Agriculture and fishing are strongly organized enterprises, and they are subsidized by the state. In remote districts, private industry may receive special incentives in the form of loans and grants or tax relief. Taxes are high, with sharply progressive income taxes and a "value added" tax of 20 percent on all economic activity imposed directly at the manufacturing level rather than as a sales tax. Total tax revenues are equivalent to almost 40 percent of the gross national product, but half of this represents transfers of income; that is, it is returned to the private sector in the form of price subsidies, social-insurance benefits, and the like. All this has added to economic problems of inflation, but increases in productivity made possible a growth of more than 43 percent in real income for industrial workers from 1959 to 1969. The strongly centralized trade unions and employer associations respect one another as well as government guidelines, thus helping to control the rapidly expanding economy.

Foreign exchange. Foreign trade, in the form of commodities exported chiefly to western Europe or as shipping services throughout the world, accounts for nearly 40 percent of Norway's national income. For more than a century, Norway has been among the four leading

shipping nations of the world, and Norwegian shipowners constantly have pioneered new trades and markets. The export of finished products has been boosted tremendously by the nation's membership in the European Free Trade Association (EFTA) since its founding in 1959. In 1970 Norway began negotiations for membership in the European Economic Community (EEC): in July 1972 a treaty was signed which would have made entry into the EEC effective January 1, 1973. This was rejected in a non-binding referendum in September 1972.

Agriculture and forestry. During the 1960s, the number of farms in Norway decreased by about 34,000, to fewer than 165,000, most of the abandoned acreage being absorbed into other farms. Only about 22,000 farms have more than 25 acres of farmland, while only about 40 have more than 250 acres. Labour for hire is scarce and most of the work must be done by the farmer-owner himself. Extensive mechanization and fertilization, however, have kept the total output on the increase. Although the country is more than self-sufficient in animal products, it remains dependent on imports for cereal crops.

In addition to the nation's 2,000,000 acres of farmland, the farmers own some two-thirds of Norway's 16,000,000 acres of productive forests. Forestry forms the basis for the wood-processing industry, which accounts for about 12 percent of Norway's total commodity exports, and it is of major importance for the nearly 80,000 farms that are so small that a second major source of income must be found in other occupations.

Employment in fisheries

Along the coast, fishing plays the same role that forestry does elsewhere. At the same time, it forms the basis for a large and growing fish-processing industry and offers seasonal employment for many farmers. Of the 61,000 fishermen registered in 1960, only a third had fishing as their sole occupation. Most vessels are owned by the fishermen themselves, the necessary crew members being paid by shares of gross income in a continuation of a centuries-old tradition of the sea. In spite of a decline in the total number of fishermen, mechanized methods have doubled—and in some years nearly trebled—the catch since 1962, with only two other nations surpassing the totals. A critical current problem is to avoid depleting the fish resources while maintaining the volume. About 76 percent of the catch, most of it near the coast, goes into fish meal and oil, but increasing quantities are being processed for human consumption in freezing plants. Fish offal is used as feed at mink farms.

Mining and metallurgy. Norway mines only a few ores in quantity, mainly pyrites and iron ore, but its ferrotitanium ore comes from Europe's largest deposit, in southwestern Norway. Coal is mined only at Svalbard. Nonetheless, the mountains of Norway have played a key role in the industrialization process by supplying huge quantities of hydroelectric energy. In 1969, the electrical energy production per capita was nearly twice that of Canada, the world's second largest per capita producer.

Almost half of Norway's annual production of hydroelectric power is consumed by its electrometallurgical plants, which place the country as the world's largest exporter of iron-based alloys and metals combined. It is among the major exporters of aluminum—here second to Canada—and of nickel, copper, and zinc. One company, which produces enough fertilizer to produce food for more than 20,000,000 people, is also the world's second largest producer of magnesium. Although the aluminum and nickel exports depend on raw-material imports, magnesium is made from seawater and locally available limestone or marble rock known as dolomite. Norway also has plenty of quartz for the iron-alloy industry, which is the primary feeder of these products to the steel industry of western Europe. In all, the electrometallurgical industries accounted for somewhat more than a quarter of Norway's total commodity exports in 1969, although they employed only 7 percent of the national industrial labour force.

Engineering and petroleum exploitation. Engineering is by far the largest single employer among Norway's industries. As late as in 1960, engineering remained an industry largely based on the domestic market. But with more liberalized world trade, especially that brought on by Norway's membership in EFTA, extensive specialization became a necessity. The result has been the fast-growing export of a large variety of products, from enormous marine tankers to integrated electronic circuits.

Oil and natural-gas reserves

Oil and natural-gas deposits with estimated exploitable reserves of at least 1,000,000,000 barrels of oil were found in 1969–70 in the Norwegian sector of the continental shelf stretching across the shallow North Sea to Denmark. Trial production began in the spring of 1971. Much larger finds are possible, especially on Norway's wide continental shelf in the Atlantic, extending northward all the way up the peninsula and into the Barents Sea, where there are Soviet claims to undersea oil rights. Norway's two existing oil refineries and its chemical industry account for some 7 to 8 percent of the commodity exports.

Shipping. Despite Norway's concern with producing goods for exports, commodity imports usually run about 42 percent higher than commodity exports. The deficit is sometimes completely offset, however, by the foreign-currency earnings of the merchant marine. Only Liberia, Great Britain, and Japan have larger shares of the world's merchant fleet. The age of the Norwegian fleet is well under the world average, and there is often a large backlog of orders for new tankers and giant bulk carriers. About 1,300 ships, accounting for more than 90 percent of Norway's total tonnage, sail only between foreign ports. Half of this foreign-going fleet consists of tankers. Most of the financing is secured abroad easily because of the trust in the profitability of Norwegian shipping. Of the crews, about a quarter are non-Norwegians, mainly from Spain and Asian countries.

Transportation. The elongated shape of Norway and its many mountains, large sparsely populated areas, and severe climate make special demands on transportation services. Only the Oslo region has sufficient traffic density to make public surface transportation profitable. About 1,700 vessels link the many fine ports along the sheltered coast. In most of Norway, regular overland transportation services are so expensive that the government must provide or subsidize both establishment and operation.

Bus transport plays a key role in public transportation, aided by almost 200 fjord ferries. The number of private automobiles is rapidly increasing, creating parking problems and traffic jams in the major cities. Of the 44,700 miles (72,000 kilometres) of public roads, only about 15 percent are hard-surfaced, and only shorter stretches of mostly substandard motorways have been completed. Demands for an additional 19,000 miles (30,000 kilometres) of road are growing, as are those for the comprehensive reconstruction of the many narrow, winding roads. The main Oslo-to-Bergen route still remains closed for four to six months during the winter.

Railways

The 2,600 miles (4,200 kilometres) of railway are operated by the Norwegian State Railways (NSB), which sustains large annual operating deficits. Vestlandet has never had north–south railway connections, only routes running east from Stavanger and Bergen to Oslo and from Møre og Romsdalen to one of the two routes linking Oslo and Trondheim. The connection to Bodø was completed in 1962. Farther north, the only railway is the extension of the Swedish railway system to Narvik, which is used mainly to carry iron ore for export. Of the three other links with Swedish railways, one runs from Trondheim and two from Oslo—the southernmost connecting Norway to the continent via the Swedish and Danish railways.

Aviation is an increasingly popular means of passenger transportation, especially in the northern regions and during the winter months. Extensive state aid is needed, however, to finance the building of airfields. The one private airline has about the same proportion of the domestic air traffic as the Scandinavian Airlines System (SAS), which is 50 percent state owned, with three-sevenths of total capital from Sweden and two-sevenths each from Denmark and Norway. SAS has pioneered commercial flights across the Arctic. Four commercial airports throughout the country are equipped to handle international flights.

THE NORWEGIAN GOVERNMENT

Norway is a constitutional hereditary monarchy. The king acts as administrative head of government and selects his own Cabinet. The legislative body is the 150-member Storting, elected by vote of all persons over 21 years of age.

Organization. The constitution of Norway, drafted in 1814 when Norway left the 500-year union with Denmark, was influenced by British political traditions, by the constitution of the United States, and by French revolutionary ideas. Amendments can be made by a two-thirds majority in the Storting. Unlike many parliamentary forms of legislature, the Storting cannot be dissolved during its four-year term of office. If a majority in the Storting votes against an important Cabinet issue, the minister responsible or even the whole Cabinet resigns. In legislative matters, the king has a suspending right of veto, but this has never been exercised since the 91-year union with Sweden was dissolved in 1905.

Five political parties were represented in the Storting in the 1970s. The Labour Party, during its 25 years of rule up to 1965, practiced moderate Socialism and established a few large state-owned factories. It nationalized private enterprises only under special circumstances. The Conservative Party advocates a modern progressive conservatism and accepts extensive government control and transfers of income. The Centre Party, called the Agrarian Party until 1958, has a policy directed beyond special group interests.

The Christian People's Party is concerned primarily with maintaining Christian principles in public life. The Liberal Party, supported by puritanic rural groups as well as city radicals, stresses social reform. Until 1961 the Communist Party was represented in the Storting. Since 1965 the four non-Socialist parties have ruled in coalition, mainly continuing along the lines followed by the Labour governments. Before elections the political parties nominate their candidates at membership meetings in each of Norway's 20 *fylker* (counties). Each *fylke* (county) elects from four to 13 representatives, according to its population, with party representation allotted on the basis of the percentage of the vote it received.

Proportional representation

Local administration. The cities of Oslo and Bergen constitute two of the country's 20 *fylker*. The others are divided into a total of 404 rural and 45 urban municipalities, with councils elected every fourth year, two years after the Storting elections. For the country as a whole, the municipal elections tend to mirror the party division of the Storting. The municipal councils elect a board of aldermen and a mayor. Much municipalities also employ councillors for such governmental affairs as finance, schools, social affairs, and housing. Norwegians pay direct taxes to both federal and municipal governments.

The *fylke* can levy taxes on the municipalities for roads, hospitals, secondary schools, and other joint projects. The *fylke* councils comprise delegates from the municipalities, while the *fylke* governor is appointed by the Cabinet.

Justice. The Supreme Court makes the final decision on legal practice. There are 104 primary courts and 464 conciliation councils. Norway is divided into five court-of-appeal regions. The rights of the citizen are guarded also by the ombudsman, who handles about 1,000 complaints a year and finds about 20 percent of them to be justified.

Defense. Military service of 12 to 15 months, plus refresher training, is compulsory for all fit Norwegian men between 22 and 44 years of age. Nonetheless, Norway's defense force is far too small to protect all of its territory against a major aggressor. Its strategy is designed to defend key areas, especially in the north, until forces from other members of the North Atlantic Treaty Organization (NATO) can be moved in. The Norwegian units have great mobility, and, with its important strategic location as NATO's northern flank and its myriad of fjords to serve as naval bases for fleets in the North Atlantic, Norway has the ultimate in early warning systems.

International military alliances

The NATO headquarters for Northern Europe is at Kolsås, near Oslo. Foreign troops and nuclear charges, however, are excluded from Norway by law except in cases of war or immediate threat of war. The Norwegian Air Force has a number of ground-to-air missiles and various aircraft from other Western nations. The navy consists of heavy coastal artillery and such light vessels as gunboats, torpedo boats, submarines, and corvettes up to 1,800 tons. In the 1970s the total military personnel numbered about 40,000, but an additional 70,000 men were members of local home-guard units and could be mobilized quickly in cases of emergency.

SOCIAL CONDITIONS

Education. Most of Norway's municipalities have extended compulsory schooling from seven to nine years. After the eighth grade, pupils may choose from among advanced courses in Norwegian, mathematics, and English (compulsory from the fifth grade) and such optional subjects as German. The ninth grade offers an even wider choice, including vocational training. With three years of additional high school, students may take the examinations leading to university study. About 10 percent of the more than 27,000 college and university students study abroad. The institutions in Norway are being expanded to accommodate the anticipated doubling of this student group in the final decades of the 20th century.

Nearly 85,000 students attend vocational schools and nearly 7,000 the folk high schools, boarding schools offering a one-year course designed for 17-year-old students from rural areas. Only a few of Norway's schools charge tuition, and all students can get government loans on favourable terms.

Health and welfare. Norway's several large, active health organizations have nearly 2,000,000 members. Compulsory membership in a national health-insurance system secures for all Norwegians free medical care in hospitals, compensations for doctors' fees, and free medicine for certain chronic illnesses. Cash benefits during illness or pregnancy, covered by another insurance fund, are compulsory for salaried employees and optional for the self-employed. Norway has one doctor per 700 inhabitants, most of them working in hospitals, the majority of which are owned by the state, counties, and municipalities. Extensive programs of preventive medicine have conquered Norway's ancient nemesis, tuberculosis. There is also a well-developed system of maternal and child health care, as well as compulsory school health services and free family counselling by professionals. A public dental service provides care for 90 percent of the children between seven and 15 years of age, and plans are under way to extend it downward to three years and upward to 18 years. There is one dentist per 1,200 inhabitants.

National programs in medicine and welfare

A "people's pension" was established in Norway in 1967, to ensure the entire population a standard of living reasonably close to the standard that the individual had achieved during his working life. The pension covers old age as well as cases of disability or loss of support. The premiums are paid by the individual members, employers, municipalities, and the state. The basic pension is adjusted every year, regardless of the plan's income. Supplementary pensions vary according to income and pension-earning time. The state pays a family allowance for all children up to 16 years of age.

Housing and living standards. Norway still feels the housing shortage created by World War II, and this has been aggravated by high costs in the densely populated urban areas. But housing standards have improved tremendously, and most families live in houses built since the war, a majority of them financed by state loans on favourable terms.

Norway ranks ninth among the nations of the world in gross national product per capita of population. In the postwar years individual income per capita has tripled in real terms. Tax rates progressing upward with income and the greatly increased social-security benefits, allocated mainly according to need, have contributed to a levelling of incomes. The perennial shortage of labour, especially of skilled workers, has had a parallel effect.

The consumer of the 1970s spends a smaller share of his income than formerly on food, beverages, and tobacco, since the saturation point apparently has been reached. Travel and leisure activities are increasing their share rapidly, as are such household goods as electrical appliances. In 1959–68 the number of automobiles per inhabitants increased from one in 21 to one in six. A four-week vacation every year with somewhat more than full wages was established by law in 1964. Working hours are restricted to nine hours a day and 42½ hours per week. A five-day work week had become the rule by the late 1960s.

Culture. Located on the outskirts of Europe and with much of its inland population almost completely isolated until this century, Norway has been able to preserve much of its old folk culture. On the other hand, as seafarers and traders the Norwegians have always received fresh cultural stimuli from abroad. A number of Norwegians have made important contributions in return, notably playwright Henrik Ibsen and the composer Edvard Grieg. The Norwegian recipients of the Nobel Prize for Literature are Sigrid Undset, Bjørnstjerne Bjørnson, and Knut Hamsun.

Literature and performing arts

Although Norway comprises one of the world's smallest language communities, the country is first in books published per capita. The annual number of new titles is close to 2,500, of which two-thirds are of Norwegian origin. Literature is subsidized through tax exemption and government purchasing for libraries. In all, there are 5,000 public or school libraries, which annually loan more than 14,000,000 books.

Permanent theatres have been established in four cities, and the state travelling theatre, the Riksteatret, organizes tours throughout the country, giving as many as 1,200 performances annually. Several Oslo theatres have closed down in recent years, however, and the Norwegian Opera, opened in 1959, requires state subsidies, as do five other theatres. Films in Norway are subject to censorship, primarily on grounds of violence and, to lesser extent, for erotic content. The production of Norwegian-made feature films is subsidized, but they usually number fewer than ten a year.

The visual arts

In addition to its National Art Gallery, Oslo opened a special museum in 1963 honouring Edward Munch, probably Norway's most famous painter. In 1968 the Sonja Henie–Niels Onstad Art Centre was opened near Oslo; it contains modern art from all over the world.

Norwegian painters of the 20th century have excelled in murals to an extent rivalled only by Mexican painters. Other artists are world known for their multimedia assemblages, pictorial weaving, and nonfigurative art in sculpture as well as painting. The works of Gustav Vigeland have been assembled in Oslo's Vigeland sculpture park in a spectacular display centred around a 60-foot granite monolith containing 121 struggling figures.

Architecture has drawn inspiration from medieval stave churches of upright logs as well as houses of horizontal logs notched at the corners. Private houses, almost all of wood, are made to fit snugly into the terrain. For larger buildings, steel and glass are supplemented by concrete that often is shaped and texturized with considerable imagination.

Arts and crafts and industrial design flourish side by side, often inspired by archaeological finds from the Viking age (around the year 1000), by the culture of the northern Lapps, and by advanced schools of design and the Norwegian Design Centre, one of the largest of its kind in the world. Norway has markedly increased its exports of furniture, enamelware, textiles, tableware, and jewelry, much of which incorporates design motifs reflecting these cultural heritages as well as avant-garde styles.

Recreation. The Norwegians have the special advantages of abundant space and a traditionally close contact with nature. Cross-country skiing is a national pastime in the long winter season. In the Olympic Winter Games, the tiny nation has won far more medals than any other nation. The Norwegians have more than 200,000 second homes, mainly along the sheltered coastline and in the mountains. Even from downtown Oslo, it takes only a 20-minute drive to get into deep forests, and on a nice winter Sunday the surrounding hills abound with skiers.

Scientific research. Science and research have limited means in a small country. In the natural sciences, however, reflecting the country's intimacy with an overpowering physical environment, individual efforts of Norwegians have won world fame. Among the most widely known are the explorers Fridtjof Nansen, Roald Amundsen, and Thor Heyerdahl. Norway also has pioneered many industrial breakthroughs, especially in the area of electronics.

The communications media. Some 185 newspapers are published in Norway, about half of them daily, except Sundays and holidays, on which no papers are published. Although most of them are small, average circulations increased from 7,700 to 10,000 in the period from 1950 to 1970. Most newspapers have affiliations with political parties, but this is reflected very little in readership. Even though the Labour Party is supported by nearly half of the electorate, the labour press has less than a quarter of the total circulation. Press ethics are on a high level, and the independence of the editors is universally recognized.

Broadcasting is a state monopoly, with no commercial sponsors or advertising over the one radio and one television network. Educational and informational programs are given priority over entertainment, and day-to-day management is quite independent of the state. Every home with radio and television pays an annual fee. Regular colour-television broadcasts are expected by 1973.

Prospects. With a high standard of living evenly distributed across a healthy, stable democracy, Norway now is concerned mainly with two of the newest problems of advanced industrial societies, the stresses of living in such a society and the threats of pollution posed to the environment. The latter is a growing problem, but so far none of the damage is irreparable. The development of hydroelectric resources, however, has destroyed the beauty of several spectacular waterfalls. The hope of energy-hungry Norway is that the "white coal" of the mountains will soon be supplemented with "black gold" from beneath the North Sea.

Nō Theatre

One of the traditional theatrical forms of Japan, Nō is unlike Western theatre in which characters come onto the stage to develop a series of incidents that lead to a dramatic climax and conclusion. The term Nō denotes skill or accomplishment. The performers of Nō are neither actors nor "representers" in the usual sense; they are simply storytellers who use their visual appearances and their

movements to suggest the essence of their tale rather than to enact it. Nō is, thus, not a drama in which definite ideas can be conveyed symbolically in character and event, as in a Western play. Nō employs the visual and the auditory to evoke response beneath—or above—the level of concrete thought.

Performance of Nō

A brief sketch of one of the most famous of Nō plays, *Takasago* by Zeami Motokiyo, best suggests the quality and nature of the Nō theatrical tradition. The stage itself is not unlike a formal architectural set for an Elizabethan or Greek play. The pavilion-like, roofed stage juts into the right side of the audience and, retreating back and to the left, a covered bridgeway fronted by three pine trees leads to a brilliantly coloured curtain, the only colour on stage save for an ancient, gnarled pine painted on the back wall of the stage. A border or path of white gravel separates stage and bridgeway from the audience. A kimono-clad chorus sits at the extreme right of the stage, facing centre, while facing forward from the front of the inner stage are a flutist and three drum players. The flute begins a high plaintive air.

A heavily robed Shintō priest with two attendants crosses slowly down the bridgeway onto the stage; he turns to face his attendants. To the flute and drum taps the three sing "Today we don our travelling dress, today we don our travelling dress, long is the journey before us," words then echoed by the chorus and repeated by the trio. The Priest then says

> I am Tomonari, priest of the Aso Shrine in Higo Province in Kyūshū. Never having seen Miyako, I intend to journey thither and shall take the excellent opportunity thus offered me to visit the Bay of Takasago in Harima Province.

They then sing a "travelling song" that in a few lines describes their long voyage, after which Tomonari sits, with attendants on his right. He announces "Travelling in haste, we have now reached Takasago. Let us stop here awhile and enquire about this place."

To further music, two other actors enter the bridgeway and stop, facing one another. One carries a broom and wears an "old woman" mask and wig, the other a rake and "old man" disguise; both are kimonoed and robed in dignified manner. They sing, beginning "The spring breezes murmur in the Takasago pine. The day is closing in. . . ." The voice reveals that the "old woman" is played by a man. The action that follows includes formal song, speech, mime, and dance involving the elderly couple and Tomonari, with commentary by the chorus. The performers assume lengthy, frozen poses or move with slow and weighty precision under their heavy garments. Finally, the couple are established as poetic personifications of the twin pines of Sumiyoshi and Takasago, symbols of longevity and conjugal fidelity.

During an interlude following the couple's exit, another actor enters and, in response to Tomonari's questions, relates the legend of the twin pines. The play's short concluding section takes place in Sumiyoshi. The chorus and the deity of the shrine, who is played by the actor that played the old man in a different costume and mask, explains the essence of the legend that has been presented. The deity stamps twice and the play is ended. (From *The Noh Drama*; Charles E. Tuttle Co., Inc., 1960.)

NATURE AND OBJECTIVES

Takasago represents a mysterious, exotic species of theatre. It is a short work and others are always played with it; its dialogue is sparse, a mere frame for the movement and music; little "happens"; and the total effect is less that of a present action than of a simile or metaphor made visual. Such is the tradition of Nō theatre.

The "action" of Nō

Though Nō does put a story on the stage, it does not aim at an interest in the story as such. If story-centred theatre were to be considered prose, Nō would be an equivalent of poetry. Suggestion and not statement is the medium's principal means, and the texture of its words and movements is so dense with allusion, symbol, and fine shadings of meaning that no translation can approximate it, nor can a spectator not steeped in Japanese cultural history grasp it fully.

The author of *Takasago*, Zeami Motokiyo (1363–1443), and his father, Kan-ami Kiyotsugu (1333–84), wrote many of the most beautiful and exemplary of Nō texts. Zeami formulated the principles of the Nō theatre that guided its performers for many centuries. His *Kakyō* ("The Mirror of the Flower," 1424) described the composition, the recitation, the mime and dance of the performers, and the staging principles of Nō. As has been noted, the term Nō denotes skill and accomplishment, and Zeami described this theatre as one of "elegant imitation."

He advised on selection of properly classical characters to be portrayed, from legend or life, and on the proper integration of the visual, the melodic, and the verbal to open the eye and ear of the mind to the supreme beauty he crystallized in the word *yūgen*. Meaning literally "dark" or "obscure," *yūgen* suggested beauty only partially perceived—fully felt but barely glimpsed by the viewer.

Nō began as a festival drama at shrines and temples in the 12th or 13th century but was continually refined up to the years of the Tokugawa period (1603–1867). It became a ceremonial drama performed on auspicious occasions by professional actors for the warrior class—as, in a sense, a prayer for peace, longevity, and the prosperity of the social elite. Outside the noble houses, however, there were performances that popular audiences could attend. The collapse of the feudal order with the Meiji restoration (1868) threatened the existence of Nō, though a few famous actors maintained its traditions. After 1945, however, a large number of educated youth came to enjoy Nō not simply for its status as a "classic theatre" but as a perfected and refined contemporary stage art.

FORMS AND TRADITIONS

In writing and in all phases of staging and performing, Nō is theatre at its most stylized. The educated spectator knows the story well and can follow the many allusions to ancient literary, legendary, and historical phenomena. Like the worshipper who has innumerable times partaken in a rite, he attends not for novelty but for a renewed personal experience of the rite itself.

Nō repertoire. About 2,000 Nō texts survive in full, of which about 230 remain in modern repertoires. Their plots were refined from stories available at the time of writing from Chinese or Indian sources, but especially from tales and legends of old Japan and from anthologies of Japanese poetry written as early as the 8th century. Themes and characters were diverse: the wonders worked by Buddha and native gods, deeds of warriors, relations of families of lord and retainer, hermits and visitants from heaven, animals and plants.

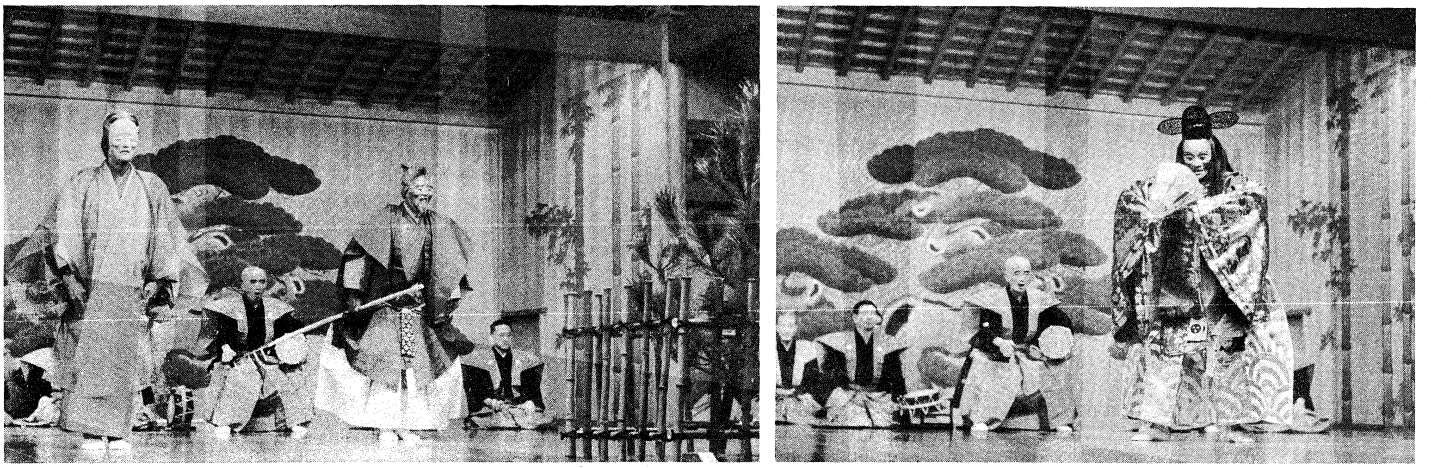
Types of Nō

The Nō repertoire includes five types of play. The first type, *waki* Nō, involves a sacred story relating the origin of, or miracle associated with, a shrine, as in *Takasago*; the second, *shura mono*, deals with defeated or, less frequently, victorious warriors; the third, *katsura mono*, or female-wig play, has a female protagonist; the group contains many of Nō's masterpieces. The fourth type is varied in content, including *genzaimono*, tales performed as if contemporary rather than from legend, and *kyōjo mono*, or "mad woman" pieces. Devils, strange beasts, and supernatural beings are featured in the *kiri* Nō, the fifth type. A program of Nō generally comprises three to five plays selected from the five types so as to achieve both an artistic unity and the desired mood; invariably a play of the *kiri* type is used as a concluding work.

Two special features of a Nō program are *okina* and *kyōgen*. *Okina* is essentially an invocation for peace and prosperity. The *kyōgen* is an interlude of humour between plays to relieve the tension engendered by them; it is also the name for the actor who relates the story between the two parts of plays, as in *Takasago*.

Structural elements of plays. The structure of Nō plays can be viewed in terms of the different types of performers, of recitation, of dance and mime, and of music, all of which have definite formulations that can be varied from play to play.

Three major Nō roles exist, *shite* ("actor"), *waki* ("by-



Scenes from Takasago.
(Left) The spirit of the pine tree assumes human form as an old man (*shite*) and woman (*tsure*) to relate its story. (Right) *Shite*, appearing in costume, mask, and headpiece indicating divinity, here represents the god of the pine tree and performs a solemn dance.

Roles and schools of performers

stander"), and *kyōgen*. Each is a specialty having several "schools" of performers, and each has it own "acting place" on the stage. Subsidiary roles include those of attendant (*tsure*), of a "boy" (*kokata*), and of nonspeaking "walk-on" (*tomo*). In *Takasago* the *shite* played both the old man and the deity Myōjin; the *waki*, the priest Tomonari; the *kyōgen*, the "man of the place" in the interlude. The old woman was a masked *tsure*, and the priest's attendants were *waki tsure*. The Nō play is essentially for the *shite*; he plays the protagonist role be it male or female. Only he dances and mimes. In two-part plays the *shite* changes costume and mask (if used) in the interlude and appears in the second part as a different character to extend and conclude the story. The *waki* is usually a Shintō priest, an imperial envoy, a travelling monk, or similar person whose interest, despite his "bystander" role, elicits from the *shite* and *kyōgen* the details of the story. *Kyōgen* performers represent a local personage, essentially narrators of the tales basic to the plays. In a second, less representative, kind of Nō play with only one part the performers appear purely as narrators who speak entirely in the third person. In both of these the *shite* and the *waki* play major roles, and the "bystander" idea of the *waki* role is absent. The *kokata*, usually playing a boy, may also play an emperor or person of high social rank, a practice based on the belief that a young person is pure and thus sacred. This, too, is characteristic of Nō in suggesting a character's essence rather than representing his appearance. An uncostumed figure at the rear of the stage is the *kōken*, who not only looks after the actors' hand props and adjusts the costumes and stage props but also stands ready to fill in for the *shite* role if necessary.

From the early days of Nō, performers have specialized in one or another of these roles, or as musicians. Four of the five *shite* schools predate Zeami, the *waki* families go back to the late 16th century, and the *kyōgen* and musician groups began in the earliest years of Nō. *Shite-tsure* and *kokata* actors and chorus members are from the *shite* group; *waki-tsure* from the *waki*. These schools, together with the careful preservation of texts and the passing of performing arts from father to son or master to pupil, contributed greatly to the continuity of Nō traditions and styles over many centuries.

The eight-to-ten-man chorus (*jiutai*) of Nō both resembles the Greek usage and differs from it. Its most unique function is to recite words in the place of a performer; alternatively, it may provide only musical accompaniment to dance or, like the Greek chorus, describe the entrance of a deity. In the "third-person Nō," the chorus may replace a performer in reciting text.

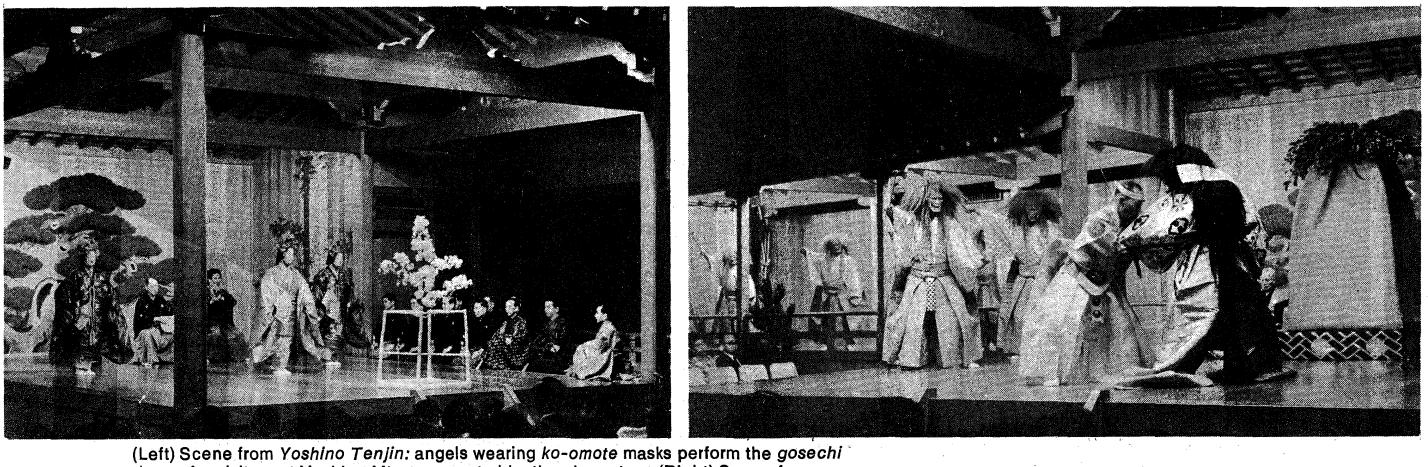
The recitation (*utai*) of Nō is the most important element in the performance. Each portion of the written text (*utaibon*) carries a prescription of the mode of recitation—as well as of accompanying movement or dance—although application of this may be varied slightly by each school or individual performer. Each type of dialogue and song has its own name: the *sashi* is like a recitative; the *uta* are the songs proper; the *rongi*, or debate, is intoned between chorus and *shite*; the *kiri* is the chorus with which the play ends. Singing is specified as high or low pitched. Plain speech is classed as name introduction (by the *waki*), dialogue, and narration. Although modern Nō is sometimes performed by all-woman casts, men generally fill all roles and, even as female characters, do not attempt to imitate a female voice. To do so would not be relevant to the spirit of Nō, for the actor, dressed and masked as a female, is on stage to suggest and never to impersonate.

