricariidae, Astroblepidae), which exhibit fascinating structural adaptations, such as holdfast organs and specialized respiratory mechanisms. In river systems where the gradients are not steep, currents are slow and quiet pools alternate with riffles, large numbers of characins, cyprinids, and suckers and other types of catfish are conspicuous elements in the fauna. In the sluggish waters of large rivers live large species of suckers, cyprinids (*e.g.*, carp), and many catfishes generally characterized by environmental tolerances and nonrestrictive feeding habits. Ponds and lakes also support large populations of characids, cyprinids, catostomids, and siluroids that prefer and are adapted to standing-water habitats. Although a few are benthic (bottom-dwelling) forms, most of the characins and cyprinids tend to live and feed in the middle and upper layers of the water column. Suckers, loaches, and most catfishes are typically benthic animals and thus are highly adapted to such an existence. Catfishes are generally most active at night or under conditions of reduced light intensities.

Among the most unusual habitats for fishes are those in subterranean waters, wells, and caves. A relatively large number of ostariophysians, belonging to unrelated families, present a striking example of convergent adaptation to life in more or less total darkness. The evolutionary trends have led to a reduction or loss of eyes, loss of pigment, and special development of certain sense organs, especially the lateral-line system, to compensate for the loss of sight. Ostariophysians adapted to such a mode of life include six genera of cyprinids in Africa, the Middle East, and Java; a characin (*Astyanax jordani*) from Mexico; ictalurids from the U.S. (*Trogloglanis* and *Satan*) and Mexico (*Prietella*); six genera of pimelodids and trichomycterids from South America; and two genera of clariids from Africa.

Cave fishes

Feeding habits. The remarkable diversity of feeding habits among ostariophysians is associated with a fantastic variety of adaptations in mouth shapes and tooth types (especially in the suborder Characoidei) probably unsurpassed by any other group. At one extreme are certain cyprinids (*e.g.*, *Notropis atherinoides*) with highly developed gill rakers that strain phytoplankton (minute plants) from the water. Mountain-stream fishes (*e.g.*, Gyrinocheilidae, Homalopteridae, Loricariidae) possess sucker-like lips for scraping algae from the rocks; their teeth are minute or entirely lacking. Because they devour large quantities of plants, herbivores such as the Chinese grass carp are used experimentally to control vegetation in weed-choked waters. Omnivores are especially common among the characins and catfishes. Suckers, long-snouted knife fishes, many catfishes, and some minnows suck up mud and bottom debris, extract the nutriments, and eject the residue. Small carnivorous species consume insect larvae, small crustaceans, worms, mollusks, and other invertebrates. At the top of the food chain are the voracious predators, the most famous of which are the piranhas. Although modest in size, they have short, powerful jaws armed with razor-sharp teeth. These fearsome predators often occur in large schools and can quickly strip the flesh from their victims. Other fishes are their usual prey, but cattle and occasionally humans are also attacked. Probably the largest predatory ostariophysian is the tiger fish, which attains a weight exceeding 45 kilograms; its huge, sharp teeth and large, tuna-like tail endow it with ferocity and speed. Parasitic habits are rarely found among bony fishes, but certain species of trichomycterid catfishes attach themselves to the gills of other fishes and feed on their hosts' blood.

Feeding habits of piranhas

FORM AND FUNCTION

Distinguishing characteristics. *Weberian apparatus and swim bladder.* The single character unique to the superorder Ostariophysi is the presence of the so-called Weberian apparatus, a complex connection between the inner ear and gas bladder (swim bladder). It is formed by the modification of the first four (or five) vertebrae immediately behind the skull, small portions of which have become separated and form a chain of four paired bones, or ossicles, named from front to back the claustrum, scaphium, intercalarium, and tripus. The first is in contact with a membranous window, or extension of the inner ear; the last touches the anterior wall of the swim bladder. The diverse modifications of the Weberian apparatus are diagnostic of orders and certain families; *e.g.*, the claustrum is absent in Gymnotidae. Although much remains to be learned about its functions, it is known to serve as a hearing organ. Changes in volume of the swim bladder due to sound waves in the water cause the ossicles to move and transmit pressure changes to the ear.

The gas bladder varies in shape and size but typically consists of two, sometimes three, chambers. In bottom-dwelling fishes, such as the Homalopteridae, Cobitidae,

and many catfishes, the posterior chamber is greatly reduced and the anterior one often more or less surrounded by a bony capsule. In some catfishes (Sisoridae), only the anterior chamber remains, and it may be encapsulated with bone.

Body covering. The nature of the body covering is variable. Most cypriniforms possess cycloid scales (smooth, overlapping scales more or less circular in shape). Exceptions are found among the Ctenoluciidae, Distichodontidae, Citharinidae, and Ichthyboridae, which have ciliate, or ctenoid, scales (*i.e.*, posterior margins of scales with fine teeth). Most catfishes have lost the scaly covering and are naked, but several families possess bony plates forming an overlapping armour on the sides of the body (Doradidae, Callichthyidae, Loricariidae).

Bony armour

Fin spines and adipose fin. Ostariophysians possess segmented, branched, flexible, soft rays in the fins, unlike the stiff spines of perchlike fishes. In some species, however, soft-ray elements may fuse during development and give rise to a spinous ray (usually called a spine), commonly found in the dorsal and pectoral fins of most catfishes and in the dorsal and anal fins of some Old World cyprinids. The presence or absence of these spines is frequently diagnostic for genera and families.

An adipose fin consists of a small to elongated fleshy or fatty structure without fin-ray supports, located dorsally between the rayed dorsal fin and caudal (tail) fin. It is present in most ostariophysian fishes.

Barbels. Diverse morphological differences in the mouth region are related to the type of diet and to the modes of locating, capturing, and ingesting food. Barbels are short to filamentous, fleshy, fingerlike projections located at the corners of the mouth or on the snout and chin of many suctorial and bottom-feeding fishes (some minnows, loaches, and catfishes). Highly sensitive to touch, they bear numerous taste buds. Taste and touch probably function together in the selection of food before ingestion.

Teeth. Teeth may be present along the jaws, in the roof of the mouth, on the tongue, or in the pharynx, or they may be entirely absent. In the minnows (Cyprinidae) and suckers (Catostomidae), the mouth is toothless, but an array of teeth is borne on a pair of branchial bones, the lower pharyngeals, located in the throat. In the minnows the pharyngeal teeth, arranged in one, two, or three rows, press or bite against a horny pad in the roof of the mouth. They have undergone specialization paralleling the diversity found in jaw teeth of other fishes. Vegetarians such as the carp have grinding, molar-like teeth; carnivores have pointed or hooked teeth. Suckers have numerous pharyngeal teeth aligned in a single row. Oral and pharyngeal teeth are of great value in classifying many families of ostariophysians.

Secondary sexual characteristics. With the onset of the breeding season, many secondary sexual characteristics develop: size differences, nuptial coloration, enlarged and modified fins, breeding tubercles, and contact organs. These features are related chiefly to courtship and mating, but differences in size obviously play a role in guarding nests and care of the young; the sex that exercises parental care is usually the larger. Brilliant red, orange, yellow, green, and blue coloration may develop on various parts of the head, body, and fins, especially in the males. Some characids and cyprinids are among the most beautiful of all fishes. The male usually has larger and more brightly coloured fins than the female. In some characins, the median and pelvic fins of the males may possess small hooks or contact organs, which aid in maintaining contact with the female during spawning. In the six families of cyprinoids, breeding tubercles, or pearl organs (epidermal excrescences), develop on the head, body, and fins of males under the influence of sex hormones. The tubercles function in maintenance of body contact during spawning, in defense of nests and territories, and possibly in the stimulation of females during breeding.

Sexual coloration

Sexual differences among the siluroids are more marked in the highly specialized families. Pelvic fins of female ariid catfishes and, to a lesser extent, of ictalurid catfishes show specialized developments whose functions are not yet fully known. Some male loricariid catfishes develop elaborate dermal, branching growths and spines around the head; in others, the lower lip is enlarged to accommodate the transport of eggs.

Drawing by D.P. Janson

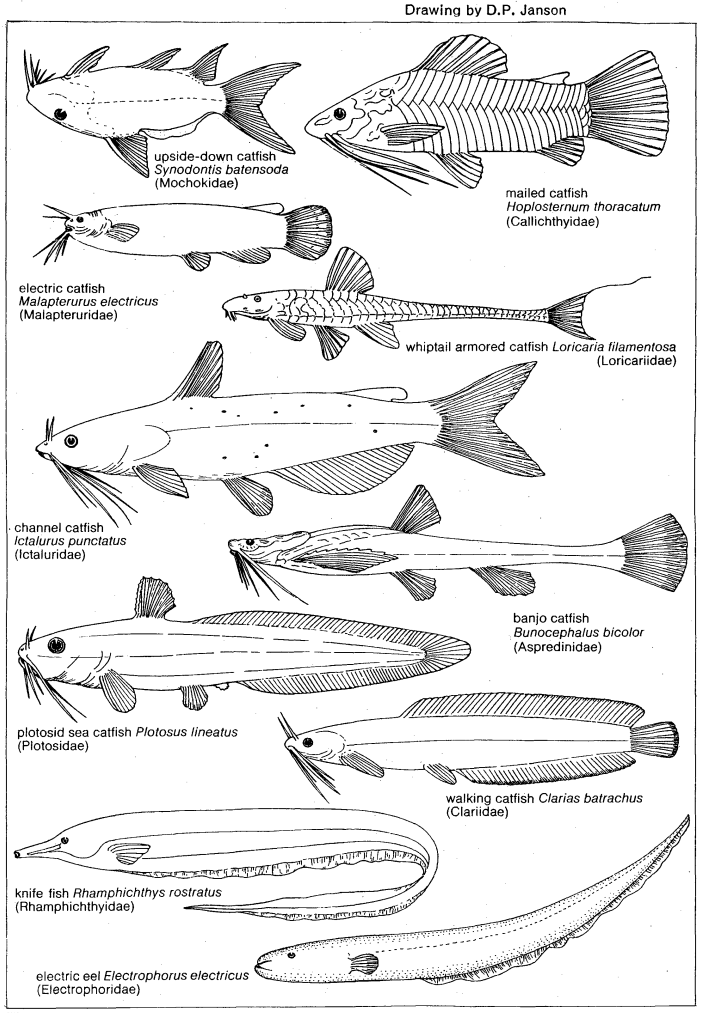

Figure 2: Body plans of representative ostariophysian fishes.

Adaptations for locomotion. *Swimming.* The body of most ostariophysian fishes is more or less streamlined, taking the most efficient form for movement through water. In this highly diversified group, however, a large array of adaptations occurs. Lateral compression (flattened from side to side) is common, especially among characins and cyprinids that inhabit quiet, weedy lakes, ponds, and backwaters. Extreme examples are the flying hatchetfishes (Gasteropelecidae) and the knife fishes (Rhamphichthyidae and Apteronotidae). Depressed body form (flattened from top to bottom), especially in the head region, is widespread among fishes spending much time on or near the bottom or under rocks and similar objects (most catfishes) or among those inhabiting torrential mountain streams (Homalopteridae, some Loricariidae). An elongated, eellike form has evolved in certain loaches (Cobitidae) and electric eels (Electrophoridae), fishes that live on soft, muddy, and sandy bottoms or in rock crevices.

The most common form of locomotion among ostariophysians is swimming by lateral undulations of the body, resulting from the contractions of muscles along the sides of the body and base of the tail. These undulating flexures culminate in a powerful back and forth sweeping of the caudal fin, which produces as much as 85 percent of the total thrust. Some fishes have departed from the normal horizontal swimming posture. The headstanders (Anostomidae) move with the head pointing downward at a slant; some of the pencil fishes (Hemiodontidae) assume a tail-standing position. Most bizarre of all are the upside-down catfishes (Mochokidae) of Africa, which can

Departures from normal posture

swim either in the normal position or inverted, with the belly uppermost. In *Synodontis batensoda,* the coloration of the belly is darker than the back, a reversal of the usual pigmentation pattern. Displacement of the gas bladder toward the underside is a further adaptation to this unusual swimming behaviour.

In fishes with specialized modifications of body form and habits, the fins are frequently modified and used for propulsion. The electric eels and knife fishes (Gymnotoidei) have lost the dorsal fin and, in some cases, the caudal fin. Slow forward and backward movements are made possible by undulations of an extremely long anal fin.

Associated with locomotion is the need for maintaining position in the water, particularly in the rapid torrents of mountain streams. A variety of modifications have evolved that function as holdfasts, anchoring the fish to rocks or similar objects. The hill-stream loaches (Homalopteridae) of southeastern Asia possess a large ventral suction disk formed by the expanded pectoral and pelvic fins. Some of the mountain-stream catfishes (Sisoridae) of Asia have an adhesive organ on the thorax (chest). Mountain-inhabiting catfishes of South America may use a sucker-like mouth (Loricariidae) or employ a combination of a disklike mouth and disklike paired fins (Astroblepidae) for adhesion to the surface.

Walking and flying. A few ostariophysians have evolved the capability to emerge from their aquatic abode and move over land, climb walls, or even fly through the air. The walking catfish (*Clarias batrachus*), recently introduced into southern Florida, uses its pectoral-fin spines as anchors to prevent jackknifing as its body musculature produces snakelike movements and can progress remarkable distances over dry land. Using suction disks and fins, the mountain-stream catfishes (Sisoridae and Astroblepidae) can climb vertical rock walls above the water surface.

Flying by characins

The small hatchetfishes, or flying characins (Gasteropelecidae), of South America normally swim near the surface of the water but are capable of jumping clear and flying short distances. They vibrate enlarged pectoral fins rapidly back and forth by using highly specialized musculature on the shoulder girdle.

Air breathing. Although gills are typical respiratory structures in fishes, many freshwater species occupy habitats where the oxygen may be depleted occasionally or where droughts may force them to live out of water temporarily. These fishes have evolved a variety of air-breathing organs, most of which are outgrowths or pouches from the pharynx, branchial (gill) chamber, or digestive tube. Some catfishes (*Clarias* and *Heterobranchus*) of Asia and Africa have treelike respiratory structures extending above the gill chambers; others (*Heteropneustes*) have elongated, tubular, lunglike sacs extending backward as far as the tail. The electric eel is a mouth breather, gaseous exchange taking place through the wrinkled mucous membrane lining the mouth cavity. Some fishes actually swallow air into the lower part of the digestive tract, which then also serves as a respiratory structure. In the armoured catfishes (*Doras, Plecostomus, Callichthys*) of South America the thin-walled stomach serves this function. The loaches swallow air into a reservoir-like bulge from the intestine and void the remaining gases through the anus.

Communication and sensory perception. *Sound.* Sounds produced by ostariophysians are usually associated with the swim bladder. Minnows produce noises by expelling air through the pneumatic duct, which connects the gas bladder with the digestive tract, and the mouth; loaches do the same by expulsion through the anus. In several catfish families the expanded ends of a spring-like mechanism (derived from modified portions of the fourth vertebra) are attached to the swim bladder. The contraction of muscles extending from the spring mechanism to the skull cause the springs and bladder wall to vibrate rapidly, producing a growling or humming noise. In other catfishes the rubbing or grating movements of the dorsal and pectoral spines produce sounds.

The sense of hearing in Ostariophysi is more highly developed than in any other fishes. The walls of the gas bladder are set in vibration by waves of underwater sound, and the Weberian ossicles then increase the amplitude of these vibrations, transmitting them to the internal ears. This combination is analogous to that of a hydrophone and endows these fishes with a remarkable sensitivity to sound. The normal frequency range detectable by ostariophysians is from 16 to 7,000 hertz (cycles per second); for some characins the maximum is 10,000 hertz. Among other functions, sound production and hearing in fishes may assist in bringing schooling fishes together; even more significant is the role of sound in reproduction. Experiments with North American cyprinids provide evidence that sounds are produced by both sexes and may serve for sexual recognition. A male is able to distinguish the calls of females of his own species from those of closely related species. Consequently, sounds may serve as isolating mechanisms in maintaining the genetic integrity of the species. For fishes living in muddy waters, sounds may be a vital communication link between individuals, especially in the breeding season. It is reasonable to suggest that the combination of sound production and acute hearing may have aided the ostariophysians in attaining their dominant role in freshwaters.

Hearing range

Electric organs. Members of the suborder Gymnotoidei and of the siluriform family Malapteruridae possess the unusual capacity to generate electricity. The best known and most powerful of this group is the electric eel (*Electrophorus electricus*). The electrical organs, three on each side of the body, are derived from modified muscle tissue. The force of the discharge has been measured at 350 to 650 volts and can produce a current strong enough to stun animals as large as a horse or man. The electric catfish (*Malapterurus electricus*) can deliver shocks up to 450 volts, but this power is apparently used only as a defensive measure. The electrical organ of this species, also derived from muscle tissue, consists of a specialized, gelatinous coat of tissue that sheathes most of the body just under the skin.

Production of electric currents

The gymnotid eels and knife fishes (*Gymnotus* and other genera) produce currents of low voltage only, emitting a continuous series of pulses (from 35 to 1,700 hertz), which create an electrical field around the fish. When this field is broken, either by a moving animal or by inanimate objects in the vicinity, the fish can locate the objects, which otherwise would be difficult to see at night or in muddy water. Experiments indicate that electrical cues may also facilitate social interactions. Perception of electrical stimuli occurs in specialized electrical receptors in the skin, and portions of the brain are enlarged to process electrosensory information.

Taste and smell. Catfishes and other fishes living in muddy waters have relatively poor vision but possess chemosensory acuity. Lips, barbels, and most of the body are covered with innumerable taste buds. Experiments have proved that taste plays a leading role in the location of food by these fishes.