Dance, mime, and music

Though at base it is more narration than drama, Nō requires at many moments a broad range of stylized movements. Several of these are carefully defined. *Furi* refers to intricate patterns of movement that accord with the words being recited, making visual their meanings; the patterns sometimes involve extravagant leaps. Pure dance, *mai*, is not ordinarily accompanied by recitation; either fast or slow, it is stately and elegant whether it is a god dance or a dance of female spirits. The number of movements of *mai* are rigidly specified, as are its gestures, postures, and steps; and the dancers carry brilliantly coloured fans. The most elaborate movement occurs in the *kiri*, or ending chorus, in which the *furi* patterns become very close to dance proper rather than to elaborate mime.

The music of Nō, *hayashi*, is played on a flute, which provides the melodic theme of songs and dances, and from a small and a large hand drum and a flat floor drum that provide the rhythmic base. Entrances of performers are marked by musical themes. The dance accompaniments evolved from an early period of Nō when persons around the dancer struck the stage with bamboo or sticks or sang to excite him into a state of rapture or possession by a god. Such primitive devices were refined into the sharp, piercing music of the dignified Nō dance.

Staging and design conventions. The traditional Nō stage was described earlier and is suggested in the accompanying photographs of productions. Until the beginning of the 17th century, however, viewers surrounded the stage on all sides. Temporary stages outside urban centres retained this aspect, in which the bridgeway is attached to the main stage by various means. Of the five main pillars on the stage, four are named for, and associated with, the performers; the fifth, the "eye-fixing pillar," serves as a landmark for the performers, whose vision may be limited by masks. Empty jars suspended under the stage act as resonators to amplify the sound of the dancer's stamping feet. Performers costume themselves in the dressing room and then, if they are to wear masks, put them on in the especially sacred "mirror room," where they "become the role" by contemplating their image.



(Left) Scene from *Yoshino Tenjin:* angels wearing *ko-omote* masks perform the *gosechi* dance for visitors at Yoshino Mt., represented by the cherry tree. (Right) Scene from *Momojigari:* female devils in *hannya* masks (expressing vengeance) attack the *waki,* a warrior figure. Structure, stage right, represents a mountain bearing maple leaves.
Hisao Maejima

The decor of the stage reflects the elemental simplicity of the Nō form. Only the painting of twisted pine and of young bamboo shoots decorate the back walls. Simple stage pieces or platforms may represent hills, a hermit's house, a rock, or a boat; they may be decorated with flowers, a tree, a sacred rope, or a candle. Smaller hand props may also be used, but by and large Nō, like the theatre of Shakespeare, leaves the connotations of time and place to the suggestion of its words and of its actors' mime and to its audience's imagination.

Costumes and masks

The sumptuous colour and material and the detailed line of the Nō costumes date from the period when support by noblemen, and even competition between nobles for actors and for brilliance of spectacle, permitted such largesse. The costumes, wigs, and head gear came to represent very elaborate aesthetic conventions, whereas the earliest Nō dress probably followed contemporary styles. A standard costume for each role evolved, but the costuming was not realistic. Poverty, for example, was not shown by rags but rather by suggestion in the kinds and arrangements of upper garments, head gear, and hand props.

The court dances known as *gigaku* and *bugaku* were imported from the Asian continent as early as the 7th century, probably the first entertainments in Japan to use masks. Names of mask makers are known from the 13th century. The mask of the deity Myōjin in *Takasago* is that of "a man of *Kantan*" created in the 14th century by a Tokuwaka to portray a noble youth. Over 100 kinds of mask have been classified as to divinities, men and women, young or aged, nonhuman figures, and the like. The principal mask is that of the divine figure *okina,* which has a movable jaw attached to the upper portion by string; others are generally in one piece. Ordinarily, the *shite* alone is masked, though a performer playing a woman or nonhuman figure is as well. The *waki,* essentially an observer, is never masked; and the kyōgen is rarely masked even when playing women, in which instances he relies on a special hair piece for suggestion of character.

CONTINUITY OF NŌ

Two factors have allowed Nō to be transmitted from generation to generation yet remain fairly close to earlier forms: first, the preservation of texts, containing detailed prescriptions of recitation, dance, mime, and music, and, second, the direct and fairly exact transmission of performing skills. On the other hand, Nō was subject to changing preferences of new audiences and new styles and patterns inevitably evolved. Further, there was constant refinement of received forms to express more clearly or intensely the objectives of Nō, but these were always and only minor deviations from traditional form. Even the differences between the five schools of *shite* performers represent only slight variations in the melodic line of the recitation or in the patterns of the *furi* or *mai* mime and dance.

Playwrights, theorists, critics

The great classic dramatists of Nō, Kan-ami, who wrote at least 18 plays, and his son Zeami, to whom 130 are attributed, performed all the essential functions of staging —text, music, dance, and movement—and themselves performed. Other playwrights include Zeami's son Motomasa (died 1432) and son-in-law Komparu Zenchiku (1405–68), Kanze Nobumitsu (1435–1516), Komparu Zempō (1454–*c.* 1520), and Kanze Nagatoshi (1488–1541). Zeami wrote his theoretical works, about 20 in number, for his descendants alone; carefully guarded and known as "the secret tradition," the writings became public only in the 20th century. Every aspect of Nō theatre, drawn from Zeami's rich personal experience, was discussed in them. Other treatises include Komparu Zenchiku's explanations, in a treatise of 1455, of Nō in metaphysical terms, but this and others were also long unknown outside the inner circles of Nō. Critics of Nō include Sakamoto Setchō (1879–1938) and Yamazaki Gakudō (1884–1944), whose commentaries on actors may have had subtle influences.

Experiments and prospects. After the late 15th century, Nō entered a long period of conservation and refinement of forms. Even the advent of the popular Kabuki theatre in the 16th and 17th centuries, with its sensuality and spectacle, failed to dim the support of Nō in high circles. In the 20th century some experimentation took place. Toki Zenmaro (1885–) and Kita Minoru (1900–) produced Nō plays that had new content but adhered to traditional conventions in production. Experiments to elaborate the humorous *kyōgen* interludes were not sustained. A so-called spotlight Nō adopted from Kabuki the long passage onto the stage through the audience and added a strong spotlight on the *shite,* but the innovation received little public acceptance.

Nō in the West

In the West the Irish poet William Butler Yeats discovered Nō through the dancing of Itō Michie and the writing of an American scholar of Japanese culture, Ernest Fenollosa. Between 1917 and 1921, Yeats wrote four dance-dramas that apparently reflected his interest. In 1954, two *shite* schools performed at the international theatre festival at Venice, and subsequently Nō companies visited several cities in Europe, performed and taught at the University of Washington in 1963, and took part in the arts exhibition at the 1968 Olympic games in Mexico City. Theatre specialists from around the world were deeply impressed by productions of Nō at the 1963 meeting of the International Theatre Institute in Tokyo.

The extreme simplicity and purity of the Nō form and its highly concentrated expression allowed much latitude for new interpretation and for an absorption of new materials. Not only did Nō seem likely to continue as a viable form in its own right, but it also offered fresh expressive means to a Western theatre that attempted to reach beyond naturalism in playwriting and production. What specific influences it would have on the performing arts of other regions remained, however, an open question.

BIBLIOGRAPHY. E.F. FENOLLOSA and EZRA POUND, *"Noh" or Accomplishment: A Study of the Classical Stage of Japan* (1916), a free translation of the texts of 15 Nō plays, including *Sotoba Komachi*, and a general outline of Nō; A. WALEY, *The Nō Plays of Japan*, new ed. (1950), full translation of 19 plays, summaries of others, one *kyōgen* play, and a bibliography; T. NOGAMI, *Japanese Noh Plays: How to See Them* (1934), an explanation written for those not familiar with Nō theatre; N. PERI, *Le nô* (1944), a bibliographic introduction to works on Nō and a general account of Nō, with a close literal translation of 10 Nō and 11 *kyōgen* plays; P.G. O'NEILL, *A Guide to Nō* (1953), a general explanation of Nō, with summaries of more than 240 plays, *Early Nō Drama: Its Background, Character and Development, 1300–1450* (1958), a study of the origin of Nō, including accounts of *shirabyōshi, kusemai, dengaku*, and *sarugaku*; Z. TOKI, *Japanese Nō Plays* (1954), a fairly detailed explanation and bibliography; NIPPON GAKUJUTSU SHINKOKAI, *Japanese Noh Drama* (1960), a general introduction and translation of 10 plays, including *Takasago*; H. BOHNER, *Nô: Die einzelnen Nô* (1956), an easy introduction to some 240 plays arranged in the conventional division into 5 parts.

(Y.H.)

Nova Scotia

One of the four British colonies federated into the Dominion of Canada in 1867, Nova Scotia comprises the peninsula of Nova Scotia, Cape Breton Island (separated from the mainland to the southwest by the narrow Strait of Canso), and a few small adjacent islands. Along the 17-mile-wide Chignecto Isthmus, which seems to thrust the peninsula into the Atlantic Ocean, runs the province's only land boundary, with New Brunswick to the west. Two arms of the Gulf of St. Lawrence, Northumberland and Cabot straits, separate it, respectively, from Prince Edward Island on the north and Newfoundland on the northeast. To the east lies the Atlantic and to the southwest the Bay of Fundy. Nova Scotia's 21,425 square miles (55,490 square kilometres) held a population of nearly 800,000 in the 1971 census, about one-third of whom lived in the two metropolitan areas of Halifax, the capital, and Sydney.

Location and general character

Nova Scotia—with New Brunswick, Prince Edward Island, and Newfoundland—is classified as one of Canada's Maritime, or Atlantic, Provinces, and both its past and its present are tied closely to the maritime life of fishing, shipbuilding, and transatlantic shipping. It was the site, in 1605, of the first permanent North American settlement north of Florida, established by the French. Among the legends that pervade the province is that found in the tale *Evangeline* by the U.S. poet Henry Wadsworth Longfellow, a fictional account of the very real deportation of the inhabitants of French descent in 1755 by a fearful British governor. The province's contemporary life retains some of the feeling of 17th-century Acadie, or Acadia, the Micmac Indian name adopted by the French for the region before Scottish colonists implanted their own name Nova Scotia, Latin for New Scotland. For information on related topics, see the articles CANADA; CANADA, HISTORY OF, and NORTH AMERICA.

The history of Nova Scotia. *Vicissitudes of settlement.* As in many of the older Canadian provinces, the 17th and 18th centuries were characterized by the instabilities of colonization, of struggles for power originating in the rivalries between London and Paris, and of migratory and military pressure from the colonies to the south that were to become the United States. The territory passed back and forth between France and England until 1713, when the French, retaining Cape Breton Island and other areas, began construction of the powerful Louisbourg fortress. Halifax was founded in 1749 as a counterbalance and populated with some 4,000 British settlers. In the 1750s the French Acadians, who refused to swear allegiance to the English crown, were expelled.

Decades as a pawn of empire

Offers of free land attracted immigrants not only from the British Isles but also from New England; it was the latter group that helped to secure the first elected assembly. By the time of the American Revolution, New Englanders comprised roughly one-half of Nova Scotia's population; though they tried to remain neutral, four delegates attended the Continental Congress in Philadelphia. During the Revolution and after, some 35,000 Loyalists added to the number of immigrants from the south. Meanwhile, Prince Edward Island had split off from Nova Scotia in 1769, and New Brunswick followed in 1784; Cape Breton Island finally was reunited with Nova Scotia in 1820. In 1848 Nova Scotia became the first British colony to exercise the prerogative of government responsible to the people through their elected representatives. There was both economic and political opposition to the proposed confederation with Ontario, Quebec, and New Brunswick, but union was carried out in 1867.

From colony to province. As a separate British colony, Nova Scotia prospered from its forestry, fisheries, and shipbuilding for the first two-thirds of the 19th century. Under the Reciprocity Treaty of 1854, the north–south flow of commerce and Nova Scotia's normal market and supply source in New England seemed secure. Nova Scotia benefitted further from the increased demand for duty-free natural products during the Civil War. The Canadian tariffs on manufactured goods, the alleged pro-Confederate sentiments of Britain and Canada, and the protectionist pressures of some states in the victorious North led to the nonrenewal of reciprocity in 1866 and the levying of further protective tariffs by both nations. Canada also lost the preferential treatment by Britain previously granted under colonial policy. Railways, meanwhile, were changing continental traffic patterns, and Canada and the U.S became rivals for the east–west inland trade. Canada's tariffs, intended both to protect its own manufactures and to assist in financing its railways from coastal ports to central Canada, were supposed to assure the province of year-round commerce, but the pioneers had not counted on the costs of transportation to the distant population centres. Nova Scotia's prospects were further set back as iron steamers replaced the wooden sailing vessels that had been the pride and chief industry of the province. The steamers usually bypassed Nova Scotian ports for those in the U.S., and even the lucrative trade with the West Indies dwindled. Further damage to the economy of the Maritime Provinces occurred with the opening of the western provinces to settlement, a step that tended to drain the older regions of some of the more vigorous elements of the population and to deprive them of investment capital and other resources, which now were directed toward the new lands.

By the early 1970s such conditions had been alleviated, and industry had made significant beginnings to add to the exploitation of natural resources. Nova Scotia, however, continued to lag well behind the more developed provinces and the Canadian averages in virtually all economic indicators.

The natural and human landscape. *Surface features.* Nova Scotia's five upland regions reach a maximum height of more than 1,700 feet (520 metres) above sea level in the Cape Breton Highlands. The most important lowlands lie along the Bay of Fundy and the Minas Basin, in the southwest and along the Northumberland Strait. Many of the tens of thousands of acres of marshland in the west created by the tremendously high tides of the Bay of Fundy have been turned to agricultural use by dikes, which were begun in the early 18th century by the Acadian French.

Lakes and rivers

Over 3,000 lakes and hundreds of short rivers and streams either have been impounded by, or have cut through, the irregularly high and low landscapes. The best known of the lakes, Bras d'Or on Cape Breton Island, is saline but tideless because of three short channels connecting it with the Atlantic. Many intruding heads of land make the lake's 360 square miles a geographical complexity; it is surrounded by steep hills and valleys.

Climate. The southwestern and southern shores of Nova Scotia have both milder and wetter climates than the rest of the province, with frost-free days numbering about 140 along the Bay of Fundy and 160 around Yarmouth, compared with 100 in the interior. Rainfall varies from 55 inches (1,400 millimetres) in the south, where

fog may occur on as many as 90 days, to 40 inches elsewhere.

Vegetation and animal life. Productive forests occupy about 75 percent of the land area. Only one-quarter of the woodland is held as crown land, some of which is used for public parks and reserves. Softwoods are by far the most numerous, led by various species of balsam, spruce, hemlock, and pine; birch and maple make up most of the hardwoods. Hunting—especially for deer and moose and for partridge, pheasant and duck among the birds—is a favourite outdoor sport for Nova Scotians and tourists. For anglers, trout and salmon are among the most popular freshwater fish; for deep-sea fishermen, Wedgeport is the scene of annual international tuna matches.

The human imprint. Subsistence living on family farms has been characteristic of Nova Scotia agriculture. In 1970 improved farmland and pastureland amounted to some 500 square miles and farm woodlands 1,700 square miles. Along the coasts many families living on marginal land have combined farming with fishing for lobsters and ground fish; in other areas farming and lumbering are often combined. Mixed farming and dairying are carried out in the fertile lands of Guysborough and other eastern counties, as well as on the Chignecto Isthmus and along the Fundy shore. Though apples and pears are also found in other sections, the Annapolis Valley orchards, dating back three centuries, are the most productive. With greater efficiency in land use and increased mechanization, both the number of farms and total acreage under cultivation have declined, but individual farms are becoming somewhat larger, production is increasing, and income improving. About 6 percent of the people live on farms, and another 35 percent are nonfarm rural dwellers.

Patterns of rural and urban employment

In the 19th century, as steamships replaced schooners, the outports dwindled. Coal and steel and textile industries drew workers to Sydney and Halifax, but some smaller towns continued enterprises like boatbuilding, woodworking, and food processing. Recently, internal population movement has been toward the Halifax–Dartmouth area, in which there is employment in the shipyards, naval dockyard, construction industries, and assembly plants. Sydney has been declining during the transition from steel and coal to other resources, but Port Hawkesbury has had a dramatic growth spurt due to the location of an oil refinery, pulp and paper plant, power generator, and other industries near the Strait of Canso.

The people of Nova Scotia. About one-eighth of Nova Scotia's people are descended from the Acadian French, who were allowed to return from exile after the British took French Canada in 1763. Most of the remaining seven-eighths are descended from settlers from the British Isles, both English and Scottish. Acadian communities are now located above Yarmouth and along St. Mary's Bay and on the west coast of Cape Breton Island. New England planters resettled the Minas Basin after 1755, and British Empire Loyalists founded Shelburne in 1783 and helped to populate Halifax. Scottish Highlanders, many victims of enclosure movement, tended to settle in the Northumberland Strait counties and Cape Breton Island. Also in the 18th century some Ulstermen established farms in the Truro and Onslow districts, and later Irish came in small family groups and settled in and near Halifax. German immigrants in the 1750s founded the seaport of Lunenburg, and others came a century later. Other minorities include small numbers of Dutch, Italian, and Hungarian who have immigrated since World War II. More significant are the Negro communities near Halifax and Shelburne, dating from the days of the West Indian slave trade and particularly the Loyalist influx after the American Revolution. Over 3,000 Micmac Indians live on reservations.

Ethnic components of the population

In 1970 over one-third of the people were Roman Catholics; among the Protestant denominations the United Church of Canada is the largest, followed by Anglicans and Baptists. Since 1960 immigration into Nova Scotia has not been numerically significant, but emigration of both the undertrained and the well educated has continued. The population has grown mainly by natural increase: the 1969 birth rate was 17.8 per 1,000 and the death rate 8.7, compared to national statistics of 17.6 for births and 7.3 for deaths. In 1971 the population of nearly 789,000 represented an increase of 2 percent in five years.

The province's economy. *Components.* With only about 5 percent of the province's land suitable for crops, agriculture has focussed mainly on livestock and poultry production and various dairying activities—though the marshlands offered the environment necessary for such crops as blueberries.

Primary resources and secondary industries

Fisheries continue as a major activity, with the major part of the catch comprising shellfish, haddock, and cod. The largest fish-processing plant in North America was opened in Lunenburg in 1964.

The generally small-scale forestry operations, about one-half of which are directed to pulp production, have been supplemented by large plants built in recent years by major companies. The pulp industry remains a significant factor within the economy, although increasing concern is evident over environmental pollution caused by plant operations. Coal seams on Cape Breton Island, mostly underwater, are becoming thin, and the future of even new mines like the one at Lingan is uncertain; but coal remains the province's single most valuable mineral resource. By 1969, however, the combined value of industrial minerals was greater than coal; among the nonmetallics, salt production was increasing, and Nova Scotia claimed the world's largest barite deposits and 85 percent of Canada's gypsum production. Such metals as silver, copper, lead, and zinc came primarily from one mine in Walton. Offshore explorations for oil, particularly those near Sable Island in 1972, gave rise to hopes for a new industry and to debates between federal and provincial officials over jurisdictional rights to such deposits. The value of export trade, particularly from the port of Halifax, with its new container piers, increased by 113 percent between 1957 and 1970.

Nova Scotia entered the 1970s with relatively unstable conditions prevailing among its industries, most of which were small-scale operations engaged in processing the province's primary products. Industrial Estates Ltd., a crown corporation, had a fair record in locating new industries by advancing up to 100 percent of factory and equipment costs, but a similar corporation met with little success in developing substitute industries on Cape Breton Island to facilitate the phasing out of the coal industry. In addition, heavy-water plants, built with considerable fanfare in the 1960s, were slow to begin output, and the provincial government showed some reluctance to join the development activities sponsored by the federal government. Bright spots included continuing growth of petrochemical facilities around the Strait of Canso and new facilities for containerized shipping in Halifax harbour. The Nova Scotia Research Foundation served to keep small industries in touch with advances in technology and science, in addition to engaging in research in pure science.

Transportation. Cape Breton Island was connected with the mainland by causeway in 1955; the other main highways, some 5,000 miles of which are paved, are located around the perimeter of both the mainland and Cape Breton Island, with a direct road as well from Truro to Halifax. Ferry services operate to ports in New Brunswick, Prince Edward Island, and the state of Maine. Both major Canadian railroads serve the province by land or ferry, and five airports handle commercial and private aviation.

Administration and social conditions. *Government and politics.* Nova Scotia's governmental structure is similar to that of all Canadian provinces. A lieutenant governor appointed by the federal government serves as representative of the crown, whereas the premier is the leader of the party in power in the provincial parliament and selects his cabinet from among his colleagues. The judiciary is federally appointed, while government employees

are recruited through a nonpolitical civil service. Local government is divided among the three cities, Halifax, Dartmouth, and Sydney; 39 towns; and 24 rural municipalities. Provincial income is derived from two virtually equal sources: the federal government and various provincial taxes and fees.

Since confederation there have been two major political parties in Nova Scotia, the dominant Liberals and the Conservatives (now the Progressive Conservatives); the New Democratic Party has had little success. In recent times provincial election campaigns have centred upon efficiency in government, economic expansion, and the quality and style of leadership. The proposed union of the Maritime Provinces is a matter of continuing study. As a proving ground for politicians, Nova Scotia had by 1970 produced three federal prime ministers and many other national figures.

Education. Nova Scotia has over 800 public schools, 13 vocational schools, 11 institutions of higher learning, and two institutes of technology. The nondenominational system of compulsory, free public education, dating from 1811, is in the final stages of consolidating the many rural school districts into fewer, larger, and more efficient districts. Considerable emphasis is placed on commercial and vocational training at the secondary as well as the college level. Dalhousie University (founded 1818) in Halifax is perhaps the best known of the institutions of higher learning, though a number of Roman Catholic and other private institutions offer diversified curricula. Agriculture, social work, and teacher training are among the specialized areas served by specific institutions. St. Francis Xavier University, in Antigonish, has attracted international interest in its adult-education programs, which have fostered social leadership through self-help projects such as cooperatives and credit unions.

Health and welfare. Since 1969 Nova Scotia has participated in the federal Medical Care Insurance Program. The premium is paid from the province's general revenues, and insured services include all medically necessary procedures by medical practitioners plus some oral surgery procedures in hospitals. The province also provides facilities for mental health, dental care, tuberculosis control, and other public-health services. In the early 1970s there were 54 hospitals. Nova Scotia's welfare services are similar to those in other provinces, covering old age assistance, allowances for the blind and disabled, social assistance, social development, child welfare and adoptions, and service to unmarried mothers and to delinquents. The Department of Public Welfare operates institutions for mentally retarded children and for delinquent youth and supervises a number of children's aid societies and other private institutions.

The standards of living approximate those of the nation generally, but costs have been higher and average incomes substantially lower. Nova Scotia is below the Canadian norm in employment, industrial wages, and housing facilities. Personal income per capita as a percentage of Canada improved from 69.7 percent in 1951 to 80.3 percent 20 years later, although the actual dollar gap widened from $349 to $610.

Cultural life and institutions. Its position as a peninsula and island thrust into the Atlantic has kept Nova Scotia somewhat removed from the mainstream of Canadian life, centred in Ontario and Quebec. The greater ease of travel and the growing impact of the nationwide communications media in recent decades have brought the province closer, making a modern way of life typical of the province and eroding in some measure the features of traditional Nova Scotian life—but many areas of the mainland peninsula and of Cape Breton Island retain an unretouched image of the past.

Preservation of traditional cultures

Scottish culture is particularly vigorous in Nova Scotia. Pictou County alone has several bagpipe bands, while St. Francis Xavier University offers courses in Celtic studies, and the Gaelic College in St. Ann's, Cape Breton, fosters piping, singing, dancing, and handicrafts. Clan gatherings take place annually at the Gaelic College to celebrate the Gaelic Mod, a festival of Highland folk arts. Both fine arts and crafts of various ethnic origins are exhibited at the arts festival held annually on the campus of Acadia University. Each summer individual and community arts are taught at Tatamagouche, and an Acadian festival is held at Clare.

Halifax is the centre of repertory drama, and the several universities have their own theatre productions. Groups of resident and visiting painters are found in such south shore communities as Mahone Bay, Lunenburg, and Peggy's Cove. Woodcarving, pottery making, hooking, and weaving are found throughout the province.

French-language programs are provided on five of the 30 radio stations and one of the 12 television stations. There is one weekly newspaper in French and 27 weeklies and 6 dailies in English.

Among the most impressive historic sites are the restored fortress of Louisbourg, Champlain's habitation at Port Royal, and the Halifax citadel. Also of historical interest are the Alexander Graham Bell National Historic Park with a museum at Baddeck and the Grand Pré memorial in the Annapolis Valley. In 1970 these sites were visited by over 1,250,000 persons, and Cape Breton Highlands National Park attracted over 700,000 tourists. A system of provincial parks and campsites is under continual development, and private accommodations and recreational facilities are rapidly increasing; but assessments of the economic value of tourism are imprecise.

Prospects. In the early 1970s, though there was little assurance of eliminating disparities that existed since confederation, Nova Scotia had realistic prospects for keeping pace with the economic growth rate of the nation. Such progress would be related to developing additional power resources, modernizing steel facilities, revitalizing the coal industry, attracting additional light and heavy industry, expanding tourism, and improving the marketing of the province's farm, fishery, and forest products. Federal and provincial efforts are coordinated under the Department of Regional Economic Expansion, the Atlantic Development Board, the Cape Breton Development Corporation, and other crown agencies. It was hoped that these objectives could be achieved without seriously eroding those cultural values and aspirations for an abundant life that have characterized the peoples of Nova Scotia for over three centuries.

BIBLIOGRAPHY. There is no comprehensive history of Nova Scotia, but numerous books provide reliable information on various phases or aspects of the province's development. In addition to the full-length works, there is a considerable body of literature in the *Collections* of the Nova Scotia Historical Society (1878–), *The Dalhousie Review*, and the *Canadian Historical Review* (both quarterly). Selected readings are J. MURRAY BECK, *The Government of Nova Scotia* (1957), a comprehensive work tracing the development of governmental institutions; W.R. BIRD, *This is Nova Scotia* (1950), a popular travelogue that captures contemporary viewpoints, conditions, and links with the past; J.B. BREBNER, *The Neutral Yankees of Nova Scotia* (1937, reprinted 1969) and *New England's Outpost: Acadia Before the Conquest of Canada* (1927, reprinted 1965), among the standard historical works on colonial Nova Scotia; ARTHUR G. DOUGHTY, *The Acadian Exiles: A Chronicle of the Land of Evangeline* (1916, reprinted 1964), a concise, more objective account than most of this controversial subject; W.S. MACNUTT, *The Atlantic Provinces: The Emergence of Colonial Society, 1712–1857* (1965), a historical synthesis of Nova Scotia in a regional context; and G.A. RAWLYK (ed.), *Historical Essays on the Atlantic Provinces* (1967), an anthology, regional in scope, with several individual essays elucidating important features of the economic, intellectual, and cultural life of Nova Scotia.

(B.O'G.)

Novel

The novel is a genre of fiction, and fiction may be defined as the art or craft of contriving, through the written word, representations of human life that instruct or divert or both. The various forms that fiction may take are best

seen less as a number of separate categories than as a continuum or, more accurately, a cline, with some such brief form as the anecdote at one end of the scale and the longest conceivable novel at the other. When any piece of fiction is long enough to constitute a whole book, as opposed to a mere part of a book, then it may be said to have achieved novelhood. But this state admits of its own quantitative categories, so that a relatively brief novel may be termed a novella (or, if the insubstantiality of the content matches its brevity, a novelette), and a very long novel may overflow the banks of a single volume and become a *roman fleuve,* or river novel. Length is very much one of the dimensions of the genre.

The term novel is a truncation of the Italian word *novella* (from the plural of Latin *novellus,* a late variant of *novus,* meaning "new"), so that what is now, in most languages, a diminutive denotes historically the parent form. The *novella* was a kind of enlarged anecdote like those to be found in the 14th-century Italian classic Boccaccio's *Decameron,* each of which exemplifies the etymology well enough. The stories are little new things, novelties, freshly minted diversions, toys; they are not reworkings of known fables or myths, and they are lacking in weight and moral earnestness. It is to be noted that, despite the high example of novelists of the most profound seriousness, such as Tolstoy, Henry James, and Virginia Woolf, the term novel still, in some quarters, carries overtones of lightness and frivolity. And it is possible to descry a tendency to triviality in the form itself. The ode or symphony seems to possess an inner mechanism that protects it from aesthetic or moral corruption, but the novel can descend to shameful commercial depths of sentimentality or pornography. It is the purpose of this article to consider the novel not solely in terms of great art but also as an all-purpose medium catering for all the strata of literacy.

The novel and the epic compared

Such early ancient Roman fiction as Petronius' *Satyricon* of the 1st century AD and Lucius Apuleius' *Golden Ass* of the 2nd century contain many of the popular elements that distinguish the novel from its nobler born relative the epic poem. In the fictional works, the medium is prose, the events described are unheroic, the settings are streets and taverns, not battlefields and palaces. There is more low fornication than princely combat; the gods do not move the action; the dialogue is homely rather than aristocratic. It was, in fact, out of the need to find—in the period of Roman decline—a literary form that was anti-epic in both substance and language that the first prose fiction of Europe seems to have been conceived. The most memorable character in Petronius is a *nouveau riche* vulgarian; the hero of Lucius Apuleius is turned into a donkey; nothing less epic can well be imagined.

The medieval chivalric romance (from a popular Latin word, probably *Romanice,* meaning written in the vernacular, not in traditional Latin) restored a kind of epic view of man—though now as heroic Christian, not heroic pagan. At the same time, it bequeathed its name to the later genre of continental literature, the novel, which is known in French as *roman,* in Italian as *romanzo,* etc. (The English term romance, however, carries a pejorative connotation.) But that later genre achieved its first great flowering in Spain at the beginning of the 17th century in an antichivalric comic masterpiece—the *Don Quixote* of Cervantes, which, on a larger scale than the *Satyricon* or *The Golden Ass,* contains many of the elements that have been expected from prose fiction ever since. Novels have heroes, but not in any classical or medieval sense. As for the novelist, he must, in the words of the contemporary British-American W.H. Auden,

> Become the whole of boredom, subject to
> Vulgar complaints like love, among the Just
> Be just, among the Filthy filthy too,
> And in his own weak person, if he can,
> Must suffer dully all the wrongs of Man.

The novel attempts to assume those burdens of life that have no place in the epic poem and to see man as unheroic, unredeemed, imperfect, even absurd. This is why there is room among its practitioners for writers of hard-boiled detective thrillers such as the contemporary American Mickey Spillane or of sentimental melodramas such as the prolific 19th-century English novelist Mrs. Henry Wood, but not for one of the unremitting elevation of outlook of a John Milton.

This article analyzes the characteristics of the novel, discusses the various uses it serves, enumerates the artistic styles it reflects and its subgenres, and treats it historically wherever it has been a significant literary form. Finally, there are discussions of its social and economic aspects and its prospects and a concluding discussion of its evaluation and study. The article is outlined as follows:

The reader may also be interested in the analogous treatment of a comparable genre in the article SHORT STORY. Critical approaches are discussed in the articles ARTS, CRITICISM OF THE; and LITERARY CRITICISM. The place of the novel within the literatures of the world is treated in articles such as LITERATURE, WESTERN; and LITERATURE, EAST ASIAN; and in articles on the arts of various peoples, such as SOUTH ASIAN PEOPLES, ARTS OF; AFRICAN PEOPLES, ARTS OF.

I. Characteristics of the novel

ELEMENTS OF THE NOVEL

Plot. The novel is propelled through its hundred or thousand pages by a device known as the story or plot. This is frequently conceived by the novelist in very simple terms, a mere nucleus, a jotting on an old envelope: for example, Charles Dickens' *Christmas Carol* (1843) might have been conceived as "a misanthrope is reformed through certain magical visitations on Christmas Eve"; or Jane Austen's *Pride and Prejudice* (1813) as "a young couple destined to be married have first to overcome the barriers of pride and prejudice"; or Fyodor Dostoyevsky's *Crime and Punishment* (1866) as "a young man commits a crime and is slowly pursued in the direction of his punishment." The detailed working out of the nuclear idea requires much ingenuity, since the plot of one novel is expected to be somewhat different from that of another, and there are very few basic human situations for the novelist to draw upon. The dramatist may take his plot ready-made from fiction or biography—a form of theft sanctioned by Shakespeare—but the novelist has to produce what look like novelties.

Original and borrowed plots

The example of Shakespeare is a reminder that the ability to create an interesting plot, or even any plot at all, is not a prerequisite of the imaginative writer's craft. At the lowest level of fiction, plot need be no more than a string of stock devices for arousing stock responses of concern and excitement in the reader. The reader's interest may be captured at the outset by the promise of conflicts or mysteries or frustrations that will eventually be resolved, and he will gladly—so strong is his desire to be moved or entertained—suspend criticism of even the most trite modes of resolution. In the least sophisticated fiction, the knots to be untied are stringently physical, and the denouement often comes in a sort of triumphant violence. Serious fiction prefers its plots to be based on psychological situations, and its climaxes come in new states of awareness—chiefly self-knowledge—on the parts of the major characters.

Melodramatic plots, plots dependent on coincidence or improbability, are sometimes found in even the most elevated fiction; E.M. Forster's *Howards End* (1910) is an example of a classic British novel with such a plot. But the novelist is always faced with the problem of whether

it is more important to represent the formlessness of real life (in which there are no beginnings and no ends and very few simple motives for action) or to construct an artifact as well balanced and economical as a table or chair; since he is an artist, the claims of art, or artifice, frequently prevail. But there are ways of constructing novels in which plot may play a desultory part or no part at all. The traditional picaresque novel—a novel with a rogue as its central character—like Alain Lesage's *Gil Blas* (1715) or Henry Fielding's *Tom Jones* (1749), depends for movement on a succession of chance incidents. In the works of Virginia Woolf, the consciousness of the characters, bounded by some poetic or symbolic device, sometimes provides all the fictional material. Marcel Proust's great *roman fleuve, À la recherche du temps perdu* (1913–27; *Remembrance of Things Past*), has a metaphysical framework derived from the time theories of the philosopher Henri Bergson, and it moves toward a moment of truth that is intended to be literally a revelation of the nature of reality. Strictly, any scheme will do to hold a novel together—raw action, the hidden syllogism of the mystery story, prolonged solipsist contemplation—so long as the actualities or potentialities of human life are credibly expressed, with a consequent sense of illumination, or some lesser mode of artistic satisfaction, on the part of the reader.

Character. The inferior novelist tends to be preoccupied with plot; to the superior novelist the convolutions of the human personality, under the stress of artfully selected experience, are the chief fascination. Without character it was once accepted that there could be no fiction. In the period since World War II, the creators of what has come to be called the French *nouveau roman* (*i.e.*, new novel) have deliberately demoted the human element, claiming the right of objects and processes to the writer's and reader's prior attention. Thus, in books termed *chosiste* (literally "thing-ist"), they make the furniture of a room more important than its human incumbents. This may be seen as a transitory protest against the long predominance of character in the novel, but, even on the popular level, there have been indications that readers can be held by things as much as by characters. Henry James could be vague in *The Ambassadors* (1903) about the provenance of his chief character's wealth; if he wrote today he would have to give his readers a tour around the factory or estate. The popularity of much undistinguished but popular fiction has nothing to do with its wooden characters; it is machines, procedures, organizations that draw the reader. The success of Ian Fleming's British spy stories in the 1960s had much to do with their hero, James Bond's car, gun, and preferred way of mixing a martini.

Objects as "characters"

But the true novelists remain creators of characters—prehuman, such as those in William Golding's *Inheritors* (1955); animal, as in Henry Williamson's *Tarka the Otter* (1927) or Jack London's *Call of the Wild* (1903); caricatures, as in much of Dickens; or complex and unpredictable entities, as in Tolstoy, Dostoyevsky, or Henry James. The reader may be prepared to tolerate the most wanton-seeming stylistic tricks and formal difficulties because of the intense interest of the central characters in novels as diverse as James Joyce's *Ulysses* (1922) and *Finnegans Wake* (1939) and Laurence Sterne's *Tristram Shandy* (1760–67).

Characters as symbols

It is the task of literary critics to create a value hierarchy of fictional character, placing the complexity of the Shakespearean view of man—as found in the novels of Tolstoy and Joseph Conrad—above creations that may be no more than simple personifications of some single characteristic, like some of those by Dickens. It frequently happens, however, that the common reader prefers surface simplicity—easily memorable cartoon figures like Dickens' never-despairing Mr. Micawber and devious Uriah Heep—to that wider view of personality, in which character seems to engulf the reader, subscribed to by the great novelists of France and Russia. The whole nature of human identity remains in doubt, and writers who voice that doubt—like the French exponents of the *nouveau roman* Alain Robbe-Grillet and Nathalie Sarraute, as well as many others—are in effect rejecting a purely romantic view of character. This view imposed the author's image of himself—the only human image he properly possessed—on the rest of the human world. For the unsophisticated reader of fiction, any created personage with a firm position in time–space and the most superficial parcel of behavioral (or even sartorial) attributes will be taken for a character. Though the critics may regard it as heretical, this tendency to accept a character is in conformity with the usages of real life. The average person has at least a suspicion of his own complexity and inconsistency of makeup, but he sees the rest of the world as composed of much simpler entities. The result is that novels whose characters are created out of the author's own introspection are frequently rejected as not "true to life." But both the higher and the lower orders of novel readers might agree in condemning a lack of memorability in the personages of a work of fiction, a failure on the part of the author to seem to add to the reader's stock of remembered friends and acquaintances. Characters that seem, on recollection, to have a life outside the bounds of the books that contain them are usually the ones that earn their creators the most regard. Depth of psychological penetration, the ability to make a character real as oneself, seems to be no primary criterion of fictional talent.

Scene, or setting. The makeup and behaviour of fictional characters depend on their environment quite as much as on the personal dynamic with which their author endows them: indeed, in Émile Zola, environment is of overriding importance, since he believed it determined character. The entire action of a novel is frequently determined by the locale in which it is set. Thus, Gustave Flaubert's *Madame Bovary* (1857) could hardly have been placed in Paris, because the tragic life and death of the heroine have a great deal to do with the circumscriptions of her provincial milieu. But it sometimes happens that the main locale of a novel assumes an importance in the reader's imagination comparable to that of the characters and yet somehow separable from them. Wessex is a giant brooding presence in Thomas Hardy's novels, whose human characters would probably not behave much differently if they were set in some other rural locality of England. The popularity of Sir Walter Scott's "Waverley" novels is due in part to their evocation of a romantic Scotland. Setting may be the prime consideration of some readers, who can be drawn to Conrad because he depicts life at sea or in the East Indies; they may be less interested in the complexity of human relationships that he presents.

Regional novels

The regional novel is a recognized species. The sequence of four novels that Hugh Walpole began with *Rogue Herries* (1930) was the result of his desire to do homage to the part of Cumberland, in England, where he had elected to live. The great Yoknapatawpha cycle of William Faulkner, a classic of 20th-century American literature set in an imaginary county in Mississippi, belongs to the category as much as the once-popular confections about Sussex that were written about the same time by the English novelist Sheila Kaye-Smith. Many novelists, however, gain a creative impetus from avoiding the same setting in book after book and deliberately seeking new locales. The English novelist Graham Greene apparently needed to visit a fresh scene in order to write a fresh novel. His ability to encapsulate the essence of an exotic setting in a single book is exemplified in *The Heart of the Matter* (1948); his contemporary Evelyn Waugh stated that the West Africa of that book replaced the true remembered West Africa of his own experience. Such power is not uncommon: the Yorkshire moors have been romanticized because Emily Brontë wrote of them in *Wuthering Heights* (1847), and literary tourists have visited Stoke-on-Trent, in northern England, because it comprises the "Five Towns" of Arnold Bennett's novels of the early 20th century. Others go to the Monterey, California, of John Steinbeck's novels in the expectation of experiencing a *frisson* added to the locality by an act of creative imagination. James Joyce, who remained inexhaustibly stimulated by Dublin, has exalted that city in a manner that even the guidebooks recognize.

The setting of a novel is not always drawn from a real-life locale. The literary artist sometimes prides himself on his ability to create the totality of his fiction—the setting as well as the characters and their actions. In the Russian expatriate Vladimir Nabokov's *Ada* (1969) there is an entirely new space–time continuum, and the English scholar J.R.R. Tolkien in his *Lord of the Rings* (1954–55) created an "alternative world" that appeals greatly to many who are dissatisfied with the existing one. The world of interplanetary travel was imaginatively created long before the first moon landing. The properties of the future envisaged by H.G. Wells's novels or by Aldous Huxley in *Brave New World* (1932) are still recognized in an age that those authors did not live to see. The composition of place can be a magical fictional gift.

Whatever the locale of his work, every true novelist is concerned with making a credible environment for his characters, and this really means a close attention to sense data—the immediacies of food and drink and colour—far more than abstractions like "nature" and "city." The London of Charles Dickens is as much incarnated in the smell of wood in lawyers' chambers as in the skyline and vistas of streets.

Narrative method and point of view. Where there is a story, there is a storyteller. Traditionally, the narrator of the epic and mock-epic alike acted as an intermediary between the characters and the reader; the method of Fielding is not very different from the method of Homer. Sometimes the narrator boldly imposed his own attitudes; always he assumed an omniscience that tended to reduce the characters to puppets and the action to a predetermined course with an end implicit in the beginning. Many novelists have been unhappy about a narrative method that seems to limit the free will of the characters, and innovations in fictional technique have mostly sought the objectivity of the drama, in which the characters appear to work out their own destinies without prompting from the author.

The epistolary method, most notably used by Samuel Richardson in *Pamela* (1740) and by Jean-Jacques Rousseau in *La nouvelle Héloïse* (1761), has the advantage of allowing the characters to tell the story in their own words, but it is hard to resist the uneasy feeling that a kind of divine editor is sorting and ordering the letters into his own pattern. The device of making the narrator also a character in the story has the disadvantage of limiting the material available for the narration, since the narrator-character can know only those events in which he participates. There can, of course, be a number of secondary narratives enclosed in the main narrative, and this device—though it sometimes looks artificial—has been used triumphantly by Conrad and, on a lesser scale, by W. Somerset Maugham. A, the main narrator, tells what he knows directly of the story and introduces what B and C and D have told him about the parts that he does not know.

Seeking the most objective narrative method of all, Ford Madox Ford used, in *The Good Soldier* (1915), the device of the storyteller who does not understand the story he is telling. This is the technique of the "unreliable observer." The reader, understanding better than the narrator, has the illusion of receiving the story directly. Joyce, in both his major novels, uses different narrators for the various chapters. Most of them are unreliable, and some of them approach the impersonality of a sort of disembodied parody. In *Ulysses*, for example, an episode set in a maternity hospital is told through the medium of a parodic history of English prose style. But, more often than not, the sheer ingenuity of Joyce's techniques draws attention to the manipulator in the shadows. The reader is aware of the author's cleverness where he should be aware only of the characters and their actions. The author is least noticeable when he is employing the stream of consciousness device, by which the inchoate thoughts and feelings of a character are presented in interior monologue—apparently unedited and sometimes deliberately near-unintelligible. It is because this technique seems to draw fiction into the psychoanalyst's consulting room (presenting the raw material of either art or science, but certainly not art itself), however, that Joyce felt impelled to impose the shaping devices referred to above. Joyce, more than any novelist, sought total objectivity of narration technique but ended as the most subjective and idiosyncratic of stylists.

The presence of the author

The problem of a satisfactory narrative point of view is, in fact, nearly insoluble. The careful exclusion of comment, the limitation of vocabulary to a sort of reader's lowest common denominator, the paring of style to the absolute minimum—these puritanical devices work well for an Ernest Hemingway (who, like Joyce, remains, nevertheless, a highly idiosyncratic stylist) but not for a novelist who believes that, like poetry, his art should be able to draw on the richness of word play, allusion, and symbol. For even the most experienced novelist, each new work represents a struggle with the unconquerable task of reconciling all-inclusion with self-exclusion. It is noteworthy that Cervantes, in *Don Quixote*, and Nabokov, in *Lolita* (1955), join hands across four centuries in finding most satisfactory the device of the fictitious editor who presents a manuscript story for which he disclaims responsibility. But this highly useful method presupposes in the true author a scholarly, or pedantic, faculty not usually associated with novelists.

Scope, or dimension. No novel can theoretically be too long, but if it is too short it ceases to be a novel. It may or may not be accidental that the novels most highly regarded by the world are of considerable length—Cervantes' *Don Quixote*, Dostoyevsky's *Brothers Karamazov*, Tolstoy's *War and Peace*, Dickens' *David Copperfield*, Proust's *À la recherche du temps perdu*, and so on. On the other hand, since World War II, brevity has been regarded as a virtue in works like the later novels of the Irish absurdist author Samuel Beckett and the *ficciones* of the Argentine Jorge Luis Borges, and it is only an aesthetic based on bulk that would diminish the achievement of Ronald Firbank's short novels of the post-World War I era or the Evelyn Waugh who wrote *The Loved One* (1948). It would seem that there are two ways of presenting human character—one, the brief way, through a significant episode in the life of a personage or group of personages; the other, which admits of limitless length, through the presentation of a large section of a life or lives, sometimes beginning with birth and ending in old age. The plays of Shakespeare show that a full delineation of character can be effected in a very brief compass, so that, for this aspect of the novel, length confers no special advantage. Length, however, is essential when the novelist attempts to present something bigger than character—when, in fact, he aims at the representation of a whole society or period of history.

No other cognate art form—neither the epic poem nor the drama nor the film—can match the resources of the novel when the artistic task is to bring to immediate, sensuous, passionate life the somewhat impersonal materials of the historian. *War and Peace* is the great triumphant example of the panoramic study of a whole society—that of early-19th-century Russia—which enlightens as the historians enlightens and yet also conveys directly the sensations and emotions of living through a period of cataclysmic change. In the 20th century, another Russian, Boris Pasternak, in his *Doctor Zhivago* (1957), expressed—though on a less than Tolstoyan scale—the personal immediacies of life during the Russian Revolution. Though of much less literary distinction than either of these two books, Margaret Mitchell's *Gone with the Wind* (1936) showed how the American Civil War could assume the distanced pathos, horror, and grandeur of any of the classic struggles of the Old World.

Needless to say, length and weighty subject matter are no guarantee in themselves of fictional greatness. Among American writers, for example, James Jones's celebration of the U.S. Army on the eve of World War II in *From Here to Eternity* (1951), though a very ambitious project, repels through indifferent writing and sentimental characterization; Norman Mailer's *Naked and the Dead* (1948), an equally ambitious military novel, succeeds much more because of a tautness, a concern with compression, and an astringent objectivity that Jones was

unable to match. Frequently the size of a novel is too great for its subject matter—as with Marguerite Young's *Miss MacIntosh, My Darling* (1965), reputedly the longest single-volume novel of the 20th century, John Barth's *Giles Goatboy* (1966), and John Fowles's *Magus* (1965). Diffuseness is the great danger in the long novel, and diffuseness can mean slack writing, emotional self-indulgence, sentimentality.

Even the long picaresque novel—which, in the hands of a Fielding or his contemporary Tobias Smollett, can rarely be accused of sentimentality—easily betrays itself into such acts of self-indulgence as the multiplication of incident for its own sake, the coy digression, the easygoing jogtrot pace that subdues the sense of urgency that should lie in all fiction. If Tostoy's *War and Peace* is a greater novel than Fielding's *Tom Jones* or Dickens' *David Copperfield*, it is not because its theme is nobler, or more pathetic, or more significant historically; it is because Tolstoy brings to his panoramic drama the compression and urgency usually regarded as the monopolies of briefer fiction.

Works in several books

Sometimes the scope of a fictional concept demands a technical approach analogous to that of the symphony in music—the creation of a work in separate books, like symphonic movements, each of which is intelligible alone but whose greater intelligibility depends on the theme and characters that unify them. The French author Romain Rolland's *Jean-Christophe* (1904–12) sequence is, very appropriately since the hero is a musical composer, a work in four movements. Among works of English literature, Lawrence Durrell's *Alexandria Quartet* (1957–60) insists in its very title that it is a tetralogy rather than a single large entity divided into four volumes; the concept is "relativist" and attempts to look at the same events and characters from four different viewpoints. Anthony Powell's *Dance to the Music of Time*, a multivolume series of novels that began in 1951 (collected 1962), may be seen as a study of a segment of British society in which the chronological approach is eschewed, and events are brought together in one volume or another because of a kind of parachronic homogeneity. C.P. Snow's *Strangers and Brothers*, a comparable series that began in 1940 and continued to appear throughout the '50s and into the '60s, shows how a fictional concept can be realized only in the act of writing, since the publication of the earlier volumes antedates the historical events portrayed in later ones. In other words, the author could not know what the subject matter of the sequence would be until he was in sight of its end. Behind all these works lies the giant example of Proust's *roman fleuve*, whose length and scope were properly coterminous with the author's own life and emergent understanding of its pattern.

Myth, symbolism, significance. The novelist's conscious day-to-day preoccupation is the setting down of incident, the delineation of personality, the regulation of exposition, climax, and denouement. The aesthetic value of his work is frequently determined by subliminal forces that seem to operate independently of the writer, investing the properties of the surface story with a deeper significance. A novel will then come close to myth, its characters turning into symbols of permanent human states or impulses, particular incarnations of general truths perhaps only realized for the first time in the act of reading. The ability to perform a quixotic act anteceded *Don Quixote*, just as *bovarysme* existed before Flaubert found a name for it.

But the desire to give a work of fiction a significance beyond that of the mere story is frequently conscious and deliberate, indeed sometimes the primary aim. When a novel—like Joyce's *Ulysses* or John Updike's *Centaur* (1963) or Anthony Burgess' *Vision of Battlements* (1965)—is based on an existing classical myth, there is an intention of either ennobling a lowly subject matter, satirizing a debased set of values by referring them to a heroic age, or merely providing a basic structure to hold down a complex and, as it were, centrifugal picture of real life. Of *Ulysses*, Joyce said that his Homeric parallel (which is worked out in great and subtle detail) was a bridge across which to march his 18 episodes; after the march the bridge could be "blown skyhigh." But there is no doubt that, through the classical parallel, the account of an ordinary summer day in Dublin is given a richness, irony, and universality unattainable by any other means.

The mythic or symbolic intention of a novel may manifest itself less in structure than in details which, though they appear naturalistic, are really something more. The shattering of the eponymous golden bowl in Henry James's 1904 novel makes palpable, and hence truly symbolic, the collapse of a relationship. Even the choice of a character's name may be symbolic. Sammy Mountjoy, in William Golding's *Free Fall* (1959), has fallen from the grace of heaven, the mount of joy, by an act of volition that the title makes clear. The eponym of *Doctor Zhivago* is so called because his name, meaning "the living," carries powerful religious overtones. In the Russian version of the Gospel According to St. Luke, the angels ask the women who come to Christ's tomb: "Chto vy ischyote zhivago mezhdu myortvykh?"—"Why do you seek the living among the dead?" And his first name, Yuri, the Russian equivalent of George, has dragon-slaying connotations.

The symbolism of names

The symbol, the special significance at a subnarrative level, works best when it can fit without obtrusion into a context of naturalism. The optician's trade sign of a huge pair of spectacles in F. Scott Fitzgerald's *Great Gatsby* (1925) is acceptable as a piece of scenic detail, but an extra dimension is added to the tragedy of Gatsby, which is the tragedy of a whole epoch in American life, when it is taken also as a symbol of divine myopia. Similarly, a cinema poster in Malcolm Lowry's *Under the Volcano* (1947), advertising a horror film, can be read as naturalistic background, but it is evident that the author expects the illustrated fiend—a concert pianist whose grafted hands are those of a murderer—to be seen also as a symbol of Nazi infamy; the novel is set at the beginning of World War II, and the last desperate day of the hero, Geoffrey Firmin, stands also for the collapse of Western civilization.

There are symbolic novels whose infranarrative meaning cannot easily be stated, since it appears to subsist on an unconscious level. Herman Melville's *Moby Dick* (1851) is such a work, as is D.H. Lawrence's novella *St. Mawr* (1925), in which the significance of the horse is powerful and mysterious.

USES OF THE NOVEL

As an expression of an interpretation of life. Novels are not expected to be didactic, like tracts or morality plays; nevertheless, in varying degrees of implicitness, even the "purest" works of fictional art convey a philosophy of life. The novels of Jane Austen, designed primarily as superior entertainment, imply a desirable ordered existence, in which the comfortable decorum of an English rural family is disturbed only by a not too serious shortage of money, by love affairs that go temporarily wrong, and by the intrusion of self-centred stupidity. The good, if unrewarded for their goodness, suffer from no permanent injustice. Life is seen, not only in Jane Austen's novels but in the whole current of bourgeois Anglo-American fiction, as fundamentally reasonable and decent. When wrong is committed, it is usually punished, thus fulfilling Miss Prism's summation in Oscar Wilde's play *The Importance of Being Earnest* (1895), to the effect that in a novel the good characters end up happily and the bad characters unhappily: "that is why it is called fiction".

That kind of fiction called realistic, which has its origins in 19th-century France, chose the other side of the coin, showing that there was no justice in life and that the evil and the stupid must prevail. In the novels of Thomas Hardy there is a pessimism that may be taken as a corrective of bourgeois Panglossianism—the philosophy that everything happens for the best, satirized in Voltaire's *Candide* (1759)—since the universe is presented as almost impossibly malevolent. This tradition is regarded as morbid, and it has been deliberately ignored by most popular novelists. The "Catholic" novelists such as François Mauriac in France, Graham Greene in England, and

others—see life as mysterious, full of wrong and evil and injustice inexplicable by human canons but necessarily acceptable in terms of the plans of an inscrutable God. Between the period of realistic pessimism, which had much to do with the agnosticism and determinism of 19th-century science, and the introduction of theological evil into the novel, writers such as H.G. Wells attempted to create a fiction based on optimistic liberalism. As a reaction, there was the depiction of "natural man" in the novels of D.H. Lawrence and Ernest Hemingway.

For the most part, the view of life common to American and European fiction since World War II posits the existence of evil—whether theological or of that brand discovered by the French Existentialists, particularly Jean-Paul Sartre—and assumes that man is imperfect and life possibly absurd. The fiction of the Communist states is based on a very different assumption, one that seems naïve and old-fashioned in its collective optimism to readers in the disillusioned democracies. It is to be noted that in the Soviet Union aesthetic evaluation of fiction has been replaced by ideological judgment. The works of the popular British writer A.J. Cronin, since they seem to depict personal tragedy as an emanation of capitalistic infamy, are rated higher than those of Conrad, James, and their peers. The novel as an art form stands or falls by its capacity to express a view of life acceptable to the Soviet authorities.

The Communist interpretation

As entertainment or escape. In a period that takes for granted that the written word should be "committed"—to the exposure of social wrong or the propagation of progressive ideologies—novelists who seek merely to take the reader out of his dull or oppressive daily life are not highly regarded, except by that reading public that has never expected a book to be anything more than a diversion. Nevertheless, the provision of laughter and dreams has been for many centuries a legitimate literary occupation. It can be condemned by serious devotees of literature only if it falsifies life through oversimplification and tends to corrupt its readers into belief that reality is as the author presents it. The novelettes once beloved of mill girls and domestic servants, in which the beggar maid was elevated to queendom by a king of high finance, were a mere narcotic, a sort of enervating opium of the oppressed; the encouragement of such subliterature might well be one of the devices of social oppression. Adventure stories and spy novels may have a healthy enough astringency, and the very preposterousness of some adventures can be a safeguard against any impressionable young reader's neglecting the claims of real life to dream of becoming a secret agent. The subject matter of some humorous novels—such as the effete British aristocracy created by P.G. Wodehouse, which is no longer in existence if it ever was—can never be identified with a real human society; the dream is accepted as a dream. The same may be said of Evelyn Waugh's early novels—such as *Decline and Fall* (1928) and *Vile Bodies* (1930)—but these are raised above mere entertainment by touching, almost incidentally, on real human issues (the relation of the innocent to a circumambient malevolence is a persistent theme in all Waugh's writing).

Any reader of fiction has a right to an occasional escape from the dullness or misery of his existence, but he has the critical duty of finding the best modes of escape—in the most efficiently engineered detective or adventure stories, in humor that is more than sentimental buffoonery, in dreams of love that are not mere pornography. The fiction of entertainment and escape frequently sets itself higher literary standards than novels with a profound social or philosophical purpose. Books like James Buchan's *Thirty-nine Steps* (1915), Graham Greene's *Travels with My Aunt* (1969), Dashiell Hammett's *Maltese Falcon* (1930), and Raymond Chandler's *Big Sleep* (1939) are distinguished pieces of writing that, while diverting and enthralling, keep a hold on the realities of human character. Ultimately, all good fiction is entertainment, and if it instructs or enlightens it does so best through enchanting the reader.

As propaganda. The desire to make the reader initiate certain acts—social, religious, or political—is the essence of all propaganda, and, though it does not always accord well with art, the propagandist purpose has often found its way into novels whose prime value is an aesthetic one. The *Nicholas Nickleby* (1839) of Charles Dickens attacked the abuses of schools to some purpose, as his *Oliver Twist* (1838) drew attention to the horrors of poorhouses and his *Bleak House* (1853) to the abuses of the law of chancery. The weakness of propaganda in fiction is that it loses its value when the wrongs it exposes are righted, so that the more successful a propagandist novel is, the briefer the life it can be expected to enjoy. The genius of Dickens lay in his ability to transcend merely topical issues through the vitality with which he presented them, so that his contemporary disclosures take on a timeless human validity—chiefly through the power of their drama, character, and rhetoric.

The ephemeral quality of propaganda

The purely propagandist novel—which Dickens was incapable of writing—quickly becomes dated. The "social" novels of H.G. Wells, which propounded a rational mode of life and even blueprinted utopias, were very quickly exploded by the conviction of man's irredeemable irrationality that World War I initiated and World War II corroborated, a conviction the author himself came to share toward the end of his life. But the early scientific romances of Wells remain vital and are seen to have been prophetic. Most of the fiction of the Soviet Union, which either glorifies the regime or refrains from criticizing it, is dull and unreal, and the same may be said of Communist fiction elsewhere. Propaganda too frequently ignores man as a totality, concentrating on him aspectively—in terms of politics or sectarian religion. When a didactic attack on a system, as in Harriet Beecher Stowe's attack on slavery in the United States in *Uncle Tom's Cabin* (1852), seems to go beyond mere propaganda, it is because the writer makes the reader aware of wrongs and injustices that are woven into the permanent human fabric. The reader's response may be a modification of his own sensibility, not an immediate desire for action, and this is one of the legitimate effects of serious fiction. The propagandist Dickens calls for the immediate righting of wrongs, but the novelist Dickens says, mainly through implication, that all men—not just schoolmasters and state hirelings—should become more humane. If it is possible to speak of art as possessing a teaching purpose, this is perhaps its only lesson.

As reportage. The division in the novelist's mind is between his view of his art as a contrivance, like a Fabergé watch, and his view of it as a record of real life. The versatile English writer Daniel Defoe, on the evidence of such novels as his *Journal of the Plague Year* (1722), a re-creation of the London plague of 1665, believed that art or contrivance had the lesser claim and proceeded to present his account of events of which he had had no direct experience in the form of plain journalistic reportage. This book, like his *Robinson Crusoe* (1719) and *Moll Flanders* (1722), is more contrived and cunning than appears, and the hurried, unshaped narrative is the product of careful preparation and selective ordering. His example, which could have been a very fruitful one, was not much followed until the 20th century, when the events of the real world became more terrifying and marvellous than anything the novelist could invent, and seemed to ask for that full imaginative treatment that only the novelist's craft can give.

In contemporary American literature, John Hersey's *Hiroshima* (1946), though it recorded the actual results of the nuclear attack on the Japanese city in 1945, did so in terms of human immediacies, not scientific or demographic abstractions, and this approach is essentially novelistic. Truman Capote's *In Cold Blood* (1965) took the facts of a multiple murder in the Midwest of the United States and presented them with the force, reality, tone, and (occasionally) overintense writing that distinguish his genuine fiction. Norman Mailer, in *The Armies of the Night* (1968), recorded, in great personal detail but in a third-person narration, his part in a citizens' protest march on Washington, D.C. It would seem that Mailer's talent lies in his ability to merge the art of fiction and the craft of reportage, and his *Of a Fire on the Moon* (1970),

which deals with the American lunar project, reads like an episode in an emergent *roman fleuve* of which Mailer is the central character in a story made up of true public events.

The presentation of factual material as art is the purpose of such thinly disguised biographies as Somerset Maugham's *Moon and Sixpence* (1919), undisguised biographies fleshed out with supposition and imagination like Helen Waddell's *Peter Abelard* (1933), and a great number of autobiographies served up—out of fear of libel or of dullness—as novels. Conversely, invented material may take on the lineaments of journalistic actuality through the employment of a Defoe technique of flat understatement. This is the way of such science fiction as Michael Crichton's *Andromeda Strain* (1969), which uses sketch maps, computer projections, and simulated typewritten reports.

As an agent of change in the language and thought of a culture. Novelists, being neither poets nor philosophers, rarely originate modes of thinking and expression. Poets such as Chaucer and Shakespeare have had much to do with the making of the English language, and Byron was responsible for the articulation of the new romantic sensibility in it in the early 19th century. Books like the Bible, Karl Marx's *Kapital*, and Adolf Hitler's *Mein Kampf* may underlie permanent or transient cultures, but it is hard to find, except in the early Romantic period, a novelist capable of arousing new attitudes to life (as opposed to aspects of the social order) and forging the vocabulary of such attitudes.

Sentiment

With the 18th-century precursors of Romanticism—notably Richardson, Sterne, and Rousseau—the notion of sentiment entered the European consciousness. Rousseau's *Nouvelle Héloïse* (1761) fired a new attitude toward love—more highly emotional than ever before—as his *Émile* (1762) changed educated views on how to bring up children. The romantic wave in Germany, with Goethe's *Sorrows of Werther* (1774) and the works of Jean-Paul Richter a generation later, similarly aroused modes of feeling that rejected the rational constraints of the 18th century. Nor can the influence of Sir Walter Scott's novels be neglected, both on Europe and on the American South (where Mark Twain thought it had had a deplorable effect). With Scott came new forms of regional sentiment, based on a romantic reading of history.

It is rarely, however, that a novelist makes a profound mark on a national language, as opposed to a regional dialect (to which, by using it for a literary end, he may impart a fresh dignity). It is conceivable that Alessandro Manzoni's *I promessi sposi* (1825–27; *The Betrothed*), often called the greatest modern Italian novel, gave 19th-century Italian intellectuals some notion of a viable modern prose style in an Italian that might be termed "national," but even this is a large claim. Günter Grass, in post-Hitler Germany, sought to revivify a language that had been corrupted by the Nazis; he threw whole dictionaries at his readers, in the hope that new freedom, fantasy, and exactness in the use of words might influence the publicists, politicians, and teachers in the direction of a new liberalism of thought and expression.

It is difficult to say whether the French Existentialists, such as Sartre and Albert Camus, have influenced their age primarily through their fiction or their philosophical writings. Certainly, Sartre's early novel *Nausea* (1938) established unforgettable images of the key terms of his philosophy, which has haunted a whole generation, as Camus's novel *The Stranger* (1942) created for all time the lineaments of "Existential man." In the same way, the English writer George Orwell's *Nineteen Eighty-four* (1949) incarnated brilliantly the nature of the political choices that are open to 20th-century humanity, and, with terms like "Big Brother" (*i.e.*, the leader of an authoritarian state) and "doublethink" (belief in contradictory ideas simultaneously), modified the political vocabulary. But no novelist's influence can compare to that of the poet's, who can give a language a soul and define, as Shakespeare and Dante did, the scope of a culture.

As an expression of the spirit of its age. The novelist, like the poet, can make the inchoate thoughts and feelings of a society come to articulation through the exact and imaginative use of language and symbol. In this sense, his work seems to precede the diffusion of new ideas and attitudes and to be the agent of change. But it is hard to draw a line between this function and that of expressing an existing climate of sensibility. Usually the nature of a historical period—that spirit known in German as the *Zeitgeist*—can be understood only in long retrospect, and it is then that the novelist can provide its best summation. The sickness of the Germany that produced Hitler had to wait some time for fictional diagnosis in such works as Thomas Mann's *Doctor Faustus* (1947) and, later, Günter Grass's *Tin Drum* (1959). Evelyn Waugh waited several years before beginning, in the trilogy *Sword of Honour*, to depict that moral decline of English society that started to manifest itself in World War II, the conduct of which was both a cause and a symptom of the decay of traditional notions of honour and justice.

The lag between events and their use in novels

The novel can certainly be used as a tool for the better understanding of a departed age. The period following World War I had been caught forever in Hemingway's *Sun Also Rises* (1926; called *Fiesta* in England), F. Scott Fitzgerald's novels and short stories about the so-called Jazz Age, the *Antic Hay* (1923) and *Point Counter Point* (1928) of Aldous Huxley, and D.H. Lawrence's *Aaron's Rod* (1922) and *Kangaroo* (1923). The spirit of the English 18th century, during which social, political, and religious ideas associated with rising middle classes conflicted with the old Anglican Tory rigidities, is better understood through reading Smollett and Fielding than by taking the cerebral elegance of Pope and his followers as the typical expression of the period.

Similarly, the unrest and bewilderment of the young in the period after World War II still speak in novels like J.D. Salinger's *Catcher in the Rye* (1951) and Kingsley Amis' *Lucky Jim* (1954). It is notable that with novels like these—and the beat-generation books of Jack Kerouac; the American-Jewish novels of Saul Bellow, Bernard Malamud, and Philip Roth; and the Negro novels of Ralph Ellison and James Baldwin—it is a segmented spirit that is expressed, the spirit of an age group, social group, or racial group, and not the spirit of an entire society in a particular phase of history. But probably a *Zeitgeist* has always been the emanation of a minority, the majority being generally silent. The 20th century seems, from this point of view, to be richer in vocal minorities than any other period in history.

As a creator of life styles and an arbiter of taste. Novels have been known to influence, though perhaps not very greatly, modes of social behaviour and even, among the very impressionable, conceptions of personal identity. But more young men have seen themselves as Hamlet or Childe Harold than as Julien Sorel, the protagonist of Stendhal's novel *The Red and the Black* (1830), or the sorrowing Werther. Richardson's novel may popularize Pamela, or Galsworthy's *Forsyte Saga* (1906–22) Jon, as a baptismal name, but it rarely makes a deeper impression on the mode of life of literate families. On the other hand, the capacity of Oscar Wilde's *Picture of Dorian Gray* (1891) to influence young men in the direction of sybaritic amorality, or of D.H. Lawrence's *Lady Chatterley's Lover* (1928) to engender a freer attitude to sex, has never been assessed adequately. With the lower middle class reading public, the effect of devouring *The Forsyte Saga* was to engender genteelisms —cucumber sandwiches for tea, supper renamed dinner —rather than to learn that book's sombre lesson about the decline of the old class structure. Similarly, the ladies who read Scott in the early 19th century were led to barbarous ornaments and tastefully arranged folk songs.