Recent studies on the sense of smell have yielded interesting results. Odours emanating from mucus produced in the skin, from secretions of the gonads, and from other body parts serve as chemical signals called pheromones. These odours provide a means of communication between individuals of the same or different species. Certain minnows (Cyprinidae) can discriminate between the odours of at least 15 species of fishes belonging to eight different families. The social behaviour of bullheads (*Ictalurus*) and other ostariophysians is related to a system of communications utilizing chemical signals. An individual not only recognizes individuals of other species but can identify and remember the identification of a particular individual of its own species after a time lapse of three weeks. Territorial and communal behaviour are evidently influenced by different pheromones.

Reactions to wounded companions

Alarm substances. In 1938 an Austrian biologist, Karl von Frisch, introduced an injured minnow (*Phoxinus*) into a school of the same species and observed that the school rapidly retreated and became very frightened. By experimentation he demonstrated that a chemical substance released from the lacerated skin produced a fright reaction when perceived through the nasal organs of

other fishes. This "alarm substance," secreted by specialized cells in the epidermis, is released only when the skin is injured. Alarm substances are present in almost all species of ostariophysians tested (except for a few species of Characidae, Hemiodontidae, Chilodontidae, and Rhamphichthyidae) and are absent in all nonostariophysian fishes examined. Although the fright reaction appears to be important insurance for the individual against predation, the alarm substances are of greatest value among those species exhibiting social behaviour by warning other members of the school. It is possible that alarm substances and the fright reaction have contributed markedly to the biological success of the Ostariophysi.

CLASSIFICATION

Distinguishing taxonomic features. Many characteristics are useful in classifying this large, diverse superorder —the nature of the body covering; presence or absence of barbels, fin spines, and adipose fin; modifications of mouth and fins; types of teeth. Less obvious but especially significant are numerous skull features, specializations of the Weberian apparatus, configuration of the gas bladder, and fusions of vertebral elements.

Annotated classification. This classification, a recent revision by P.H. Greenwood (U.S.) and colleagues, raises to family rank many groups of fish often treated as sub-families. The smallest families are grouped for brevity or are included under a closely related family.

SUPERORDER OSTARIOPHYSI

Gas bladder and internal ear connected by chain of ossicles (Weberian apparatus). All inhabit freshwater unless otherwise noted.

Order Cypriniformes

Body usually covered with cycloid scales; about 3,500 species.

Suborder Characoidei

Cretaceous (about 136,000,000 years ago to present). Mouth not protractile; jaws toothed. Characidae most generalized; other families have specialized skeletal structures, jaws, and teeth.

Family Characidae (characins). Fresh to brackish waters; Africa, South and Central America. Tremendous morphological and ecological diversity. Many brilliantly coloured. Variable food habits. Popular aquarium and food fishes. Size 2.5–150 centimeters (1–60 inches). Examples: tetras, piranhas.

Families Erythrinidae, Ctenoluciidae, and Cyndontidae. South America. Large mouths, canine teeth. Erythrinidae lacks adipose fin; Ctenoluciidae has ciliated scales; Cynodontidae, long anal fin. Carnivorous. Food fishes for man. Size to 120 cm (4 ft).

Family Hepsetidae. Africa. Pikelike; large canine teeth. Carnivorous. Food fishes. Size to 100 cm (40 in.), 55 kilograms (120 pounds).

Family Lebiasinidae. South and Central America. Lateral line and adipose fin usually absent. Small to moderate-sized predators.

Family Gasteropelecidae (hatchetfishes). South and Central America. Deep, strongly compressed body; pectoral fins with well-developed musculature. Capable of true flight. Insectivorous. Aquarium fishes. Size to 10 cm (4 in.).

Family Anostomidae (headstanders). South America. Elongated snout; small mouth with folded or fleshy lips or sucking disk. Head-standing habits. Herbivorous. Aquarium and food fishes. Size to 40 cm (16 in.). The South American families Prochilodontidae (predorsal spine, rough scales), Curimatidae (toothless jaws), and Chilodontidae (specialized pharyngeal teeth) are similar to the Anostomidae.

Family Hemiodontidae (pencil fishes). South and Central America. Lower jaw toothless. Tail-standing posture. Herbivorous. Aquarium fishes. Size to 20 cm (8 in.). Family Parodontidae is similar.

Family Citharinidae (moonfishes). Africa. Deep-bodied, scales often denticulate (toothed), small mouth and teeth. Herbivorous. Aquarium and food fishes. Size to 90 cm (3 ft). The African families Distichodontidae (upper jaw not or scarcely movable) and Ichthyboridae (slender body, upper jaw freely movable, carnivorous) are similar but have ctenoid (ciliate) scales.

Suborder Gymnotoidei

No fossil record. Body elongated; anal fin very long; electric organs present.

Families Gymnotidae (gymnotid eels), *Apteronotidae, and Rhamphichthyidae* (knife fishes). South and Central America. Body greatly compressed, scaled. Weak electrical powers. Rhamphichthyidae with elephant-like snout; herbivorous. Other families carnivorous. Size to 90 cm (3 ft).

Family Electrophoridae (electric eels). South America. Body eellike, scaleless. Powerful electric organs. Size to 275 cm (about 9 ft), weight to 22 kg (48 lb).

Suborder Cyprinoidei

Paleocene to present. Mouth toothless, protractile. Adipose fin rarely present.

Family Cyprinidae (minnows and carps). Most in fresh but some in brackish water; Asia, Europe, Africa, North America. Pharyngeal teeth in 1 to 3 rows. Some with 1 or 2 pairs of small barbels. Food habits variable. Food fishes of sport and commercial value; aquarium fishes. Size 2.5–250 cm (1 in. to more than 8 ft). Examples: minnows, carp, goldfish, barb, bitterling.

Family Catostomidae (suckers). North America, Asia. Protractile, sucking mouth on underside of head. Detritus feeders. Food fishes. Size to 90 cm.

Families Gyrinocheilidae (algae eaters), *Psilorhynchidae, and Homalopteridae* (hill-stream loaches). Mountain streams, Asia. Adaptations to fast currents include fleshy, suctorial mouth and inhalant–exhalant gill openings (Gyrinocheilidae); ventral sucking disk formed by paired fins (Homalopteridae). Algae feeders. Size to 10 cm.

Family Cobitidae (loaches). Asia, Europe, Africa. Wormlike; scales minute or absent; barbels 3–6 pairs. Intestine sometimes modified for aerial respiration. Mostly carnivorous. Aquarium fishes. Size to 30 cm.

Order Siluriformes (catfishes)

Paleocene to present. Body naked or covered with bony plates; adipose fin usually present; pectoral and dorsal fins often with spines. Mostly omnivorous. About 2,500 species.

Family Diplomystidae. South America. One pair of barbels; primitive Weberian apparatus. Size to 24 cm.

Family Ictaluridae (North American freshwater catfishes). Few enter brackish water. North America; widely introduced. Barbels 4 pairs; some with venom glands. Valuable food fishes (sport and commercial). Size to 170 cm (67 in.), 50 kg (110 lb). Examples: bullhead, channel catfish.

Family Bagridae. Asia, Africa. Similar to Ictaluridae but with elongated adipose fin. Food, aquarium fishes. Size to 90 cm.

Family Siluridae. Asia, Europe, Africa. Body compressed; adipose fin lacking, anal fin very long; short dorsal fin (often lacking) without spine. Food aquarium fishes. Size to 400 cm (13 ft), 300 kg (660 lb). Examples: wels, glass catfish.

Family Schilbeidae. Asia and Africa. Similar to Siluridae, but with adipose fin usually present and spine in dorsal fin. Food fishes. Size to 230 cm (91 in.), 110 kg (240 lb).

Families Amblycipitidae and Akysidae. Asia. Similar to Bagridae but with reduced gas bladder. Akysids inhabit mountain streams, have tuberculated skin. Small size.

Family Amphiliidae. Africa. Similar to Bagridae, but paired fins expanding horizontally for adhesion in fast currents. Size to 21 cm (8½ in.).

Family Sisoridae (mountain-stream catfishes). Asia. Ventral surface flat; thorax with longitudinal plates or adhesive organ. Size to 30 cm (12 in.).

Family Clariidae (labyrinthic catfishes). Asia, Africa; widely introduced elsewhere. Long dorsal and anal fins without spines; adipose fin usually lacking. Treelike air-breathing organ. Food fishes. Size to 130 cm (51 in.). Example: walking catfish. The similar family Heteropneustidae has long, hollow air sacs.

Families Cranoglanididae, Pangasiidae, Chacidae, and Olyridae. Small Asian families, each containing 1 to several species.

Family Malapteruridae (electric catfishes). Africa. Rayed dorsal fin lacking; spines lacking. Electric organs. Food fishes. Size to 120 cm (47 in.), 23 kg (50 lb).

Family Mochokidae (upside-down catfishes). Africa. Bony shield on head and nape. Some swim upside down. Food fishes. Size to 60 cm (24 in.).

Families Ariidae and Plotosidae (sea catfishes). Marine, a few entering freshwater. Tropical coasts; Plotosidae restricted to Indo-Pacific. Nasal barbels lacking; oral incubation of eggs in Ariidae. Adipose fin lacking; long anal and caudal fins (confluent in Plotosidae). Food fishes. Size to 115 cm (45 in.).

Family Dordadidae (thorny catfishes). South America. Overlapping plates cover sides of body. Intestinal modifications for aerial respiration. Aquarium fishes. Generally small, to 100 cm (40 in.). The related family, Auchenipteridae, has naked flanks and apparent internal fertilization.

Family Aspredinidae (banjo catfishes). A few enter brackish waters and salt waters. South America. Adipose lacking; broad, flat head; large tubercles on naked body. Aquarium fishes. Size to 30 cm (12 in.).

Family Pimelodidae. South and Central America. Similar to Bagridae, but lack nasal barbels. Food, aquarium fishes. Size to 130 cm (51 in.), 65 kg (145 lb). Families Ageneiosidae (maxillary barbels only), Hypophthalmidae (1 species, toothless), and Helogeneidae (1 species, no dorsal spine) are South American families similar to the Pimelodidae.

Family Trichomycteridae (parasitic catfishes). South America. Operculum (gill cover) usually with spines. Many parasitic. Size to 10 cm (4 in.). Example: candiru. The similar family Cetopsidae lacks opercular spines.

Families Callichthyidae (mailed catfishes), *Loricariidae* (armoured catfishes), *and Astroblepidae.* South and Central America. Two longitudinal series of overlapping bony plates in Callichthyidae. Three or 4 rows of bony scutes in Loricariidae. Skin naked in Astroblepidae. Sucking mouth (Loricariidae), or mouth and fins modified for adhesion to rocks in mountain streams (Astroblepidae). All herbivores, closely related. Aquarium fishes. Size to 75 cm (30 in.).

Critical appraisal. Ostariophysians are relatively primitive bony fishes, singularly distinct from all other fishes except the Gonorynchiformes. Their specialized Weberian apparatus precludes their having given rise to any higher groups. Differences among various classifications of the superorder are not as great as they appear; the same or similar subgroups are widely recognized, but they may be assigned to different levels in the taxonomic hierarchy. L.S. Berg placed all ostariophysians in one order (Cypriniformes) with two divisions (Cyprini and Siluri). The many families of characins listed by Greenwood are recognized as subfamilies under the single family Characidae by many authorities. Present consensus favours the characoids as the most primitive suborder, an ancestral stock giving rise to cyprinoids in southeastern Asia and to gymnotoids in South America.

The siluriform fishes are more highly specialized than the cypriniforms, and the diplomystids undoubtedly are the most primitive of the catfishes. There is little agreement on the relationships of the other families, but recent research on the caudal skeleton indicates that the Ictaluridae, Bagridae, and Schilbeidae (among others) tend to retain primitive characters. Advanced features indicate a relationship between the Clariidae and Heteropneustidae; the Doradidae and Auchenipteridae; the Loricariidae, Astroblepidae, and Callichthyidae; and the Plotosidae and Chacidae. Extensive studies of morphological and other genetic characters of both cypriniform and siluriform fishes are needed before a satisfactory classification and phylogeny can be achieved.

Osteoglossomorpha

The superorder Osteoglossomorpha is a group of morphologically and biologically diverse primitive fishes primarily found in freshwaters; a few species enter slightly brackish water. Their relationship with other teleosts (*i.e.*, advanced bony fishes) is obscure; they probably were an early offshoot from the basal teleost stock. Osteoglossomorpha comprises six extant families and about 150 species. Although the group is of little importance to man, in parts of Africa, Asia, and South America certain osteoglossomorph species are sometimes sought commercially as food fishes.

Except for one North American family (Hiodontidae), the Osteoglossomorpha are tropical fishes. The families Mormyridae (elephant-snout fishes, mormyrs), Gymnarchidae, and Pantodontidae (butterfly fishes) are confined to Africa; the Notopteridae (featherbacks) occur in Africa, Southeast Asia, and India. The distribution of the Osteoglossidae (*e.g.*, pirarucu, arawana) in Africa, South America, and Australasia (believed by many authorities to have once been joined as a single landmass called Gondwana) is of particular zoogeographical interest.

The pirarucu (*Arapaima*) of the Amazon, one of the world's largest freshwater fishes, attains a length of three metres (about ten feet); other osteoglossomorphs—for example, certain mormyrids—are only a few centimetres long.

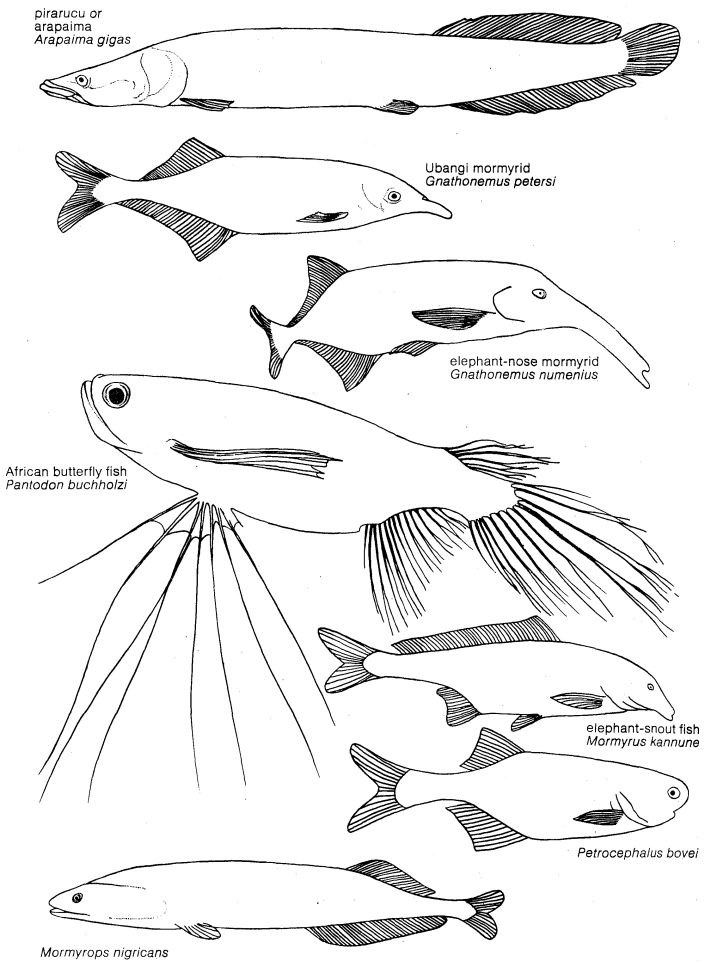
Natural history. *Life cycle and reproduction.* A variety of breeding habits have evolved among the Osteoglossomorpha. In some species there is considerable care of the young by the parents. Although no species is known to undertake extensive breeding migrations, many leave the usual habitat and move into floodplains or streams at breeding time.

The breeding biology of the Mormyridae has been little studied; it does not seem likely, however, that they prepare spawning nests or exercise much parental care. In contrast, *Gymnarchus niloticus* (Gymnarchidae) prepares a large floating nest from the matted stems of swamp grasses, biting off the stems and fashioning them into a trough-shaped structure with an internal length of about 50 centimetres (20 inches). Spawning takes place in the nest, and one or both parents guard the developing young for approximately 18 days.

Nests are not made by notopteroids, but they do establish a breeding territory. Both *Hiodon* species (goldeye and mooneye) spawn in the spring. Eggs are laid on gravel or rocks in shallow, quiet water, which the adults reach after a short migration. The young of the goldeye (*H. alosoides*) remain there until late summer before migrating downstream. In *Notopterus chitala* (Notopteridae), one parent, probably the male, clears an area of the bottom near some submerged object (*e.g.*, rock, plant stem, or piling) on which the eggs are later laid in circular bands; the male guards the developing embryos.

Care of the young

Members of the Osteoglossidae care for their young in a variety of ways. The South American *Osteoglossum bicirrhosum* and its Indo-Australian relatives *Scleropages leichardti* and *S. formosus* carry the eggs and young in the mouth of one parent; little else is known of their breeding habits. The African *Heterotis niloticus* prepares a crude nest from grasses in newly flooded swamp plains. The male guards the young and leads them from the nest on feeding excursions. Both sexes of *Arapaima gigas* of South America dig a spawning pit and guard the developing embryos, which hatch and leave the pit after about seven days; care is provided by the male, around whose



Representative osteoglossomorphic fishes.

Sterba, *Freshwater Fishes of the World*, (*Gnathonemus numenius*) New York Zoological Society Photo, (*Pantodon buchholzi*) T. Dennett in *International Wildlife Encyclopaedia* (1969)

head the young congregate. The dark colour of the male's head seems to provide the chief stimulus for shoal orientation; *i.e.*, forming groups or schools. Apparently there is also a gustatory (*i.e.*, taste) or olfactory (*i.e.*, smell) stimulus in a secretion from glands on the male's head. Parent–young groups persist for two to three months; if the male dies, the young join other shoals.