Fiction has to be translated into one of the dramatic media—stage, film, or television—before it can begin to exert a large influence. *Tom Jones* as a film in 1963 modified table manners and coiffures and gave American visitors to Great Britain a new (and probably false) set of expectations. The stoic heroes of Hemingway, given to drink, fights, boats, and monosyllables, became influential only when they were transferred to the screen. They engendered other, lesser heroes—incorruptible pri-

Fiction in other media

vate detectives, partisans brave under interrogation—who in their turn have influenced the impressionable young when seeking an identity. Ian Fleming's James Bond led to a small revolution in martini ordering. But all these influences are a matter of minor poses, and such poses are most readily available in fiction easily adapted to the mass media—which means lesser fiction. Proust, though he recorded French patrician society with painful fidelity, had little influence on it, and it is hard to think of Henry James disturbing the universe even fractionally. Films and television programs dictate taste and behaviour more than the novel ever could.

STYLE

Romanticism. The Romantic movement in European literature is usually associated with those social and philosophical trends that prepared the way for the French Revolution, which began in 1789. The somewhat subjective, anti-rational, emotional currents of romanticism transformed intellectual life in the revolutionary and Napoleonic periods and remained potent for a great part of the 19th century. In the novel, the romantic approach to life was prepared in the "sentimental" works of Richardson and Sterne and attained its first major fulfillment in the novels of Rousseau. Sir Walter Scott, in his historical novels, turned the past into a great stage for the enactment of events motivated by idealism, chivalry, and strong emotional impulse, using an artificially archaic language full of remote and magical charm. The exceptional soul—poet, patriot, idealist, madman—took the place of dully reasonable fictional heroes, such as Tom Jones, and sumptuous and mysterious settings ousted the plain town and countryside of 18th-century novels.

The romantic novel must be seen primarily as a historical phenomenon, but the romantic style and spirit, once they had been brought into being, remained powerful and attractive enough to sustain a whole subspecies of fiction. The cheapest love story can be traced back to the example of Charlotte Brontë's *Jane Eyre* (1847), or even Rousseau's earlier *Nouvelle Héloïse*. Similarly, best-selling historical novels, even those devoid of literary merit, can find their progenitor in Scott, and science fiction in Mary Shelleys' *Frankenstein* (1818), a romantic novel subtitled *The Modern Prometheus,* as well as in Jules Verne and H.G. Wells. The aim of romantic fiction is less to present a true picture of life than to arouse the emotions through a depiction of strong passions, or to fire the imagination with exotic, terrifying, or wonderful scenes and events. When it is condemned by critics, it is because it seems to falsify both life and language; the pseudo-poetical enters the dialogue and *récit* alike, and humanity is seen in only one of its aspects—that of feeling untempered with reason.

If such early romantic works as those of Scott and of the Goethe of *The Sorrows of Werther* have long lost their original impact, the romantic spirit still registers power and truth in the works of the Brontës—particularly in Emily Brontë's *Wuthering Heights,* in which the poetry is genuine and the strange instinctual world totally convincing. Twentieth-century romantic fiction records few masterpieces. Writers like Daphne du Maurier, the author of *Jamaica Inn* (1936), *Rebecca* (1938), and many others, are dismissed as mere purveyors of easy dreams. It is no more possible in the 20th century to revive the original romantic élan in literature than it is to compose music in the style of Beethoven. Despite the attempts of Lawrence Durrell to achieve a kind of decadent romantic spirit in his *Alexandria Quartet,* the strong erotic feeling, the exotic setting, the atmosphere of poetic hallucination, the pain, perversion, and elemental force seem to be contrivances, however well they fulfill the original romantic prescription.

Decline of the romantic novel

Realism. Certain major novelists of the 19th century, particularly in France, reacted against romanticism by eliminating from their work those "softer" qualities—tenderness, idealism, chivalric passion, and the like—which seemed to them to hide the stark realities of life in a dreamlike haze. In Gustave Flaubert's works there are such romantic properties—his novel *Salammbô* (1862), for instance, is a sumptuous representation of a remote pagan past—but they are there only to be punctured with realistic irony. On one level, his *Madame Bovary* may be taken as a kind of parable of the punishment that fate metes out to the romantic dreamer, and it is the more telling because Flaubert recognized a strong romantic vein in himself: "Madame Bovary, c'est moi" ("Madame Bovary is myself"). Stendhal and Balzac, on the other hand, admit no dreams and present life in a grim nakedness without poetic drapery.

Balzac's mammoth fictional work—the 20-year succession of novels and stories he published under the collective title *The Human Comedy*—and Stendhal's novels of the same period, *The Red and the Black* (1830) and *The Charterhouse of Parma* (1839), spare the reader nothing of those baser instincts in man and society that militate against, and eventually conquer, many human aspirations. Rejecting romanticism so energetically, however, they swing to an extreme that makes "realism" a synonym for unrelenting pessimism. Little comes right for the just or the weak, and base human nature is unqualified by even a modicum of good. But there is a kind of affirmative richness and energy about both writers that seems to belie their pessimistic thesis.

The pessimistic view

In England, George Eliot in her novel *Middlemarch* (1871–72) viewed human life grimly, with close attention to the squalor and penury of rural life. If "nature" in works by romantic poets like Wordsworth connoted a kind of divine benevolence, only the "red in tooth and claw" aspect was permitted to be seen in the novels of the realists. George Eliot does not accept any notion of Divine Providence, whether Christian or pantheistic, but her work is instinct with a powerful moral concern: her characters never sink into a deterministic morass of hopelessness, since they have free will, or the illusion of it. With Thomas Hardy, who may be termed the last of the great 19th-century novelists, the determinism is all-pervasive, and his final novel, *Jude the Obscure* (1896), represents the limit of pessimism. Behind him one is aware of the new science, initiated by the biologists Charles Darwin and T.H. Huxley, which displaces man as a free being, capable of choice, by a view of him as the product of blind mechanistic forces over which he has little control.

Realism in this sense has been a continuing impulse in the 20th-century novel, but few writers would go so far as Hardy in positing man's near-total impotence in a hostile universe, with the gods killing human creatures for their sport. Realism in the Existentialist fiction of 20th-century France, for instance, makes man not merely wretched but absurd, yet it does not diminish his power of self-realization through choice and action. Realism has frequently been put in the service of a reforming design, which implies a qualified optimism. War novels, novels about the sufferings of the oppressed (in prison, ghetto, totalitarian state), studies of human degradation that are bitter cries against man-made systems—in all of these the realistic approach is unavoidable, and realistic detail goes much further than anything in the first realists. But there is a difference in the quality of the anger the reader feels when reading the end of Hardy's *Tess of the D'Urbervilles* (1891) and that generated by Upton Sinclair's *Jungle* (1906) or Erich Maria Remarque's *All Quiet on the Western Front* (1929). In Hardy's novel, pessimistic determinism, reducing human character to pain, frustration, and impotent anger, was—paradoxically—appropriate to an age that knew no major cataclysms or oppressions. The novels of Sinclair and Remarque reflect the 20th century, which saw the origin of all wrong in the human will, and set on a program of diagnosis and reform.

Realism as reform

Naturalism. The naturalistic novel is a development out of realism, and it is, again, in France that its first practitioners are to be found, with Émile Zola leading. It is difficult to separate the two categories, but naturalism seems characterized not only by a pessimistic determinism but also by a more thoroughgoing attention to the physical and biological aspects of human existence. Man is less a soul aspiring upward to its divine source than a

product of natural forces, as well as genetic and social influences, and the novelist's task is to present the physical essence of man and his environment. The taste of Balzac's and Stendhal's audiences was not easily able to accommodate itself to utter frankness about the basic processes of life, and the naturalists had to struggle against prejudice, and often censorship, before their literary candour was able to prevail. The 20th century takes the naturalistic approach for granted, but it is more concerned with a technique of presentation than with the somewhat mechanistic philosophy of Zola and his followers.

Naturalism received an impetus after World War I, when novelists felt they had a duty to depict the filth, suffering, and degradation of the soldier's life, without euphemism or circumlocution. Joyce's *Ulysses*, when it appeared in 1922, was the first novel to seek to justify total physical candour in terms of its artistic, as opposed to moral, aim—which was to depict with almost scientific objectivity every aspect of an ordinary urban day. Though Joyce had read Zola, he seems to invoke the spirit of a very much earlier naturalistic writer—the ribald French author of the 16th century, François Rabelais—and this is in keeping with the Catholic tradition that Joyce represents. Zola, of course, was an atheist.

It would have been a sin against his aesthetic canons for Joyce to have shown Leopold Bloom—the protagonist of *Ulysses*—eating breakfast or taking a bath and yet not defecating or masturbating. The technique of the interior monologue, which presented the unedited flow of a character's unspoken thought and emotion, also called for the utmost frankness in dealing with natural functions and urges. Joyce, it is now recognized, had no prurient or scatological intention; his concern was with showing life as it is (without any of the didactic purpose of Zola), and this entailed the presentation of lust, perversion, and blasphemy as much as any of the traditionally acceptable human functions.

The naturalistic novelists have had their social and legal problems—obscenity indictments, confiscation, emasculation by timid publishers—but the cause was ultimately won, at least in Great Britain and the United States, where there are few limits placed on the contemporary novelist's proclaimed right to be true to nature. In comparison with much contemporary fiction the pioneer work of Zola seems positively reticent.

Impressionism. The desire to present life with frank objectivity led certain early-20th-century novelists to question the validity of long-accepted narrative conventions. If truth was the novelist's aim, then the tradition of the omniscient narrator would have to go, to be replaced by one in which a fallible, partially ignorant character—one involved in the story and hence himself subject to the objective or naturalistic approach—recounted what he saw and heard. But the Impressionist painters of late-19th-century France had proclaimed a revision of the whole seeing process: they distinguished between what the observer assumed he was observing and what he actually observed. That cerebral editing which turned visual data into objects of geometric solidity had no place in Impressionist painting; the visible world became less definite, more fluid, resolving into light and colour.

The influence of the painters

The German novelists Thomas Mann and Hermann Hesse, moving from the realist tradition, which concentrated on closely notated detail in the exterior world, sought the lightness and clarity of a more elliptical style, and were proclaimed Impressionists. But in England Ford Madox Ford went much further in breaking down the imagined rigidities of the space–time continuum, liquidating step-by-step temporal progression and making the visual world shimmer, dissolve, reconstitute itself. In Ford's tetralogy *Parade's End* (1924–28), the reader moves freely within the time continuum, as if it were spatial, and the total picture is perceived through an accumulation of fragmentary impressions. Ford's masterpiece, *The Good Soldier* (1915), pushes the technique to its limit: the narrator tells his story with no special dispensation to see or understand more than a fallible being can, and, in his reminiscences, he fragments whole sequences of events as he ranges freely through time (such freedom had traditionally been regarded as a weakness, a symptom of the disease of inattention).

In the approach to dialogue manifested in a book that Ford wrote jointly with Conrad—*The Inheritors* (1901)—a particular aspect of literary impressionism may be seen whose suggestiveness has been ignored by other modern novelists. As the brain imposes its own logical patterns on the phenomena of the visual world, so it is given to editing into clarity and conciseness the halting utterances of real-life speech; the characters of most novels are impossibly articulate. Ford and Conrad attempted to present speech as it is actually spoken, with many of the meaningful solidities implied rather than stated. The result is sometimes exasperating, but only as real-life conversation frequently is.

The interior monologue, which similarly resists editing, may be regarded as a development of this technique. To show pre-articulatory thought, feeling, and sensuous perception unordered into a rational or "literary" sequence is an impressionistic device that, beginning in Edouard Dujardin's minor novel *Les Lauriers sont coupés* (1887; *We'll to the Woods No More*), served fiction of high importance, from Dorothy Richardson, Joyce, and Virginia Woolf to William Faulkner and Samuel Beckett.

Novelists like Ronald Firbank and Evelyn Waugh (who studied painting and was a competent draftsman) learned, in a more general sense, how to follow the examples of the Impressionist and Postimpressionist painters in their fiction. A spare brilliance of observation, like those paintings in which a whole scene is suggested through carefully selected points of colour, replaced that careful delineation of a whole face, or inventorying of a whole room, that had been the way of Balzac and other realists. In four or five brief lines of dialogue Waugh can convey as much as the 19th-century novelists did in as many pages.

Expressionism. Expressionism was a German movement that found its most congenial media in painting and drama. The artist's aim was to express, or convey the essence of, a particular theme, to the exclusion of such secondary considerations as fidelity to real life. The typical Expressionist play, by Bertolt Brecht, for example, concerns itself with a social or political idea that is hurled at the audience through every possible stage device—symbols, music, cinematic insertions, choral speech, dance. Human character is less important than the idea of humanity, and probability of action in the old realist sense is the least of the dramatist's concerns. The emotional atmosphere is high-pitched, even ecstatic, and the tone is more appropriate to propaganda than to art. Expressionistic technique, as the plays of Brecht prove, was an admirable means of conveying a Communist program, and it was in the service of such a program that John Dos Passos, in the trilogy of novels *U.S.A.* (1937), used literary devices analogous to the dramatic ones of Brecht—headlines, tabloid biographies, popular songs, lyric soliloquies, and the like.

Expressionism as alienation

But the Austrian Franz Kafka, the greatest of the Expressionist novelists, sought to convey what may crudely be termed man's alienation from his world in terms that admit of no political interpretation. Joseph K., the hero of Kafka's novel *The Trial* (1925), is accused of a nameless crime, he seeks to arm himself with the apparatus of a defense, and he is finally executed—stabbed with the utmost courtesy by two men in a lonely place. The hallucinatory atmosphere of that novel, as also of his novel *The Castle* (1926), is appropriate to nightmare, and indeed Kafka's work has been taken by many as an imaginative forecast of the nightmare through which Europe was compelled to live during the Hitler regime. But its significance is more subtle and universal; one of the elements is original sin and another filial guilt. In the story *The Metamorphosis* (1915) a young man changes into an enormous insect, and the nightmare of alienation can go no further.

Kafka's influence has been considerable. Perhaps his most distinguished follower is the English writer Rex Warner, whose *Wild Goose Chase* (1937) and *Aero-*

drome (1941) use fantasy, symbol, and improbable action for an end that is both Marxist and Freudian; the filial guilt, however, seems to be taken directly from Kafka, with an innocent hero caught in a monstrously oppressive web that is both the totalitarian state and paternal tyranny. More recently, the American expatriate writer William Burroughs has developed his own expressionistic techniques in *The Naked Lunch* (1959), which is concerned with the alienation from society of the drug addict. His later novels *Nova Express* (1964) and *The Ticket That Exploded* (1962) use obscene fantasy to present a kind of metaphysical struggle between free spirit and enslaved flesh, evidently an extrapolation of the earlier drug theme. Burroughs is a didactic novelist, and didacticism functions best in a fictional ambience that rejects the complexities of character and real-life action.

Avant-gardism. Many innovations in fiction can be classified under headings already considered. Even so revolutionary a work as Joyce's *Finnegans Wake* represents an attempt to show the true nature of a dream; this can be regarded as a kind of Impressionism pushed so far that it looks like Surrealism. The brief novels of Samuel Beckett (which, as they aim to demonstrate the inadequacy of language to express the human condition, become progressively more brief) seem to have a kind of Expressionist derivation, since everything in them is subordinated to a central image of man as a totally deprived creature, resentful of a God he does not believe in. The French anti-novel, dethroning man as a primary concern of fiction, perhaps represents the only true break with traditional technique that the 20th-century novel has seen.

Technical innovation

Dissatisfaction not only with the content of the traditional novel but with the manner in which readers have been schooled to approach it has led the contemporary French novelist Michel Butor, in *Mobile*, to present his material in the form of a small encyclopaedia, so that the reader finds his directions obliquely, through an alphabetic taxonomy and not through the logic of sequential events. Nabokov, in *Pale Fire* (1962), gives the reader a poem of 999 lines and critical apparatus assembled by a madman; again the old sense of direction (beginning at the beginning and going on to the end) has been liquidated, yet *Pale Fire* is a true and highly intelligible novel. In England, B.S. Johnson published similar "false-directional" novels, though the influence of Sterne makes them seem accessible, even cozily traditional. One of Johnson's books is marketed as a bundle of disjunct chapters—which may thus be dealt aleatorially and read in any order—packed in a box, not a binding.

Available avant-garde techniques are innumerable, though not all of them are salable. There is the device of counterpointing a main narrative with a story in footnotes, which eventually rises like water and floods the other. A novel has been written, though not published, in which the words are set (rather like the mouse's tail or tale in *Alice in Wonderland*) to represent graphically the physical objects in the narrative. Burroughs has experimented with a tricolumnar technique, in which three parallel narratives demand the reader's attention. But the writers like Borges and Nabokov go beyond mere technical innovation: they ask for a reconsideration of the very essence of fiction. In one of his *ficciones*, Borges strips from the reader even the final illusion that he is reading a story, for the story is made to dissolve, the artist evidently losing faith in his own artifact. Novels, as both Borges and Nabokov show, can turn into poems or philosophical essays, but they cannot, while remaining literature, turn into compositions disclaiming all interest in the world of feeling, thought, and sense. The novelist can do anything he pleases with his art so long as he interprets, or even just presents, a world that the reader recognizes as existing, or capable of existing, or capable of being dreamed of as existing.

TYPES OF NOVEL

Historical. For the hack novelist, to whom speedy output is more important than art, thought, and originality, history provides ready-made plots and characters. A novel on Alexander the Great or Joan of Arc can be a flimsy and superficial as any schoolgirl romance. But historical themes, to which may be added prehistoric or mythical ones, have inspired the greatest novelists, as Tolstoy's *War and Peace* and Stendhal's *Charterhouse of Parma* reveal. In the 20th century, distinguished historical novels such as Arthur Koestler's *The Gladiators* (1939), Robert Graves's *I, Claudius* (1934), Zoé Oldenbourg's *Destiny of Fire* (1960), and Mary Renault's *The King Must Die* (1958) exemplify an important function of the fictional imagination—to interpret remote events in human and particular terms, to transform documentary fact, with the assistance of imaginative conjecture, into immediate sensuous and emotional experience.

There is a kind of historical novel, little more than a charade, which frequently has a popular appeal because of a common belief that the past is richer, bloodier, and more erotic than the present. Such novels, which include such immensely popular works as those of Georgette Heyer, or Baroness Orczy's Scarlet Pimpernel stories in England in the early 20th century, and *Forever Amber* (1944) by Kathleen Winsor in the United States, may use the trappings of history but, because there is no real assimilation of the past into the imagination, the result must be a mere costume ball. On the other hand, the American novelist John Barth showed in *The Sot-Weed Factor* (1960) that mock historical scholarship—preposterous events served up with parodic pomposity—could constitute a viable, and not necessarily farcical, approach to the past. Barth's history is cheerfully suspect, but his sense of historical perspective is genuine.

It is in the technical conservatism of most European historical novels that the serious student of fiction finds cause to relegate the category to a secondary place. Few practitioners of the form seem prepared to learn from any writer later than Scott, though Virginia Woolf—in *Orlando* (1928) and *Between the Acts* (1941)—made bold attempts to squeeze vast tracts of historical time into a small space and thus make them as fictionally manageable as the events of a single day. And John Dos Passos' *U.S.A.*, which can be taken as a historical study of a phase in America's development, is a reminder that experiment is not incompatible with the sweep and amplitude that great historical themes can bring to the novel.

Picaresque. In Spain, the novel about the rogue or *pícaro* was a recognized form, and such English novels as Defoe's *Jonathan Wild* (1725) and *The Fortunate Mistress* (1724) can be regarded as picaresque in the etymological sense. But the term has come to connote as much the episodic nature of the original species as the dynamic of roguery. Fielding's *Tom Jones*, whose hero is a bastard, amoral, and very nearly gallows-meat, has been called picaresque, and the *Pickwick Papers* of Dickens—whose eponym is a respectable and even childishly ingenuous scholar—can be accommodated in the category. The requirements for a picaresque novel are apparently length, loosely linked episodes almost complete in themselves, intrigue, fights, amorous adventure, and such optional items as stories within the main narrative, songs, poems, or moral homilies. Perhaps inevitably, with such a structure or lack of it, the driving force must come from a wild or roguish rejection of the settled bourgeois life, a desire for the open road, with adventures in inn bedrooms and meetings with questionable wanderers. In the modern period, Saul Bellow's *Adventures of Augie March* (1953) and Jack Kerouac's *Dharma Bums* (1959) have something of the right episodic, wandering, free, questing character. But in an age that lacks the unquestioning acceptance of traditional morality against which the old picaresque heroes played out their villainous lives, it is not easy to revive the *novela picaresca* as the anonymous author of *Lazarillo de Tormes* (1554) conceived it, or as such lesser Spanish writers of the beginning of the 17th century as Mateo Alemán, Vicente Espinel, and Luis Vélez de Guevara developed it. The modern criminal wars with the police rather than with society, and his career is one of closed and narrow techniques, not compatible with the gay abandon of the true *pícaro*.

Sentimental. The term sentimental, in its mid-18th-century usage, signified refined or elevated feeling, and it

is in this sense that it must be understood in Laurence Sterne's *Sentimental Journey* (1768). Richardson's *Pamela* (1740) and Rousseau's *Nouvelle Héloïse* (1761) are sentimental in that they exhibit a passionate attachment between the sexes that rises above the merely physical. The vogue of the sentimental love novel was one of the features of the Romantic movement, and the form maintained a certain moving dignity despite a tendency to excessive emotional posturing. The germs of mawkishness are clearly present in Sterne's *Tristram Shandy* (1760–67), though offset by a diluted Rabelaisianism and a certain cerebral quality. The debasement by which the term sentimental came to denote a self-indulgence in superficial emotions occurred in the Victorian era, under the influence of sanctimony, religiosity, and a large commercial demand for bourgeois fiction. Sentimental novels of the 19th and 20th centuries are characterized by an invertebrate emotionalism and a deliberately lachrymal appeal. Neither Dickens nor Thackeray was immune to the temptations of sentimentality—as is instanced by their treatment of deathbed scenes. The reported death of Tiny Tim in *A Christmas Carol* (1843) is an example of Dickens' ability to provoke two tearful responses from the one situation—one of sorrow at a young death, the other of relief at the discovery that the death never occurred. Despite such patches of emotional excess, Dickens cannot really be termed a sentimental novelist. Such a designation must be reserved for writers like Mrs. Henry Wood, the author of *East Lynne* (1861). That the sentimental novel is capable of appeal even in the Atomic Age is shown by the success of *Love Story* (1970), by Erich Segal. That this is the work of a Yale professor of classics seems to indicate either that not even intellectuals disdain sentimental appeal or that tear-jerking is a process to be indulged in coldly and even cynically. Stock emotions are always easily aroused through stock devices, but both the aim and the technique are generally eschewed by serious writers.

Gothic. The first Gothic fiction appeared with works like Horace Walpole's *Castle of Otranto* (1765) and Matthew Gregory Lewis' *Monk* (1796), which countered 18th-century "rationalism" with scenes of mystery, horror, and wonder. Gothic (the spelling "Gothick" better conveys the contemporary flavour) was a designation derived from architecture, and it carried—in opposition to the Italianate style of neoclassical building more appropriate to the Augustan Age—connotations of rough and primitive grandeur. The atmosphere of a Gothic novel was expected to be dark, tempestuous, ghostly, full of madness, outrage, superstition, and the spirit of revenge. Mary Shelley's *Frankenstein*, which maintains its original popularity and even notoriety, has in overplus the traditional Gothic ingredients, with its weird God-defying experiments, its eldritch shrieks, and, above all, its monster. Edgar Allan Poe developed the Gothic style brilliantly in the United States, and he has been a considerable influence. A good deal of early science fiction, like H.G. Wells's *Island of Doctor Moreau* (1896), seems to spring out of the Gothic movement, and the Gothic atmosphere has been seriously cultivated in England in the later novels of Iris Murdoch and in the Gormenghast sequence beginning in 1946 of Mervyn Peake. It is noteworthy that Gothic fiction has always been approached in a spirit of deliberate suspension of the normal canons of taste. Like a circus trick, a piece of Gothic fiction asks to be considered as ingenious entertainment; the pity and terror are not aspects of a cathartic process but transient emotions to be, somewhat perversely, enjoyed for their own sake.

Ingredients of the typical Gothic novel

Psychological. The psychological novel first appeared in 17th-century France, with Madame de La Fayette's *Princesse de Clèves* (1678), and the category was consolidated by works like the Abbé Prévost's *Manon Lescaut* (1731) in the century following. More primitive fiction had been characterized by a proliferation of action and incidental characters; the psychological novel limited itself to a few characters whose motives for action could be examined and analyzed. In England, the psychological novel did not appear until the Victorian era, when George Eliot became its first great exponent. It has been assumed since then that the serious novelist's prime concern is the workings of the human mind, and hence much of the greatest fiction must be termed psychological. Dostoyevsky's *Crime and Punishment* deals less with the ethical significance of a murder than with the soul of the murderer; Flaubert's interest in Emma Bovary has less to do with the consequences of her mode of life in terms of nemesic logic than with the patterns of her mind; in *Anna Karenina*, Tolstoy presents a large-scale obsessive study of feminine psychology that is almost excruciating in its relentless probing. The novels of Henry James are psychological in that the crucial events occur in the souls of the protagonists, and it was perhaps James more than any serious novelist before or since who convinced frivolous novel-readers that the "psychological approach" guarantees a lack of action and excitement.

The theories of Sigmund Freud are credited as the source of the psychoanalytical novel. Freud was anticipated, however, by Shakespeare (in, for example, his treatment of Lady Macbeth's somnambulistic guilt). Two 20th-century novelists of great psychological insight—Joyce and Nabokov—professed a disdain for Freud. To write a novel with close attention to the Freudian or Jungian techniques of analysis does not necessarily produce new prodigies of psychological revelation; Oedipus and Electra complexes have become commonplaces of superficial novels and films. The great disclosures about human motivation have been achieved more by the intuition and introspection of novelists and dramatists than by the more systematic work of the clinicians.

The movement away from Freud

The novel of manners. To make fiction out of the observation of social behaviour is sometimes regarded as less worthy than to produce novels that excavate the human mind. And yet the social gestures known as manners, however superficial they appear to be, are indices of a collective soul and merit the close attention of the novelist and reader alike. The works of Jane Austen concern themselves almost exclusively with the social surface of a fairly narrow world, and yet she has never been accused of a lack of profundity. A society in which behaviour is codified, language restricted to impersonal formulas, and the expression of feeling muted, is the province of the novel of manners, and such fiction may be produced as readily in the 20th century as in the era of Fanny Burney or Jane Austen. Such novels as Evelyn Waugh's *Handful of Dust* (1934) depend on the exact notation of the manners of a closed society, and personal tragedies are a mere temporary disturbance of collective order. Even Waugh's trilogy *Sword of Honour* is as much concerned with the minutiae of surface behaviour in an army, a very closed society, as with the causes for which that army fights. H.H. Munro ("Saki"), in *The Unbearable Bassington* (1912), an exquisite novel of manners, says more of the nature of Edwardian society than many a more earnest work. It is conceivable that one of the novelist's duties to posterity is to inform it of the surface quality of the society that produced him; the great psychological profundities are eternal, manners are ephemeral and have to be caught. Finally, the novel of manners may be taken as an artistic symbol of a social order that feels itself to be secure.

Epistolary. The novels of Samuel Richardson arose out of his pedagogic vocation, which arose out of his trade of printer—the compilation of manuals of letter-writing technique for young ladies. His age regarded letter writing as an art on which could be expended the literary care appropriate to the essay or to fiction, and, for Richardson, the creation of epistolary novels entailed a mere step from the actual world into that of the imagination. His *Pamela* (1740) and *Clarissa* (1748) won phenomenal success and were imitated all over Europe, and the epistolary novel—with its free outpouring of the heart—was an aspect of early romanticism. In the 19th century, when the letter-writing art had not yet fallen into desuetude, it was possible for Wilkie Collins to tell the mystery story of *The Moonstone* (1868) in the form of an exchange of letters, but it would be hard to conceive of a detective novel using such a device in the 20th century, when the well-wrought letter is considered

artificial. Attempts to revive the form have not been successful, and Christopher Isherwood's *Meeting by the River* (1967), which has a profoundly serious theme of religious conversion, seems to fail because of the excessive informality and chattiness of the letters in which the story is told. The 20th century's substitute for the long letter is the transcribed tape recording—more, as Beckett's play *Krapp's Last Tape* indicates, a device for expressing alienation than a tool of dialectic. But it shares with the Richardsonian epistle the power of seeming to grant direct communication with a fictional character, with no apparent intervention on the part of the true author.

Pastoral. Fiction that presents rural life as an idyllic condition, with exquisitely clean shepherdesses and sheep immune to foot-rot, is of very ancient descent. Longus' *Daphnis and Chloe,* written in Greek in the 2nd or 3rd century AD, was the remote progenitor of such Elizabethan pastoral romances as Sir Philip Sidney's *Arcadia* (1590) and Thomas Lodge's *Rosalynde* (1590), the source book for Shakespeare's *As You Like It.* The *Paul et Virginie* of Bernardin de St. Pierre (1787), which was immensely popular in its day, seems to spring less from the pastoral utopian convention than from the dawning romanticism that saw in a state of nature only goodness and innocence. Still, the image of a rural Eden is a persistent one in Western culture, whatever the philosophy behind it, and there are elements of this vision even in D.H. Lawrence's *Rainbow* (1915) and, however improbable this may seem, in his *Lady Chatterley's Lover* (1928). The more realistic and ironic pictures of the pastoral life, with poverty and pig dung, beginning with George Crabbe's late-18th-century narrative poems, continuing in George Eliot, reaching sour fruition in Thomas Hardy, are usually the work of people who know the country well, while the rural idyll is properly a townsman's dream. The increasing stresses of urban life make the country vision a theme still available to serious fiction, as even a work as sophisticated as Saul Bellow's *Herzog* (1964) seems to show. But, since Stella Gibbons' satire *Cold Comfort Farm* (1932), it has been difficult for any British novelist to take seriously pastoral lyricism.

Realism in the pastoral novel

Apprenticeship. The *Bildungsroman,* or novel about upbringing and education, seems to have its beginnings in Goethe's work, *Wilhelm Meisters Lehrjahre* (1796), which is about the processes by which a sensitive soul discovers its identity and its role in the big world. A story of the emergence of a personality and a talent, with its implicit motifs of struggle, conflict, suffering, and success, has an inevitable appeal for the novelist; many first novels are autobiographical and attempt to generalize the author's own adolescent experiences into a kind of universal symbol of the growing and learning processes. Charles Dickens embodies a whole *Bildungsroman* in works like *David Copperfield* (1850) and *Great Expectations* (1861), but allows the emerged ego of the hero to be absorbed into the adult world, so that he is the character that is least remembered. H.G. Wells, influenced by Dickens but vitally concerned with education because of his commitment to socialist or utopian programs, looks at the agonies of the growing process from the viewpoint of an achieved utopia in *The Dream* (1924) and, in *Joan and Peter* (1918), concentrates on the search for the right modes of apprenticeship to the complexities of modern life.

The school story established itself in England as a form capable of popularization in children's magazines, chiefly because of the glamour of elite systems of education as first shown in Thomas Hughes's *Tom Brown's School Days* (1857), which is set at Rugby. In France, *Le Grand Meaulnes* (1913) of Alain-Fournier is the great exemplar of the school novel. The studies of struggling youth presented by Hermann Hesse became, after his death in 1962, part of an American campus cult indicating the desire of the serious young to find literary symbols for their own growing problems.

Samuel Butler's *Way of All Flesh,* which was written by 1885 but not published until 1903, remains one of the greatest examples of the modern *Bildungsroman;* philosophical and polemic as well as moving and comic, it presents the struggle of a growing soul to further, all unconsciously, the aims of evolution, and is a devastating indictment of Victorian paternal tyranny. But probably James Joyce's *Portrait of the Artist as a Young Man* (1916), which portrays the struggle of the nascent artistic temperament to overcome the represssions of family, state, and church, is the unsurpassable model of the form in the 20th century. That the learning novel may go beyond what is narrowly regarded as education is shown in two remarkable works of the 1950s—William Golding's *Lord of the Flies* (1955), which deals with the discovery of evil by a group of shipwrecked middle class boys brought up in the liberal tradition, and J.D. Salinger's *Catcher in the Rye* (1951), which concerns the attempts of an adolescent American to come to terms with the adult world in a series of brief encounters, ending with his failure and his ensuing mental illness.

Roman à clef. Real, as opposed to imaginary, human life provides so much ready-made material for the novelist that it is not surprising to find in many novels a mere thinly disguised and minimally reorganized representation of actuality. When, for the fullest appreciation of a work of fiction, it is necessary for the reader to consult the real-life personages and events that inspired it, then the work is a *roman à clef,* or novel that needs a key. In a general sense, every work of literary art requires a key or clue to the artist's preoccupations (the jail in Dickens; the mysterious tyrants in Kafka, both leading back to the author's own father), but the true *roman à clef* is more particular in its disguised references. Chaucer's "Nun's Priest's Tale" has puzzling naturalistic details that can be cleared up only by referring the poem to an assassination plot in which the Earl of Bolingbroke was involved. Swift's *Tale of a Tub* (1704), Dryden's *Absalom and Achitophel* (1681), and Orwell's *Animal Farm* (1945) make total sense only when their hidden historical content is disclosed. These, of course, are not true novels, but they serve to indicate a literary purpose that is not primarily aesthetic. Lawrence's *Aaron's Rod* requires a knowledge of the author's personal enmities, and to understand Aldous Huxley's *Point Counter Point* fully one must know, for instance, that the character of Mark Rampion is D.H. Lawrence himself and that of Denis Burlap is the critic John Middleton Murry. Proust's *À la recherche du temps perdu* becomes a richer literary experience when the author's social milieu is explored, and Joyce's *Finnegans Wake* has so many personal references that it may be called the most massive *roman à clef* ever written. The more important the *clef* becomes to full understanding, the closer the work has come to a special kind of didacticism. When it is dangerous to expose the truth directly, then the novel or narrative poem may present it obliquely. But the ultimate vitality of the work will depend on those elements in it that require no key.

Anti-novel. The movement away from the traditional novel form, in France in the form of the *nouveau roman,* tends to an ideal that may be called the anti-novel—a work of the fictional imagination that ignores such properties as plot, dialogue, human interest. It is impossible, however, for a human creator to create a work of art that is completely inhuman. Contemporary French writers like Alain Robbe-Grillet in *Jealousy* (1957), Nathalie Sarraute in *Tropisms* (1939) and *The Planetarium* (1959), and Michel Butor in *Passing Time* (1957) and *Degrees* (1960) wish mainly to remove the pathetic fallacy from fiction, in which the universe, which is indifferent to man, is made to throw back radar reflections of man's own emotions. Individual character is not important, and consciousness dissolves into sheer "perception." Even time is reversible, since perceptions have nothing to do with chronology, and, as Butor's *Passing Time* shows, memories can be lived backward in this sort of novel. Ultimately, the very appearance of the novel—traditionally a model of the temporal treadmill—must change; it will not be obligatory to start at page 1 and work through to the end; a novel can be entered at any point, like an encyclopaedia.

The two terms most heard in connection with the

French anti-novel are *chosisme* and *tropisme*. The first, with which Robbe-Grillet is chiefly associated, relates to the novelist's concern with things in themselves, not things as human symbols or metaphors. The second, which provided a title for Nathalie Sarraute's early novel, denotes the response of the human mind to external stimuli—a response that is general and unmodified by the apparatus of "character." It is things, the furniture of the universe, that are particular and variable; the multiplicity of human observers melts into an undifferentiable mode of response. Needless to say, there is nothing new in this epistemology as applied to the novel. It is present in Laurence Sterne (in whom French novelists have always been interested), as also in Virginia Woolf.

Chosisme and tropisme

Such British practitioners of the anti-novel as Christine Brooke-Rose and Rayner Heppenstall (both French scholars, incidentally) are more empirical than their French counterparts. They object mainly to the falsification of the external world that was imposed on the traditional novel by the exigencies of plot and character, and they insist on notating the minutiae of the surface of life, concentrating in an unhurried fashion on every detail of its texture. A work like Heppenstall's *Connecting Door* (1962), in which the narrator-hero does not even possess a name, is totally unconcerned with action but very interested in buildings, streets, and the sound of music. This is properly a fresh approach to the materials of the traditional novel rather than a total liberation from it. Such innovations as are found in the *nouveau roman* can best show their value in their influence on traditional novelists, who may be persuaded to observe more closely and be wary of the seductions of swift action, contrived relationships, and neat resolutions.

Cult, or coterie, novels. The novel, unlike the poem, is a commercial commodity, and it lends itself less than the materials of literary magazines to that specialized appeal called coterie, intellectual or elitist. It sometimes happens that books directed at highly cultivated audiences—like *Ulysses, Finnegans Wake,* and Djuna Barnes's *Nightwood* (1936)—achieve a wider response, sometimes because of their daring in the exploitation of sex or obscenity, more often because of a vitality shared with more demotic fiction. The duplicated typescript or the subsidized periodical, rather than the commercially produced book, is the communication medium for the truly hermetic novel.

The novel that achieves commercial publication but whose limited appeal precludes large financial success can frequently become the object of cult adulation. In the period since World War II, especially in the United States, such cults can have large memberships. The cultists are usually students (who, in an era of mass education, form a sizable percentage of the total population of the United States), or fringes of youth sharing the student ethos, and the novels chosen for cult devotion relate to the social or philosophical needs of the readers. The fairy stories of Tolkien, *The Lord of the Flies* of Golding, the science fiction of Kurt Vonnegut, Jr., have, for a greater or lesser time, satisfied a hunger for myth, symbols, and heterodox ideas, to be replaced with surprising speed by other books. The George Orwell cult among the young was followed by a bitter reaction against Orwell's own alleged reactionary tendencies, and such a violent cycle of adoration and detestation is typical of literary cults. Adult cultists tend, like young ones, to be centred in universities, from which they circulate newsletters on *Finnegans Wake,* Anthony Powell's *Music of Time* sequence, and the works of Evelyn Waugh. Occasionally new public attention becomes focussed on a neglected author through his being chosen as a cult object. This happened when the novellas of Ronald Firbank, the anonymous comic novel *Augustus Carp, Esq.*, and G.V. Desani's *All About Mr. Hatterr* got back into print because of the urging of minority devotees. Despite attempts to woo a larger public to read it, Malcolm Lowry's *Under the Volcano* obstinately remained a cult book, while the cultists performed their office of keeping the work alive until such time as popular taste should become sufficiently enlightened to appreciate it.

Student cultists

Detective, mystery, thriller. The terms detective story, mystery, and thriller tend to be employed interchangeably. The detective story thrills the reader with mysterious crimes, usually of a violent nature, and puzzles his reason until their motivation and their perpetrator are, through some triumph of logic, uncovered. The detective story and mystery are in fact synonymous, but the thriller frequently purveys adventurous *frissons* without mysteries, like the spy stories of Ian Fleming, for example, but not like the spy stories of Len Deighton, which have a bracing element of mystery and detection. The detective novel began as a respectable branch of literature with works like Poe's "Murders in the Rue Morgue" (1841), Dickens' unfinished *Edwin Drood* (1870), and Wilkie Collins' *Moonstone* (1868) and *Woman in White* (1860). With the coming of the Sherlock Holmes stories of Sir Arthur Conan Doyle, at the beginning of the 20th century, the form became a kind of infra-literary subspecies, despite the intellectual brilliance of Holmes's detective work and the high literacy of Doyle's writing. Literary men like G.K. Chesterton practiced the form on the margin, and dons read thrillers furtively or composed them pseudonymously (*e.g.*, J.I.M. Stewart, reader in English literature at Oxford, wrote as "Michael Innes"). Even the British poet laureate, C. Day Lewis, subsidized his verse through writing detective novels as "Nicholas Blake." Dorothy L. Sayers, another Oxford scholar, appeared to atone for a highly successful career as a mystery writer by turning to religious drama and the translating of Dante, as well as by making her last mystery novel —*Gaudy Night* (1935)—a highly literary, even pedantic, confection.

Such practitioners as Agatha Christie, Ellery Queen, Erle Stanley Gardner, Raymond Chandler, to say nothing of the highly commercial Edgar Wallace and Mickey Spillane, have given much pleasure and offended only the most exalted literary canons. The fearless and intelligent amateur detective, or private investigator, or police officer has become a typical hero of the modern age. And those qualities that good mystery or thriller writing calls for are not to be despised, since they include economy, skillful sustention of suspense, and very artful plotting.

The mystery novel was superseded in popularity by the novel of espionage, which achieved a large vogue with the James Bond series of Ian Fleming. Something of its spirit, if not its sadism and eroticism, had already appeared in books like John Buchan's *Thirty-nine Steps* and the "entertainments" of Graham Greene, as well as in the admirable novels of intrigue written by Eric Ambler. Fleming had imitators, as well as a more than worthy successor in Len Deighton, but the espionage novel had a comparatively short-lived popularity. It appeared that the novel of crime and detection, or of intrigue and adventure unrelated to the Cold War in which James Bond was engaged, had a sempiternal vitality, while the spy book was of very ephemeral appeal.

Western. Man's concern with taming wild land, or advancing frontiers, or finding therapy in reversion from the civilized life to the atavistic is well reflected in adventure novels, beginning with James Fenimore Cooper's novels of the American frontier *The Pioneers* (1823) and *The Last of the Mohicans* (1826). As the 19th century advanced, and new tracts of America were opened up, a large body of fiction came out of the men who were involved in pioneering adventure. Mark Twain's *Roughing It* (1872) may be called a frontier classic. Bret Harte wrote shorter fiction, like "The Luck of Roaring Camp" (1868), but helped to spread an interest in frontier writing to Europe, where the cult of what may be termed the western novel is as powerful as in America. Owen Wisters' *Virginian* (1902), Andy Adams' near-documentary *Log of a Cowboy* (1903), Emerson Hough's *Covered Wagon* (1922), from which the first important western film was made in 1923, Hamlin Garland's *Son of the Middle Border* (1917), and O.E. Rölvaag's *Giants in the Earth* (1927) all helped to make the form popular, but it is to Zane Grey—who wrote more than 50 western novels —that lovers of frontier myth have accorded the greatest devotion. The western is now thought of predominantly

as a cinematic form, but it arose out of literature. Other frontier fiction has come from another New World, the antipodes—South Africa as well as the Australian outback—but the American West has provided the best mythology, and it is still capable of literary treatment. Sophisticated literary devices may be grafted onto the western—surrealistic fantasy or parallels to Shakespeare or to the ancient classics—but the peculiar and perennial appeal of the western lies in its ethical simplicity, the frequent violence, the desperate attempt to maintain minimal civilized order, as well as the stark, near-epic figures from true western history, such as Billy the Kid, Calamity Jane, Wyatt Earp, Annie Oakley, and Jesse James.

The enduring and the ephemeral

The best seller. A distinction should be made between novels whose high sales are an accolade bestowed on literary merit and novels that aim less at aesthetic worth than at profits. The works of Charles Dickens were best sellers in their day, but good sales continue, testifying to a vitality that was not purely ephemeral. On the other hand, many best-selling novels have a vogue that is destined not to outlast the time when they were produced. It is a characteristic of this kind of best seller that the writing is less interesting than the content, and that the content itself has a kind of journalistic oversimplification that appeals to unsophisticated minds. The United States is the primary home of the commercial novel whose high sales accrue from careful, and sometimes cold-blooded, planning. A novel in which a topical subject—such as the Mafia, or corruption in government, or the election of a new pope, or a spate of aircraft accidents, or the censorship of an erotic book—is treated with factual thoroughness, garnished with sex, enlivened by quarrels, fights, and marital infidelities, presented in nonliterary prose, and given lavish promotion by its publisher may well become a best seller. It is also likely to be almost entirely forgotten a year or so after its publication. The factual element in the novel seems to be necessary to make the reader feel that he is being educated as well as diverted. Indeed, the conditions for the highest sales seem to include the reconciliation of the pornographic and the didactic.

A novel with genuine aesthetic vitality often sells more than the most vaunted best seller, but the sales are more likely to be spread over decades and even centuries rather than mere weeks and months. The author of such a book may, in time, enrich others, but he is unlikely himself to attain the opulence of writers of best sellers such as Harold Robbins or Irving Wallace.

Fantasy and prophecy. The term science fiction is a loose one, and it is often made to include fantastic and prophetic books that make no reference to the potentialities of science and technology for changing human life. Nevertheless, a novel like Keith Roberts' *Pavane* (1969), which has as a premise the conquest of England by Spain in 1588, and the consequent suppression rather than development of free Protestant intellectual inquiry, is called science fiction, though such terms as "fiction of hypothesis" and "time fantasy" would be more fitting. The imaginative novelist is entitled to remake the existing world or present possible future worlds, and a large corpus of fiction devoted to such speculative visions has been produced in the last hundred years, more of it based on metaphysical hypotheses than on scientific marvels. Jules Verne and H.G. Wells pioneered what may be properly termed science fiction, mainly to an end of diversion. Since the days of Wells's *Time Machine* (1895) and *Invisible Man* (1897), the fiction of hypothesis has frequently had a strong didactic aim, often concerned with opposing the very utopianism that Wells—mainly in his nonfictional works—built on the potentialities of socialism and technology. Aldous Huxley's *Brave New World* (1932) showed how dangerous utopianism could be, since the desire for social stability might condone conditioning techniques that would destroy the fundamental human right to make free choices. Toward the end of his life Huxley produced a cautious utopian vision in *Island* (1962), but the dystopian horrors of his earlier novel and of his *Ape and Essence* (1948) remain more convincing. Orwell's *Nineteen Eighty-four* (1949) showed a world in which a tyrannic unity is imposed by a collective solipsism, and contradictions are liquidated through the constant revision of history that the controlling party decrees. Anthony Burgess' *Clockwork Orange* (1962) and *Wanting Seed* (1962) portray ghastly futures that extrapolate, respectively, philosophies of crime control and population control out of present-day tendencies that are only potentially dangerous.

A large number of writers practice prophetic fantasy with considerable literary skill and careful factual preparation—Kurt Vonnegut, Jr., Ray Bradbury, Italo Calvino, Isaac Asimov, J.G. Ballard, to name a few—and novelists whose distinction lies mainly in more traditional fields have attempted the occasional piece of future-fiction, like L.P. Hartley with his *Facial Justice* (1961) and Evelyn Waugh in *Love Among the Ruins* (1953). The fantasist who fantasizes without prophetic or warning intent is rarer, but works like Nabokov's *Ada*, Tolkien's *Lord of the Rings* cycle, and Christine Brooke-Rose's *Out* (1964) represent legitimate and heartening stretching of the imagination, assurances that the novelist has the right to create worlds, as well as characters, of his own. But the dystopian novel can have a salutary influence on society, actively correcting regressive or illiberal tendencies, and *Brave New World* and *Nineteen Eighty-four* can be cherished as great didactic landmarks, not just as works of literary art.

Proletarian. The novel that, like Dickens' *Hard Times* (1854), presents the lives of workingmen or other members of the lower orders is not necessarily an example of proletarian fiction. The category properly springs out of direct experience of proletarian life and is not available to writers whose background is bourgeois or aristocratic. Thus, William Godwin's *Caleb Williams* (1794), or Robert Bage's *Hermsprong* (1796), though, like *Hard Times*, sympathetic to the lot of the oppressed worker, is more concerned with the imposition of reform from above than with revolution from within, and the proletarian novel is essentially an intended device of revolution. The Russian Maksim Gorky, with works like *Foma Gordeyev* (1900) and *Mother* (1907), as well as many short stories portraying the bitterness of poverty and unemployment (the pseudonym *Gorky* means "bitter"), may be taken as an exemplary proletarian writer. The United States has produced a rich crop of working-class fiction. Such Socialist writers as Jack London, Upton Sinclair, John Dos Passos, and Edward Dahlberg, however, did not witness the triumph of the workers' revolution in their own country, as Gorky did in his, and it is the fate of the American proletarian novelist, through literary success, either to join the class he once dreamed of overthrowing or to become anarchic and frustrated. In the Soviet Union the proletarian novel was doomed to disappear in the form that Gorky knew; a present-day Gorky would presumably write, in exile, novels about Soviet oppression or else join Yuly Daniel (who writes under the pseudonym Nikolay Arzhak) and Aleksandr Solzhenitsyn in enforced silence and disgrace. For it is the essence of the revolutionary novel only to possess vitality and validity when written under capitalist "tyranny." England has produced its share of working-class novelists exuding bitterness, such as Alan Sillitoe, with his *Saturday Night and Sunday Morning* (1958), but conditions apt for revolution have not existed in Britain for over a century. British novelists who emerged after World War II, such as John Braine (*Room at the Top*), Keith Waterhouse (*There is a Happy Land*), Kingsley Amis (*Lucky Jim*), and Stan Barstow (*A Kind of Loving*), showed a solution to working-class frustration in a fluid system of class promotion: revolution is an inadmissible dream. Generally speaking, in the novel, which is preoccupied with individuals rather than with groups, it is difficult to make the generalized political statements that are meat and drink to the revolutionary propagandist.

Reform versus revolution

Other types. The categories briefly discussed above are among the most common fictional forms. Theoretically there is no limit to the number available, since changing social patterns provide fresh subjects and fresh taxonomies, and new metaphysical and psychological doctrines

may beget new fictional approaches to both content and technique. Other categories of fictional art include the erotic novel (which may or may not be pornographic), the satirical novel, the farcical novel, the novel for or about children, the theological novel, the allegorical novel, and so on. Types of fiction no longer practiced, since their real-life referents no longer exist, include the colonial novel—such as E.M. Forster's *Passage to India* (1924), Henri Fauconnier's *Malaisie* (1930), and the African sequence of Joyce Cary—and space fantasy like H.G. Wells's *First Men in the Moon* (1901). One may read examples of a departed category with pleasure and profit, but the category can no longer yield more than parody or pastiche. New kinds of fiction fill in the gaps, like the novel of negritude, the structuralist novel (following the linguistic sociologists and anthropologists), the homosexual novel, the novel of drug hallucination, and so on. So long as human society continues to exist, the novel will exist as its mirror, an infinitude of artistic images reflecting an infinitude of life patterns.

Outmoded types

II. Development of the novel: the novels of specific nations or languages

THE NOVEL IN ENGLISH

The United Kingdom. England's chief literary achievements lie in the fields of drama and poetry, and the attitude of English novelists to their form was, for a long time, cheerfully empirical and even amateurish. Elizabethan novels, *novelle* rather, imitated the Spanish picaresque story, and Thomas Nashe's *Unfortunate Traveller* (1594) is a good, bustling, vital example of a rapidly composed commercial work more concerned with sensational incident and language than with shape or character. Daniel Defoe (1660?-1731) is often considered to be the true progenitor of the long English novel, but his *Robinson Crusoe* and *Moll Flanders* are loosely constructed, highly episodic, and presented as mock-biography rather than real fiction. It is with *Pamela*, by Samuel Richardson (1689–1761), that the tradition of serious, moral fiction in English may be said to begin, but later 18th-century novelists reverted to the picaresque and comic. Henry Fielding (1707–54) wrote his first novel, *Joseph Andrews*, as a parody on *Pamela*, but his masterpiece, *Tom Jones*, is original if shapeless, an example of English literary genius sinking thankfully back into the casual and improvisatory. Laurence Sterne (1713–68) produced a great mad work, *Tristram Shandy*, that, in its refusal to truckle to any rules of structure, remains still a quarry for avant-garde novelists; and Tobias Smollett (1721–71) wrote picaresque satire in *Roderick Random* and *Peregrine Pickle*, full-blooded portraits of the age that impress more with their vigour than with their art.

The Romantic Age brought, paradoxically, the cool and classically shaped novels of Jane Austen (1775–1817), a major practitioner and still a model for apprentices in the craft. Sir Walter Scott (1771–1832), a Scotsman who wrote about romantic historical Scotland, must be regarded as an international figure whose influence was greater even than Richardson's, since he more than anyone established the historical novel as the primary fictional form in Europe. In his work, nevertheless, the traditional faults of the British novel may be descried—episodic formlessness, an ebullience of texture rather than a clean narrative line. The Victorian Age moved out of the romantic past, or, as with William Makepeace Thackeray (1811–63), stayed with it only to deromanticize it. Charles Dickens (1812–70) was indebted to the picaresque tradition but turned reformist eyes on his own age. Thackeray and Dickens are complementary in that the first attacks the upper classes while the second showers sympathy, sometimes of a mawkish kind, on the lower classes. With George Eliot (1819-80), the first true English psychological novels appear, strong in their moral content, and George Meredith (1828–1909) may be said to have anticipated—in *The Ordeal of Richard Feverel* and *The Egoist*—the approach in depth that characterized the psychological novel of the 20th century.

The Romantic and Victorian ages

Both Charlotte Brontë (1816–55) and Emily Brontë (1818–48) exemplify the capacity of the English novel to achieve solitary "sports" unrelated to any current or tradition. Both *Wuthering Heights*—a superb evocation of the soul of a locality, with a love story that is fierce and primitive but recounted with poetic sophistication—and *Jane Eyre*, an exceedingly frank and still shocking study of a love that rides over Victorian conventions, are unlike any other books of their time, or of any other time, though their qualities have been diluted into hundreds of popular 20th-century romances. Later Victorians, particularly Samuel Butler (1835–1902) and Thomas Hardy (1840–1928), reflected those changes in the educated English sensibility that had been brought about by the new science. Hardy's world is one in which the Christian God has been replaced by a malevolent Providence—the poet-novelist's theologization of scientific determinism. Butler's *Way of All Flesh*, a work that contrives to be both bitterly realistic and high comic, demonstrates the working of Darwinian evolution in social institutions such as the family and even the church. In many ways, Butler leads English fiction into the modern age.

John Galsworthy (1867–1933) showed himself interested in the processes by which old institutions, such as a great Whig family, decay as history advances, but in both style and characterization he is firmly set in the Victorian Age. Of Arnold Bennett (1867–1931) it may be said that he brought to a kind of Thackerayan social realism something of the spirit of the French novel, particularly the anglicized tones of Balzac and Zola. W. Somerset Maugham (1874–1965), though his most considerable achievements lie in the short story form, wrote novels, like *Of Human Bondage*, that are infused with the delicious acerbities of French naturalism, and all his work, long or short, is exalted by the influence of Guy de Maupassant. Early 20th-century British fiction needed the impact of an alien tradition to jolt it out of bourgeois empiricism, and perhaps the two major influences were both foreigners who had elected to write fiction in England—Joseph Conrad (1857–1924), Polish-born, to whom English was a second language, and Henry James (1843–1916), an American who had drunk deeply at French fountains and brought to the exercise of his craft a scrupulousness and a concern with aesthetic values that was almost obsessive and, it may be said, very un-English. James's influence on such major English-born novelists as Virginia Woolf (1882–1941), E.M. Forster (1879–1970), and Ford Madox Ford (1873–1939) was in the direction of that concern with style which the English novel, unlike the French, has always tried to resist, and this influence remains a potent one on succeeding generations of novelists, not only in England.

Other important Englishmen have remained more interested in content than in style, though in Graham Greene (1904–), a Catholic convert, who is primarily known for his "theological" content, there is a very interesting attempt to bring to this a Conradian concern for the solitary-man theme and a Jamesian preoccupation with style. D.H. Lawrence (1885–1930) remains the great modern English novelist who reconciles a highly traditional style (in *The Rainbow*, for example, he often resembles George Eliot) with a subject matter that is revolutionary in the profundity of its human relationships. And Aldous Huxley (1894–1963), though he indulged in formal experiment in *Point Counter Point* and *Eyeless in Gaza*, was always essentially a didactic writer who used the novel form somewhat casually. The same may be said of George Orwell (1903–50), who eschewed stylistic complexity in the interests of a clear message. On the other hand, Evelyn Waugh (1902–66) and Anthony Powell (1905–), in a cautious and conservative way, consulted the claims of allusive and evocative prose, as did Wyndham Lewis (1884–1957), who also brought to his novels the aesthetic of an alien art—that of painting.

Novelists like Kingsley Amis (1922–) and Angus Wilson (1913–) are seen to belong to traditions already old in the time of Samuel Butler. Amis derives from Fielding (Amis' *Take a Girl Like You* has a moral quality reminiscent of Fielding's *Amelia*), and Wilson never pretends to be other than a disciple of novelists like George Eliot and Dickens. The Victorian kind of novel,

as practiced by writers like J.B. Priestley (1894–), satisfies large numbers of British readers, and Jamesian scrupulosity and Joycean experiment alike are regarded with amiable suspicion. Such Englishmen as have experimented in fictional technique have usually found a larger audience abroad than at home. Thus Lawrence Durrell (1912–) found his *Alexandria Quartet* hailed as a masterpiece in France, while English readers merely liked or disliked it. *A Clockwork Orange* by Anthony Burgess (1917–) achieved a large readership in the United States, but it recorded little positive response in the country of its origin.

Irish and Scottish novels

The fiction of the British Isles is not clearly differentiated into national or regional groups, and to speak of Irish novelists is often to do no more than refer to an irrelevant place of birth. Oscar Wilde (1854–1900) was more French than Irish; his one novel, *The Picture of Dorian Gray*, has no progenitors in English fiction, but it owes much to the late-19th-century French novelist Joris-Karl Huysmans. George Moore (1852–1933) was born in County Mayo, Ireland, but studied art in Paris, and works like *A Modern Lover* and *A Mummer's Wife* were intended to teach the British novel how to absorb the spirit of Flaubert and Zola. Moore's *Lake*, written under the influence of the Irish literary revival, is dutifully set in Ireland, but this essentially international writer was quick to move back to France for *Héloïse and Abélard* and on to Palestine for *The Brook Kerith*. James Joyce (1882–1941), conceivably the greatest novelist in English in the 20th century, never moves from his native Dublin in any of his fiction, but no less parochial writer can well be imagined. *Ulysses*, in the depth of its historical coverage, may be regarded as one of the last great artistic monuments of the Austro-Hungarian Empire, and *Finnegans Wake* was stimulated by the avant-garde climate of Paris, the resting place of so many Irish "wild geese." It is only perhaps negatively that Ireland shaped Joyce's literary personality; the oppressiveness of the new nationalism made him react in the direction of internationalism, and it eventually forced him to a lifelong exile. Flann O'Brien, possibly Joyce's true successor, stayed in Dublin and draws, in works like *At Swim-Two-Birds* (1939) and *The Hard Life* (1961), on the native demotic experience, but his techniques come from Europe, not from the Anglo-Irish bourgeois stockpot.

The Scottish novel hardly exists as a national entity; there is nothing in fiction that matches the exploitation of Lallans in the poetry of Burns or of Hugh MacDiarmid (C.M. Grieve). Scott, as has been indicated, belongs to European literature, and later novelists like Robert Louis Stevenson (1850–94) and Sir James Barrie (1860–1937), though Scottish themes and settings are featured triumphantly in their fiction, are essentially men whose literary metropolis was London rather than Edinburgh.

Wales sedulously cultivates Welsh as a living artistic medium, but few novels by Welshmen reach the English or international market, unless—like Emyr Humphreys—they write their works in English as well as Welsh. The English-language novel from Wales hardly exists, except in the form of best sellers like Richard Llewellyn's *How Green Was My Valley* (1940)—a deliberate capitalization on Welsh picturesqueness—and the very Joycean prose of the poet Dylan Thomas (1914–53), whose one novel, *Adventures in the Skin Trade*, has very little of Wales in it.

The United States. If the American novel appears to begin with the *Wieland* and *Edgar Huntly* of Charles Brockden Brown (1771–1810), then the fiction of the mother country may be said to have no start on that of the newly independent daughter. Admittedly, Brown owes something to the English Gothic novel, but already a typically American note is struck in the choice of a violent and bizarre form that, in various mutations, was to prove fruitful in the development of American fiction. James Fenimore Cooper (1789–1851) struck out, in the pentateuch called the "Leatherstocking" tales, in another direction suitable to the American genius and experience: *The Last of the Mohicans* and *The Prairie*, though their prose style is perhaps overelaborate, are full of the spirit of a young nation confronting the wilderness and advancing its frontiers. Harriet Beecher Stowe (1811–96) produced, in *Uncle Tom's Cabin*, an anti-slavery novel whose sensational devices owe something to the Gothic movement but whose style is rooted in that European romantic tradition fathered by Scott. Even Edgar Allan Poe (1809–49) and Nathaniel Hawthorne (1804–64) are incompletely emancipated from Europe, though Hawthorne's *Scarlet Letter* shows a preoccupation with sin that finds no fictional counterpart in the main stream of the European novel. America, aware of the darkness and mystery of a land still mainly undiscovered, was correspondingly aware, in both Gothic and eschatological fiction, of the dark places of the mind.

The true emancipation from Europe comes in the works of Hawthorne's friend Herman Melville (1819–91), whose *Moby Dick* creates a totally American fusion by combining plain adventure with a kind of Manichaean symbolism—implying a belief that the universe is under the dominion of two opposing principles, one good and the other evil. Mark Twain (1835–1910) brought the Mississippi frontier region into the literary geography of the world with *Tom Sawyer* and *Huckleberry Finn*, combining very American humour with harsh social criticism, as also in the unique *Puddn'head Wilson*. From Twain on, the new regions of the United States become the materials of a wealth of fiction. Thus, while Bret Harte (1836–1902) wrote about California and George W. Cable (1844–1925) on Louisiana, Indiana was celebrated in *The Hoosier Schoolmaster* of Edward Eggleston (1837–1902) and the *Penrod* stories of Booth Tarkington (1869–1947).

American innocence and European sophistication

But America could not wholly turn its back on Europe, and the early 20th century was characterized by the discovery of the phenomenon called American "innocence" in confrontation with the decadent wisdom and sophistication of the Old World. If, in *Innocents Abroad*, Mark Twain and his fellow travellers remained unimpressed by Europe, Henry James (1843–1916) devoted millions of words to the response of impressionable Americans to the subtle deciduous culture their ancestors had abandoned in the search for a new life. Zolaesque realism entered the American novel with William Dean Howells (1837–1920). Theodore Dreiser (1871–1945) shocked his audiences with the candour and pessimism of *Sister Carrie* and *An American Tragedy*, while Stephen Crane (1871–1900) and Frank Norris (1870–1902) made realism enter, respectively, the traditionally romantic field of war (*The Red Badge of Courage*) and the pastoral life of the promised land of California (*The Octopus*). American innocence ceased to be a fictional property. The brutality in Jack London (1876–1916) joins hands with the depictions of "natural man" in the works of Ernest Hemingway (1899–1961), while the urban fiction of James T. Farrell (1904–) and John O'Hara (1905–70) has a wholly American realism that leaves Zola far behind.

The 20th-century American novel is "compartmentalized" in a manner that seems to give the lie to any allegation of cultural unity. The cult of the regional novel has continued. Ohio came under the microscopic scrutiny of Sherwood Anderson (1876–1941) in *Winesburg, Ohio*, just as the small-minded hypocrisy and materialism of the Midwest fired the brilliant sequence of Sinclair Lewis (1885–1951) from *Main Street* on. But the best regional fiction has come from the South, with William Faulkner (1897–1962), whose technical master is Joyce, Ellen Glasgow (1874–1945), Erskine Caldwell (1903–), and Robert Penn Warren (1905–). The immigrant communities of Nebraska were the subject of the *My Ántonia* of Willa Cather (1873–1947), while Ole Rölvaag (1876–1931) dealt with the South Dakota Norwegians in *Giants in the Earth*. The urban Jew has become the very spokesman of the contemporary American experience with writers like Saul Bellow (1915–), Herbert Gold (1924–) and Bernard Malamud (1914–); while the black American has been made highly articulate in works like *Go Tell It on the Mountain* by James Baldwin (1924–), and *Invisible Man* by Ralph Ellison (1914–).

Meanwhile, the fiction of social criticism that derives from Howells and was made popular by men like Upton Sinclair (1878–1968) goes on, either in "muckraking" best sellers or in such specialized attacks on the American ethos as are exemplified by war books like Joseph Heller's *Catch-22* and Kurt Vonnegut's *Slaughterhouse-Five*. American realism has gained a reputation for candour unequalled in any other literature of the world, so that the *Tropic of Cancer* and *Tropic of Capricorn* of Henry Miller (1891–) remain models for sexual frankness that encouraged writers like Hubert Selby, Jr. (*Last Exit to Brooklyn*), and Philip Roth (*Portnoy's Complaint*) to uncover areas of eroticism still closed to the European novel. But to balance the concern with naked subject matter, American fiction has also fulfilled the promise of its earlier expatriates beginning with Gertrude Stein (1874–1946) to match the French in a preoccupation with style. The distinction of F. Scott Fitzgerald (1896–1940) lay in the lyrical intensity of his prose as much as in his "jazz age" subject matter, and writers like Truman Capote (1924–) and John Updike (1932–) have dedicated themselves similarly to perfecting a prose instrument whose effects (like those of Joyce) touch the borders of poetry. Perhaps the glories and potentialities of American fiction are best summed up in the novels of Vladimir Nabokov (1899–). His earlier works belong to Europe, but when he took to writing in English he created a sophisticated, cosmopolitan, and highly poetic style. His work, as in *Lolita* and *Pale Fire*, concentrates with unparalleled intensity on the immediacies of American life in the 20th century.

The British Commonwealth. Canada has two literatures—one in French as well as one in English—and, in the taxonomy of this article, it will be as well to forget the course of history and consider French Canadian novelists along with those of the separated, and officially abandoned, mother country. The Canadian novel in English begins, appropriately enough, with a Richardson—John Richardson (1796–1852), author of *Wacousta*, a story of the Indian uprising led by Pontiac. But, with the exception of James DeMille (1836–80), author of a remarkable novel, *A Strange Manuscript Found in a Copper Cylinder*, and William Kirby (1817–1906), whose *Golden Dog* is an interesting long romance of 18th-century Quebec, no novelist of stature emerged in what was a great period of literary expansion in the United States. The historical novels of Sir Gilbert Parker (1862–1932), the western romances of Ralph Connor (1860–1937), and the world-famous *Anne of Green Gables* by Lucy Maud Montgomery (1874–1942) exhibit a stylistic tameness, along with that jejune oversimplification of psychology that is a mark of the deliberately "popular" novel. More distinctive work came in the early 20th century, as in the prairie novels of Robert Stead (1880–1959) and Frederick Philip Grove (1871–1948). Morley Callaghan (1903–), a chronicler of urban life, may be seen as a writer approaching international stature, and that tough "European" realism that braces his work is also to be found, along with a rather exotic elegance, in the novels of Robertson Davies (1913–). Younger novelists, like Brian Moore (1921–) and Mordecai Richler (1931–), have sought artistic stimulation outside Canada, and they show general uneasiness about the lack of a cultivated audience in their great but underpopulated land.