Spawnings in aquaria suggest that *Pantodon* (Pantodontidae), the African butterfly fish, produces floating eggs and provides minimal parental care. A complicated courtship in this species has also been observed.

Electrical organs

Behaviour and ecology. Mormyridae and Gymnarchidae are of particular interest because they have electrical organs. Electrical discharges from these organs are in the form of pulses, the frequency and nature of which are different in each species. In nature, electrical discharges ranging from an output of about 120 to 300 pulses per second have been recorded.

The flow pattern of the electric field around the fish is distorted by the different conductivity of objects that pass into it. These variations are detected by modified nerve cells (mormyromasts) in the skin. The greatly varying conductivity differences among animals and inorganic objects make it possible for mormyrids to use their electrical organs to distinguish between prey, predators, and obstacles in the turbid water they often inhabit. Discharges from the organs also serve as signals to other mormyrids.

Some mormyriforms tend to swim with little body movement, using instead the dorsal fins for propulsion. This unusual swimming method is probably associated with the use of electric organs in navigation and detection; *Gymnarchus*, for example, swims with its body held straight, propulsion being provided by undulations of the dorsal, or back, fin. Since electrical organs lie near the tail, side-to-side movements of the tail end (as in normal swimming movement) would constantly change their position relative to that of the receptor organs, which are in the head area.

Rigid-bodied swimming like that of the mormyriforms also occurs in the featherbacks (Notopteridae), which use the long anal fin for propulsion. There is no electrical organ in the notopterids, however; the rigid body of these fishes may be correlated with the long, gas-filled swim bladder that extends into the tail end of the body.

All other osteoglossomorphs swim by using the body musculature and caudal (tail) fin in the usual manner. The little African butterfly fish (*Pantodon*) has greatly expanded winglike pectoral fins (behind the gills), which are used for short flights in the air, either to escape predators or to catch insects. *Pantodon* habitually swims or drifts just below the water surface. It leaps from the water by means of a powerful thrust of the pectorals, sending the fish 30 centimetres (about a foot) or more vertically out of the water. Short horizontal flights of about one metre (40 inches) are also executed.

Some species of Osteoglossidae (*Heterotis, Arapaima*), the related Pantodontidae, certain Notopteridae (*Notopterus, Papyrocranus, Xenomystus*), and the Gymnarchidae are able to breathe air at the surface; thus they can live in areas where the water is deoxygenated.

The swim bladder, noise-making, and hearing

The notopterid *Xenomystus* produces sounds that are used as warnings and in courtship. Swim-bladder structure in other Notopteridae suggests that they are also capable of emitting sounds. In all Notopteroidei (including the Hiodontidae) the swim bladder is closely connected with the inner ear, a condition that may be an aid to hearing. Except for the osteoglossid *Heterotis*, all the osteoglossomorphs are carnivorous, the smaller species (and young of all species) feeding on insects and other invertebrates, the larger species on fish. *Heterotis* feeds on microscopic plants and animals filtered from the water.

Osteoglossomorph fishes occupy a diversity of habitats in rivers and lakes, often in turbid waters or in regions with dense aquatic vegetation. A few species seem to require open waters, and some Notopteridae can tolerate slightly brackish water.

Form and function. All living Osteoglossomorpha have strongly toothed jaws. The jaws are not protrusible, but in piscivorous (*i.e.*, fish-eating) species the gape is sometimes considerable. The Mormyridae show a great variety of head shape and mouth form. Many insectivorous (*i.e.*, insect-eating) species have a small mouth at the tip of a long, curved, tubular snout; they feed by probing among rocks or in soft mud. Piscivores have larger mouths and short snouts.

The mouth is large in all Osteoglossidae, which, like the Notopteridae and Hiodontidae, have a more typical head shape than do the Mormyridae. *Heterotis* has complex spiralled structures lying above the gill arches on each side of the head and opening into the pharynx. Food particles, drawn into the pharynx with the respiratory current, are filtered out and concentrated in these organs.

In all Mormyridae and in the Gymnarchidae, a short length of body musculature toward the tail is modified to form the electric organ. These muscles have lost the ability to contract and have undergone considerable cellular reorganization, from slender fibres of ordinary muscle into thin, flat, electroplates, the structures in which electricity is produced. There are about 300 to 400 electroplates in mormyrid electric organs, and 600 to 800 in those of *Gymnarchus*. The brain, particularly the cerebellum, of mormyriforms is the largest known among fish; the cerebellum is associated with the electroreceptor organs (mormyromasts) in the skin.

A well-developed swim bladder is present in all Osteoglossomorpha. In the air-breathing osteoglossids, pantodontids, and gymnarchids, it is highly vascularized (*i.e.*, has many blood vessels), and its inner surface is honeycombed with tiny pits.

Paired extensions in the Notopteridae and Hiodontidae connect the swim bladder with the auditory region of the

skull. In the African genus *Papyrocranus,* diverticula (outpocketings) of the swim bladder actually penetrate the skull, a condition that probably improves hearing. Posteriorly the swim bladder in notopterids extends beyond the abdominal cavity and runs back on either side of the vertebral column. In the early embryos of Mormyridae and Gymnarchidae, a pair of thin tubes extends forward from the swim bladder into the skull; later the tubes atrophy, leaving an isolated vesicle—a blister, or balloon-like structure—within the skull surrounded by the semicircular canals of each ear.

The inner ear shows various modifications; in notopterids, gymnarchids, and mormyrids, the upper portion (for balance) is completely separated from the lower part (for hearing).

In the Mormyridae and Pantodontidae, the anal fin shows considerable sexual dimorphism in shape—*i.e.,* the anal fin of males differs from that of females. These differences may be related to spawning activity.

Classification. *Distinguishing taxonomic features.* Classification in the superorder Osteoglossomorpha is based largely on skeletal characters, in particular the caudal-fin skeleton; the bones around the eye; and the gill arches and their associated dentition. Details of the inner ear and swim-bladder anatomy are also of importance.

Annotated classification. The classification used here is based on that of P.H. Greenwood, D.E. Rosen, S.H. Weitzman, and G.S. Myers (1966), with subsequent research by Greenwood (1970) and G.J. Nelson (1968, 1969). Groups indicated by a dagger (†) are extinct and known only from fossils.

SUPERORDER OSTEOGLOSSOMORPHA

Primitive; well-developed teeth on tongue, skull base, and bones of the mouth cavity; caudal fin skeleton of characteristic form. Lower Cretaceous to Recent.

Order Osteoglossiformes

Osteoglossomorph fishes without electric organs.

Suborder Osteoglossoidei

Swim bladder not connected with skull; semicircular canals and lower part of inner ear connected.

Family Osteoglossidae. Fishes of diverse body form; pectoral fins not greatly enlarged, pelvic fins abdominal in position. Genera: *Arapaima* (1 species) and *Osteoglossum* (2 species), South America; *Scleropages* (2 species), Australia, New Guinea, Borneo, Sumatra, Malaysia, Thailand; *Heterotis* (1 species), Africa. Fossils from Eocene of North America and Tertiary of Australia (*Phareodus*); Eocene of Sumatra and Tertiary of India (*Musperia*).

†*Family Singididae.* Extinct. Apparently toothless; monotypic genus (*Singida*) from Paleocene of Tanzania (East Africa).

Family Pantodontidae. Greatly expanded winglike pectoral fins; pelvic fins thoracic. A monotypic genus, *Pantodon buchholzi,* from Africa. No fossil record.

Suborder Notopteroidei

Swim-bladder connected with the skull; semicircular canals separate from lower part of ear, or, if connected, utriculus greatly enlarged.

†*Family Lycopteridae.* Extinct. Lower Cretaceous of northeast Asia; small freshwater fishes resembling the Hiodontidae. 4 genera (6 species).

Family Notopteridae. Long anal fin confluent with reduced caudal; dorsal fin small or absent. Genera: *Papyrocranus* (1 species) and *Xenomystus* (1 species) in Africa, *Notopterus* (4 species) in Asia and Indonesia. Fossil *Notopterus* from Eocene of Sumatra.

Family Hiodontidae (goldeye and mooneye). Probably the most primitive living osteoglossomorphs. One genus, *Hiodon,* confined to North America. Fossil from Eocene of British Columbia (*Eohiodon rosei*).

Order Mormyriformes

With electrical organs; very diverse head shape and mouth form. Confined to Africa; fossils from Pliocene of Egypt; 2 families, about 130 species.

Family Mormyridae (mormyrs and elephant-snout fishes). Anal, caudal, and dorsal fins present; several genera; about 130 species.

Family Gymnarchidae. No anal fin; long dorsal confluent with reduced caudal fin. One genus and species, *Gymnarchus niloticus.*

Critical appraisal. Taxonomic problems of the osteoglossomorphs concern intragroup relationships, particularly whether the Mormyriformes are more closely related to the Osteoglossoidei or to the Notopteroidei. Some authorities relate the Mormyriformes with the Notopteroidei; others suggest closer affinity with the osteoglossoids and propose that one order, rather than two, should be recognized. The superorder as a whole presents problems of relationship with the other teleostean lineages. Certain fossil groups—*e.g.,* the Eocene genus *Brychaetus* and the Mesozoic families Plethodontidae and Ichthyodectidae—may be osteoglossomorphs, but their relationship with the living groups is still obscure. *Brychaetus* can probably be classified in the Osteoglossiformes, but it may represent a distinct suborder.

Osteopathic Medicine

Osteopathic medicine is a complete school of medical practice. It parallels the school of medicine, whose members hold the degree of bachelor or doctor of medicine, in utilizing all scientifically accepted methods of diagnosis and treatment, including the use of pharmaceuticals, surgery, and X-rays, but differs from them in its greater emphasis on the relationship between the musculoskeletal structure and organ function. Osteopathic physicians develop skill in recognizing and correcting structural problems through manipulative therapy and other forms of treatment. This use of manipulative therapy in diagnosis and treatment is an integral part of osteopathy.

Origin and development of osteopathy. Osteopathic medicine began in the United States in the 19th century as a reform movement against the then rather primitive armamentarium of drugs and surgical techniques. The founder, Andrew Taylor Still, developed a system of osteopathic medicine in reaction to the conditions and types of treatment that he observed while serving as an army physician during the American Civil War.

After failing to persuade various medical schools to incorporate his ideas into their teachings, Still established a new medical school in 1892 in Kirksville, Missouri, where he began conferring the doctor of osteopathy degree (D.O.) upon those physicians who adhered to his concepts of medicine. Still's emphasis on treating the whole man has remained an ideal of the profession.

Osteopathic medicine still has its main base in the United States. Canadian osteopathic physicians have received their training in the United States, and osteopathic medicine in the British Isles is in part a form of postgraduate specialization by holders of the M.D. degree. Most osteopathic physicians who practice elsewhere in the world have also been trained in the U.S. For these reasons the present article is focussed primarily on osteopathy as it is practiced in the United States.

Despite difficulties during its three quarters of a century

Present status

of existence, the osteopathic profession has achieved status as a recognized school of medicine. There are now 13,000 doctors of osteopathy in the United States, and others who received their education there are now located in other countries. The profession maintains nearly 300 hospitals, with a total of more than 20,000 beds.

General osteopathic hospitals provide health care of all kinds, and specialty-oriented hospitals include maternity centres, proctology clinics, arthritis centres, emergency clinics, and alcoholism and drug abuse centres. In the United States, osteopathic institutions are accredited by the American Osteopathic Association (AOA), and most are members of the American Osteopathic Hospital Association.

Training. Professional education leading to the degree doctor of osteopathy is similar to that for doctors of medicine. Although some students enter osteopathic colleges with a minimum of three years of professional training, the majority have completed degree programs.

Admission to colleges is dependent on scholastic achievement, aptitude as measured by the Medical College Admissions Test, and personal interviews. The four years of osteopathic medical education cover the basic sciences and clinical work. Throughout the curriculum special emphasis is placed on the importance of body mechanics and the relationship of body structure to function.

Upon graduation and completion of an internship in one of the AOA approved hospitals, osteopathic physicians enter either general practice—as do three out of four—or various specialties. Although the association particularly encourages general practice, doctors of osteopathy are also certified by AOA specialty boards in anesthesiology, dermatology, internal medicine, neurology, psychiatry, obstetrics and gynecology, ophthalmology, pathology, pediatrics, physical medicine and rehabilitation, proctology, radiology, and many surgical specialties. These men take two- to five-year residencies in osteopathic hospitals equipped to provide the additional training.

Doctors of osteopathy practicing in Canada receive their education at one of the colleges of osteopathic medicine in the United States. The Canadian Osteopathic Association, however, became a recognized national osteopathic association in 1970.

In Great Britain there are two schools of osteopathic medicine. Entrants to the British School of Osteopathy require only a secondary school education, and their four-year course is limited to manipulative therapy and diagnosis. Upon graduation, their practice is limited to these areas. The London College of Osteopathy limits its entrants to those who possess the M.D. degree, and the 14-month course is meant to be a postgraduate training that stresses the musculoskeletal system and manipulative therapy. Graduates are accepted into the British system of socialized medicine and have unlimited practice rights. Both groups may belong to the British Osteopathic Association. Neither British school is inspected, regulated, or approved by the AOA.

Legal status of osteopathy. Osteopathic physicians are licensed to practice medicine in all states of the United States and have the same professional rights and responsibilities as do holders of the M.D. degree under federal law and under the statutes of 48 states and the District of Columbia. In most cases, physicians of both schools of medical practice take their examinations before a medical licensing board composed of both doctors of medicine and doctors of osteopathy. In a very small number of instances doctors of osteopathy are examined by an all-medical board. Sixteen states have separate medical and osteopathic examining boards.

Licensing of osteopathic physicians

In two states—Louisiana and Mississippi—old laws limiting the scope of osteopathic practice continue to exist. Though there are fewer than 100 osteopathic physicians practicing in these states, legislation to guarantee full practice rights is under way in one of them.

In Canada, osteopaths' rights to practice are determined by the individual provinces. British regulations have been noted above.

In other countries, regulation of the practice of the healing arts varies greatly. While the practice of osteopathic medicine as such is not provided for by law outside the countries already discussed, osteopathic physicians practice in many other places.

Research and special programs. Osteopathic research, while encompassing a fairly wide range, considering its relatively limited financial resources, concentrates on topics that ordinarily would not be studied outside osteopathic auspices. Various phases of interrelationship between structure and function are under scrutiny. In the basic science category, studies include anatomy and function of nerve-muscle junctions, transmission of nervous impulses, somatic reflex functions, renal (kidney) growth and function, and blood flow dynamics. In the category of clinical sciences, there are studies of structural findings in hospitalized patients, the effects of manipulation under anesthesia for specific orthopedic problems, the effect of osteopathic manipulation on hypertension, and management of chronic obstructive lung disease by regular medical means, with and without osteopathic manipulation.

At the College of Osteopathic Medicine and Surgery in Des Moines, Iowa, a rehabilitation and treatment centre has been established on an in-patient basis for the alcoholic. At the Kirksville (Missouri) College of Osteopathy and Surgery, a program of rural clinics provides medical care to 40,000 patients by operating 11 clinics staffed by senior students. The clinics are in areas without resident physicians.

STODDARD, *Manual of Osteopathic Practice* (1969), a modern textbook covering osteopathic concepts, treatment, and technique.

(E.P.C.)

Ottawa

Ottawa reflects in many ways the character of the Canadian nation, of which it has been the capital city since being so designated by Queen Victoria in 1857. Its metropolitan area straddles the provincial border of English-speaking Ontario and French-speaking Quebec, and in native language the more than 600,000 inhabitants are divided almost equally. The city itself is entirely in Ontario. In 1884 Sir Wilfrid Laurier, the first French-Canadian premier of Canada, referred justifiably to Ottawa as a city about which it was difficult to say anything good and about which little in the way of visual delight could be predicted. His forebodings, however, held true only until 1937, when the French architect Jacques Gréber began the refashioning of Ottawa into one of the most beautiful of Canadian cities.

The Ottawa area, a harmonious blend of forest, farmlands, and water, is located in a lowland that is hot and humid in summer, nearly polar in winter. It is almost completely walled in by rocks of the so-called Canadian Shield dating from the Precambrian Era over 570,000,000 years ago. Among the deposits left by the great ocean arm known as the Champlain Sea are the deep sand beds along the Rideau River, which flows through the city from the south, and whale skeletons. Across the Ottawa River to the north, in Quebec, lie the heavily wooded Laurentian Hills and the valley of the Gatineau River, which, like the Rideau, joins the Ottawa by the city (for details on related subjects, see CANADA; ONTARIO).

History. The first descriptions of Ottawa's future site were written by the French explorer and founder of New France, Samuel de Champlain, in 1613. The three rivers

Centre block of the Parliament buildings on Parliament Hill, Ottawa. The Peace Tower is at centre, with the Commons wing at left and the Senate wing at right. The spire of the Library of Parliament is in the background.

served as passageways for explorers and traders over the following two centuries. Early in the 19th century the Napoleonic Wars increased Britain's need for shipbuilding timber, and the Ottawa Valley offered just such resources. In 1800 an American, Philemon Wright, had begun timbering across the Ottawa River in what became the city of Hull. With the War of 1812 between Britain and the U.S., the Rideau provided the route for a safe canal way from the Ottawa River to Kingston, on Lake Ontario. The settlement of Ottawa was under way. It was hastened by the arrival in 1826 of Lt. Col. John By of the Royal Engineers to work on the canal, and the town became Bytown. The first white child was born the same year, and in 1827 a Methodist meetinghouse became the first church, a school opened, and a team of doctors opened a practice. A primitive Rideau Street stirred with life, later to become the main commercial artery of the Lower Town, the downtown area.

Canada's compromise capital

Ottawa might still be a modest city had not political quarrels between Quebec city and Toronto and between Montreal and Kingston induced leaders to call upon Queen Victoria to designate a capital for United Canada. From a population of only a little more than 7,700 in 1851, Bytown doubled in the following decade and found itself, in 1855, incorporated and rechristened Ottawa after an Indian tribe, the Outaouacs or Outaouais, that had moved down from the Lake Huron region. It became the fastest growing metropolis in eastern Canada, a development due largely to the presence of the national government. In 1937 Prime Minister William L. Mackenzie King brought Gréber from France to begin the redevelopment of the national capital district.

The contemporary city. The more than 1,800 square miles of the Ottawa metropolitan area, on both sides of the Ottawa River and the provinicial border, comprises about 70 municipalities. Nearly three-quarters of the population lives on the Ontario side. Ottawa itself completely encircles the separate village of Rockcliffe Park, known as the wealthiest in Canada, and the city of Vanier, formerly Eastview. With the linguistic split in the region, bilingualism flourishes in Ottawa more than in any other Canadian city.

The federal buildings in Ottawa are dominated by the 291-foot-high Peace Tower, with its 53-bell carillon, atop the Parliament building, which was rebuilt between 1916 and 1927 after a disastrous fire in the former year. There are few apartment buildings in the city, the residents having a strong preference for single-family units. The many private and public lawns and flowerbeds throughout its environs have made Ottawa something of a garden city from spring until late autumn.

Demography. It is often said, as it is of many cities whose growth has been around government, that no one is born in Ottawa. Though the statement is obviously an exaggeration, Ottawa is populated by Canadiáns of many ethnic origins from across the nation. There is really no melting pot, for the predominant French- and English-speaking populations tend to retain their traditions and religion as well as mother tongue. The harmony of their coexistence has been something of a trend-setting example for Canada since the adoption of an official national policy of bilingualism in 1969.

Linguistic and cultural coexistence

Forecasters have projected a population of more than 1,200,000 for the region by the year 2001, all but about 60,000 living in urban areas. To prevent a monstrous, unhealthy city from developing, a policy known as "open-space therapy" has brought about the creation of a greenbelt around the city. The 41,000 acres of the belt extend in a semicircle for more than 24 miles.

Economic life. The fur trade and lumbering of its early years have faded from Ottawa's life, and the city's industry employs only a small fraction of the labour force. The largest industry is a fine-paper company with about 700 workers. The federal government employs more than 75,000 workers in nearly 150 buildings. As the national capital, Ottawa also attracts many commercial and financial associations from around the country as well as embassies, trade associations, and the like.

Political institutions. The city proper is self-governing and forms part of a vast regional community, the Ottawa-Carleton communities, but the city's attentions are focussed on the federal government. Along with the governmental institutions and crown corporations, the diplomatic missions also contribute to its way of life and give Ottawa a multilingual, cultural, and cosmopolitan atmosphere.

Services. Ottawa is served by both of Canada's major railroads and several Canadian and foreign airlines. The Ottawa Transportation Company supplies bus service throughout the city, but navigation on the Ottawa and Rideau rivers, except for pleasure craft, is a thing of the past. Inexpensive hydroelectric power is purchased in bulk by Ottawa-Hydro from Ontario-Hydro.

Two English-language newspapers, the *Citizen* and the *Journal*, plus *Le Droit* in French, serve the metropolitan area. Two of the six radio stations and one of the three television stations are French. There are seven hospitals in the city.

Cultural life and recreation. The open-space therapy has focussed recreation in Ottawa around parks, playgrounds, pools, and beaches. Pollution has made the beaches hazardous, but it is believed that purification plants along the Ottawa and Rideau rivers will cure this by the mid-1970s.

The presence of large numbers of people from other provinces and nations gives Ottawa a cosmopolitan atmosphere. The inauguration in 1969 of the National Arts Centre has brought cultural life, long hampered by lack of facilities, to a level with that of other North American cities. The centre includes a large opera house and two smaller theatres as well as a salon and foyer for huge festivities or balls. The major cultural centres remain the city's three universities. The University of Ottawa and St. Paul University are bilingual institutions, whereas Carleton University is entirely English. A large community college, Algonquin, provides technical training.

New art centres, museums, and galleries

The National Library and Public Archives Building and the National Museum of Science and Technology, both inaugurated during the 1960s, are bright new features of Ottawa's life. Use of the Parliamentary Library is restricted to legislators and governmental officials. The Public Library moved into a high-rise office complex in 1973. The superb collections of the National Gallery of Canada date back to the 13th century, although its emphasis is on the Canadian arts.

BIBLIOGRAPHY. WILFRID EGGLESTON, *The Queen's Choice* (1961), is a history of Canada's capital in which the author describes the development of the city and relates the history of the National Capital Commission. More detailed information pertaining to Ottawa may be found in LUCIEN

BRAULT, *Ottawa, Old and New* (1946), although now somewhat dated. Ottawa's history is so closely linked with the history of the Ottawa Valley that the only way to really know it is to follow the historical guide provided by COURTNEY C.J. BOND in *The Ottawa Country* (1968), the companion volume of *City on the Ottawa*, rev. ed. (1967). An interesting feature of the latter book is that it introduces the reader, briefly, to the Canadian authors, poets, and artists who lived in Ottawa.

(Ma.G.)

Otto I the Great, Emperor

Otto I, German king and Holy Roman emperor, consolidated the German *Reich*—the old kingdom of the East Franks—by his suppression of the rebellious nobles and his decisive defeat of the invading Magyars, leaving a solid and durable government to two successors.

By courtesy of the Metropolitan Museum of Art, New York, gift of George Blumenthal, 1941

Otto I (left) offering a model of Magdeburg cathedral to Christ in majesty, ivory altarpiece, *c.* 970. In the Metropolitan Museum of Art, New York.

Otto was born on November 23, 912, the son of the future king Henry I, of the Liudolfing, or Saxon, dynasty, and his second wife, Matilda. Little is known of his early years, but he probably shared in some of his father's campaigns. He married Edith, daughter of the English king Edward the Elder, in 930; she obtained as her dowry the flourishing town of Magdeburg. Nominated by Henry as his successor, Otto was elected king by the German dukes at Aachen on August 7, 936, a month after Henry's death, and crowned by the archbishops of Mainz and Cologne.

While Henry I had controlled his vassal dukes only with difficulty, the new king firmly asserted his suzerainty over them. This led immediately to war, especially with Eberhard of Franconia and his namesake, Eberhard of Bavaria, who were joined by discontented Saxon nobles under the leadership of Otto's half brother Thankmar. Thankmar was defeated and killed, the Franconian Eberhard submitted to the King, and Eberhard of Bavaria was deposed and outlawed. In 939, however, Otto's younger brother Henry revolted; he was joined by Eberhard of Franconia and by Giselbert of Lotharingia and supported by the French king Louis IV. Otto was again victorious: Eberhard fell in battle, Giselbert was drowned in flight, and Henry submitted to his brother. Nevertheless, in 941 Henry joined a conspiracy to murder the King. This was discovered in time; and, whereas the other conspirators were punished, Henry was again forgiven. Thenceforward he remained faithful to his brother and, in 947, was given the dukedom of Bavaria. The other German dukedoms were likewise bestowed on relatives of Otto.

Suppression of the nobles

Despite these internal difficulties, Otto found time to strengthen and to extend the frontiers of the kingdom. In the east the margraves Gero and Hermann Billung were successful against the Slavs, and their gains were consolidated by the founding of the Monastery of St. Maurice in Magdeburg, in 937, and of two bishoprics, in 948. In the north, three bishoprics (followed in 968 by a fourth) were founded to extend the Christian mission in Denmark. Otto's first campaign in Bohemia was, however, a failure, and it was not until 950 that the Bohemian prince Boleslav I was forced to submit and to pay tribute.

Having thus strengthened his own position, Otto could not only resist France's claims to Lorraine (Lotharingia) but also act as mediator in France's internal troubles. Similarly, he extended his influence into Burgundy. Moreover, when the Burgundian princess Adelaide, the widowed queen of Italy whom the margrave Berengar of Ivrea had taken prisoner, appealed to him for help, Otto marched into Italy in 951, assumed the title of king of the Lombards, and married Adelaide himself, his first wife having died in 946. In 952 Berengar did homage to him as his vassal for the kingdom of Italy.

Otto had to break off his first Italian campaign because of a revolt in Germany, where Liudolf, his son by Edith, had risen against him with the aid of several magnates. Otto found himself compelled to withdraw to Saxony; but the position of the rebels began to deteriorate when the Magyars invaded Germany in 954, for the rebels could now be accused of complicity with the enemies of the *Reich*. After prolonged fighting, Liudolf had to submit in 955. This made it possible for Otto to defeat the Magyars decisively in the Battle of the Lechfeld, near Augsburg, in August 955; they never invaded Germany again. In the same year Otto and the margrave Gero also won a victory over the Slavs. A further series of campaigns led, by 960, to the subjection of the Slavs between the middle Elbe and the middle Oder. The archbishopric of Magdeburg was founded in 968 with three suffragan bishoprics. Even Mieszko of Poland paid tribute to the German king.

Foreign conquests

In May 961 Otto procured the election and coronation of the six-year-old Otto II, his elder son by Adelaide, as German king. Then he went for a second time to Italy on the appeal of Pope John XII, who was hard pressed by Berengar of Ivrea. Arriving in Rome on February 2, 962, Otto was crowned emperor, and 11 days later a treaty, known as the *Privilegium Ottonianum,* was concluded, to regulate relations between emperor and pope. This confirmed and extended the temporal power of the papacy; but it is a matter of controversy whether the proviso enabling the emperor to ratify papal elections was included in the original version of the treaty or added in December 963, when Otto deposed John XII for treating with Berengar and set up Leo VIII as pope. Berengar was captured and taken to Germany, and in 964 a revolt of the Romans against Leo VIII was suppressed.

When Leo VIII died in 965, the Emperor chose John XIII for pope, but John was expelled by the Romans. Otto, therefore, marched for a third time to Italy, where he stayed from 966 to 972. He subdued Rome and even advanced into the Byzantine south of Italy. Prolonged negotiations with Byzantium resulted in the marriage of Otto II to the Byzantine princess Theophano, in 972. Having returned to Germany, the Emperor held a great assembly of his court at Quedlinburg on March 23, 973. He died in Memleben on May 7, 973, and was buried in Magdeburg at the side of his first wife.

Otto I's achievement rests mainly on his consolidation of the *Reich*. He deliberately made use of the bishops to strengthen his rule and thus created that "Ottonian church system of the *Reich*" that was to provide a stable and long-lasting framework for Germany. By his victorious campaigns, he gave Germany peace and security from foreign attack; and the pre-eminent position that he won as ruler gave him a sort of hegemony in Europe. His Italian policy and the acquisition of the imperial crown constituted a link with the old Carolingian tradition and was to prove a great responsibility for the German people in the future. All areas under Otto's rule prospered, and the resultant flowering of culture has been called the Ottonian renaissance.

Assessment

BIBLIOGRAPHY. RUDOLF KOEPKE and ERNST DUEMMLER, *Jahrbücher der deutschen Geschichte: Kaiser Otto der Grosse* (1876; 2nd ed., 1962), the yearbook of the German government that offers a description of the actual events in chronological order and the people involved, using all critically han-

dled sources; GERD TELLENBACH, "Otto der Grosse, 912-973," in *Die grossen Deutschen*, new ed., vol. 1, pp. 35–51 (1956), a short character sketch in essay form; HERMANN AUBIN, *Otto der Grosse und die Erneuerung des abendländischen Kaisertums im Jahre 962* (1962); and HELMUT BEUMANN and HEINRICH BUETTNER, *Das Kaisertum Ottos des Grossen* (1963)—all the above-mentioned works assess the historical significance of the renewal of the empire in reaction to the idea of the Millennium; HAGEN KELLER, "Das Kaisertum Ottos des Grossen im Verständnis seiner Zeit," *Deutsches Archiv für Erforschung des Mittelalters*, 20:325–388 (1964), a discussion of the thesis that Otto was crowned emperor by the Pope versus the idea that he was already emperor, although only with the title of king. Very little has been published on Otto I in English. JOHN J. GALLAGHER, *Church and State in Germany Under Otto the Great* (1938); and chapters by C.W. PREVITE-ORTON and A.L. POOLE in *The Cambridge Medieval History*, vol. 3 (1964), are of interest.

(Ku.R.)

Otto, Rudolf

German theologian, philosopher, and historian of religions, Rudolf Otto exerted worldwide influence upon religious thought during the early decades of the 20th century following the publication of his pioneering work, *Das Heilige* (1917; Eng. trans., *The Idea of the Holy*, 1923). In this book Otto undertook to characterize the experience of apprehending the Holy—the sense of a sacred, ultimate power and reality—as disclosed in all religions, and thus to identify what is common to all of them as a distinctly religious phenomenon (see also SACRED OR HOLY). Within a decade after its publication, the book became world-famous and Otto stood forth among Protestant theologians as potentially the most fruitful religious thinker of the postwar period. With the more recent upsurge of interest in the phenomenological study of religion (the systematic study of religious experience and its expressions), his work is receiving attention, especially among younger historians of religion.

Foto-Jannasch, Marburg/L.

Rudolf Otto, 1925.

Academic and public career. Otto was born on September 25, 1869, in Peine (Hanover, now Niedersachsen), Germany, the son of William Otto, a manufacturer, and Karoline Reupke Otto. Little is known of Otto's early life, except that he was educated at the gymnasium in Hildesheim before becoming a student of theology and philosophy at the University of Erlangen and, later, at the University of Göttingen, where he was made a *Privatdozent* ("lecturer") in 1897, teaching theology, history of religions, and history of philosophy. In 1904 he was appointed professor of systematic theology at Göttingen, a post he held until 1914, when he became professor of theology at the University of Breslau. In 1917 he became professor of systematic theology at the University of Marburg and for one year (1926–27) served as rector of the university. He retired from his university post in 1929, though he continued to live in Marburg the rest of his life.

Otto took time from his scholarly pursuits, more out of a sense of duty than of preference, to participate in community and public affairs. He was a member of the Prussian Parliament from 1913 to 1918 and a member of the Constituent Chamber in 1918, where he asserted a liberal and progressive influence. And he was later to concern himself with the political questions of the Weimar Republic. Otto also participated widely in Christian ecumenical activities, both as they related to divisions within the Christian community and as they concerned relations between Christianity and other religions of the world.

Scholarly pursuits. *Early development of Otto's inquiry.* What initially prompted Otto's inquiry into man's experience of the Holy was a specifically Christian, even Protestant, concern that had awakened in him while studying the life and thought of Martin Luther. This concern—to elucidate the distinctive character of the religious interpretation of the world—is reflected in his first book, *Die Anschauung vom heiligen Geiste bei Luther* (1898), literally, "The Perception of the Holy Spirit by Luther." He was to expand his inquiry in his book, *Naturalistische und religiöse Weltansicht* (1904; Eng. trans., *Naturalism and Religion*, 1907), in which he contrasted the naturalistic and the religious ways of interpreting the world, indicating first their antitheses and raising the question of whether the contradictions can be or should be reconciled. Otto resisted an easy reconciliation between the world view offered by the sciences and the religious interpretation but opposed equally the religionist's hostility toward science and the scientist's disregard of religion. The two perspectives, he insisted, are to be embraced and heeded for what they purport to disclose concerning the world in which men live; but it was clear that Otto's principal concern was to justify and to clarify what it is that the religious interpretation of the world, even within its rational aspect, conveys to man as a distinctive dimension of understanding beyond the discoveries of the sciences and the generalized knowledge following from them. Five years later came his work, *Kantische-Fries'sche Religionsphilosophie* (1909; Eng. trans., *The Philosophy of Religion Based on Kant and Fries*, 1931), a discussion of the religious thought of the German philosophers Immanuel Kant and Jacob Friedrich Fries, in which he sought to specify the kind of rationality that is appropriate to religious inquiry.

Distinctive character of religious understanding

During 1911–12 Otto undertook an extended journey, visiting many countries of the world, beginning with North Africa, Egypt, and Palestine, continuing to India, China, and Japan, and returning by way of the United States. These experiences were to set his problem in a worldwide context, turning him to an extended and searching exploration of the diverse ways in which the religious response had manifested itself among various religions of the world. He proved to be remarkably well equipped for such an exploration, both in his mastery of languages and his knowledge of the history of world religions. In addition to being at home with the languages of Near Eastern religions, he had mastered Sanskrit sufficiently to translate many ancient Hindu texts into German as well as to write several volumes comparing Indian and Christian religious thought.

From Schleiermacher to "The Idea of the Holy." Otto's initial mentor guiding his inquiry into the specific character of the religious response was the eminent German philosopher and theologian Friedrich Schleiermacher. It was Schleiermacher's early work, specifically his book *Über die Religion. Reden an die Gebilden unter ihren Verächtern* (1799; Eng. trans., *On Religion: Speeches to its Cultured Despisers*, 1893), to which Otto gave particular attention. What appealed to him in this work was Schleiermacher's fresh way of perceiving religion as a unique feeling or awareness, distinct from ethical and rational modes of perception, though not exclusive of them. Schleiermacher was later to speak of this unique feeling

"Absolute dependence" and "creature-feeling"

as man's "feeling of absolute dependence." Otto was deeply impressed by this formulation and credited Schleiermacher with having rediscovered the sense of the Holy in the post-Enlightenment age. Yet he later criticized the formulation on the grounds that what Schleiermacher had pointed up here was no more than a close analogy with ordinary, or "natural," feelings of dependence. For "absolute dependence" Otto substituted "creature-feeling." Creature-feeling, he said,

> is itself a first subjective concomitant and effect of another feeling element, which casts it like a shadow, but which in itself indubitably has immediate and primary reference to an object outside of the self.