Australian and New Zealand novels

A similar complaint may be heard in Australia and New Zealand, where the fictional tradition has long accommodated itself to the simple literary needs of unsophisticated settlers. The first true Australian novel was probably *For the Term of His Natural Life*, by Marcus Clarke (1846–81), which dealt, appropriately, considering the penal origins of the Australian settlements, with life in prison; and Rolf Boldrewood, the pseudonym of Thomas A. Browne (1826–1915), had a cognate approach of excessive simplicity and melodrama to the days of the gold rush in his *Robbery Under Arms*. Australian farm life was the theme of the novels that Arthur Hoey Davis (1868–1935) wrote under the pen name of Steele Rudd, beginning with *On Our Selection*. But something that can only be termed native Australianism—which has less to do with trades and scenic backgrounds than with a whole new language and collective philosophy of life—appears for the first time in *My Brilliant Career* (1901), by Miles Franklin (1879–1954). The expression of a national personality is not, however, enough. Progressive 20th-century Australian novelists look hungrily toward Europe, aware that native conservatism will not support the kind of experimentalism in literature that it is prepared to take for granted in painting and architecture. The most considerable modern Australian novelist is Patrick White (1912–), but even such massive achievements as *Voss* and *Riders in the Chariot* are set firmly in the Dostoyevskian tradition. Morris West (1916–) is Australian only by birth; he seeks international themes and the lure of the American best-seller market. It seems that an Australian writer can succeed only if he renounces his Australianism and goes into exile. It is still a source of humiliation to Australian litterateurs that the finest novel about Australia was written by a mere visitor—*Kangaroo* (1923), by D.H. Lawrence.

New Zealand, with its much smaller population, presents even greater problems for the native novelist seeking an audience, and this—along with New Zealand's closer tie with the mother country—explains why such fiction writers as Katherine Mansfield (1888–1923) and Dame Ngaio Marsh (1899–) made London their centre. Young novelists like Janet Frame, Ian Cross, and Maurice Shadbolt show, however, a heartening willingness to render the New Zealand scene in idioms and techniques more progressive than anything to be found in Australia, and they are prepared to resist the temptations of the expatriate life.

Inevitably, territories like India and Africa entered the federation of English literature very much later than those dominions founded on the English language. With few exceptions, African and Indian novelists employ English as a second language, and one of the charms of their novels lies in a creative tension between the adopted language and the native vernacular (needless to say, this is usually self-consciously exploited—often for poetic, but more frequently for comic, effect).

English as a second language of the novelist

Of Indian novelists, R.K. Narayan (1906–), in works like *The English Teacher* (U.S. title *Grateful to Life and Death*) and *The Man-Eater of Malgudi*, exhibits an individual combination of tenderness and humour, as well as a sharp eye for Indian foibles. Raja Rao (1909–), whose best known novel is *The Serpent and the Rope*, achieves remarkable prosodic effects through allowing Sanskrit rhythm and idiom to fertilize English. Of younger Indian novelists, Balachandra Rajan (1920–) is notable, in *The Dark Dancer* and *Too Long in the West*, for an ability to satirize the Anglo-American way of life with the same suave elegance that informs his tragicomic view of the East. Khushwant Singh (1915–) presents, in *I Shall Not Hear the Nightingale*, a powerful chronicle of Sikh life during that period of imperial dissolution that began with World War II. English seems established as the medium for the Indian novel, and it is interesting to note an ability on the part of nonnative Indian residents who have practiced the form to be absorbed into a new "Indo-Anglian" tradition. Rudyard Kipling's *Kim* is respected by Indian writers, and E.M. Forster's *Passage to India* is a progenitor of one kind of Indian novel. The novels of Paul Scott (1920–)—such as *Johnnie Sahib* and *The Birds of Paradise*—spring out of a love of the country and an understanding of its complexities not uncommon among former British soldiers and administrators. The Indian novel is perhaps a product of territory rather than of blood.

African novelists

The most important of the new African writers come from the West Coast, traditional fount of artists, and they are mostly characterized by immense stylistic vigour, a powerful realism, and, often, a satirical candour unseduced by the claims of the new nationalism. Chinua Achebe (1930–), in *Things Fall Apart* and *No Longer at Ease*, renders remarkably the tones of Umuaro speech and thought, and exhibits, as also in *Arrow of God*, a concern for that rich native culture whose extirpation is

threatened by imported Western patterns of life and government. His *Man of the People* deals sharply with corruption and personality cult in a newly independent African state modelled on his own Nigeria. A fellow Nigerian, Amos Tutuola (1920–), has gained an international reputation with *The Palm-Wine Drinkard*—a richly humorous novel permeated with the spirit of folklore. Cyprian Ekwensi (1921–) is best known for his *Jagua Nana*, a wry study of the impact of the new materialism (symbolized by the "Jagua" car of the title) on the tribal mind. Onuora Nzekwu (1928–), in *Blade Among the Boys*, has a graver theme: the conflict between Ibo religion and imported Christianity in the upbringing of a sensitive and confused young man.

South African novels have, traditionally, dealt with those pioneering themes still exemplified in the work of Laurens van der Post and Stuart Cloete, but the territory has made its entry into world literature comparatively recently chiefly because the official racist policies have inspired a powerful fiction of protest. William Plomer (1903–) may be regarded as the father of anti-apartheid literature, although his *Turbott Wolfe* appeared in 1925, long before the state doctrine was articulated. The theme of this novel was the necessity for white and black blood to mix and ensure a liberal South African future not given over purely to white domination. Alan Paton (1903–), in *Cry, the Beloved Country*, has produced the most popular novel of protest, but Dan Jacobson (1929–), Nadine Gordimer (1923–), and especially Doris Lessing (1919–) have amplified mere protest into what may be termed a kind of philosophical fiction, often distinguished enough to rank with the best work of Europe and America. Mrs. Lessing's sequence *Children of Violence* finds in South Africa a kind of starting point for denunciation of wrongs that turn out to be social and sexual as well as racial.

Caribbean works

The varied fictional achievements of the Caribbean are large. Trinidad has produced the two best known West Indian writers—Samuel Selvon and V.S. Naipaul (1932–), both of East Indian descent. Selvon's work (*A Brighter Sun, An Island is a World, The Lonely Londoners*) is grim, bitter, capable of vivid evocation of the Trinidadian scene, but Naipaul, after *A House for Mr. Biswas*, has shown signs of habituation to his English exile, so that his *Mr. Stone and the Knights Companion* seems to be a novel totally nourished by the London world in which it is set. Most Caribbean novelists, finding their publishers and their audiences in England, transfer themselves thither and cut themselves off from all but remembered roots. This is true of Edgar Mittelhölzer (1909–65), an ebullient and prolific writer whose later books all had English settings. Wilson Harris has, in English exile, created an astonishing Guianan tetralogy in which poetry and myth and symbolic difficulty have a place. George Lamming (1927–) and John Hearne (1926–) are both notable for firm and economical prose and masterly scene painting. The aesthetic prospects for the West Indian novel seem excellent, but the absorption of its practitioners into the larger English-speaking world represents a symptom that plagues the practice of literature in so many Commonwealth countries—the lack of adequate publishing facilities and, more than that, the failure of a cultivated readership to emerge. It is undoubtedly unhealthy for an author to have to seek primary communication with foreigners.

EUROPE

Russian. The Russian novel properly begins with Nikolay Karamzin (1766–1826), who introduced into Russian literature not only the exotic sentimental romanticism best seen in his novels *Poor Lisa* and *Natalya, the Boyar's Daughter* but that large Gallic vocabulary which was to remain a feature of the literary language. But those qualities that best distinguish Russian fiction—critical realism and spirituality—first appeared in the work of Mikhail Lermontov (1814–41), whose *Hero of Our Time* is the pioneering Russian psychological novel. Nikolay Gogol (1809–52), satirizing provincial mores in *Dead Souls*, ushered in, perhaps unintentionally, a whole fictional movement—the "literature of accusation." Vissarion Belinsky (1811–48), the father of Russian literary criticism, formulated the theory of literature in the service of society, and Ivan Turgenev (1818–83), produced a classic "accusatory" novel in *A Sportsman's Sketches*. But he, and the other major novelists who emerged in the mid-19th century, can hardly be considered in terms of literary movements. Fyodor Dostoyevsky (1821–81), with *The Possessed, The Idiot, Crime and Punishment*, and *The Brothers Karamazov*, affirmed with idiosyncratic power the great spiritual realities, and Leo Tolstoy (1828–1910) produced two of the greatest novels of all time—*War and Peace* and *Anna Karenina*, revelatory of the Russian soul but also of the very nature of universal man and human society. The later days of the 19th century saw a shift in fictional radicalism. Marx influenced the accusatory writers in the direction of the plight of the proletariat, not, as had been the old way, that of the peasantry. Maksim Gorky (1868–1936), Leonid Andreyev (1871–1919), Aleksandr Kuprin (1870–1938) and the Nobel Prize winner (1933) Ivan Bunin (1870–1953) wrote of the Russian urban experience and helped to create the literary climate of the Soviet regime. Generally, since the beginning of the first five-year plan in 1928, there has been a division between what the regime regards as valuable in the practice of the novel and what the rest of the world thinks. Mikhail Sholokhov (1905–) depicted, with no evident propagandist slanting, the Revolution and civil war in *Quiet Flows the Don*, and Fyodor Gladkov (1883–1958) was one of the few novelists readable outside the ranks of the Soviet devout in the new category of economic or industrial fiction. The Russian novel of the age following World War II, however, has undergone a dramatic schism, in which writers like Aleksandr Solzhenitsyn (1918–) and Boris Pasternak (1890–1960) receive the Nobel Prize but are officially condemned in the U.S.S.R., while the fictional darlings of the regime are recognized, in the non-Communist world, as possessing little or no aesthetic merit.

The influence of the Soviet government

German. Goethe (1749–1832), who practiced so many arts with such notable brilliance, may be regarded as the first major novelist of Germany. His life covers the whole period of the Enlightenment, with its insistence on a national literary spirit, the *Sturm und Drang* movement, and that phase of *Weltschmerz* which *The Sorrows of Werther* fostered. It was *Werther* more than any other work that carried German literature into the world arena; it remained influential in Europe when German Romanticism had already burned itself out. The German reaction against Romanticism was expressed in the regionalism of Theodor Storm (1817–88) and Fritz Reuter (1810–74), who sought to render with objective fidelity the life of their native provinces (northwestern and northeastern Germany, respectively). Swiss writers like Gottfried Keller (1819–90) belonged to the movement of mainstream German regional realism, featuring the picturesque solidities of Switzerland. But the post-Goethean major achievements in the novel had to wait for the Impressionist movement, which produced the works of Thomas Mann (1875–1955) and Hermann Hesse (1877–1962)—fiction concerned less with a roughly hacked slice of life than with form and aesthetic delicacy. World War I brought Expressionism—the nightmares of the German-Czech Franz Kafka (1883–1924) and the psychoanalytical novels of Jakob Wassermann (1873–1934), with their pleas for humanity and justice. When the true historical nightmare of the Nazi regime followed—predicted, in a sense, by Kafka—liberal German fiction was suppressed, and liberal German novelists like Mann and Erich Maria Remarque (1898–1970), author of *All Quiet on the Western Front*, went into exile. The brutal, philistine, and nationalistic novels of the true Nazi novelists exist only as curious and frightening relics of an era of infamy. The task of postwar novelists like Günter Grass (1927–)—author of *The Tin Drum* and *Dog Years*—and Uwe Johnson (1934–) has been to diagnose the long sickness and force German fiction into new directions—often with the help of surrealism, irony, and verbal experiment.

Suppression of the novel by the Nazis

French. Although the mid-16th-century satirical piece *Gargantua and Pantagruel* of François Rabelais has had, and is still having, a profound influence on the world novel, it would be wrong to place it in the line of true French fiction, which has always manifested a preoccupation with form, order, and economy—qualities totally un-Rabelaisian. The first notable French novel—*The Princess of Clèves* by Madame de La Fayette (1634–93)—shows none of the vices of the English novels of a century later: it is firmly constructed and takes character seriously, as does the *Manon Lescaut* of l'Abbé Prévost (1697–1763). With such works the psychological novel was established in Europe. A keen hold on reality and a concern with the problems of man as a social being animates even the fiction of the Romantic school—works like *Indiana* and *Lélia* by George Sand (1804–76) and the heavyweight romances of Victor Hugo (1802–85). But the true glories of French fiction come with the reaction to romanticism and sentimentality, as exemplified in the novels of Jean-Jacques Rousseau (1712–78). The great fathers of realism are Stendhal (1783–1842), Balzac (1799–1850), and Flaubert (1821–80), and their influence is still active. Émile Zola (1840–1902) moved away from the artistic detachment that Flaubert preached and practiced, but, in his *Chronicles of the Rougon Macquart Family*, he tried to emulate the encyclopaedic approach to the novel of Balzac, whose *Human Comedy* is meant to be a history of society in a hundred episodes. The leader of the Naturalist school, Zola saw human character as a product of heredity and environment. It was left to the 20th-century French novel to cast doubt on a mechanistic or deterministic view of man, to affirm the irrational element in his makeup, and to emphasize the primacy of the will. The temporal treadmill of Balzac and Zola has no place in the masterpiece of Marcel Proust (1871–1922); *Remembrance of Things Past*, if it has a philosophy, says more about the creative élan vital of Bergson, the human essences that underlie the shifting phenomena of time and space, than the social jungle the realists had taken for reality. André Gide (1869–1951) seems to make a plea for human aloofness from environment so that the essentially human capacity for change and growth may operate. André Malraux (1901–), the forerunner of the Existentialist novelists, demonstrated, in *Man's Fate*, the necessity for human involvement in action as the only answer to the absurdity of his position in a huge and indifferent or malevolent universe. Jean-Paul Sartre (1905–) and Albert Camus (1913–60) similarly emphasized man's freedom to choose, to say no to evil, to define himself through action.

The realist masters

Other French novelists have been more concerned with recording the minutiae of human life as a predominantly sensuous and emotional experience, like Colette (1873–1954), or with taking the religious sensibility as a fictional theme, like François Mauriac (1855–1970). The practitioners of the *anti-roman*—Butor, Robbe-Grillet, Nathalie Sarraute—pursue their attempts at liquidating human character in the traditional novelistic sense. Samuel Beckett (1906–), an Irishman who has turned himself into a major French stylist, goes his own way, presenting—in works like *Molloy, Malone Dies, Watt* and *The Unnamable*—mankind reduced to degradation and absurdity but somehow admirable because he survives.

French-Canadian fiction inevitably suffers from comparison with the glories of the mother country. Before 1900 there is little of value to record—except perhaps the historical romance of Philippe de Gaspé (1786–1871), *Les Anciens Canadiens*—but Louis Hémon (1880–1913) produced a genuine classic in *Maria Chapdelaine*, a story of Canadian pioneer life, original, moving, and sensitive. The somewhat provincial character of French-Canadian life, dominated by the Church and by outmoded notions of morality, has not been conducive either to fictional candour or to formal experiment, and metropolitan France is unimpressed, for the most part, by the literature of the separated brethren. But there is time for an avant-garde to develop and great masters to appear.

French-Canadian novels

Spanish. The great age known as "El Siglo de Oro," or Golden Age, produced what is conceivably (it must contest this claim with *War and Peace*) the most magnificent of all novels—the *Don Quixote* of Miguel de Cervantes Saavedra (1547–1616). A satire on chivalry which ends as a humane affirmation of the chivalric principle, it encloses—in tender or comic distortion—other fictional forms that flourished in the Spanish Golden Age. The *novela picaresca* fathered a whole European movement, and its best monuments are perhaps the anonymous *Lazarillo de Tormes* (1554), the *Guzmán de Alfarache* of Mateo Alemán (1547–?1614) and *The Limping Devil* (*El diablo cojuelo*) of Luis Vélez de Guevara (1579–1644). The pastoral novel, another popular but highly stylized form, was less true fiction than a sort of prose poem, in which lovers in shepherd's disguise bewailed an unattainable or treacherous mistress. But here, since the fictional lovers were often real-life personages in the cloak of a rustic name, the germs of the *roman à clef* are seen stirring. The *novela Morisca* was an inimitable Spanish form, a kind of fictional documentary about the wars between Christians and Muslims, as in *Guerras civiles de Granada* (*Civil Wars of Granada*) by Ginés Pérez de Hita (1544?–?1619).

The Golden Age in Spain

The decline of Spain as a European power is associated, in literature, with feeble nostalgia for the Golden Age or feebler imitations of French classicism. The Spanish novel began to re-emerge only in the early 19th century, when a kind of journalism celebrating regional customs encouraged the development of the realistic regional novel, with Fernán Caballero (1796–1877), Armando Palacio Valdés (1853–1938), and the important Vicente Blasco Ibáñez (1867–1928), whose *Sangre y arena* (*Blood and Sand*), *Mare nostrum*, and *Los cuatro jinetes del Apocalipsis* (*The Four Horsemen of the Apocalypse*) achieved universal fame and were adapted for the screen in the 1920s. The fiction of the so-called Generation of 1898—which took its name from the year of the Spanish-American War, a cataclysmic event for Spain that bereaved it of the last parts of a once great empire—wasted no time on national nostalgia or self-pity, but concentrated on winning a new empire of style. Ramón Mariá del Valle-Iclán (1866–1936) and Pérez de Ayala (1880–1962) brought a highly original lyricism to the novel, while Pío Baroja (1872–1956) concentrated on representing a world of discrete events, unbound by a unifying philosophy. The fiction that came out of the Civil War of 1936–39 returned to a kind of didactic realism, as with José Mariá Gironella (1917–), who depicted a ravaged and suffering Spain. Camilo José Cela (1916–), perhaps the most important modern Spanish novelist, combines realism with a highly original style. His *Familia de Pascual Duarte*—harrowing, compassionate, brilliantly economical—is a novel of towering merit.

Italian. Though Italy originated the *novella*, it was slow in coming to the full-length novel. There is little to record before *I promessi sposi* (*The Betrothed*) by Alessandro Manzoni (1785–1873), a romantic and patriotic novel that describes life in Italy under Spanish domination in the 17th century. That combination of regionalism and realism already noted in the fiction of Germany and Spain did not appear in Italy until after the unification in 1870, when Giovanni Verga (1840–1922) celebrated his native Sicily in *I malavoglia* (*The House by the Medlar Tree*) and Antonio Fogazzaro (1842–1911) showed life in northern Italy during the struggle for unification in *Piccolo mondo antico* (*Little World of the Past*). Gabriele D'Annunzio (1863–1938) and Luigi Pirandello (1867–1936) were too original for easy classification, and both worked in all the literary media. Pirandello, especially, helped to bring Italian literature into the modern world through such philosophical novels as *Il fu Mattia Pascal* (*The Late Matthew Pascal*), which raises very profound questions about the nature of human identity and yet contrives to be witty, sunny, and essentially Italianate. The importance of Italo Svevo (1861–1928) was obscured for some time because of the difficulty of Italian literati in accepting the Triestine dialect as a literary medium, but works like *Zeno* and *Senilitá* (a title which James Joyce, Svevo's friend and English teacher, translated *As a Man Grows Older*) are recog-

nized as being major contributions to the international novel.

The significant fiction of the Mussolini regime was produced by anti-Fascist exiles like Giuseppe Borgese (1882–1952) and Ignazio Silone (1900–), whose *Pane e vino* (*Bread and Wine*) is accepted as a 20th-century classic. Alberto Moravia (1907–), with his *Romana* (*Woman of Rome*) and *Noia* (*The Empty Canvas*), is perhaps the most popular Italian novelist outside Italy, but he is probably less important than Giuseppe Berto (1914–), Cesare Pavese (1908–1950), and Elio Vittorini (1908–1966). Giuseppe di Lampedusa (1896–1957) created a solitary masterpiece in *Il gattopardo* (*The Leopard*). The experimental writing of Italo Calvino and Carlo Emilio Gadda is becoming better known outside Italy, but, generally speaking, the Italian novel remains linguistically conservative and needs the impact of some new powerfully iconoclastic literary figure like James Joyce.

Scandinavian languages. Norway is better known for Ibsen's contribution to the drama and Grieg's to music than for fiction of the first quality. Nevertheless, the novels of Knut Hamsun (1859–1952) earned him the Nobel Prize in 1920, and Sigrid Undset (1882–1949) received the same honour in 1928, though the work of both has failed to engage the lasting attention of world readers of fiction. In Denmark, Johannes Vilhelm Jensen (1873–1950), another Nobel prizeman, Isak Dinesen, the pen name of Baroness Karen Blixen (1885–1962), and Martin Nexö (1869–1954) have contributed to their country's fictional literature but made little mark beyond. The achievement of Sweden's novelists is very inconsiderable, but Halldór Kiljan Laxness (1902–) has restored to Iceland the literary fame it once earned for its sagas.

Slavic and east European. Czechoslovakia's greatest novelist, Franz Kafka, wrote in German, but its writers in the vernacular include world-famous names, such as Jaroslav Hasek (1883–1923), whose *Good Soldier Schweik* is acknowledged to be a comic masterpiece, and Karel Čapek (1890–1938), best-known for the plays *R.U.R.* (which gave "robot" to the world's vocabulary) and *The Life of the Insects*, but also notable for the novels *The Absolute at Large*, *Krakatit*, and *War with the Newts*. The Czech fictional genius tends to the satirical and the fantastic. The fiction of Yugoslavia has made little impact on the progress of the novel, but Radomir Konstantinovič (1928–) should be noted: his *Exitus* is a remarkable study of the death of Christ. Poland can claim two Nobel prizewinning novelists in Henryk Sienkiewicz (1846–1916), the author of *Quo Vadis?*, and Władysław S. Reymont (1868–1925), whose novel *The Peasants* is an aromatic piece of bucolic realism. Witold Gombrowicz (1904–1969) wrote a novel, *Ferdydurke*, which has been subjected to two separate modes of suppression—first Fascist, later Communist. A remarkable surrealist essay on "anal tyranny" and depersonalisation, it still awaits the acclaim that is due. Romania, which produced outstanding novelists in E. Lovínescu and Titu Maiorescu, has suffered, like other Balkan countries, from the totalitarian suppression of the free creative spirit; but Dumitru Radu Popescu, author of *The Blue Lion*, was bold enough in the 1960s to question Communist orthodoxy through the medium of fiction. The Hungarian Gusztáv Rab (1901–1966) awaits recognition. His brilliant *Sabaria* develops very courageously the theme of the conflict between Communism and Christianity and reaches conclusions favourable to neither. It is a disturbing and beautifully composed book. Modern Greece, more famous for its poets George Seferis and Constantine Cavafy, has produced at least one major novelist in Nikos Kazantzakis (1885–1957), whose *Zorba the Greek* became famous through its film adaptation. *The Last Temptation*, which presents the life of Christ as a struggle to overcome "the dark immemorial forces of the Evil One, human and pre-human," glows with the writer's personality and bristles with the dialectic that was one of the first Greek gifts to Western civilization.

The Jewish novel. The literature of the Diaspora—the dispersion of the Jews after their exile from ancient Babylonia—records many large achievements in the languages of exile and that dialect of Low German—Yiddish—which the Ashkenazi Jews have taken around the world. Perhaps the most interesting of modern Jewish novelists in Yiddish is Isaac Bashevis Singer (1904–), an American who refuses to be absorbed linguistically into America, unlike Bellow and Malamud, who have brought to the Anglo-American language typical tones and rhythms of the ghetto. Israel, which is producing its own rich crop of national writers, began with an existing corpus of literature in modern Hebrew, a language promoted and nurtured by such scholars as Eliezer ben Yehuda (1858–1923) and the members of the neologizing Hebrew Academy of Israel. Among the early novelists is Abraham Mapu (1808–1867); among the later ones is the brilliant Moshe Shamir (1921–). The first Nobel Prize for Literature ever awarded to a Hebrew novelist went, justly, to Shmuel Yosef Agnon (1888–1970). The contemporary Hebrew novel is notable for a fusion of international sophistication and earthy homegrown realism.

ASIA, AFRICA, LATIN AMERICA

China. The tradition of storytelling is an ancient one in China, and the full-length novel can be found as far back as the late 16th century. The fiction of the 18th century shows a variety of themes and techniques not dissimilar to those of Europe, with social satire, chivalric romance, and adventure stories. Ts'ao Hsüeh-ch'in (died 1763) wrote a novel called *Hung lou meng* (translated as *The Dream of the Red Chamber* in 1892), which has features not unlike those of Galsworthy's *The Forsyte Saga* and Mann's *Buddenbrooks*—a story of a great aristocratic family in decline, garnished with love interest and shot through with pathos. The early days of the 20th century saw the foundation of the Chinese republic and the development of popular fiction in the national language (*pai-hua*). From 1917 until the Sino-Japanese War (1937–1945), a period of social and intellectual ferment, there was a great influx of Western novels, and, under their influence, movements like those devoted to realism and naturalism in Europe produced a great number of didactic novels. Novels like Mao Tun's *Rickshaw Boy* and Pa Chiu's *Chinese Earth* appeared in the postwar period, but the Communist regime has quelled all but propagandist fiction. Such novels as Liu Ching's *Wall of Bronze*, Chao Shu-li's *Changes in Li Village*, and Ting Ling's *Sun Shines over the Sangkan River* are typical glorifications of the Mao philosophy and the socialist achievements of the people.

Japan. A literature that admires economy, like the Japanese, is bound to favour, in fictional art, the short story above the full-length novel. Nevertheless, some of the ancient pillow-books, with their diary jottings and anecdotes, have the ring of autobiographical novels; while Murasaki Shikibu's *Tale of Genji*, produced nearly a thousand years ago, is a great and sophisticated work of fictional history. The 20th-century Japanese novel has been developed chiefly under Western influence, like the work of Akutagawa Ryūnosuke (1892–1927), whose *Yabunoaka* became the highly applauded film *Rashomon*. Tanizaki Jun-ichirō (1886–) is well known in America and Europe for *The Key*, *The Makioka Sisters*, and *Diary of a Mad Old Man*. His novels, all set in a modern, Westernized Japan, are assured of universal popularity because of their frank and lavish sexual content. Mishima Yukio (1925–1970), who committed ceremonial suicide at the height of his reputation, was perhaps the most successful, and certainly the most prolific, of all modern Japanese novelists. Ten of his fictions had been filmed; he had won all the major Japanese literary awards and appeared to be destined for the Nobel Prize. His works are characterized by ruthless violence and a perversity that, however much it seems to derive from the pornographic excesses of Western fiction, is certainly in the Japanese tradition. His work is hard to judge, but he was the most considerable literary figure of the East.

Western influences

The Indies. The Indian novel is a branch of British Commonwealth literature. That is to say, it is practiced by writers who have received a British literary education and, for the most part, publish their books in London.

There is no evidence of any great development of fiction in any of the native Indian tongues: a taste for reading novels, as opposed to seeing films or reading short stories in the Hindi or Punjabi press, is acquired in India along with an education in English, which is still the unifying tongue of the subcontinent. In Malaysia, where the same tradition holds among the literate, short stories are being written in Malay, Chinese, and Tamil, but the full-length novel is almost exclusively written in English. It is as much a matter of literary markets as of literary education. No novel in any of the tongues of the peninsula is likely to be a remunerative publishing proposition, as Han Suyin (1917–)—a best selling Chinese woman doctor from Johore, who found large fame with *A Many-Splendoured Thing*—would be the first to admit, for all her dislike of the British colonial tradition. Indonesia's abandonment of all vestiges of its Dutch colonial past is associated with the encouragement of a literature in Bahasa (a dialect of Malay), and there are a number of Indonesian novelists still looking for a large educated audience—inevitably in translation, in the West. Among these Mochtar Lubis (1922–) is notable; his *Twilight in Djakarta* is a bitter indictment of the Sukarno regime, which promptly sent him to prison. This was not the kind of fiction that the new Indonesia had in mind.

Africa. What applies to India and the East Indies applies also to Africa: there is still an insufficiently large audience for fiction written in any of the major African languages, and African novelists brought up on English are only too happy to continue working in it. Other European languages—chiefly Afrikaans (a South African variety of Dutch) and French—are employed as a fictional medium. Arthur Fula, who wrote *Janie Giet die Beeld* (*Janie Casts the Image*), is an Afrikaans novelist whose reputation has not, as yet, stretched to Europe or America, but the novelists of the former French possessions are gaining a name among serious students of the African novel. Mongo Beti (1932–), from the Cameroons, is known for his *Pauvre Christ de Bomba* and *Roi miraculé*; the Ivory Coast has Aké Loba, and Hamidou Kane (1928–) represents Senegal. This new African French deserves to be regarded as a distinct literary language, unrelated to that of Paris or Quebec, but the critical and linguistic tools for appraising the fiction of French-speaking Africans are not yet available.

Latin America. One of the greatest contemporary writers of fiction, Jorge Luis Borges (1899–), is an Argentinian, but his *ficciones* are very short short stories and must, with regrets, be excluded from any survey of the novel. It is significant, however, that the circumstances for the creation of a great fictional literature are in existence in Latin America, signifying (unlike the case in many former British dependencies) a shedding of the old colonial provincialism, which relied on the opinion of Madrid or, in Brazil, of Lisbon. The first Latin American novel was probably *The Mangy Parrot*, by the Mexican José Joaquín Fernández de Lizardi (1776–1827), a picaresque work satirizing colonial conditions. In Argentina, José Mármol (1817–1871) published the first major novel of the continent—*Amalia*, a powerful study of the fear and degradation that were rife in Buenos Aires during the dictatorship of the corrupt and tyrannical Rosas. The Romantic period in Europe had its counterpart in the sentimental wave that overtook such novelists as the Colombian Jorge Isaacs (1837–1895), while the new humanitarianism found a voice in *Birds Without a Nest*, a protest-novel on the conditions forced on the Indians of Peru, written by Clorinda Matto de Turner (1854–1901). Juan León Mera followed the same trend in *Cumandá*, a novel about the oppression of the Ecuadorian Indians. As Latin America moved toward the modern age, the inevitable novels of urban social protest made their appearance. Alberto Blest Gana (1830–1920) of Chile, Carlos Reyles (1868–1938) of Uruguay, and Gustavo Martínez Zuviría of the Argentine are names of some historical significance; and Reyles's naturalistic novel *La Raza de Caín* (*Cain's Race*) is original in that it finds a parallel between the breeding of stock and the building of a human society.

Rise of nativism

A 20th-century reaction against the bourgeois novel led to the movement known as nativism, with its concentration on the land itself, the lot of the indigenous peoples, the need for an anti-racist revolution with the aim of true egalitarianism. *The Underdogs*, by the Mexican Mariano Azuela (1873–1952), and *El Señor Presidente*, by Miguel Angel Asturias (1899–) from Guatemala, typify the new revolutionary novel. Much of the didactic energy that went to the making of such work resulted in a lack of balance between subject matter and style: the literature of revolt tends to be shrill and crude. The inevitable reaction to a more sophisticated kind of literature, in which the individual became more important than society and the unconscious more interesting than the operation of reason, led to the highly refined experimentation that is the mark of Borges, the Brazilian Érico Veríssimo, and Eduardo Barrios of Chile.

The fiction of Brazil is in many ways more interesting than the fiction of the mother country, which has produced only one major novelist in the realist José Maria de Eça de Queirós (1845–1900). Gregório de Matos Guerra, as early as the 17th century, wrote bitterly of colonial administration and painted a realistic picture of Brazilian life. Irony and keen observation have been characteristic of the Brazilian novel ever since—as in the *Brás Cubas* and *Dom Casmurro* of Joaquim Maria Machado de Assis (1839–1908); the *Canaan* of José Pereira da Graça Aranha (1868–1931), a remarkable study of the disillusion of German settlers in a new land; and the *Os Sertões* (*Rebellion in the Backlands*) of Euclides da Cunha (1866–1909), an account of a revolt against the newly formed Brazilian republic. The social consciousness of Brazilian novelists is remarkable, especially when it is associated with a strong concern for stylistic economy and grace. Monteiro Lobato (1882–1948), with his rustic hero Jeca Tatú; José Lins do Rêgo (1901–1957), chronicler of the decay of the old plantation life; Jorge Amado (1912–), a socialist novelist much concerned with slum life in Bahia; Érico Veríssimo (1905–), an experimental writer grounded in the traditional virtues of credible plot and strong characterization—these attest a vigour hardly to be found in the fiction published in Lisbon.

III. Social and economic aspects of the novel

Though publishers of fiction recognize certain obligations to art, even when these are unprofitable (as they usually are), they are impelled for the most part to regard the novel as a commercial property and to be better pleased with large sales of indifferent work than with the mere unremunerative acclaim of the intelligentsia for books of rare merit. For this reason, any novelist who seeks to practice his craft professionally must consult the claims of the market and effect a compromise between what he wishes to write and what the public will buy. Many worthy experimental novels, or novels more earnest than entertaining, gather dust in manuscript or are circulated privately in photocopies. Indeed, the difficulty that some unestablished novelists find in gaining a readership (which means the attention of a commercial publisher) has led them to take the copying machine as seriously as the printing press and to make the composition, mimeographing, binding, and distribution of a novel into a single cottage industry. For the majority of novelists the financial rewards of their art are nugatory, and only a strong devotion to the form for its own sake can drive them to the building of an *oeuvre*. The subsidies provided by university sinecures sustain a fair number of major American novelists; others, in most countries, subvent their art by practicing various kinds of subliterature—journalism, film scripts, textbooks, even pseudonymous pornography. Few novelists write novels and novels only.