Otto called this object "the numinous" or "Wholly Other"—*i.e.*, that which utterly transcends the mundane sphere, roughly equivalent to "supernatural" and "transcendent" in traditional usage.

Various influences had played upon Otto's reflections through the years, aiding him in reformulating the religious category that was to carry him beyond Schleiermacher. His early teacher at Göttingen, Albrecht Ritschl, had located religion in the realm of value judgments, whereas, more significantly, his theological colleague at Göttingen, Ernst Troeltsch, sought for a religious a priori as the ground of religious interpretation and judgment. Otto was impressed by William James's shrewd insights in *The Varieties of Religious Experience* (1902), yet he found James's empirical method inadequate for interpreting such phenomena. Otto was particularly attracted to the thought of J.F. Fries, already mentioned, whose notion of *Ahndung* (obsolete form of *Ahnung*; literally, "presentiment," or "intuition"), a yearning that yields the feeling of truth, opened up to him a way of dealing with religious phenomena, sensitively and appropriately. These "feelings of truth" Otto sought to schematize in his *Idea of the Holy*.

The "numinous" and *mysterium tremendum*

In that work, however, Otto was conscious of moving beyond his previous efforts, exploring more specifically the nonrational aspect of the religious dimension, for which he coined the term "numinous," from the Latin *numen* ("god," "spirit," or "divine"), on the analogy of "ominous" from "omen." The numinous, the awe-inspiring element of religious experience, Otto contended,

> evades precise formulation in words. Like the beauty of a musical composition, it is non-rational and eludes complete conceptual analysis; hence it must be discussed in symbolic terms.

Thus, *The Idea of the Holy*, while benefitting from earlier studies, represented for Otto a new venture and a radical shift in the nature and ground of his inquiry. The concern here was to attend to that elemental experience of apprehending the numinous itself. In such moments of apprehension, said Otto,

> we are dealing with something for which there is only one appropriate expression, *mysterium tremendum*. . . . The feeling of it may at times come sweeping like a gentle tide pervading the mind with a tranquil mood of deepest worship. It may pass over into a more set and lasting attitude of the soul, continuing, as it were, thrillingly vibrant and resonant, until at last it dies away and the soul resumes its "profane," non-religious mood of everyday experience. . . . It has its crude, barbaric antecedents and early manifestations, and again it may be developed into something beautiful and pure and glorious. It may become the hushed, trembling, and speechless humility of the creature in the presence of—whom or what? In the presence of that which is a *Mystery* inexpressible and above all creatures.

Although the *mysterium*, which Otto represents as the form of the numinous experience, is beyond conception, what is meant by the term, he insists, is something intensely positive. This can be experienced in feelings that convey the qualitative content of the numinous experience. This content presents itself under two aspects: (1) that of "daunting awfulness and majesty," and (2) "as something uniquely attractive and *fascinating*." From the former comes the sense of the uncanny, of divine wrath and judgment; from the latter, the reassuring and heightening experiences of grace and divine love. This dual impact of awesome mystery and fascination was Otto's characteristic way of expressing man's encounter with the Holy.

After "The Idea of the Holy." Otto employed the method he had developed in *The Idea of the Holy* in three major publications that followed: *West-Östliche Mystik* (1926; Eng. trans., *Mysticism East and West*, 1932); *Die Gnadenreligion Indiens und das Christentum* (1930; Eng. trans., *India's Religion of Grace and Christianity*, 1930); and *Reich Gottes und Menschensohn* (1934; Eng. trans., *The Kingdom of God and Son of Man*, 1938). Of the three books, the latter is especially important for glimpses of new insight that seem to point beyond the earlier, more widely acclaimed volume; it renders the hint of ultimacy that appears in present history.

Otto's concern with experiencing the numinous also gave rise to experimenting with new forms of liturgy designed to give urgency and vividness to such experiences in Protestant services of worship under critically controlled conditions. Here he employed a "Sacrament of Silence" as a culminating phase, a time of waiting comparable to the Quaker moment of silence, which he acknowledged to have been the stimulus to his own innovation.

Interest in non-Christian religions

Otto took all religions seriously as occasions to experience the Holy and thus pressed beyond involvement in his own historic faith as a Christian to engage in frequent encounter with people of other religious traditions. He had much respect for the distinctive characteristics of the various religions and thus resisted universalizing religion in the sense of reducing all to the lowest common denominator. Yet he strongly argued for a lively exchange between representatives of the various religions. It was this concern that led him to create in Marburg the Religious Collection of religious symbols, rituals, and apparatus on a worldwide basis for purposes of inspection and study and to advocate establishing an Inter-Religious League as "a cultural exchange in which the noblest . . . of our art and science and of our whole spiritual heritage would be mutually interpreted and shared."

Personal life and characteristics. Never having married, Otto shared his home with his widowed sister and her daughter. A tall, erect man of subtle mien and movement, Otto created an imposing presence. His students at Marburg called him "Der Heilige" ("the Holy One" or "the Saint"). Someone said of him after his death, "After all, he was something of a king; yet a king who did not lack humility."

Rudolf Otto was first and foremost a scholar, absorbed in his special field of inquiry and rigorous in the pursuit of it. This in itself presented him on initial contact as being austere in manner and remote in his reflections. People who encountered him did not readily intrude upon the man or engage him in light conversation. To interrupt his reflections, they felt, one must have something of significance to talk about. That this was in part a facade of their own making, based upon the impressiveness of the man himself, was discovered again and again by those who came to know him well; for, despite this outward austerity, Otto was a gentle person, reticent in his response to people. Yet he could be gracious and outgoing once the barrier of formality had relaxed. Nevertheless, the style of the man was that of a serious and dedicated scholar, and no amount of congeniality or friendliness dispelled that tone of an encounter with him.

Otto died at Marburg March 6, 1937.

Ottoman Empire and Turkey, History of the

A term without ethnic significance, Ottoman is a dynastic application derived from the Arabic "'Uthmān," for Osman (died 1324), who is regarded as the founder of the Turkish empire that spanned six centuries and came to an end only in 1922, when Turkey was proclaimed a republic. This empire, centred in Anatolia, varied greatly in extent during its checkered history. At various times it included the Balkan States, Greece, Crete, and Cyprus; parts of Hungary, Austria, and southern Russia; Iraq, Palestine, and Egypt; North Africa as far west as Algeria; and parts of Arabia. For the previous history of the Turkish or Turkmen tribes that Osman led, see SELJUQS; and for the history of the area of modern Turkey before the Ottomans, see ANATOLIA, ANCIENT.

This article is divided into the following sections:

I. The period of growth and world power

THE OTTOMAN STATE TO 1481: THE AGE OF EXPANSION

The first period of Ottoman history was characterized by almost continuous territorial expansion, during which the Ottoman dominion spread out from a small northwestern Anatolian principality to cover an empire encompassing southeastern Europe, Anatolia, and the Arab world. At the same time, the political, economic, and social institutions of the Middle East were amalgamated with those inherited from Byzantium and the great Turkish empires of Central Asia and re-established in new forms that were to be characteristic of the area into modern times.

Origins and expansion of the Ottoman state, c. 1300–1402. In their initial stages of expansion, the Ottomans were leaders of the Turkish *gazis*, or fighters for the faith of Islām, against the shrinking Christian Byzantine state. The ancestors of Osman, the founder of the dynasty, were members of the Kayı tribe who had entered Anatolia along with a mass of Turkmen Oğuz nomads who overwhelmed Byzantium after the Battle of Manzikert in 1071 and came to occupy eastern and central Anatolia during the 12th century. The *gazis* fought against the Byzantines and then the Mongols, who invaded Anatolia following the establishment of the Īl-Khānid (Ilhanid) Empire in Iran and Mesopotamia starting in the last half of the 13th century. Following the Mongol defeat of the Seljuq army in 1293, Osman I emerged as prince (*amīr*) of the border principality of Bithynia, in northwestern Anatolia, and was in command of the *gazis* leading the fight against the Byzantines in that area. With the disintegration of Seljuq power and its replacement by Mongol suzerainty, enforced by direct military occupation of much of eastern Anatolia, independent Turkmen principalities emerged in the remainder of Anatolia, among which was that led by Osman. Hemmed in on the east by the more powerful Turkmen principality of Germiyan, Osman and his immediate successors concentrated their attacks on Byzantine territories bordering the Bosporus and the Sea of Marmara to the west. Left as the most important Muslim rivals of Byzantium, the Ottomans became the main focus for the mass of nomads and urban unemployed then searching for means to gain their livelihoods and to fulfill their religious desire to expand the territory of Islām. The Ottomans were able to take advantage of the opportunity offered by the decay of the Byzantine frontier defense system and the rise of economic, religious, and social discontent in the Byzantine Empire (*q.v.*) and, starting under Osman I and continuing under his successors Orhan (Orkhān; ruled 1324–60) and Murad I (ruled 1360–89), took over Byzantine territories, first in western Anatolia and then in southeastern Europe. It was only under Bayezid I (ruled 1389–1402) that the wealth and power gained by this initial expansion was used to assimilate the Anatolian Turkish principalities to the east.

By 1300 Osman ruled an area stretching from Eskişehir (Dorylaium) to the plains of İznik (Nicaea), having defeated several organized Byzantine efforts to curb his expansion. Byzantine attempts to secure Īl-Khānid support against the Ottomans from the east were unsuccessful, and the emperor's use of mercenary troops from western Europe caused more damage to his own territory than to that of the Turks. At the time, however, the Ottomans lacked effective siege equipment and were unable to take the major cities of Bithynia. Nor could they move against their increasingly powerful Turkmen neighbours at Aydın and Karası, in southwestern Anatolia, who had arisen as the result of Byzantine weakness in the area. Orhan's capture of Bursa in 1324 provided the first means for developing the administrative, financial, and military power necessary to make the principality into a real state and to create an army. It was Orhan who began the military policy (successfully developed by his successors) of employing Christian mercenary troops, thus lessening his dependence on the nomads as well as providing fighting forces better able to meet the military needs of the time. Orhan soon was able to capture the remaining Byzantine towns in northwestern Anatolia: İznik (1331), İzmit (1337), and Üsküdar (1338). He then moved against his major Turkmen neighbours to the south. Taking advantage of internal conflicts he annexed Karası in 1345 and gained control of the area between the Gulf of Edremit and Kapı Dağı (Cyzicus), reaching the Sea of Marmara. He thus put himself in a position to end Aydin's lucrative monopoly in providing mercenary troops to competing Byzantine factions in Thrace and Constantinople. In 1346 Orhan replaced Aydın as the principal ally of the Byzantine emperor John VI Cantacuzenus. The consequent entry of Ottoman troops into Europe gave them a direct opportunity to see the possibilities for conquest offered by the decline of Byzantium. The collapse of Aydın following the death of its ruler, Umur Bey, left the Ottomans alone as the leaders of the *gazis* against the Byzantines. Orhan helped Cantacuzenus take the throne of Byzantium from John V Palaeologus, and as reward secured the right to ravage Thrace and to marry the emperor's daughter Theodora. Ottoman raiding parties began to move regularly through Gallipoli into Thrace. Huge quantities of captured booty strengthened Ottoman power and attracted into Ottoman service thousands from the uprooted masses of Anatolia. Starting in 1354, Orhan's son Süleyman transformed Gallipoli, on the European side of the Dardanelles, into a permanent base for expansion into Europe, and refused to leave, despite the protests of Cantacuzenus and others. From this base, his bands moved into the Balkans, up the Maritsa River, raiding as far as Adrianople (Edirne). Cantacuzenus soon fell from power, at least partially because of his

cooperation with the Turks, and Europe began to be aware of the extent of the Turkish danger.

It was only under Orhan's son Murad I that Gallipoli was used for permanent conquests. Constantinople itself was bypassed because its thick walls and well-organized defenses, despite the weakness and disorganization of its defenders, remained too strong for the rudimentary Ottoman army. Murad's initial conquests were northward into Thrace, culminating with the capture in 1361 of Adrianople—the second city of the Byzantine Empire; renamed Edirne, the city became the new Ottoman capital, providing the Ottomans with a centre for the administrative and military control of Thrace. As the main fortress between Constantinople and the Danube, it controlled the principal invasion road through the Balkan mountains, assured Ottoman retention of their European conquests, and gave them the means for further expansion to the north. Murad then moved through the Maritsa Valley and captured Philippopolis (Filibe) in 1363. Control of the main sources of Constantinople's grain and tax revenues enabled Murad to force the emperor to accept his suzerainty. The death of the Serbian emperor Stefan Dušan in 1355 left his successors too divided and weak to defeat the Ottomans, despite an alliance with King Louis the Great of Hungary and Tsar Shishman of Bulgaria in the first European crusade against the Ottomans. The Byzantine emperor John V tried to mobilize European assistance by uniting the churches of Constantinople and Rome, but only further divided Byzantium without assuring any concrete help from the West. Murad was thus able to rout the allies at Chirmen, on the Maritsa in 1371, increasing his own confidence and demoralizing his smaller enemies, who rapidly accepted his suzerainty without further resistance. Murad next inaugurated an Ottoman empire of vassals in Europe. He retained local native rulers, who in return accepted his suzerainty, paid annual tributes, and provided contingents for his army when required to do so. This policy enabled the Ottomans to avoid a great deal of local resistance to conquest by assuring rulers and subjects alike that their lives, properties, traditions, and positions would be preserved if they peacefully accepted Ottoman rule. It also enabled the Ottomans to govern the newly conquered areas without building up a vast administrative system of their own or maintaining occupation garrisons.

Creation of European vassals

Moving rapidly to consolidate his empire south of the Danube, Murad captured Macedonia (1371–87), central Bulgaria (including Monastir (1382), Sofia (1385), and Niš (Nish) (1386), and Serbia, all culminating in the climactic defeat of the Balkan allies at the Battle of Kosovo (Kosovo Polje) in 1389. South of the Danube, only Walachia, Bosnia, Albania, Greece, and the Serbian fort of Belgrade remained outside Ottoman rule, and to the north, Hungary alone was in a position to resist further Muslim advances.

Murad was killed during the Battle of Kosovo. His son and successor Bayezid I was unable to take advantage of his father's victory to achieve further European conquest, and was, in fact, compelled to restore the defeated vassals and return to Anatolia to face the rising threat of the Turkmen principality of Karaman, created on the ruins of the Seljuq Empire of Anatolia, with its capital at Konya. Bayezid's predecessors had avoided forceful annexation of Turkmen territory in order to concentrate on Europe. They had, however, expanded by such peaceful means as marriage alliances and the purchase of territories. The acquisition of territory in central Anatolia from the amirates of Hamid and Germiyan had brought the Otto-

mans into direct contact with Karaman for the first time. Murad had been compelled to take some military action to prevent Karaman from occupying his newly acquired territories, but once this was accomplished he had turned back to Europe leaving the unsolved problem to his successor son. Karaman willingly cooperated with Serbia in stirring opposition to Ottoman rule among Murad's vassals in both Europe and Anatolia. It had strengthened the Balkan Union that was routed by the Ottomans at Kosovo, and had stimulated a general revolt in Anatolia that Bayezid was forced to meet by an open attack as soon as he was able to do so. By the end of 1390, Bayezid had overwhelmed and annexed all the remaining Turkmen principalities in western Anatolia. He attacked and defeated Karaman in 1391, annexed several Turkmen states in eastern Anatolia, and was preparing to complete his conquest in the area when he was forced to turn back to Europe to deal with a revolt of some of his Balkan vassals, encouraged and helped by Hungary and Byzantium. Bayezid quickly smashed the rebels (1390–93), occupied Bulgaria and put it under direct Ottoman administration for the first time, and put Constantinople under siege. In response, Hungary organized a major European crusade against the Ottomans. The effort was beaten back by Bayezid at Nicopolis (Niğbolu) on the Danube in 1396. Europe was terrorized and Ottoman rule south of the Danube was so assured, and Bayezid's prestige in the Islāmic world was so extended that he was given the title of *sulṭān* by the shadow ʿAbbāsid caliph of Cairo—this despite the opposition of the caliph's Mamlūk masters, the rulers of Egypt, Syria, and the Holy Cities, who wanted to retain the title only for themselves.

War with Timur

Turning back to Anatolia to complete the conquests aborted by his move against the crusaders, Bayezid thoroughly overran Karaman, the last Turkmen principality, in 1397. His advances, however, now attracted the attention of Timur (Tamerlane), who had been building a powerful Tatar empire in Central Asia, Iran, Afghanistan, and Mesopotamia, and whose invasion of India in 1398 had been halted by his fear of the rising Ottoman power on his western flank. Encouraged by several Turkmen princes who had fled to his court when their territories were taken by Bayezid, Timur decided to destroy Bayezid's empire before resuming his campaigns in India and thus invaded Anatolia. As Bayezid and Timur moved toward battle, the former's Turkmen vassals and Muslim followers deserted him because he had abandoned the old Ottoman *gazi* tradition of advancing against the infidel. Left only with forces provided by his Christian vassals, Bayezid was decisively overwhelmed by Timur at the Battle of Ankara in 1402. Taken captive by the victor, he died within a year.

Restoration of the Ottoman Empire, 1402–81. Timur's objective in Anatolia had not been conquest, and he followed his victory by retiring from Anatolia after restoring to power the Turkmen princes who had joined him. Even Bayezid's sons were able to assume control over the family's former possessions in western Anatolia, and the Ottoman Empire in Europe was left largely untouched. At this time a strong European crusade might have pushed the Ottomans out of Europe altogether, but weakness and division south of the Danube and diversion in other matters to the north left an opportunity for the Ottomans to restore what had been torn asunder without significant loss.