Awards, patronage, and ancillary activities

There are certain marginal windfalls, and the hope of gaining one of these tempers the average novelist's chronic desperation. America has its National Book Award as well as its book club choices; France has a great variety of prizes; there are also international bestowals; above all, there glows the rarest and richest of all accolades—the Nobel Prize for Literature. Quite often the Nobel prizeman needs the money as much as the fame, and his

election to the honour is not necessarily a reflection of a universal esteem which, even for geniuses like Samuel Beckett, means large sales and rich royalties. When Sinclair Lewis received the award in 1930, wealth and fame were added to wealth and fame already sufficiently large; when William Faulkner was chosen in 1949, most of his novels had been long out of print in America (if not in Sweden).

Prizes come so rarely, and often seem to be bestowed so capriciously, that few novelists build major hopes on them. They build even fewer hopes on patronage: Harriet Shaw Weaver, James Joyce's patroness, was probably the last of a breed that, from Maecenas on, once intermittently flourished; state patronage—as represented, for instance, by the annual awards of the Arts Council of Great Britain—can provide little more than a temporary palliative for the novelist's indigence. Novelists have more reasonable hopes from the world of the film or the stage, where adaptations can be profitable and even salvatory. The long struggles of the British novelist T.H. White came to an end when his Arthurian sequence *The Once and Future King* (1958) was translated into a stage musical called *Camelot*, though by treating the lump sum paid to him as a single year's income instead of a reward for decades of struggle, nearly all the windfall would have gone for taxes if White had not taken his money into low-tax exile. Such writers as Graham Greene, nearly all of whose novels have been filmed, must be tempted to regard mere book sales as an inconsiderable aspect of the rewards of creative writing. There are few novelists who have not received welcome and unexpected advances on film options, and sometimes the hope of film adaptation has influenced the novelist's style. In certain countries, such as Great Britain but not the United States, television adaptation of published fiction is common, though it pays the author less well than commercial cinema.

When a novelist becomes involved in film-script writing —either in the adaptation of his own work or that of others—the tendency is for him to become subtly corrupted by what seems to him an easier as well as more lucrative technique than that of the novel. Most novelists write dialogue with ease, and their contribution to a film is mostly dialogue: the real problem in novel writing lies in the management of the *récit*. A number of potentially fine novelists, like Terry Southern and Frederic Raphael, have virtually abandoned the literary craft because of their continued success with script writing. In 70-odd years the British novelist Richard Hughes produced only three novels, the excellence of which has been universally recognized; fiction lovers have been deprived of more because of the claims of the film world on Hughes's talent. This kind of situation finds no counterpart in any other period of literary history, except perhaps in the Elizabethan, when the commercial lure of the drama made some good poets write poor plays.

The importance of the paperback

The majority of professional novelists must look primarily to book sales for their income, and they must look decreasingly to hard-cover sales. The novel in its traditional format, firmly stitched and sturdily clothbound, is bought either by libraries or by readers who take fiction seriously enough to wish to acquire a novel as soon as it appears: if they wait 12 months or so they can buy the novel in paper covers for at most a fifth of its original price. The paperback edition of a novel has become, for the vast majority of fiction readers, the form in which they first meet it, and the novelist who does not achieve paperback publication is missing a vast potential audience. He may not repine at this, since the quantitative approach to literary communication may safely be disregarded: the legend on a paperback cover—FIVE MILLION COPIES SOLD—says nothing about the worth of the book within. Nevertheless, the advance he will receive from his hard-cover publisher is geared to eventual paperback expectations, and the "package deal" has become the rule in negotiations between publisher and author's agent. The agent, incidentally, has become important to both publisher and author to an extent that writers like Daniel Defoe and Samuel Richardson would, if resurrected, find hard to understand.

The novelist may reasonably expect to augment his income through the sale of foreign rights in his work, though the rewards accruing from translation are always uncertain. The translator himself is usually a professional man and demands a reasonable reward for his labours, more indeed than the original author may expect: the reputations of some translators are higher than those of some authors, and even their names may be better known. Moreover, the author who earns most from publication in his own language will usually earn most in translation, since it is the high initial home sales that attract foreign publishers to a book. The more "literary" a novel is, the more it exploits the resources of the author's own language, the less likely is it to achieve either popularity at home or publication abroad. Best-selling novels like Mario Puzo's *Godfather* (1969) or Arthur Hailey's *Airport* (1968) are easy to read and easy to translate, so they win all round. It occasionally happens that an author is more popular abroad than he is at home: the best-selling novels of the Scottish physician-novelist A.J. Cronin are perhaps no longer highly regarded in England and America, as they were in the 1930s and 1940s, but they still sell by the million in the U.S.S.R. But a novelist is wisest to expect most from his own country and to regard foreign popularity as an inexplicable bonus.

Problems of obscenity and libel

As though his financial problems were not enough, the novelist frequently has to encounter those dragons unleashed by public morality or by the law. The struggles of Flaubert, Zola, and Joyce, denounced for attempting to advance the frontiers of literary candour, are well known and still vicariously painful, but lesser novelists, working in a more permissive age, can record cognate agonies. Generally speaking, any novelist writing after the publication in the 1960s of Hubert Selby's *Last Exit to Brooklyn* or Gore Vidal's *Myra Breckenridge* can expect little objection, on the part of either publisher or police, to language or subject matter totally unacceptable, under the obscenity laws then operating, in 1922, when *Ulysses* was first published. This is certainly true of America, if not of Ireland or Malta. But many serious novelists fear an eventual reaction against literary permissiveness as a result of the exploitation by cynical obscenity mongers or hard-core pornographers of the existing liberal situation.

In some countries, particularly Great Britain, the law of libel presents insuperable problems to novelists who, innocent of libellous intent, are nevertheless sometimes charged with defamation by persons who claim to be the models for characters in works of fiction. Disclaimers to the effect that "resemblances to real-life people are wholly coincidental" have no validity in law, which upholds the right of a plaintiff to base his charge on the corroboration of "reasonable people." Many such libel cases are settled before they come to trial, and publishers will, for the sake of peace and in the interests of economy, make a cash payment to the plaintiff without considering the author's side. They will also, and herein lies the serious blow to the author, withdraw copies of the allegedly offensive book and pulp the balance of a whole edition. Novelists are seriously hampered in their endeavours to show, in a traditional spirit of artistic honesty, corruption in public life; they have to tread carefully even in depicting purely imaginary characters and situations, since the chance collocation of a name, a profession, and a locality may produce a libellous situation.

EVALUATION AND STUDY

It has been only in comparatively recent times that the novel has been taken sufficiently seriously by critics for the generation of aesthetic appraisal and the formulation of fictional theories. The first critics of the novel developed their craft not in full-length books but in reviews published in periodicals: much of this writing—in the late 18th and early 19th centuries—was of an occasional nature, and not a little of it casual and desultory; nor, at first, did critics of fiction find it easy to separate a kind of moral judgment of the subject matter from an aesthetic judgement of the style. Such fragmentary observations on the novel as those made by Dr. Johnson in conversation

or by Jane Austen in her letters, or, in France, by Gustave Flaubert during the actual process of artistic gestation, have the charm and freshness of insight rather than the weight of true aesthetic judgment. It is perhaps not until the beginning of the 20th century, when Henry James wrote his authoritative prefaces to his own collected novels, that a true criteriology of fiction can be said to have come into existence. The academic study of the novel presupposes some general body of theory, like that provided by Percy Lubbock's *Craft of Fiction* (1921) or E.M. Forster's *Aspects of the Novel* (1927) or the subsequent writings of the critics Edmund Wilson and F.R. Leavis. Since World War II it may be said that university courses in the evaluation of fiction have attained the dignity traditionally monopolized by poetry and the drama.

The distinction between reviewing and criticism

A clear line should be drawn between the craft of fiction criticism and the journeyman work of fiction reviewing. Reviews are mainly intended to provide immediate information about new novels: they are done quickly and are subject to the limitations of space; they not infrequently make hasty judgments that are later regretted. The qualifications sought in a reviewer are not formidable—smartness, panache, waspishness, qualities that often draw the attention of the reader to the personality of the reviewer rather than the work under review—will always be more attractive to circulation-hunting editors than a less spectacular concern with balanced judgment. A thoughtful editor will sometimes put the reviewing of novels into the hands of a practicing novelist, who—knowing the labour that goes into even the meanest book—will be inclined to sympathy more than to flamboyant condemnation. The best critics of fiction are probably novelists *manqués*, men who have attempted the art and, if not exactly failed, not succeeded as well as they could have wished. Novelists who achieve very large success are possibly not to be trusted as critics: obsessed by their own individual aims and attainments, shorn of self-doubt by the literary world's acclaim or their royalty statements, they bring to other men's novels a kind of magisterial blindness.

Novelists can be elated by good reviews and depressed by bad ones, but it is rare that a novelist's practice is much affected by what he reads about himself in the literary columns. Genuine criticism is a very different matter, and a writer's approach to his art can be radically modified by the arguments and summations of a critic he respects or fears. As the hen is unable to judge of the quality of the egg it lays, so the novelist is rarely able to explain or evaluate his work. He relies on the professional critic for the elucidation of the patterns in his novels, for an account of their subliminal symbolism, for a reasoned exposition of their stylistic faults. As for the novel reader, he will often learn enthusiasm for particular novelists through the writings of critics rather than from direct confrontation with the novels themselves. The essays in Edmund Wilsons' *Axel's Castle* (1931) aroused an interest in the Symbolist movement which the movement was not easily able to arouse by itself; the essay on *Finnegans Wake*, collected in Wilson's *Wound and the Bow* (1941), eased the way into a very difficult book in a manner that no grim work of solid exegesis could have achieved. The essence of the finest criticism derives from wisdom and humanity more than from mere expert knowledge. Great literature and great criticism possess in common a sort of penumbra of wide but unsystematic learning, a devotion to civilized values, an awareness of tradition, and a willingness to rely occasionally on the irrational and intuitive.

All this probably means that the criticism of fiction can never, despite the efforts of aestheticians schooled in modern linguistics, become an exact science. A novel must be evaluated in terms of a firmly held literary philosophy, but such a philosophy is, in the final analysis, based on the irrational and subjective. If the major premises on which F.R. Leavis bases his judgments of George Eliot, Mark Twain, and D.H. Lawrence are accepted, then an acceptance of the judgments themselves is inescapable. But many students of fiction who are skeptical of Leavis will read him in order that judgments of their own may emerge out of a purely negative rejection of his. In reading criticism a kind of dialectic is involved, but no synthesis is ever final. The process of revaluation goes on for ever. One of the sure tests of a novel's worth is its capacity for engendering critical dialectic: no novel is beyond criticism, but many are beneath it.

THE FUTURE OF THE NOVEL

It is apparent that neither law nor public morality nor the public's neglect nor the critic's scorn has ever seriously deflected the dedicated novelist from his self-imposed task of interpreting the real world or inventing alternative worlds. Statistics since World War II have shown a steady increase in the number of novels published annually, and beneath the iceberg tip of published fiction lies a whole submarine Everest of unpublished work. It has been said that every person has at least one novel in him, and the near-universal literacy of the West has produced dreams of authorship in social ranks traditionally deprived of literature. Some of these dreams come true, and taxi drivers, pugilists, criminals, and film stars have competed, often successfully, in a field which once belonged to professional writers alone. It is significant that the amateur who dreams of literary success almost invariably chooses the novel form, not the poem, essay, or autobiography. Fiction requires no special training and it can be readable, even absorbing, when it breaks the most elementary rules of style. It tolerates a literary incompetence unthinkable in the poem. If all professional novelists withdrew their labour, the form would not languish: amateurs would fill the market with first and only novels, all of which would find readership somewhere.

Amateur novelists

But the future of any art lies with its professionals. Here a distinction has to be made between the Joyces, Henry Jameses, and Conrads on the one hand, and the more ephemeral Mickey Spillanes, Harold Robbinses, and Irving Wallaces on the other. Of the skill of the latter class of novelists there can be no doubt, but it is a skill employed for limited ends, chiefly the making of money, and through it the novel can never advance as art. The literary professionals, however, are dedicated to the discovery of new means of expressing, through the experiential immediacies that are the very stuff of fiction, the nature of man and society. In the symbiosis of publishing, the best seller will probably continue to finance genuine fictional art. Despite the competition from other art media, and the agonies and the indigence, there are indications that the serious novel will flourish in the future.

It will flourish because it is the one literary form capable of absorbing all the others. The technique of the stage drama or the film can be employed in the novel (as in *Ulysses* and *Giles Goat-Boy*), as can the devices of poetry (as in Philip Toynbee's *Pantaloon* and the novels of Wilson Harris and Janet Frame). In France, as Michel Butor has pointed out, the new novel is increasingly performing some of the tasks of the old essay; in America, as Capote's *In Cold Blood* and Mailer's *Armies of the Night* have shown, the documentary report can gain strength from its presentation as fictional narrative. There are few limits on what the novel can do, there are many experimental paths still to be trod, and there is never any shortage of subject matter.

For all this, periods of decline and inanition may be expected, though not everywhere at once. The strength of the American novel in the period after World War II had something to do with the national atmosphere of breakdown and change: political and social urgencies promoted a quality of urgency in the works of such writers as Mailer, Bellow, Ellison, Heller, and Philip Roth. In the same period, England, having shed its empire and erected a welfare state, robbed its novelists of anything larger to write about than temporary indentations in the class system, suburban adultery, and manners. An achieved or static society does not easily produce great art. France, which has known much social and ideological turmoil, has generated a new aesthetic of the novel as well as a philosophy that, as Sartre and Camus have shown, is very suitable for fictional expression. A state on which intellectual quietism or a political philosophy of art is imposed

by the ruling party can, as the Soviet Union and China show, succeed only in thwarting literary greatness, but the examples of Pasternak and Solzhenitsyn are reminders that repression can, with rare artistic spirits, act as an agonizing stimulus.

Every art in every country is subject to a cyclical process; during a period of decline it is necessary to keep the communication lines open, producing minor art so that it may some day, unexpectedly, turn into major art. Wherever the novel seems to be dying it is probably settling into sleep; elsewhere it will be alive and vigorous enough. It is important to believe that the novel has a future, though not everywhere at once.

BIBLIOGRAPHY. The following works deal in general terms with the reader's approach to the novel: WALTER ALLEN, *Reading a Novel,* rev. ed. (1963); VAN METER AMES, *Aesthetics of the Novel* (1928, reprinted 1966); CLEANTH BROOKS and R.P. WARREN (eds.), *Understanding Fiction,* 2nd ed. (1959); ALEXANDER COMFORT, *The Novel and Our Time* (1948); PELHAM EDGAR, *The Art of the Novel* (1933, reprinted 1966); WILSON FOLLETT, *The Modern Novel: A Study of the Purpose and Meaning of Fiction,* rev. ed. (1923); E.M. FORSTER, *Aspects of the Novel* (1927, many reprintings); PERCY LUBBOCK, *The Craft of Fiction,* new ed. (1957).

The following are concerned with the problems of writing fiction and are all the work of novelists: PHYLLIS BENTLEY, *Some Observations on the Art of Narrative* (1946); *Conrad's Prefaces to His Works,* with an essay by EDWARD GARNETT (1937); HENRY JAMES, *The Art of Fiction and Other Essays,* ed. by MORRIS ROBERTS (1948), and *The Art of the Novel,* introduction by R.P. BLACKMUR (1934); EDITH WHARTON, *The Writing of Fiction* (1925); THOMAS WOLFE, *The Story of a Novel* (1936).

The various elements of the novel are dealt with in the following: BONAMY DOBREE, *Modern Prose Style,* 2nd ed. (1964); MAREN ELWOOD, *Characters Make Your Story* (1942); MANUEL KOMROFF, *How to Write a Novel* (1950); W. VAN O'CONNOR (ed.), *Forms of Modern Fiction* (1948); GEORGE G. WILLIAMS (ed.), *Readings for Creative Writers* (1938).

The following studies deal with the style and philosophy of the novel in the wider sense: DAVID DAICHES, *The Novel and the Modern World,* rev. ed. (1960); AGNES HANSEN, *Twentieth Century Forces in European Fiction* (1934); ALFRED KAZIN, *On Native Grounds* (1942); Y. KRIKORIAN (ed.), *Naturalism and the Human Spirit* (1944); GEORGE LUKACS, *Studies in European Realism* (1950); H.J. MULLER, *Modern Fiction* (1937).

(An.B.)

Novosibirsk

One of the most important cities of the Soviet Union, Novosibirsk is the administrative centre of Novosibirsk *oblast* (province) of the Russian Soviet Federated Socialist Republic and in many respects the capital of all Siberia. Its nodal position on the Trans-Siberian Railroad has caused the town to expand very greatly and rapidly, in step with the economic development of Siberia as a whole. With a population of 1,286,000 in 1976, Novosibirsk is the eighth largest city of the Soviet Union and outstanding both for industrial production and for its educational and scientific research facilities. The town stands on the Ob River, here about half a mile wide, where it is bridged by the Trans-Siberian Railroad just below the confluence of the Inya River. The relatively flat plateau on which Novosibirsk is built is deeply cut by ravines, the continued growth of which presents the city with a major problem; already ravines occupy nearly 15,000 acres (6,000 hectares) of the city territory. Novosibirsk *oblast* covers 68,800 square miles (178,200 square kilometres) and in 1975 had a population of 2,543,000; apart from Novosibirsk itself, it is mainly an agricultural area, with small local urban centres.

Climate

Novosibirsk has an extreme continental climate with a very severe winter. The mean temperature in January is 3.2° F (−16° C), in July 65.8° F (18.8° C). The highest summer temperatures reach 98.6° F (37° C), and in winter the temperature has been known to drop to −58° F (−50° C). In early winter, strong and bitterly cold winds are common. Annual precipitation averages 19.5 inches (495 millimetres), but it is extremely variable from year to year; more than half the total falls in summer, frequently in the form of torrential thunderstorms and hailstorms.

HISTORY

Novosibirsk might well be described as an offspring of the railway. In 1891 the engineer N.G. Garin-Mikhaylovsky, surveying the route for the Trans-Siberian Railroad, chose the small village of Krivoshchekovo on the Ob as the site for the bridging of the river. In 1893 work on the bridge was begun, and beside it a small settlement grew up. By 1897 the bridge was completed, and the settlement had developed into a township of 7,832 people. A landing was built on the Ob, and transshipment and river trade developed briskly. The new settlement was known variously as Gusevka or Aleksandrovsky, but in 1895 it was renamed Novonikolayevsk in honour of the accession of Tsar Nicholas II.

The next two decades saw steady growth, based chiefly on movement of freight by rail and river and on the locomotive depot. A number of small industrial enterprises were established, using local products and including two saw mills, seven flour mills, a tannery, a distillery, a soap works, and two iron-casting works—the beginnings of what was to become a major metallurgical and engineering industry. Shops, warehouses, a small hospital, and a cathedral were built, and in 1903 formal town status was conferred. By the time of the Revolution of 1917 the population had reached 69,000 within the old city boundaries. During the subsequent civil war, Novonikolayevsk was occupied in turn by the independent Czech brigade, the White Army of Adm. A.V. Kolchak and finally, at the end of 1919, by the Red Army. In 1925 the town was renamed Novosibirsk (meaning New Siberia).

The opening up of the mineral and timber wealth of Siberia in the Soviet period, especially after the beginning of the five-year plans in 1928, brought about a remarkably rapid growth of the city. In particular the development of the Kuznetsk (Kuzbass) Basin coalfield about a hundred miles to the east of the town, where mining had begun in the late 19th century, and the establishment there of a large-scale metallurgical industry, fostered the importance of Novosibirsk as a transit point. In 1934 a railway was completed directly linking the town to Novokuznetsk (then called Stalinsk), the principal town on the coalfield. A second factor in the growth of Novosibirsk was the completion in the early 1930s of the Turkistan–Siberian (Turksib) Railway, providing a direct link with Tashkent and Central Asia. Large new factories were established, and the town grew to 120,100 population in 1926 and to 405,600 in 1939, an average annual increment of almost 22,000, mostly by in-migration from other parts of the country.

Kuzbass

World War II, with its eastward evacuation of people and industrial plant from the war zone, still further stimulated growth. By 1959 the population was 886,000, and in 1963 the city passed the million mark. Although growth in the postwar years has been continuous, its rate has slackened; average growth between 1959 and 1970 was 3 percent per year, compared with 6 percent between 1939 and 1959 and 18 percent between 1926 and 1939. In terms of absolute increment there has been relatively little change, 24,000 annually between 1939 and 1959 and 25,000 between 1959 and 1970. To some extent Novosibirsk is affected by the high rate of labour turnover and out-migration that has been characteristic of most of Siberia since about 1960, although less acutely so than elsewhere; many migrants to the city are young and unskilled and leave after only a short stay, giving rise to problems of establishing a stable and skilled labour force.

THE CONTEMPORARY CITY

Administration and setting. Novosibirsk is designated an *oblast* town; that is, its town council is subordinated to the Novosibirsk *oblast* council, although both administrations are located in the town itself. The city limits enclose an area of 184 square miles (477 square kilometres), the third largest city territory in the Soviet Union, although this includes considerable areas of farmland and forest beyond the built-up area. Originally only on the right bank of the Ob, the town now extends to either side of the river and comprises nine administrative wards. Central Ward, on the right bank, is the oldest part

The opera and ballet theatre, Novosibirsk.
Sovfoto

of Novosibirsk and contains most of the principal public buildings, many constructed in the ponderous architectural style of the Stalin era, with much use of locally quarried gray granite. These include the offices of the city council and the local Communist Party organization and various branches of all-union and republican ministries, concerned with the economic development of West Siberia as a whole. In this central area some buildings of the pre-Revolutionary period survive, but, because of its relative youth, the city lacks buildings of historic interest. Most of the theatres and cultural establishments and the largest shops are in the centre. Krasny Prospekt (Red Avenue), the principal street, bisects the centre, running north from the Ob to the local airport and linking the town's three largest squares, Kalinin and Lenin squares and Square of the Soviets. As in most Soviet cities, multistory apartment buildings with two- and three-room flats account for high population densities even in the most central parts.

Although industry is found in all parts of the city, the principal industrial sectors are in the east along the Trans-Siberian line, and on the opposite, left bank of the Ob, where are located the largest engineering and metallurgical factories. An imposing road bridge over the Ob links Kirov Ward to the rest of the city. North of the centre is found a large range of light industrial and food-processing plants. Housing everywhere is in very large apartment buildings. Those in central areas are usually five to seven stories high and generally constructed of stone or brick; those in outer parts of the built-up area, prefabricated buildings constructed in the later 1960s and '70s, are frequently 12 to 20 stories high, giving population densities as great as in the centre. The apartment buildings are grouped in "micro-regions," or neighbourhood units, each of which is provided with basic services such as shops, schools, a polyclinic, and a cinema.

Economy. Novosibirsk is one of the most important manufacturing centres in the Soviet Union. Although there is a wide range of industries, metallurgy and engineering predominate, employing two-thirds of all industrial workers in Novosibirsk. The old, pre-Revolutionary iron industry has been transformed into the modern Kuzmin steelworks, producing hot and cold rolled steel, cold rolled sheet steel, and steel tubes. The tin smelter is the largest in the country, utilizing tin concentrates from distant sources in northern Yakutiya, Transbaikalia, the Far East, and Kirgiziya. A highly specialized metalworking plant is the gold refinery, which refines all gold mined in the Soviet Union. In the range of engineering works, pride of place is taken by the Yefremov heavy machinery and hydraulic press factory and by the large electrical generator plant. Other plants manufacture electrothermal equipment in the form of steel furnaces of 180 tons' capacity, ore concentrating and mining machinery, and agricultural machinery (including disk harrows, seeding and husking machines, and tractor spares). Precision and light engineering plants make machine tools, instruments, radios, and automatic looms. Also part of this vast engineering complex are the big locomotive repair and servicing shops and the ship repair yards on the Ob.

Industries

During the 1960s and '70s the chemical industry developed rapidly, producing synthetic resin, plastics, and pharmaceutical goods. Other industries are primarily concerned with supplying the city and surrounding area with construction materials and with consumer goods—furniture, pianos, shoes, textiles, knitwear, and foodstuffs. The early-established flour-milling industry continues.

Power for the industries is supplied by a 220-kilovolt line from the Kuzbass coalfield and by the Novosibirsk hydroelectric station, constructed between 1951 and 1959 on the Ob some 15 miles (24 kilometres) upstream from the city. The barrage is three miles long and impounds a reservoir that has flooded more than 400 square miles (1,000 square kilometres) and that extends 110 miles upstream. The station has seven generators with a total capacity of 400,400 kilowatts. There are also two thermal power stations in the city itself. Novosibirsk is on the trunk petroleum pipeline that crosses Siberia from the Urals to Angarsk.

Electricity

Communications and transport. In addition to the trunk railway services via the Trans-Siberian, Kuzbass, and Turksib lines, which have played such a major part in the city's growth, local electric commuter trains link the suburbs to the city centre. Up to 70,000 passengers daily use Novosibirsk Main station alone. In First of May Ward, in the southeast sector of the town, is one of the largest marshalling yards in the country. There are two airports, a smaller one serving local air connections and a large main airport with direct flights to Moscow and other major cities of the Soviet Union. The river port has been enlarged and modernized with electric gantry cranes, and in the ice-free season it handles bulk freight moving on the Ob; this is made up chiefly of timber and building materials, with lesser quantities of coal, cement, fuel oil, and grain. There are also passenger services along the Ob, and small craft, including hydrofoils, link the parts of the town along the river. Transportation within the city is by bus, streetcar, and trolleybus.

Culture and education. Novosibirsk is the principal cultural and educational centre in Siberia. Its six theatres

include an imposing opera and ballet theatre, begun in 1931 and opened in 1945, seating 2,000 persons, the Red Torch Drama Theatre, a children's theatre, and a circus. There are botanical gardens, an art gallery, and four museums, as well as a symphony orchestra. The city has a television and radio centre, linked to Moscow (1,752 miles away) by communications satellite. It is an important publishing centre, with the Siberian branch of the Nauka (Science) Publishing House and the West Siberian Publishing House. Several local newspapers and journals are published. The State Public Scientific and Technical Library of the Academy of Sciences of the U.S.S.R. is one of the copyright libraries of the Soviet Union, with a collection of more than 5,000,000 books and reading rooms that can seat 1,000 persons.

Novosibirsk has some 220 general schools and 37 specialist schools—music, ballet, languages, science, and technology. There are 14 higher educational institutions, headed by the Novosibirsk State University, founded in 1959; other higher educational establishments include railway engineering, electrotechnical, medical, agricultural, and teacher-training institutes. The university and a number of these institutes are located in one of the most remarkable developments of Novosibirsk. This is the satellite town of Akademgorodok (Academic Town), which lies 15 miles south of the city centre on the shores of the Novosibirsk reservoir but within the city limits in Soviet Ward. Construction of this suburb was begun in the 1950s to house the Siberian Department of the Academy of Sciences of the U.S.S.R., established in 1957, initially under the energetic directorship of M.A. Lavrentyev. Since then a very large concentration of research and educational institutions has grown up in Akademgorodok. Among these are most of the 22 specialist research institutes that the Academy of Sciences maintains in Novosibirsk, with staffs totalling about 11,500 persons, of whom more than 3,000 are research workers. In Akademgorodok also are the Siberian branches of the All-Union Agricultural Academy, constructed in the early 1970s, and the Academy of Medical Sciences. This concentration of scientific research workers and higher educational teachers has attracted a great deal of attention, both within the Soviet Union and internationally. A feature of the town is the special scientific boarding school for specially gifted children. Akademgorodok is regarded as a prototype for further academic settlements planned for Leningrad, Vladivostok, and other Soviet cities.

Akademgorodok

Health and recreation. Each micro-region of the town has a polyclinic, providing day to day medical, dental, and public health services. The city is adequately supplied with hospitals, including a large unit of 1,500 beds, built in the 1970s. There are several parks, the principal one of which lies along the right bank of the Ob in the north of the city. In the outer rural fringe are children's holiday camps, while the reservoir and its shores are much used for recreation, with boating and swimming facilities. (R.A.F.)

Nuclear Fission

Under certain circumstances it is possible for the atomic nucleus (*i.e.*, the heavy mass at the centre of an atom) to split into two pieces of almost equal mass with the simultaneous liberation of a large amount of energy: this phenomenon is called nuclear fission. Each of the two nuclear fragments will consist of protons (nuclear particles of positive charge) and neutrons (nuclear particles of no charge) that comprised the original nucleus. Normally, only heavy nuclei, such as uranium, can be induced to fission.

GENERAL CONSIDERATIONS

Stages of nuclear fission. The sequence of events that occurs in fission is shown in six stages, for convenience, in Figure 1. The heavy nucleus receives excitation energy as the result of a nuclear reaction having taken place, such as the absorption of a neutron from outside the atom (Stage 1). The excess energy added by the neutron causes the nucleus to undergo rapid changes of shape, oscillating from one form to another until finally it assumes the elongated shape called the transition state nucleus, which is a critical part of the fission process (Stage 2).

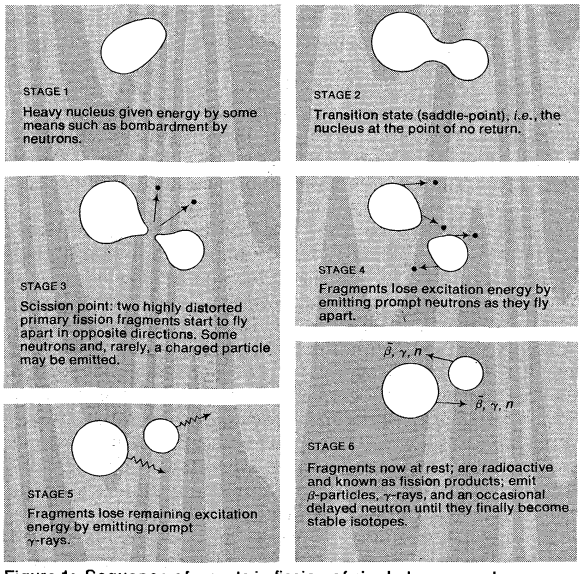


Figure 1: Sequence of events in fission of single heavy nucleus. Time (in seconds) between stages: 1–2, 10^{-15}; 2–3, 10^{-20}; 3–4, 10^{-15}; 4–5, 10^{-11}; 5–6, 10^{-1} up to 10^{7} or more.

At this point of its history, also referred to as the saddle point, the various forces within the nucleus are momentarily in balance. If the nucleus contracts slightly, it will return to its oscillations and will probably rid itself of its excess energy by emitting gamma rays (electromagnetic radiation of high energy). On the other hand, if it stretches a little more, the internal disruptive forces gain control and the nucleus is irrevocably committed to fission and will follow through the rest of the stages in the figure.

At the splitting or scission point (Stage 3) it will finally break into two large pieces, called fission fragments, and it may also emit several neutrons. Because both fission fragments are positively charged, and thus have a mutual electrostatic repulsion, they will fly apart in opposite directions in much the same way as the like poles of two magnets repel each other. Besides their kinetic energy (energy due to their motion), the fragments will also have a large excess of internal excitation energy (analogous to heat energy), most of which they will next lose, first by boiling off prompt neutrons (Stage 4), and after this by emitting prompt gamma rays (Stage 5). The term prompt is used to differentiate these rays from those of delayed emissions that occur at a later stage.

The process from the original excitation of the nucleus to the emission of the gamma rays will take about 10^{-11} second. These fragments have now come to rest and will have become radioactive elements listed in the middle of the periodic table, known as fission products (Stage 6). These then proceed to emit gamma rays, X-rays, and beta rays (consisting of negatively charged electrons that are produced when neutrons turn into protons) and occasionally a delayed neutron over a period of time that may be only a few seconds or may be many years, until they finally have no more excess energy left to disintegrate further, and turn into ordinary stable isotopes. (An isotope is a stable or radioactive atom of specified mass of a given element; an element may have several isotopes. A nuclide, on the other hand, is a general term referring to an atom of any mass and atomic number.)

Fission products

The importance of nuclear fission. The supreme importance of the fission reaction lies in the enormous amount of energy that it releases from the atom, about 2×10^{8} electron volts for each fission, equivalent to around 600,000 kilowatt-hours from the fission of one ounce of uranium-235, the uranium isotope with an atom-

ic mass number of 235. The object of nuclear weapon design is to create an uncontrolled chain reaction (see below) so as to cause as many atoms as possible to undergo fission in a short space of time. The tremendous energy from the fission of one nucleus is thus multiplied a large number of times, and it is this sudden surge of energy released almost instantaneously that constitutes the explosion. A fission explosion is about 400,000 times as powerful as the explosion of an equivalent weight of the chemical explosive TNT. The bombs exploded at Hiroshima and Nagasaki in World War II were fission bombs of this kind, but in 1952 the U.S. fired a nuclear weapon of another type, called a hydrogen or thermonuclear bomb. Whereas in fission the energy comes from the breakup of a nucleus, in this kind of reaction it comes as a result of the fusing together of two light nuclei to form a heavier one (see NUCLEAR FUSION). Nuclear explosives may be used for peaceful purposes, and both the United States and the Soviet Union have research programs that are investigating their possible advantages for such operations as excavation of harbours and canals and for other large earth-moving projects.

The enormous energy of fission may also be employed constructively in the generation of electric power, by harnessing the heat of the reaction to drive turbines. To do this it is necessary that the chain reaction proceed slowly and in a completely controlled manner, a situation that is achieved in a nuclear reactor. In many parts of the world reactors today can supply electricity more cheaply than any other fuel, and they are generating a larger fraction of the world's domestic and industrial power every year (see NUCLEAR REACTOR).