Disputed succession

But internal divisions were to hinder Ottoman efforts to restore their power. Bayezid's four sons fought for the right of succession. His eldest son Süleyman assumed control in Europe, with his capital at Edirne, and gained the support of the Christian vassals and those who had stimulated Bayezid to turn toward conquest in the East. The descendants of the Turkmen notables who had assisted the early Ottoman conquests in Europe supported the claims of Mehmed, who with the additional support of the Anatolian Muslim religious orders and artisan guilds was able to defeat and kill his brothers Mûsa Bey, who had established his capital at Bursa, and İsa Bey of Balıkesir, in southwestern Anatolia, as well as Süleyman, and so assume undisputed possession of the entire empire as Sultan Mehmed (Muḥammad) I. He was to reign from 1413 to 1420.

Under Mehmed and Murad II (ruled 1421–51), there was a new period of expansion in which Bayezid's empire was restored and new additions made. Mehmed restored the vassal system in Bulgaria and Serbia and promised the vassal princes that he would not undertake new European adventures and would restore his position within the state. Murad II was also compelled to devote most of the early years of his reign to internal problems, and particularly to the efforts of the *gazi* commanders and Balkan vassal princes in Europe, as well as the Turkmen vassals and princes in Anatolia, to retain the autonomy and even independence gained during the decade following the Battle of Ankara. In 1422–23, Murad suppressed the Balkan resistance and put Constantinople under a new siege that ended only after the Byzantines had provided him with huge amounts of tribute. He then restored Ottoman rule in Anatolia and eliminated all of the Turkmen principalities left by Timur with the exception of Karaman and Candar (Jandar), which he left autonomous though tributory so as not to excite the renewed fears of Timur's successors in the east. Murad then inaugurated the first Ottoman war with Venice (1423–30), which had maintained friendly relations with the sultans in order to develop a strong trade position in the Ottoman dominions and the Black Sea area. Venice, however, had accepted Salonica from Byzantium in order to prevent Ottoman expansion across Macedonia to the Adriatic, which it considered to be a Venetian lake. The war was indecisive for some time; Venice was diverted by conflicts in Italy, and the Ottomans needed time to build a naval force sufficient to compete with that of the Venetians. In addition, Murad was diverted by an effort of Hungary to establish its rule in Walachia, between the Danube and the Transylvanian Alps, a move which inaugurated a series of Ottoman-Hungarian conflicts that were to occupy much of the remainder of his reign. Murad finally built a fleet strong enough to blockade Salonica and enable his army to take it (1430), after which Ottoman naval raids against Venetian ports in the Adriatic and the Aegean compelled Venice in 1432 to make a peace in which it abandoned its efforts to prevent the Ottoman advance to the Adriatic, and was allowed to assume a role as the leading commercial power in the sultan's dominions.

Outbreak of Venetian War

Murad, who had been put on the throne by Turkish notables who had joined the Ottoman state during the first century of its existence, soon began to resent the power they had gained in return as well as in consequence of the great new estates they had built up in the conquered areas of Europe and Anatolia. To counteract their power, he began to build up the power of various non-Turkish groups in his service, particularly those composed of Christian slaves and converts to Islām, whose military arm was organized into a new infantry organization called the Janissary corps. To strengthen this group, Murad began to distribute most of his new conquests to its members, and to add new supporters of this sort he developed the famous *devşirme* system by which Christian youths were drafted from the Balkan provinces for conversion to Islām and life service to the sultan. With their revenues and numbers increasing, the *devşirme* men and their supporters achieved considerable political power. Because the new European conquests were being used by the sultan to build up the *devşirme* relative to the Turkish notables, the former wanted them to continue and expand, while the latter opposed them. Murad, wanting to return to aggressive policies of European expansion in order to help the *devşirme* reduce the power of the Turkish notables, renewed the struggle with Hungary in Serbia and Wallachia starting in 1434. He took advantage of the death in 1437 of the Hungarian king Sigismund to reoccupy Serbia, excepting Belgrade, and to ravage much of Hungary, and he then annexed Serbia in 1439, beginning a policy of replacing the vassals with direct Ottoman rule throughout the empire. Hungarian control of Belgrade was now the major bar to large-scale advances north of the Danube. Ottoman attacks on it and raids on Transylvania failed to move the Hungarians, largely because

Organization of the Janissary corps

of the leadership of János Hunyadi (*q.v.*), originally a leader of the Walachian border resistance to the *gazis* in 1440–42. Although Murad finally defeated Hunyadi at the Battle of Zlatica (İzladi) in 1443, the increased influence of the Turkish notables at Murad's court led the sultan to agree to the Peace of Adrianople in 1444. By its terms Serbia regained its autonomy, Hungary kept Wallachia and Belgrade, and the Ottomans promised to end their raids north of the Danube. In 1444 Murad also made peace with his main Anatolian enemy, Karaman, and retired to a life of religious contemplation, voluntarily passing the throne to his son Mehmed II who, still very young, already showed the qualities of leadership that were later to distinguish his long reign. The Byzantines and the pope sought to use the opportunity created by the existence of a youthful sultan to push the Ottomans out of Europe, organizing a new crusade joined by Hungary and Venice when the pope assured them that they were not bound to honour the peace treaty they had signed with Muslim infidels. A crusader army moved through Serbia across the Balkan Mountains to the Black Sea at Varna, where it was to be supplied and transported to Constantinople by a Venetian fleet, which was to sail through the Straits, at the same time using its power to prevent Murad from returning from Anatolia with the bulk of the Ottoman army. Though the crusaders reached Varna, a Serbian decision to remain loyal to the sultan, combined with Venetian reluctance to fulfill its part of the agreement for fear of losing its trade position should the Ottomans win, left the crusaders stranded. Further quarrels among the crusade leaders gave Murad time to return from Anatolia and organize a new army. The Turkish victory at Varna on November 10, 1444, ended the last important European crusading effort against the Ottomans. Murad now reassumed the throne and brought back to power with him the *devşirme* party, whose insistent demands for conquest led him to spend the remainder of his reign eliminating the vassals and establishing direct rule in much of Thrace, Macedonia, Bulgaria, and Greece. In the process, he divided the newly acquired lands into estates the revenues of which further increased the power of the *devşirme* at the expense of the Turkish notables. Only Albania was able to resist because of the leadership of its national hero, Skanderbeg (George Kastrioti). He was routed by the sultan at the second Battle of Kosovo (1448). By the time of Murad's death in February 1451, the Danube frontier was secure, and it seemed that the Ottoman Empire was in Europe to stay.

New European crusade

Whereas the victory at Varna brought new power to the *devşirme* party, the grand vizier Candarlı Halil Paşa was able to retain a dominant position for the Turkish notables whom he led by keeping the confidence of the sultan and by successfully dividing his opponents. Prince Mehmed therefore became the candidate of the *devşirme*, and it was only with his accession that they were able to achieve the political and military power made possible by the financial base built up during the previous two decades. Under Sultan Mehmed II (1451–81), the *devşirme* increasingly came to dominate, and to press their desire for new conquests in order to take fuller advantage of the situation created at Varna. Constantinople became their first objective. To Mehmed and his supporters, the Ottoman dominions in Europe could never reach their full extent or be molded into a real empire so long as their natural administrative and cultural centre remained outside their hands. The grand vizier (the sultan's chief adviser) and other Turkish notables bitterly opposed the attack, ostensibly because it might draw a new crusade, but in fact because of their fear that the capture of the Byzantine capital might bring about a final triumph of the *devşirme*. The siege (April 6–May 29, 1453) and conquest of Constantinople and its transformation into the Ottoman capital of Istanbul marked an important new state in Ottoman history. Internally, it saw the end of power and influence for the old Turkish nobility, whose leaders soon were executed or exiled and whose properties were confiscated, and the triumph of the *devşirme* and their supporters. Externally, the conquest made Mehmed II the most famous ruler in the Muslim world, even though the lands of the old caliphate still remained in the hands of the Mamlūks of Egypt and Timur's successors in Iran. Moreover, it was not long before possession of Constantinople stimulated Mehmed to nourish an ambition to place under his dominion not merely the Islāmic and Turkic worlds but also a re-created Byzantine Empire and, perhaps, the entire world of Christendom.

Final attack on Constantinople

To pursue these objectives, Mehmed II developed various bases of power. Domestically, his primary objective was to restore Istanbul as the political, economic, and social centre of the area that it formerly had dominated. To this end, he worked to repopulate the city, not only with its former inhabitants but also with elements of all the conquered peoples of the empire, whose residence and intermingling there would provide a microcosm for a similar process that Mehmed hoped would weld the entire empire into a powerful and integrated whole. Special tax concessions were established to encourage the most active and skilled of his subjects to settle in the capital. The major religious groups were allowed to establish their own self-governing communities, called *millets*, under the leadership of their religious chiefs, each retaining its own civil laws, traditions, and language under the general protection of the sultan. Mehmed also worked to restore the physical aspects of the city. Old buildings were repaired; streets, aqueducts, and bridges were constructed; sanitary facilities were modernized; and a vast supply system was set up to provide for the city's inhabitants. Great attention was paid to restoring Istanbul's industry and trade, with special concessions to attract merchants and artisans from all parts of the empire.

Restoration of Istanbul

Mehmed also devoted much time in expanding his dominions in Europe and Asia in order to establish his claim to world leadership. To this end, he eliminated the last princes who might dispute his claims to be legitimate successor to the Byzantine and Seljuq dynasties, and replaced the remaining vassal princes with direct, Ottoman administration. In addition, he extended Ottoman rule far beyond the territories inherited from Murad II; from 1454 to 1463, he concentrated mainly on southeastern Europe, annexing Serbia (1454–55), conquering the Morea (1458–60), and eliminating in the process the last major claimants to the Byzantine throne. When Venice refused to surrender its important forts on the Aegean coast of the Morea, Mehmed inaugurated the second Venetian-Ottoman war (1463–79). At the same time he annexed Trebizond (1461) and the Genoese commercial colonies that had survived along the Black Sea coast of Anatolia, including Sinop and Kafa, and began the process by which the Crimean Tatar *khāns* were compelled to accept Ottoman suzerainty. In 1463 he occupied and annexed Bosnia, helped by the native Bogomils, an evangelical Christian sect that had been badly treated by the Catholic Hungarians. When Albania continued to hold out, helped by supplies sent by sea from Venice, Mehmed sent in large numbers of Turkmen irregulars, who in the process of conquering Albania settled there and formed a Muslim community. Whereas the papacy and Venice were unable to raise a new crusade, they were able to divert Mehmed by encouraging attacks by his Eastern enemies, the Turkmen principality of Karaman and the Tatar Ak Koyunlu ("White Sheep") dynasty, which under the leadership of Uzun Ḥasan, had replaced Timur's descendants in Iran. Mehmed, however, skillfully used dynastic divisions to conquer Karaman in 1468, extending direct Ottoman rule in Anatolia to the Euphrates. When Uzun Ḥasan responded by invading Anatolia in the company of many Turkmen princes, Venice intensified its attacks in the Morea, Hungary moved into Serbia, and Skanderbeg attacked Bosnia. Mehmed, however, was able to defeat these enemies, one after the other. In 1473 he routed Uzun Ḥasan, who acknowledged Ottoman rule in all of Anatolia and returned to Iran. This brought the Ottomans into conflict with the Mamlūk empire in Syria, which Mehmed neutralized, though he could not defeat it. He then turned to Venice, and several naval raids along the Adriatic coast finally led to a peace in 1479 whereby Venice surrendered its bases in Albania and the

Second Venetian war

Morea and agreed to pay a regular annual tribute in return for restoration of its commercial privileges. Mehmed then used his new naval power to send a large force that landed at Otranto in southern Italy in August 1480, and to attack Rhodes. Success seemed within sight when his premature death in 1481 brought his effort to an end. But he had, indeed, laid the foundations for Ottoman rule in Anatolia and southeastern Europe that was to survive for the next four centuries.

In addition to conquering a large empire, Mehmed worked to consolidate it and to codify the political, administrative, religious, and legal institutions developed during the previous century in a series of law codes called *kanun-names*. The immensity of the task, however, and his diversion in numerous campaigns delayed the process to such an extent that it was completed only during the mid-16th century. Nor was Mehmed overly successful in building the economic and social bases of his empire. His most important problem was securing sufficient money to finance his military expeditions and the new apparatus of government and society. The tax systems inherited from his predecessors did not provide the required money, particularly because most of the conquered lands were turned into estates whose taxes went entirely to their holders in return for military and administrative services. Mehmed therefore turned to a number of expedients that achieved their immediate objectives, but at the cost of grave economic and social difficulties. He regularly withdrew all coins from circulation and issued new ones with a larger proportion of base metal alloys. To enforce acceptance of the new issues, he sent armed bands around the empire with the right to confiscate without compensation all of the older and more valuable coins that had not been voluntarily exchanged for the new. The debasement of the coinage soon caused a rapid inflation, and this in turn greatly disturbed the industry and trade that the sultan had hoped to assist. In addition, in his search for revenues, Mehmed created monopolies over the production and use of essential goods, distributing them among the highest bidders, who in turn charged excessive prices and created artificial scarcities to secure their profits. Finally, Mehmed established the principle that all revenue-producing property belonged to the sultan. In pursuance of this, he confiscated much private property and religious foundation lands, creating tremendous resentment and opposition among those who lost their revenues, including members of the religious *'ulamā'* class, the Turkish notables, and even some *devşirme* men, whose discontent threatened to undermine both state and sultan. It was only by playing these groups off against each other that Mehmed was able to maintain his own position and power and to continue his conquests.

Financial difficulties

Ottoman institutions in the 14th and 15th centuries. Ottoman dynasts were transformed from simple tribal leaders to border princes (*uc bey*) and *gazi* leaders under Seljuq and then Īl-Khānid suzerainty in the 13th and early 14th centuries. With the capture of Bursa, Orhan had been able to declare himself independent of his suzerains and assume the title of *bey*, which was retained by his successors until Bayezid I was named sultan by the shadow 'Abbāsid caliph of Cairo following his victory over the Christian crusaders at the Battle of Nicopolis (1396). These title changes were not immaterial in the position of the Ottoman ruler within the state and in the organization of the state itself. As *uc bey* and even *bey*, the Ottoman leader remained little more than a tribal chief, sharing administrative and military leadership with the Turkmen chiefs surrounding him. Like the tribal chiefs, he had the right to the loyalty and obedience of his followers only so long as he led them to victory, and only in relation to his military functions. Beyond this, he was only one among equals in the councils that decided general internal policies; the tribes and clans remained autonomous in their internal affairs. The *bey* was accessible to the tribe and clan leaders as well as to their followers. He could intervene in disputes among the clans, but jurisdiction was limited indeed. Muslim law and jurists had little influence, whereas Turkish tribal law and custom prevailed. In such a situation, the idea of rule was very limited; administration was conceived mainly in financial terms, with each clan or family or tribe accepting Ottoman military leadership largely for the financial rewards it could bring. Ottoman chiefs collected the booty in conquered lands, and following the conquest had the right to collect taxes from lands left in their possession. The only advantage that the *bey* had over the chiefs surrounding him was, as tribal war leader, the right called *pençik*, to collect an extra fifth of the booty taken by his followers. Because the *bey* was dependent for his power and revenues on the assent of his followers, his authority was limited in scope and in time.

Powers of Ottoman rulers

But as the territory of the Ottoman principality expanded, and the Ottomans fell heirs to the administrative apparatus left by the Byzantines, this simple tribal organization was replaced by a more complex form of government, so that by the time the Ottoman rulers became sultans, they already had far more extensive power and authority than had been the case a half-century earlier. The simple tribal organization of the Ottoman *bey* could suffice only for so long as the state was small enough for the individual tribal leaders to remain on their lands and fight the nearby enemy at the same time. But as the principality expanded and the frontiers and enemies became further removed from previously conquered territory, the financial and administrative functions at home had to be separated from the military. Taxes had to be collected to exploit the conquered territories and support the officers and soldiers while they were away. The treasury of the sultan had to be separated from that of the state so that each would have an independent income and organization. Throughout the 14th and 15th centuries, the Ottoman state gradually evolved its institutions of government and the army to meet the needs of administering and defending an expanding empire. As this was done, it was natural that it should be influenced by those states that had preceded it, not only in the areas it came to rule, but also in the lands of its ancestors. So it was that the developing Ottoman state was influenced by the traditions of the nomadic Turkic empires of Central Asia, particularly in military organization and tactics. It was also influenced heavily by the classical High Islāmic civilization of the 'Abbāsids, as passed through the hands of the Seljuqs, particularly in the development of orthodox Islām as the basis of its institutions of administration, religion, law, and education, and in the development of the *mukataa* as the basic unit of its administrative and financial systems. In the court hierarchy, the central financial structure, and the tax and administrative organizations developed in the European provinces, the Ottomans were influenced by the Byzantines and, to a lesser extent, by the Serbian and Bulgarian empires. Whereas conversion to Islām was not demanded of those conquered at this time, many Christians and Jews voluntarily converted to secure full status in the new empire. Most, however, continued to practice their old religions without restriction. A particularly important source of Christian influence during the 14th century came from the close marriage ties between the Ottoman and Christian courts. Sultan Orhan married Theodora, daughter of Byzantine emperor John VI Cantacuzenus. Theodora was the mother of Murad I, who in turn married Byzantine and Bulgarian princesses, whereas Bayezid I married Despina, daughter of the Serbian prince Lazar. Each of these marriages brought Christian followers and advisers into the Ottoman court, and it was under their influence that Bayezid I in particular abandoned the simple nomadic courts and practices of his predecessors and isolated himself behind elaborate court hierarchies and ceremonials borrowed primarily from the Byzantines. At the same time, the Greek and Serbian languages tended to dominate Ottoman court life, and to a lesser extent its administration.

Influences of early states

The triumph of Sultan Mehmed I in 1413 was due at least in part to the support of the Turkish notables and Muslim religious orders of Anatolia who strongly resented the Christian predominance in Bayezid's court and

attributed his abandonment of the *gazi* tradition and attacks in Turkish Muslim Anatolia to their influence. As a result, Turkish and Muslim influences dominated the Ottoman court during the 15th century, although the hierarchies, institutions, and ceremonies introduced in the previous century remained largely without change.

Growth of administration

The same process that isolated the sultans from their subjects also removed them from the daily administration of government. Formal institutions of administration therefore had to be evolved to take their place, with the rulers delegating more and more of their duties to executive ministers, to whom the Seljuq title *vezīr* (vizier) was given. The continued close connections of the Ottoman family with the urban guilds and orders of Anatolia, many of the members of which were descendants of officials of the Great Seljuq and Īl-Khānid empires, as well as the empire of the Seljuqs of Konya, provided continuity with the Islāmic Turkish traditions of government. With them came the basic unit of Islāmic administrative and financial organization, the *mukataa*, which intimately associated each office with a source of revenues and made each official the collector of his own salary, at the same time that it circumscribed his administrative powers within those tasks directly involved with the financial function. It was relatively simple for the Ottomans to preserve previous methods of taxing on the local levels in different parts of the empire while weaving them into a united whole through the veneer provided by the *mukataa* units in which the resulting tax revenues were assigned to Ottoman officials.

As the central administration was divided into functional departments, a vizier was appointed to direct each. Most of the early viziers were former Turkmen princes who had entered Ottoman service, though some, particularly under Bayezid I, were Christians and Christian converts. State policy was discussed and decided in a council (*divan*) of these viziers, who were joined by religious, judicial, and military leaders under the direction and chairmanship of the sultan. As the duties of the state became more extensive and complex, the individual viziers gained increased financial and political power, and as the Byzantine influence caused the sultan to isolate himself, it was inevitable that the viziers would come to dominate. As if to emphasize his removal from the daily affairs of state, the sultan began to appoint one of his viziers as his chief minister, or grand vizier. From 1360 to the conquest of Constantinople, this powerful position was reserved for members of the Çandarlı family, which came to lead and represent the powerful and assertative Turkmen notable families, who thus benefitted most from the 14th-century expansion of the empire.

Office of grand vizier

The first Ottoman army had been composed entirely of Turkmen nomads, who had remained largely under the command of their own tribe and clan leaders, and under the influence of the *şeyh*s of the heterodox and mystic religious orders that had converted most of them to Islām. Armed with bows and arrows and spears, these nomadic cavalrymen had lived mostly on booty, but those assigned as *gazi*s to border areas or sent to conquer and raid Christian lands had also been given more permanent revenues in the form of taxes levied on the lands they garrisoned. These revenue holdings were formalized as *mukataʿa*s, with the tribal leaders and *gazi* commanders holding them and collecting their revenues to feed, supply, and arm their followers. It was this type of *mukataa* that developed into the Ottoman form of fief called *timar*, that was the basis of Ottoman military and administrative organization as the European portions of the empire were conquered from the vassals in the 15th century and placed under direct Ottoman administration.

These troops had predominated through Orhan's reign until he had seen that such mounted and undisciplined men were of limited use in besieging and taking large cities. In addition, once he had established his state, he had found it difficult to maintain order with such an army because the nomads still preferred to maintain themselves by the traditional forms of looting, in the lands of their commander as well as in those of the enemy. To replace the nomads, Orhan had organized a separate standing army of hired mercenaries paid by salary rather than booty or by *timar* estates. Those mercenaries organized as infantry were called *yaya*s, those organized as cavalry, *müsellem*s. Although the new force included some Turkmen who were content to accept salaries in place of booty, most of its men were Christian soldiers from the Balkans who were not required to convert to Islām as long as they obeyed their Ottoman commanders. As Murad I had conquered more and more of southeastern Europe these forces had become mainly Christian, and as they came to dominate the Ottoman army, the older Turkmen cavalrymen were maintained mainly as irregular shock troops, called *akıncı*s, who were compensated only by booty. As the *yaya*s and *müsellem*s expanded in numbers, their salaries became too burdensome for the Ottoman treasury, so in most cases the newly conquered lands were assigned to their commanders in the form of *timar*s. It was this new regular army that developed the techniques of battle and siege used to achieve most of the 14th-century Ottoman conquests, but because it was commanded by members of the Turkish notable class, it became the major vehicle for their rise to predominance over the sultans, whose direct military supporters were limited to the vassal contingents.

Growth of a regular army

Only late in the 14th century did Murad I and Bayezid I attempt to build up their personal power by building a military slave force for the sultan under the name *kapıkulu* (pl. *kapikullari*), or slaves of the Porte. Murad based the new force on his right to a fifth of the war booty, which he interpreted to include captives taken in battle. As these men entered his service, they were converted to Islām and trained as Ottomans, gaining the knowledge and experience required for service in the government, as well as the army, while remaining in the sultan's personal service. During the late 14th century, this force became the most important element of the Ottoman army, particularly its infantry branch, called *yeniçeri* ("new soldiers"), or the Janissary corps. The provincial forces provided by the timar holders comprised the Ottoman cavalry and were called *sipahi*s, while the irregular *akıncı*s and salaried *yaya*s and *müsellem*s were relegated to rear-line duties and lost their military and political importance. But when Bayezid I abandoned the *gazi* tradition and moved into Anatolia, he lost the support of the Turkish notables and their *sipahi*s before his new *kapıkulu* army was fully established. He thus had to rely only on the Christian vassal forces in the Battle of Ankara, and whereas they demonstrated considerable valour and fighting ability, they were not alone sufficient to resist Timur's powerful army.

When the Ottoman Empire was restored under sultan Mehmed I, the Turkish notables, in order to deprive the sultan of the only military force he could use to resist their control, required him to abandon the *kapıkulu* as contrary to the Islāmic tradition that Muslims could not be kept in slavery. The European and Anatolian revolts that arose early in the reign of Murad II were at least partly stimulated and supported by members of the *kapıkulu* as well as the Christian slaves and vassals who had been losing their power to the Turkish notables. But as soon as Murad II was established, he resumed earlier efforts to make the sultanate more independent, building up the strength of the Janissaries and their associates and playing them off against the notables. He distributed most of his conquests to members of the *kapıkulu* force, occasionally as *timar*s, but more often as tax farms (*iltizam*s), so that the treasury could obtain the money it needed to maintain the Janissary army entirely on a salaried basis. In addition, in order to man the new force, Murad developed the *devşirme* system of recruiting the best Christian youths from southeastern Europe.

The *devşirme* system

Whereas Mehmed II used the conquest of Constantinople to destroy the major Turkish notable families, and build up the power of the *devşirme*, he sought only to establish a balance of power and function between the two groups so that he could use and control both for the benefit of the empire. So it was that he enlarged the concept of *kapıkulu* to include members of the Turkish nobility and their Turkmen followers as well as the products of the

devşirme. Now only persons accepting the status of slaves of the sultan could hold positions in the Ottoman government and army. Persons of Muslim and non-Muslim origin could achieve this status, so long as they accepted the limitations involved, namely absolute obedience to their master and the devotion of their lives, properties, and families to his service. After this time, all important ministers, military officers, judges, governors, *timar* holders, tax farmers, Janissaries, *sipahis*, and the like were made members of this class and attached to the will and service of the sultan. The salaried Janissary corps remained the primary source of strength of the *devşirme* class whereas the *sipahis* and the *timar* system remained the bases of power of the Turkish notables.

Mehmed II thus avoided the fate of the great Middle Eastern empires that had preceded that of the Ottomans, in which rule had been shared among members of the ruling dynasty and with others, and rapid disintegration had resulted. The Ottomans established the principle of indivisibility of rule, with all members of the ruling class subjected to the absolute will of the sultan. To assure this, Mehmed II began the process of developing a firm law of succession, beginning the practice of executing all the brothers of the reigning sultan so that succession would be limited to one of his sons, preferably the ablest one.

THE PEAK OF OTTOMAN POWER, 1481–1566

Domination of southeastern Europe and the Near East. During much of the century that followed the reign of Mehmed II, the Ottoman Empire achieved the peak of its power and wealth. New conquests extended its domain well into central Europe and throughout the Arab portion of the old Islāmic caliphate; and a new amalgam of political, religious, social, and economic organizations and traditions was institutionalized and developed into a living, working whole.

Bayezid II (ruled 1481–1512). The reign of Mehmed II's immediate successor, Sultan Bayezid II, was largely a period of rest. The previous conquests were consolidated, and many of the political, economic, and social problems caused by Mehmed's internal policies were dealt with, leaving a firm foundation for the conquests of the 16th-century sultans.

The economic stringencies imposed to finance Mehmed II's campaigns had led during the last year of his reign to a virtual civil war encouraged and participated in by the major factions in Istanbul—the *devşirme* party and the Turkish aristocracy. Bayezid was put on the throne by the Janissaries because of their military domination of the capital, whereas his more militant brother Cem fled to Anatolia, where he led a revolt initially supported by the Turkish notables. Bayezid managed to conciliate the latter, however, by exposing to them his essentially pacific plans, which he concealed from the Janissaries. Left without major support, Cem fled into exile to Mamlūk Syria in the summer of 1481. He returned the next year with the help of the Mamlūks and the last Turkmen ruler of Karaman, but his effort to secure the support of the Turkmen nomads failed because of Bayezid's heterodox religious policies. Cem remained in exile, first at Rhodes, then with the pope in Rome, until his death in 1495. European efforts to use him as the spearhead of a new crusade effort against Istanbul were unsuccessful.

Conciliation of Turkish notables

In the meantime, however, the threat that Cem might lead a foreign attack compelled Bayezid to concentrate on internal consolidation. Most of the property expropriated by his father was restored to its original owners. Equal taxes were established around the empire so that all subjects could fulfill their obligations to the government without the kind of disruption and dissatisfaction that had characterized the previous regime. Particularly important was the establishment of the *avârız-i divaniye* (war chest) tax, which provided for the special expenditures of war without special confiscations or heavy levies. The value of the coinage was restored, and Mehmed II's plans for economic expansion were at long last brought to fruition. The vassal system was replaced by direct Ottoman administration throughout the empire. For the first time the central government was given a budget system in which expenditures were balanced against revenues on a regular basis.

Culturally, Bayezid stimulated a strong reaction against the Europeanizing trends of the previous half century. The Turkish language and Muslim traditions were emphasized. He worked to develop and establish the institutions of orthodox Islām in order to save the empire from the increasing menace of heterodox Shīʿism among the tribes of eastern Anatolia, until, late in his life, his own tendency toward mystic Ṣūfism led him largely to abandon the effort.

Though Bayezid preferred to maintain peace so as to have the time and resources to concentrate on internal development, he was forced into a number of campaigns by the exigencies of the time and the demands of his more militant *devşirme* followers. In Europe, he rounded off the empire south of the Danube and Sava by taking Hercegovina (1483), leaving only Belgrade outside Ottoman control. The Hungarian king Matthias Corvinus (ruled 1458–90) was interested mainly in establishing his rule over Bohemia and agreed to peace with the Ottomans (1484), and after his death, struggles for succession left this front relatively quiet for the remainder of Bayezid's reign. To the northeast, the sultan pushed Ottoman territory north of the Danube, along the shores of the Black Sea, capturing (1484) the ports of Kilia and Akkerman, which controlled the mouths of the Danube and Dniester, thus giving the Ottomans control over the major entrepôts of northern Europe's trade with the Black Sea and Mediterranean. Bayezid was there able to compel Moldavia to accept his suzerainty—an important step toward the incorporation of the Romanian principalities in his empire. Because these advances conflicted with the ambitions of Poland, war followed (1483–89) until the diversion of Poland by the threat of Muscovy under Ivan the Great (ruled 1462–1505) left this front quiet also after 1484.

Extension of the empire

Bayezid then turned to the East, where previous conquests as far as the Euphrates had for the first time brought the Ottomans up to the Mamlūk Empire. Conflict over control of the small Turkmen principality of Dulkadir (Dhū al-Qadr), which controlled much of Cilicia and the mountains south of Lake Van, and an Ottoman desire to share in the control of the Muslim holy cities of Mecca and Medina, led to an intermittent war (1485–91); but there were no concrete results, and Bayezid's disinclination to commit major forces to the endeavour led to dissention and criticism on the part of his militant followers. To counter this, Bayezid tried to use Hungarian internal dissention to take Belgrade; but he failed, and raiding forces sent into Transylvania, Croatia, and Carinthia were turned back.

In the same year that Cem died (1495) a new peace with Hungary left Bayezid's objectives unfulfilled, so he turned toward his other major European enemy, Venice, to rebuild his reputation. Venice had been encouraging revolts against the sultan in the Morea, Dalmatia, and Albania, which it had ceded to the Ottomans in 1479. It also gained control of Cyprus (1489), where it built a major naval base, which it refused to allow Bayezid to use against the Mamlūks, thus pointing up the strategic importance of Cyprus to the sultan. Bayezid also hoped to conquer the last Venetian ports in the Morea to establish the bases for complete Ottoman naval control of the eastern Mediterranean. All these objectives except control of Cyprus were achieved in the war that followed (1499–1503). The Ottoman fleet emerged for the first time as a major Mediterranean naval power, and the Ottomans became an integral part of European diplomatic relations.

Bayezid never was able to use this situation to make new conquests in Europe because the rise of revolts in eastern Anatolia occupied much of his attention during the last years of his reign. There the old conflict resumed between the autonomous, uncivilized nomads and the stable, settled Middle Eastern civilization—the Turkmen nomads resisted the efforts of the Ottomans to expand their administrative control to all parts of the empire. In reaction to the orthodox Muslim establishment, the nomads

showed a fanatical attachment to the leaders of the Ṣūfī and Shīʿah mystic orders, of whom the most successful were the Ṣafavids of Ardabīl, who at this time used a religious-military appeal to conquer most of Iran. Under Shāh Esmāʿīl (ruled 1502–24), the Ṣafavids sent missionaries throughout Anatolia, spreading a message of religious heresy and political revolt, not only among the tribesmen but also to cultivators and some urban elements, who began to see in this movement the answers to their own problems. A series of revolts resulted, with Bayezid, because of his involvements in Europe, able to do little to suppress them. Finally, at the start of the 16th century, a general Anatolian uprising forced Bayezid into a major expedition (1502–03), which pushed the Ṣafavids and many of their Turkmen followers back into Iran; there the Ottomans turned from Ṣūfism to Shīʿism as a means of gaining the loyalty of the Persians to a Turkish dynasty. Shāh Esmāʿīl continued, however, to spread his message as Ṣūfī leader in Anatolia, leading to a second major revolt of his followers against the Ottomans (1511). All the grievances of the time coalesced into what was basically a religious uprising against the central government, and only a major expedition led by the grand vizier Ali Paşa could suppress it. But the conditions that had caused the uprising remained a major problem for Bayezid's successor. In the end, Bayezid's increasingly mystical and pacific nature led the Janissaries to dethrone him in favour of his militant and active son, Sultan Selim I.

The Ṣafavids

Selim I (ruled 1512–20). Whereas Bayezid, despite his pacific nature, had been put on the throne by the Janissaries, Selim I was their candidate because he shared their desire to return to an aggressive policy of conquest. But Selim did not wish to be dependent on, or under the control of, those who had brought him to power; he killed not only his brothers but also all seven of their sons and four of his own five sons, leaving only the ablest, Süleyman, as the sole possible heir to the throne. This deprived potential opponents of alternative leaders around whom they could coalesce. Selim was then able to leave the *devşirme* in control of the government; but with a single heir, and with the sultan establishing his personal control over the Janissaries, it was he who dominated, rather than the *devşirme*.

Selim's ambitions encompassed Europe as well as Asia; but Bayezid had left the European fronts relatively quiet, so the new sultan turned first to the East, and chose the Ṣafavids of Iran as his initial victims. Selim first launched a vigorous campaign against the Ṣafavid supporters in eastern Anatolia, massacring thousands of tribesmen and missionaries and espousing a strict defense of Islāmic orthodoxy as a means of regaining political control. In the summer of 1514 he launched a major expedition against the Ṣafavids, hoping to add Iran to his empire and finally to eliminate the threat of heterodoxy. Esmāʿīl employed a scorched-earth policy, retiring into central Iran and hoping that winter would force the Ottomans to retire without a battle. But the militant Kızılbâş (Kizilbash) followers of the Ṣafavids forced the *shāh* to accept battle by intercepting the Ottomans before they entered Azerbaijan. The Ottoman and Ṣafavid armies clashed at Chāldirān, on the eastern side of the Euphrates (August 23, 1514), and the Ṣafavids were routed by Ottoman superiority in weapons and tactics (particularly because of Selim's use of cannons and gunpowder, in contrast to Ṣafavid reliance on spears and arrows). Though Azerbaijan was occupied, the Ottoman victory led to neither the conquest of Iran nor to the collapse of the Ṣafavid empire. The Ottoman army became increasingly discontented under the impact of Ṣafavid propaganda among the already-heterodox Janissaries and because of a relative lack of booty and supplies compared to campaigns in Europe. Selim was compelled to retire, and the Ṣafavids regained their lost province without resistance. The major result of the Chāldirān battle was to convince Shāh Esmāʿīl and his successors to avoid open conflict with the Ottomans at all costs—a policy followed for the next century. This preserved the Ṣafavid army, but it enabled Selim to overcome the last independent Turkmen dynasties in eastern Anatolia (1515–17) and to establish a strong strategic position relative to the Mamlūk Empire, which was falling into internal decay and was ripe for conquest by either the Ottomans or the Ṣafavids.

Defeat of the Ṣafavids

With Shāh Esmāʿīl still busy restoring his army, Selim I was able to overwhelm the Mamlūks in a single year's campaign during the summer and winter of 1516–17. The Mamlūk army fell easily to the well-organized and disciplined Ottoman infantry and cavalry, supported by artillery. The conquest was aided by the support of many Mamlūk officials, who betrayed their masters in return for important positions and revenues promised by the conquerors. In addition, most of the major populated centres of Syria and Egypt turned out their Mamlūk garrisons, preferring the security and order offered by the Ottomans to the anarchy and terror of the prior century of Mamlūk dominion.

Thus in a single sweep, Selim doubled the size of his empire, adding to it all of the lands of the old Islāmic caliphate with the exception of Iran, which remained under the Ṣafavids, and Mesopotamia, which was later taken by his successor. These acquisitions were of immense importance to the Ottomans. Under an efficient administration, the Arab world provided Istanbul with new revenues that solved the financial problems left from the 15th century and made the empire into one of the most powerful and wealthy states in the 16th century. Acquisition of the holy places of Islām cemented the position of the sultan as the most important ruler of Islām. The Ottomans had gained direct access to the intellectual, artistic, and administrative heritage of high Islāmic civilization, previously transmitted to them only indirectly. Now from the Arab world there came to Istanbul the leading Muslim intellectuals, artisans, administrators, and artists of the time. They penetrated every facet of Ottoman life and made the empire much more of a traditional Islāmic state than it ever had been before. Finally, the Ottomans replaced the Mamlūks in control of the Middle Eastern trade routes—part of the old international routes between Europe and the Far East.

Control of the Arab world

One of the major reasons for the Mamlūk decline had been Portuguese discoveries in India and the establishment of an all-water route around southern Africa in place of that through the Middle East. It now remained for the Ottomans to restore the full prosperity of their Arab dominions by countering Portuguese naval activities in the Eastern seas. The Ottoman conquests in the East, combined with the Ṣafavid survival in Iran, ended the long period of political vacuum and anarchy that had followed the collapse of the universal ʿAbbāsid Empire, starting in the 11th century. Order and security finally were re-established, and the stability of Middle Eastern society was restored under the guidance and protection of powerful imperial orders. But the Islāmic world was left permanently divided, with Iran and Transoxania, once centres of the Islāmic caliphates, separated from the Arab world, to which Anatolia and southeastern Europe were for the first time added as integral parts of the Middle East.

Süleyman I (ruled 1520–66). Selim I's last years were spent in Istanbul solidifying the supremacy of the sultan, exploiting the prestige and revenues resulting from his Eastern victories. It was therefore only during the long reign of his son and successor Süleyman I (ruled 1520–66)—called the Magnificent in Europe and the Lawgiver among the Ottomans—that the foundations left by Selim were fully used to establish the classical Ottoman state and society and to make important new conquests in East and West. Süleyman assumed the throne with a position unequalled by any sultan before or after him. He was without opposition and with a great deal of control over the *devşirme* class as well as over the remnants of the Turkish notables. The conquest of the Arab world had doubled the revenues of the treasury without imposing important additional financial obligations, leaving Süleyman with wealth and power unparalleled in Ottoman history. Although Süleyman never took full advantage of the opportunities left him and, in fact, began a process of Ottoman decline, his reign still marked

the peak of Ottoman grandeur, and it has always been regarded as the Golden Age of Ottoman history.

Expansion in Europe

The chief battlefields of Ottoman expansion in Europe now were Hungary and the Mediterranean. The weak southeastern European enemies of Süleyman's predecessors had been replaced by the powerful Habsburg Empire, bolstered by the appeals of the pope against the menace of Islām. Süleyman's main European ally was France, which sought to use Ottoman pressure in the East to lessen the pressure of the Habsburgs.

The land war with the Habsburgs centred in Hungary and was fought in three main stages. From 1520 to 1526 the independent Hungarian kingdom bore the direct brunt of the Ottoman attack and acted as a buffer between the two great empires; but a weak king, Louis II (ruled 1516–26) and feudal anarchy and misrule made a united defense impossible. A split among Hungarian nobles over the question of accepting Habsburg rule, combined with the social and national divisions stimulated by the Reformation, further weakened the opposition to Ottoman attack, and, as a result, Süleyman was able to take Belgrade in August 1521, opening the way for a large-scale advance north of the Danube. The only real army the Hungarian notables could muster was routed at the Battle of Mohács (August 29, 1526), and the death of Louis II ended the last hope for Hungarian unity and independence.

The second period of Ottoman-Habsburg relations (1526–41) was characterized by Hungarian autonomy under the anti-Habsburg prince of Transylvania, John Zápolya (ruled 1528–40), who accepted the suzerainty of the sultan in return for the right to continue native administration and military defense. The Habsburg prince Ferdinand, brother of the Emperor Charles V (ruled 1519–58), occupied the northern areas of Hungary with the support of the Hungarian nobles who desired Habsburg aid against the Turks, and for all practical purposes he annexed them to Austria before, in 1527–28, undertaking an effort to conquer the remainder of Hungary. In response Süleyman returned from Anatolia; drove the Habsburgs from all of Hungary; and besieged Vienna (1529), an effort that failed due to the difficulty of supplying a large force so far from the major centres of Ottoman power. Vienna thus was the chief remaining European bulwark against further Muslim advance. Under the existing conditions of supply, transport, and military organization, the Ottomans had reached the limit of their possible expansion in the West from a winter base that had to be maintained in Istanbul because of the constant threat of possible military needs in the East.

Siege of Vienna (1529)

The siege of Vienna had important benefits for the Ottomans—it secured Süleyman's rule of Hungary, and it prevented Ferdinand from launching a new attack against Zápolya for some time to come. Although the siege frightened the other states of Europe sufficiently for them to agree to a temporary Catholic-Protestant truce (1532), the result was only temporary, and Ferdinand never was certain of the support of the independent German princes and of other European rulers who promised him help. Even Charles V was too preoccupied with the problems of the Reformation and with France to devote much attention to the Ottomans. Thus, when Süleyman went on a second Austrian campaign (1532), he was unable to draw the imperial army into conflict and had to content himself with devastating large parts of the Habsburg realm.

By the peace of 1533 Ferdinand abandoned his claims to central Hungary and recognized Zápolya's rule there as Ottoman vassal, whereas Süleyman agreed to accept Ferdinand as ruler of northern Hungary in return for the payment of an annual tribute. This arrangement lasted until 1540, when Zápolya died and left his dominions to Ferdinand in defiance of his agreement with the sultan. When Ferdinand tried to assume his heritage by force, Süleyman occupied and annexed Hungary (August 1541) under the guise of championing the cause of Zápolya's infant son, John Sigismund Zápolya. Thus began the third and final period of Ottoman-Habsburg relations, with the two great powers in direct contact and almost continuous border conflict; diversions on both sides, however, prevented long periods of open warfare.

Many historians have accused Francis I of France (ruled 1515–47) of encouraging Ottoman expansion into central Europe to relieve Habsburg pressure on him. But the Ottoman advances were due less to any French overtures than to Süleyman's own ambitions, together with his fears of a possible alliance among the Habsburgs, the Hungarians, and the Ṣafavids and of Habsburg rule in Hungary. The sultan regarded the French king largely as a supplicant for commercial favours, which were granted in the Capitulations of 1536—an agreement by which French subjects were given the freedom to travel and trade in the sultan's dominions, and subjects of other states wishing to do the same were required to secure French protection as a condition of the necessary permission. French and other merchants and travellers in the Ottoman Empire were allowed to remain under French laws and courts in cases concerning themselves and to have special privileges when involved with Ottoman law. Thus was established the foundation of the French predominance in the Levant, which remained to modern times. The Capitulations served as a model for later trade agreements between the Ottomans and the other European powers, who subsequently used them, during the centuries of Ottoman weakness, as means to dominate commerce within the Ottoman dominions and thus prevent the rise of a native commercial class.

The stalemate between the Ottomans and Habsburgs in Hungary led their conflict to shift periodically from the land to the sea, with the Ottomans emerging as a major naval power for the first time. The decline of the Venetian navy led Charles V to try for complete control of the Mediterranean, enlisting as his naval commander a great Genoese seaman, Andrea Doria, and thus securing the support of the powerful Genoese fleet. Süleyman responded by driving the Knights Hospitallers—a Christian religious and military order—from Rhodes (1522), but Charles then established them on Malta (1530) and captured Tunis (1535). While Süleyman was busy in Anatolia, Doria captured a number of ports in the Morea (Peloponnese) and began to raid the Ottoman coasts, largely severing the sea lines of communication between Istanbul and Alexandria. To counter this, Süleyman in 1533 enrolled in his service as grand admiral Barbarossa (Khayr ad-Dīn), a Turkish captain who had built a major pirate fleet in the western Mediterranean and had used it to capture Algiers (1529) and other North African ports. The Ottomans annexed Algiers to the empire, but as a special province permanently assigned to the grand admiral to support the fleet. Ottoman land troops were sent to defend Algiers against Habsburg attacks—probably the main reason Barbarossa agreed to join the sultan.

The Mediterranean front

Barbarossa built a powerful Ottoman fleet, able to meet the Habsburgs on equal terms. In 1537 he launched a major attack on southern Italy, expecting a promised French attack in the north, with the objective of a joint conquest of Italy. But France, fearing a hostile European reaction to its alliance with the infidel, withheld the diversion. Doria then organized and led an allied European naval force against the Ottomans; but it was routed at the Battle of Preveza (September 25–28, 1538), off the Albanian coast. Venice then surrendered its last possessions in the Aegean, the Morea, and Dalmatia, thus assuring Ottoman naval supremacy in the eastern Mediterranean, which remained unbroken for the next three decades.

Süleyman failed to pursue his ambitions in Europe after 1541, largely because of his increasing preoccupation with problems in the East. He ruthlessly suppressed Ṣafavid propagandists and supporters in eastern Anatolia and stimulated the Turkmen Özbek Empire of Transoxania to attack Iran from the East. Iran fell into disorder following the death of Shāh Esmāʿīl and the accession of his infant son Ṭahmāsp I (ruled 1524–76), but Süleyman was able to use this situation only during periods of peace in Europe. He personally led three campaigns into northwestern Iran—in 1534–35, 1548–50, and 1554—but although he captured Ṣafavid territories in the southern Caucasus, Azerbaijan, and Iraq on each occasion, he

The eastern front

never was able to catch the Iranian army to defeat it; and supply problems invariably compelled him to retire to Anatolia during the winter months, allowing the Persians to regain their territories with little difficulty. Süleyman finally despaired of defeating his elusive enemies, so he agreed to the Peace of Amasya (May 29, 1555), by which he retained Iran and eastern Anatolia but renounced Ottoman claims to Azerbaijan and the Caucasus and agreed to allow Shīʿah Persian pilgrims to visit Mecca and Medina as well as their own holy places in Iraq. Thus the same geographical problems that had limited Ottoman conquests in central Europe made western Azerbaijan the viable limit of Ottoman expansion in the East; preventing the final elimination of the Ṣafavid danger.

Süleyman was somewhat more successful in restoring the old international trade routes through his Middle East possessions. To counteract the Portuguese fleet, supplied by the Ṣafavids from their Persian Gulf ports, he built major naval bases—at Suez (1517) and, as soon as he took Iraq, at Basra (1538)—establishing garrisons and fleets that not only resisted the Portuguese naval attacks but also went out against them in the Eastern seas. As a result the old trade route regained some of its former volume in the 16th century; the Ottomans never were able to fully restore it, however, because Portugal still was able to pay higher prices in the East and sell at lower prices in Europe because of their use of a sea route, which avoided the duties and local charges levied on goods sent through Ottoman territory. (It should be noted that it was the Ottomans who fought to keep the old Middle Eastern trade route open; the route was closed only when the Cape route was taken over from the Portuguese by the much more powerful fleets of Great Britain and Holland.)

Classical Ottoman society and administration. During the 16th century the institutions of society and government that had been evolving in the Ottoman dominions for two centuries reached the classical forms and patterns that were to characterize them until modern times.

Social divisions

The basic division in Ottoman society was the traditional Middle Eastern distinction between the small group of rulers who formed the ruling class, and the large mass of subjects. Possession of three attributes was essential for membership in the Ottoman ruling class: (1) profession of loyalty to the sultan and his state; (2) acceptance and practice of the Muslim religion and the system of thought and action that was an integral part of it; and (3) knowledge and practice of the complicated system of customs, behaviour, and language known as the Ottoman Way. Those who lacked any of these attributes were considered to be members of the subject class, *reayas* (*rayahs*), the "protected flock" of the sultan. There was a system of social mobility based on the possession of these definable and attainable attributes; *reayas* able to acquire them could rise into the ruling class, and Ottomans who came to lack any of them would become members of the subject class.

Members of the Ottoman ruling class were considered to be the sultan's slaves, and thus acquired their master's social status. As slaves, however, their properties, lives, and persons were entirely at his disposition; and he could do with them as he wished. Their basic function was to preserve the Islāmic nature of the state and to rule and defend the empire. By Ottoman theory, the main attribute of the sultan's sovereignty was the right to possess all sources of wealth in the empire together with the authority necessary to exploit them. The function of enlarging, protecting, and exploiting that wealth for the benefit of the sultan and his state, therefore, was the main duty of the ruling class. The primary duty of the *reayas* was to produce the wealth—by farming the land or engaging in trade and industry—and then paying a part of the resulting profits to the ruling class in the form of taxes.

The Ottoman state encompassed organizations and hierarchies developed by the ruling and subject classes to carry out their functions in Ottoman society. The ruling class divided itself into four functional institutions: the Imperial (Mülkiye) Institution, led by the Sultan himself, provided the leadership and direction for the other institutions as well as for the entire Ottoman system; the Military (Seyfiye) Institution was in charge of expanding and defending the empire and keeping order and security within the sultan's dominions; the Administrative (Kalemiye) Institution, organized as the Imperial Treasury (Hazine-i Amire), was in charge of collecting and spending the imperial revenues; and the Religious/Cultural (İlmiye) Institution, which included the *ʿulamāʾ* (all Ottomans expert in the religious sciences), was in charge of organizing and propagating the faith and maintaining and enforcing the religious law (Sharīʿah), its interpretation in the courts, its expounding in the mosques and schools, and its study and interpretation.

To cover the areas of life not included within the scope of the ruling class, members of the subject class were allowed to organize themselves as they wished. As a natural manifestation of Islāmic society their organization was determined largely by religious and occupational distinctions. The basic class divisions within the subject class were determined by religion, with each important group organizing into a relatively self-centred autonomous community called a *millet*, under its own laws and forms of internal organization, directed by a religious leader who was responsible to the sultan for the fulfillment of the duties and responsibilities of the *millet* members, particularly those of paying taxes and security. In addition, each *millet* cared for the many social and administrative functions not assumed by the Ottoman state, concerning such matters as marriage, divorce, birth and death, health, education, internal security, and justice.

The *millets*

Within the *millets*, just as in Ottoman society as a whole, there was a social mobility, with persons moving up and down the ladder according to ability and luck. Individuals could pass from one *millet* to another if they wished to convert, but because all the *millets* were extremely antagonistic toward those who left them to convert to another religion, the state discouraged such action as much as possible to preserve social harmony and tranquility, the main object of the system. The *millet* system succeeded for 500 years by keeping the different peoples of the empire as much apart as possible, thus reducing to a minimum the possible sources of conflict and keeping social order in a highly heterogeneous state.

All of the classes, institutions, and communities described above were, in essence, means by which the slaves and subjects of the sultan were divided and organized so as best to fulfill their functions. But there also were means by which they were related to one another and united into the whole of Ottoman society. The principal cement was the sultan, the keystone of the system who alone was the common focus of loyalty of the ruling and ruled subjects alike. But such loyalty was an abstract; it could not have held Ottoman society together without the help of the artisan and religious guilds, which cut across the boundaries and made members of different groups brothers in common organizations based not on class, rank, or religion but on mutually shared values and beliefs, economic activities, and social needs. Through contact and cooperation in such guilds, members of the different groups of Ottoman society were cemented into a common whole, performing many of the social and economic functions outside the scope of the ruling class and of the *millets*, particularly those functions associated with economic regulation and social security, and receiving a more personal religious experience than that provided by the established religious organizations, whether Muslim or non-Muslim.

Within the Ottoman ruling class, the most important unit of organization and action was the *mukataʿa*, in which a member of the ruling class "cut off" a portion of the sultan's revenues and had sufficient authority to exploit it for purposes determined by the sultan. The exact nature of the *mukataʿa* depended on the extent to which the holder remitted his revenues to the treasury and what portion he retained for himself. The *timar* type of *mukataʿa*, traditionally described as a fief, only marginally approached the concept of feudalism as it was known in Europe because it was part of a centralized system and did not involve the kind of mutual rights and obligations

The *mukataʿa*

characteristic of Western feudalism. In return for services to the state, the *timar* holder was given the full profits of the source of revenue for his personal exploitation and profit, which were independent of, and in addition to, those connected with the exploitation of the *timar* itself. For many military and administrative positions, *timar*s normally were given in lieu of salaries, thus relieving the treasury of the trouble and expense of collecting revenues and disbursing them to its employees as salaries. Almost all the 14th- and 15th-century Ottoman conquests in southeastern Europe were distributed as *timar*s to military officers, who in return performed the tasks of administration in peacetime and provided soldiers and military leadership for the Ottoman army in war. Many of the officers of the central government also were rewarded with *timar*s in place of, or in addition to, salaries paid by the treasury.