Nuclear power for submarines

Nuclear reactors are also used for propulsion of ships. Many nuclear-powered submarines are in service in the navies of the world, their supremacy over conventional types arising from the fact that they do not run on batteries that require recharging. Since they need only refuel with fissionable material at intervals of several months, they can remain submerged for weeks at a time when necessary. For economic reasons, nuclear-powered surface ships have been less successful, but several countries including the United States, the Soviet Union, and Japan have built experimental ones.

The other important application of nuclear reactors is in the production of copious numbers of neutrons. The majority of radioactive isotopes used extensively in medical treatment, in research, and in industry (see RADIOISOTOPES, APPLICATIONS OF) are made by bombarding nonradioactive substances with neutrons in reactors. Neutrons from nuclear reactors also serve an invaluable purpose in research and development work, which is designed to increase the economic potential of nuclear power.

History of fission research and technology. The discovery of fission was made by two German chemists, Otto Hahn and Fritz Strassmann, in 1938. They and other scientists had been trying to make transuranic elements (*i.e.*, elements that are heavier than uranium, then the heaviest known element in the periodic table) by bombarding uranium with neutrons, when, in a series of experiments, they proved conclusively that the products of their bombardments were not transuranic elements, but elements from the middle of the periodic table. Papers published in 1939 by the theoretical physicists Yakov Frenkel of the Soviet Union, Niels Bohr of Denmark, and John A. Wheeler of the United States provided a description of fission that to this day remains the basis of its theoretical treatment.

Enrico Fermi, an Italian physicist, then suggested that neutrons might be emitted in the fission reaction and that they in turn could induce fission reactions; and if this were so, it should be possible to sustain a chain reaction in uranium that, under certain conditions, might multiply fast enough to cause a nuclear explosion.

First nuclear reactor

A controlled chain reaction was first successfully initiated in the world's first nuclear reactor, set up by Fermi at the University of Chicago in 1942.

Bohr and Wheeler had suggested that only a small amount of the uranium in the natural element was undergoing fission, specifically, the isotope uranium-235, which is present only to the extent of one part in 140. This was confirmed by experiment and it was also discovered that the other isotope, uranium-238, when bombarded by neutrons, gave rise to the transuranic element neptunium, which, upon disintegrating radioactively, produced still another transuranic element, also fissionable or fissile like uranium, which was then named plutonium. The chain of nuclear reactions leading to its formation can be expressed as follows:

$$^{238}\mathrm{U} + n(\text{neutron}) \longrightarrow {}^{239}\mathrm{U} \longrightarrow {}^{239}\mathrm{Np}(\text{neptunium}) \longrightarrow {}^{239}\mathrm{Pu}(\text{plutonium}).$$

(^{239}U: emits a β^- particle; ^{239}Np: emits a β^- particle)

From the experiment it was clear that whereas natural uranium was satisfactory for the production of a slow chain reaction, either uranium-235 or else plutonium-239 would be needed, and in kilogram amounts, to make a bomb. Both these isotopes were produced. The uranium-235 was used for the bomb exploded over Hiroshima and the plutonium-239 for the one exploded over Nagasaki.

After the war major efforts in fission research continued in many countries and resulted in such activities as the development of the fusion bomb, economic nuclear power stations, and isotopes for medical research. Current research is concerned largely with the continued development of reactor systems and thermonuclear bombs. It is also concerned with finding more uses for radioactive materials, and with ever more complex experiments designed to elucidate the complicated mechanism of the basic fission process.

PHENOMENON OF NUCLEAR FISSION

General principles. *Types of fission and why it occurs.* It is a fundamental principle of nature that, if there is nothing to prevent it, every system will arrange itself in such a way that its potential energy will be reduced as much as possible. A simple example of this is water flowing down a hill. The potential energy of the system is high when the water is at the top of the hill but, in moving down, energy is released in the form of kinetic energy, so that when the water reaches the bottom of the hill the potential energy of the system has been greatly reduced.

Atomic nuclei behave in an analogous way. Albert Einstein in 1905 showed that mass and energy are merely different aspects of the same thing and that when mass is converted into energy, the energy is equal to the product of the mass and the velocity of light squared (*i.e.*, by the equation $E = mc^2$, in which E is the energy, m is the transformed mass, and c is the velocity of light). The masses of atomic nuclei have been carefully measured, and reference to these measurements will show that if any heavy nucleus breaks into two pieces of comparable size, the total mass of those pieces will be less than that of the original nucleus. This is to say, the difference in mass will be converted to energy that will be released in the breakup, and that the system after fission will be at a lower energy level than it was before. As a matter of fact, application of this mass test shows that all nuclei heavier than iron in the periodic table are potentially able to undergo fission in this way. All nuclei do not undergo fission at once because there is in the nucleus a potential hump, the equivalent of a dam that prevents the water from flowing down the hill. Called the fission barrier, it exists because of the very different nature of the two kinds of force in the nucleus, the nuclear force, and the electrostatic or coulomb force. The nuclear force is attractive and acts between both types of nucleons—neutrons and protons—but is short ranged so that a nucleon can act only on its immediate nucleon neighbours; the coulomb force, on the other hand, acts between the positively charged protons only, and extends throughout and beyond the whole nucleus (see NUCLEUS, ATOMIC). The lower the fission barrier, the less energy the nucleus requires for it to be overcome, and hence for fission to occur. Since the barrier gets lower as one moves up the periodic table, the trend is for nuclei to be more easily fissioned the heavier they are.

There are two ways, in fact, in which the fission barrier can be overcome. Carrying on the simple analogy, a little energy could be expended in lifting water confined by a dam up over the top of the dam, or perhaps the water might escape through a hole in the side of the dam. In induced fission, the nucleus receives energy from an external source: it might, for example, absorb a neutron, in which case it takes over both the rest mass energy and the kinetic energy of the neutron, and this extra excitation energy may be sufficient to lift it over the barrier and start the sequence of events shown in Figure 1. Fission can be induced in this way, not only by a neutron but also by other particles such as protons, alpha particles (consisting of two protons and two neutrons, identical to a helium nucleus), and gamma rays.

Spontaneous fission

In spontaneous fission a quantum mechanical effect, just like a hole in the dam (see MECHANICS, QUANTUM), allows the fission barrier of the nucleus to be penetrated, which offers another way that the fission sequence takes place, but this time without the outside intervention of a neutron as in induced fission. Spontaneous fission is not too likely, except in some artificially produced heavy isotopes: for example, the half-life (the time required by a large number of atoms for half their number to disintegrate; half-life is different for every nuclide) of the common uranium isotope uranium-238 for spontaneous fission is about 10^{16} years compared to its half-life for alpha decay of only just over 10^{9} years.

Fission cross section

Besides the fission barrier, there is one other important parameter of the fission reaction that must be understood: this is the cross section. In a situation in which a neutron moves toward a heavy nucleus, the cross section for fission is in effect simply the probability that fission will, in fact, take place. The nucleus may be thought of as a target with a certain effective area over which the fission will certainly occur if the neutron strikes within it. The area is not usually the same as the actual geometrical area of the nucleus; indeed, it may be hundreds of times greater or smaller, but it is determined by a variety of complex considerations that are outside the scope of this article. It is measured in units called barns, one barn being equal to 10^{-24} square centimetre.

Fission fragments. Examination of Figure 1 will show that fission of a nucleus can result in the production of fission fragments, charged particles, gamma rays, and neutrons. Since it is not possible to observe the fission process actually occurring, information about it has to be gleaned by experimenting on these diverse products. The fission fragments themselves have proved to be the most fruitful source of information, partly because they are the most important fraction of the debris, and partly because they are the easiest to examine.

There are two quite different approaches to the study of fission fragments. The most direct of these is to catch the fragments in flight and measure either the distribution of their kinetic energies or their angular distribution; that is, to measure the relative numbers of fragments for each increment of kinetic energy or the relative numbers for each direction. This sort of experiment is called on-line (from computer terminology) because the measurements are made during the actual bombardment of the fission target immediately after the emission of the prompt gamma rays. The measurements are taken earlier in the fission process than in the case of the off-line experiment, described below, in which radiochemistry is employed. The kinetic energy distributions give information about the way in which excitation energy is used in the fissioning nucleus, the excitation energy of the fragments themselves, the neutron emission of the fragments, and the way in which the total mass of the nucleus is split up. Angular distributions tell something about the possible energy levels (see NUCLEUS, ATOMIC) of the fissioning nucleus while in its transition stage (Stage 2).

In radiochemical off-line experiments the target is bombarded until sufficient fission has occurred, when the bombardment is stopped, and the target investigated. The fission process will thus have entered its final stage, in which the fragments have become fission products. When the nucleus is torn apart the fragments lose many of their atomic electrons (see ATOMIC STRUCTURE), but these are restored to them as the nuclei come to rest. The chemical properties that characterize the elements of the periodic table depend on these electrons, and so they have now become isotopes of middle-mass elements that can be identified by their radioactive properties and, if required, separated from each other by radiochemical means. They still have not quite reached their lowest possible energy state, however, and so they continue to lose energy by emitting beta particles, gamma rays, and occasionally a delayed neutron. Each time a negative beta particle is ejected, a rearrangement occurs within the nucleus itself and, whereas the mass changes only by a very small amount, the positive charge increases by one unit, and thus the atomic number increases by one and the fission product nucleus moves up one place in the periodic table. This process of beta decay continues until all the excess energy is lost, at which time the nucleus is termed stable. The half-lives of the nuclei that disintegrate or decay by beta emission in these decay chains range from about one second to many years and tend to get longer and longer towards the end of the chain, thus making it easier to do the radiochemistry on the decay products. This sort of experiment is less direct than the on-line type but it permits a greater variety of measurements and leads to positive identification of the isotopes that are produced.

Decay chains

Examples of the shape of the mass distributions of the fission products for two different kinds of fission are given in Figure 2. One curve represents the yield for radium-226 and the other for uranium-235. These distributions

From (top) I.F. Croall, Atomic Energy Research Establishment, Harwell, Berkshire, report R5086 (1967), (bottom) J. Milton and J. Fraser, *Proceedings of the Symposium of the Physics and Chemistry of Fission* (1965)

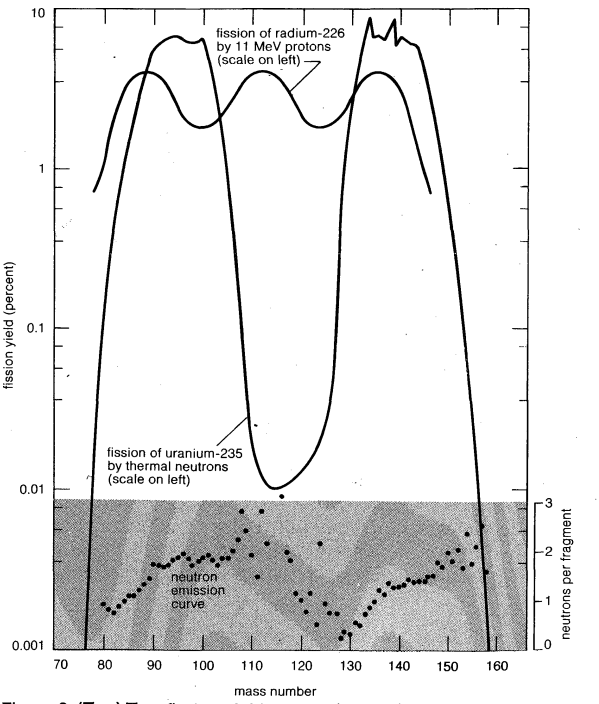

Figure 2: (Top) Two fission yield curves. (Bottom) Shaded area shows prompt neutron emission from uranium-235 thermal neutron fission.

show the percentage of fissions that result in the formation of fission products having any particular mass number, plotted against the mass numbers. These percentages are called fission yields. A glance at the curve for uranium-235 will show, for example, that about 6 percent of all the fissions in a quantity of uranium-235 will give rise to fission products of mass 99 and mass 133, or for 1 percent, masses of 84 and 149, or 105 and 128 (the total must be less than 235). The shapes of the curves reveal a great deal of information about the fission process, and a useful theory of fission must be able to explain the considerable differences in their shapes.

Another distribution that can be examined by radiochemical means, but only in a limited way by on-line

experiments, is the charge distribution. The nuclear charge of the different products along any fission decay chain increases by one unit with each beta decay. The charge distribution gives the probabilities of formation of all the members of a chain in the original fission act; and hence it gives clues as to what actually happened during this act.

Fission neutrons, gamma-rays, and other particles. Prompt neutrons, after fragments, are the most important product of fission because it is they that link successive fissions into the chain that is fundamental to the use of atomic energy in any form. Of these neutrons, 80 to 90 percent come off in Stage 4 of Figure 1 as part of the process that removes the excitation energy from the fission fragments, whereas the remainder are released slightly earlier, in Stage 3.

The first essential piece of information that is needed in a study of prompt particles emitted is the average number of prompt neutrons that are emitted per fission (always designated by the symbol $\bar{\nu}$). When neutrons are emitted, each carries away, on the average, about 7×10^6 electron volts of the excitation energy of the fragment, of which about 2×10^6 electron volts is kinetic energy and 5×10^6 electron volts is binding energy (this is an average, as energies can range from 0 to 17 million electron volts). The easiest way to understand the meaning of binding energy is to imagine the reverse process. When a neutron is absorbed by a nucleus, the mass of the latter after absorption is less than the total mass of nucleus and neutron before absorption. The difference in mass, given off in the form of energy in accordance with Einstein's equation already mentioned, is called the binding energy of the neutron in that particular nucleus because it is equal to the amount of energy that must be put into the nucleus again in order to "unbind" or expel the neutron. Since one neutron removes about 7×10^6 electron volts of energy from the fragment, the number of neutrons released or emitted per fission depends on the total amount of energy the fragments must lose, and this in turn depends on how much excitation energy was given to the nucleus in Stage 1. For fission of uranium-235 by thermal neutrons (a thermal neutron is a neutron in thermal equilibrium with matter at room temperature and has an energy of 1/40 electron volt), $\bar{\nu}$ has a value of about 2.5 neutrons per fission; but when fission is caused by neutrons of say 14.8×10^6 electron volts, $\bar{\nu}$ rises to nearly five neutrons per fission because the extra energy of the bombarding neutrons is added to the excitation energy of the fragments. Something else important about prompt neutrons is the way in which the average number emitted depends on the mass of the fragments. This dependence, for the case of thermal neutron fission of uranium-235, is shown by the series of points superimposed on the mass distribution curves of Figure 2.

Delayed neutrons

Besides the prompt neutrons, delayed neutrons are also found in fission, as part of the beta decay process of the fission products in Stage 6. The half-life of delayed neutron emission ranges from about 0.2 second to about 56 seconds. The Table summarizes the various pieces into which the nucleus of Stage 1 may break up in the fission of uranium-235.

Fragment Distribution in Uranium-235 Fission

fragment	approximate average energy (MeV)	approximate number per fission	stage
Fission fragments	166 (total for pair)	2.5	3
Prompt neutrons	2 (kinetic energy only)	2.5	3, 4
Alpha particles (^{4}He)	15	0.002	3
Tritons (^{3}H)	8	0.0001	3
Prompt γ-rays	1.1	7.5	5
β^--particles	1.2	6.5	6
Delayed γ-rays	0.9	many	6
Delayed neutrons	0.5 (kinetic energy only)	0.016	6

The energy of fission. The energy released in fission is carried away by the fission fragments, neutrons and gamma rays. Eventually these products are halted by matter and their energy is converted almost entirely to heat. It is important to utilize as much as possible of this heat if fission is to be employed to the best advantage and, since the ease with which the various products can be stopped varies enormously, it is important to know how the energy is distributed among them.

The so-called energy release in fission is found by subtracting the sum of the masses of the primary fission fragments (Stage 3 in Figure 1) from the original mass (Stage 1) and converting it into energy units by means of Einstein's equation. This is the energy that appears in Stages 3, 4, and 5. The delayed emission of particles in Stage 6 releases additional energy, some of which is bound up in the kinetic energy of antineutrinos, which accompany the beta decays. Antineutrinos are antiparticles of neutrinos, particles of zero charge and negligible mass that are virtually unstoppable by matter and therefore do not share their energy.

The energy arising from the fission of uranium-235 by thermal neutrons is distributed as follows:

Energy released, prompt	
Kinetic energy of fission fragments	166 MeV
Kinetic energy of prompt neutrons	5
Binding energy of prompt neutrons	12
Energy carried by prompt gamma rays	8
Energy released, delayed	
Energy of beta particles	8
Energy of antineutrinos	12
Energy of delayed gamma rays	7
	218 MeV

Most of this energy is converted into heat within an operating nuclear reactor and so can be used to generate electrical power. The energy available from the binding of the prompt neutrons, however, depends on the way in which they are finally stopped; whereas some of the energy of the delayed gamma rays and beta particles is lost because the fuel has to be removed from the reactor before they are emitted. All of the antineutrino energy is lost because these elusive particles are unstoppable and thus cannot be contained.

Fission chain reactions and their control. *The principle.* Although fission can be initiated by any process that imparts sufficient energy to the heavy nucleus, the neutron provides by far the most efficient way of doing it. The reason for this is because a neutron has no electrical charge and so can approach the nucleus without having to overcome the ever-increasing repulsion between itself and the protons in the nucleus, which a positively charged particle like a proton experiences. As a result of this, even thermal neutrons, that is, neutrons that have kinetic energies the same as the energy of the molecules in the surrounding matter, can enter a nucleus: these energies are less than 0.1 electron volt. In contrast, a proton must have a kinetic energy of about 13×10^6 electron volts, a factor of over 1.3×10^8, if it is to be able to penetrate a uranium-235 nucleus.

The neutron then can be an effective means of giving a nucleus the excitation energy it needs to enable it to pass through the sequence of events shown in Figure 1; but the reason why fission can be used as a source of atomic power is because of the emission of prompt fission neutrons in Stages 3 and 4. Each of these neutrons can enter another fissile nucleus and start the sequence again so that the process can continue indefinitely in what is called a chain reaction. Since there are on the average about 2.5 neutrons produced in each thermal neutron fission of uranium-235, it is easy to see that the number of fissions occurring can multiply enormously. For example, if every one of these neutrons were to cause another fission, there would be 2.5 fissions in the second cycle, 6.25 ($=2.5^2$) in the third, 15.63 ($=2.5^3$) in the fourth, and so on, each cycle taking only about 10^{-15} second. This type of increase is called a geometrical progression and is so rapid that if no other factors intervened, the result would be a nuclear explosion. In fact, many of the prompt neutrons will not cause fission at all, but will be absorbed, either by accident or design, in other types of nuclear reaction; but so long as the average number of neutrons

Chain reaction

per fission that do initiate another fission is greater than one, the total number of fissions will increase. This is called a diverging chain reaction. If the number is less than one, a converging chain reaction results and the number of fissions will decrease. The ratio of the number of fissions occurring in one cycle to the number in the next is called the multiplication factor.

Critical mass. If a fission bomb is to be made, the multiplication factor must be as large as possible; whereas if the requirement is for a controlled nuclear reactor, the multiplication factor must be somewhere near one. The important point is that for both purposes one must be able to achieve values of the factor greater than unity. On the face of it, this would seem to be an easy thing to do. Because about 2.5 prompt neutrons are emitted in the fission of one atom of uranium-235, it should be simple to ensure that at least one of them is available to cause the fission of another atom. It is, in fact, easy to attain a multiplication factor greater than one for uranium-235 but much harder for natural uranium, which has only about one part of this isotope in 140, most of the remainder being uranium-238. The latter isotope captures the fast prompt neutrons quite easily, eventually producing plutonium-239 as mentioned earlier; but it is not nearly as easily fissioned as uranium-235, and so it uses up the neutrons needed to raise the multiplication factor above one.

In most of the reactors in use today the fissile material is mixed with a moderator substance, the purpose of which is to slow down the fission neutrons to thermal energies. It does this by a process called elastic scattering in which neutrons collide with moderator nuclei and give up some of their energy to them in much the same way as a billiard ball loses energy if it is in collision with another one. The lighter the moderator nuclei are, the greater will be the average amount of energy lost by the neutrons in each collision. This is why hydrogenous materials such as water are good moderators, although carbon in the form of graphite has many advantages and is also frequently used.

Besides being captured by some nucleus that does not fission, the neutrons may fail to cause a fission for the much simpler reason that they escape from the piece of material without actually striking another nucleus at all. The smaller the piece of material is, the greater the chance that this will happen, and there must therefore be some critical mass or point of criticality below which so many neutrons escape that the multiplication factor falls below one and a chain reaction cannot occur at all. In a piece of uranium-235 metal the critical mass is only a few pounds, but in natural uranium so many neutrons are absorbed by the uranium-238 that it is not possible for a single piece of metal of any size to become critical. The shape of the fissile material must also be considered since the greater the ratio of its surface area to its volume, the greater is the chance of neutrons escaping. Thus the critical mass of a spherical piece of material will be less than if the same material is made into a cylinder. It is for this reason that vessels used for holding solutions of fissile isotopes in processing plants often have a narrow cylindrical shape. Equipment of this type is termed critically safe.

The control of chain reactions. If fission is to be used in reactors to produce power, or for other purposes, it is essential that one be able to control the chain reaction. It is immediately obvious that means are required whereby the value of the multiplication factor can be smoothly increased or decreased for normal operation, or instantly reduced to well below unity if it becomes necessary to shut down the reactor suddenly. To do this, a way must be found to change the number of neutrons that are absorbed and so to alter the fission rate.

The picture is complicated by the fact that the fission cross section for any isotope is not constant, but depends strongly on the kinetic energy of the neutrons: for example, the uranium-235 fission cross section for thermal neutrons is about 580 barns, whereas for the fast neutrons in a typical reactor it is only about 1.5 barns. The control of the reactor is usually accomplished by means of movable mechanical rods made of some material that has a high absorbing power for the neutrons; that is, it has a high neutron capture cross section; boron is commonly used in thermal reactors for this purpose because its isotope boron-10 has a thermal neutron absorption cross section of about 4000 barns, which drops off smoothly as the neutron energy rises. When the reactor is shut down the rods are inserted into the reactor fuel core; to start it up they are gradually withdrawn until the multiplication factor rises to the desired value. The rate at which the number of neutrons produced increases depends on the length of time between successive cycles of neutron generation in the chain reaction as well as on the value of the multiplication factor. This time is increased by the presence of the delayed fission neutrons and this factor helps to ease the problem of control of the reactor. One final factor that affects control is brought about by the gradual accumulation of fission products in the fuel. Some of these products have high neutron-capture cross sections and so produce a progressive reduction in the maximum value of the multiplication factor that can be achieved in the reactor. Eventually, the effect of these fission-product poisons is to reduce power and make the reactor too expensive to run. It is then necessary to change to fresh fuel.

THEORETICAL ASPECTS OF NUCLEAR FISSION

Nuclear models. An atomic nucleus is composed of a grouping of neutrons and protons. Its stability derives from a balance between the two main kinds of force acting on these nucleons; *i.e.,* the repulsive force between the positively charged protons and the attractive nuclear force between all the nucleons. A complete theoretical treatment of a nuclear event such as fission would involve calculating the effect of these forces on all the nucleons at every stage of the fission process, thus providing detailed predictions of all the phenomena resulting from it. Unfortunately, it is impossible to perform these calculations at present and it is likely that this will remain the case for a long time to come, because the nature of the nuclear force is not yet properly understood, and even if it were, it would be impossible to carry out the incredibly complex computations required.

The solution of this dilemma is to resort to the use of models. The idea is to choose some system that can be regarded as being comparable to the nucleus for some aspects of the fission process but that is itself much simpler than the fissioning nucleus. Calculations are then performed on this system in the hope that the results can be applied to the real nucleus itself. Classification of the various models is not easy because there are so many variants that they tend to shade into one another; but the most important are the liquid-drop model, the adiabatic model, and the statistical model, which are described below.

Liquid-drop model. The liquid-drop model of the nucleus was first used by Bohr and Wheeler in 1939, following a suggestion made shortly after the discovery of fission. The model likens the nucleus to a drop of an incompressible liquid having a uniform electric charge. The nucleons inside the drop all attract each other because of the nuclear force, but the attraction is one-sided at the surface of the drop and this results in a so-called surface tension, which is rather like a stretchable skin surrounding the drop that tries to retract to a minimum area. The positive charge of the protons produces a repulsive force acting in the direction opposite to that of the surface tension. In a stable nucleus the surface forces are stronger than this repulsive force and so the drop is squeezed into a spherical shape. If energy is now given to this drop, for example by its absorption of a bombarding neutron, it will oscillate through a whole variety of different shapes about the spherical. If the nucleus starts to stretch out during one of these contortions, the surface tension will at first try to pull it back to the equilibrium shape. The surface tension, however, falls off very rapidly in comparison to the repulsive force, and so a point may be reached beyond which the latter overcomes it and there is then nothing to prevent the nucleus from breaking up. The point at which the two forces are just in balance is

Surface tension

the transition state, Stage 2 in Figure 1. The further a nucleus can be stretched before it reaches the transition state, the more difficult it is to make it fission. Bohr and Wheeler introduced a fissionability parameter, ranging from zero to one, to provide a measure of the stability of a nucleus toward fission, the smaller its value the greater being the stability. Its approximate value is equal to 1/50 of the square of the atomic number divided by the nuclear mass. It is equal to $1/50\ (Z^2/A^2)$, in which Z is the atomic number and A is the mass number of the nucleus. For a nucleus whose fissionability parameter is equal to 1, the transition state shape is a sphere; but a sphere is also the equilibrium shape for a nucleus before any energy is added, and so such a nucleus is always unstable toward fission and hence cannot exist at all. On the other hand, the transition-state shape of a nucleus having a fissionability parameter equal to zero would be two spheres in contact and such a nucleus would be extremely stable against fission. As an example of a typical real nucleus, one may take uranium-235, whose fissionability parameter has a value of 0.72. The liquid-drop model, although simple in concept, has not proved as successful as at first expected. In its original form it predicted that the mass distributions for the heavy fissile nuclides would be symmetrical, whereas experimental results show that the distributions have two pronounced asymmetrical peaks, as Figure 2 will show. Modern variants of the model have overcome this difficulty, but the additional complications that these variants introduce, together with the complexity of calculations on very distorted drop shapes, have led to the development of other models that may be used either in place of it or to supplement it.

Adiabatic models. In a nucleus, the nucleons have different energy states that may be arranged in a series of energy levels, each representing a different energy and capable of holding a limited number of nucleons. Adiabatic is a term used in thermodynamics to describe a system in which a gas is made to expand or contract sufficiently rapidly so that it does not gain or lose heat from its surroundings, but compensates for the change in volume by raising or lowering its temperature. In adiabatic nuclear models the overall motions of the whole nucleus (collective motions) are slow when compared with the motions of the individual nucleons (particle motions), and when the nucleus is excited and starts its contortions, there is thus time for the particle motions to adjust themselves to the shape changes and there is no exchange of energy between the various levels; that is, the nucleus is behaving adiabatically.

The liquid-drop model posits the nucleus as a blob of matter in which all the nucleons interact strongly with each other. In rival groups of models, called independent-particle models, of which the shell model is the best known, an opposite assumption is made, namely, that there is little or no interaction between individual nucleons, but each moves in an orbit in a force field (the nuclear potential) generated by all the nucleons. In the liquid-drop model the nuclear properties result from the behaviour of the whole nucleus, whereas in the independent-particle models they are the result of the behaviour of just a few of the nucleons. Adiabatic fission models combine some features of both types; that is, calculations are made on the basis of the individual particle interactions, modified by the collective motions of the nucleus, and it is assumed that the nucleus behaves adiabatically as well. Considerable success has resulted in predicting those properties of fissioning nuclei that are dependent on events occurring up to the transition state, such as the angular distributions of the fission fragments (Stage 2, Figure 1), but have been less successful with the scission stage (Stage 3), at which such features as the mass and charge distributions of the fission fragments are probably determined.

Shell model

Statistical models. As originally conceived, the statistical model possessed the great advantage that it contained no arbitrary assumptions put in simply to make the model fit the experimental facts. It assumed that there are forces at work in the nucleus that are not adiabatic in nature and that the effect of these is to establish thermodynamic equilibrium between the different possible conditions of the nucleus at the scission point. The meaning of this can be explained in the following way: a large number of nuclei, all at the scission point, can have any one of a number of different configurations, each of which leads to a different pair of fission fragments. If equilibrium exists, the number of nuclei in each of the various configurations will depend only on the properties of the configurations and will not be influenced in any way by events that have gone before, simply because there has been enough time for the equilibrium to be established.

Non-adiabatic model

In detail, it was assumed that the probability of a nucleus fissioning so as to produce any one of the possible pairs of fission fragments depends only on the closeness of the energy levels of those fragments. Since the fragments must have a definite energy level, the more possible levels each fragment pair can have the better is the chance of being able to produce these particular fragments. It was also assumed that there is no nuclear interaction between the fragments after scission. The mass distribution of the fission fragments of uranium-235 thermal neutron fission was accurately predicted, but it was soon clear that predictions of the mass distribution for plutonium-239 thermal neutron fission fragments and for the kinetic energy distributions of fission fragments were completely wrong.

Limitations of statistical model

The difficulty with the statistical model as it was originally conceived is that while it uses only properly defined physical properties as the basis of its calculations, these properties relate mainly to the fission fragments at the moment of scission. Such fragments exist only for a very brief moment of time and their properties are virtually unmeasurable. This means that the required data must be obtained by extrapolation from measurements on the behaviour of ordinary nuclei, and such long extrapolations may be very inaccurate. Since the original statistical model was proposed innumerable modifications have been made, and these have tended to erode somewhat its independence from arbitrary assumptions. In compensation for this, however, modern statistical models predict accurately many mass distributions and other fission properties and it seems certain that improvements will continue to be made.

The present position. Some important new ideas concerning the stability of nuclei have emerged in the last few years as a direct result of the discovery in 1962 by the Soviet physicist S.M. Polikanov and others of fission isomers. This term can best be explained by means of an example. The normal isotope americium-241 has a spontaneous fission half-life of about 2×10^{14} years, but there is another isotope, also americium-241, which has a spontaneous fission half-life of just over one-thousandth of a second. This is the fission isomer americium-241. Although it seems very short, the half-life of americium-241 is far too long to be explained in terms of existing models. V.M. Strutinskii, a physicist of the Soviet Union, and others have developed a model in which the average properties of nuclei are described by liquid-drop ideas but then have small variations superimposed on them by the action of individual nucleons.

One effect of these developments has been to change the shape of the fission barrier, mentioned earlier. Instead of a single smooth hump, at the top of which the nucleus is in the transition state, there may be two humps. A fission isomer is a nucleus that is stretched out so that its potential energy has fallen to the value represented by the bottom of the hollow between the two humps. It therefore has to surmount or penetrate the second hump in order to fission and so it has rather more stability than would be expected.

The Strutinskii model also changes the earlier predictions concerning the stability of nuclei as the atomic number and mass number increase. It now seems probable that super transuranic nuclei having high atomic numbers around 114 and 126 will be comparatively stable against spontaneous fission and that some of them may therefore have half-lives of the order of many years. Theoretical predictions of the nuclear properties of these super-heavy

Long-lived super transuranics

nuclides suggest that they will have a high fission energy release and may emit as many as ten prompt neutrons per fission. Scientists throughout the world are trying to prepare samples of these nuclides by particle bombardment, or to find them in a natural state, and it seems clear that there are many interesting developments still to come in the field of nuclear fission.

BIBLIOGRAPHY. The classical papers of O. HAHN and F. STRASSMANN, in which the original fission discovery was reported, may be found in *Naturwissenschaften*, vol. 27 (1939). N. BOHR and J.A. WHEELER, "The Mechanism of Nuclear Fission," *Phys. Rev.*, 56:426–450 (1939), is the classical paper that proposed the liquid-drop model, still of basic theoretical importance in fission. A popular type article well worth reading is R.B. LEACHMAN, "Nuclear Fission," *Scient. Am.*, 213:49–59 (1965). More advanced references include: L. WILETS, *Theories of Nuclear Fission* (1964), an excellent work but not easy reading; I. HALPERN, "Nuclear Fission," *A. Rev. Nucl. Sci.*, 9:245–342 (1959); J.R. HUIZENGA and R. Nuclear Fusion

Nuclear fusion refers to the phenomenon in which two or more relatively light atomic nuclei combine to form a heavier atomic nucleus. If the interacting nuclei belong to elements with low atomic numbers, the reactions are exothermic; that is, they release energy. This is due to the fact that, as the number of subatomic particles, or nucleons (neutrons and protons), packed into the nuclei of the lighter elements increases, the tightness of their packing, expressed as binding energy, also increases. The term denoting the binding energy, however, has a minus sign when the total energy of the atomic nucleus is computed from the rest energies of the free nucleons. Since an unstable system will release energy if thereby it becomes more stable, fusion reactions in substances composed of light nuclides may, under certain conditions, occur spontaneously.

DISCOVERY OF FUSION

The scientific and technical problems relating to nuclear fusion have been the subject of research since the 1930s, when exothermic fusion reactions were first discovered. In 1939, the U.S. physicist Hans A. Bethe proposed that most of the energy of stars, including that of the sun, derives from fusion reactions proceeding at very high temperatures and densities. This hypothesis is almost universally accepted today. Soon after World War II, the attempt began to create a weapon of tremendous power by utilizing fusion reactions in a mixture of deuterium and tritium (the heavy isotopes of hydrogen), and in 1952–53 the so-called hydrogen bomb became a reality.

Hydrogen bomb

Early in the 1950s separate research efforts in the Soviet Union, in the United States, and in Great Britain began to seek ways of harnessing fusion reactions for peaceful needs. Each of these nations pursued its objectives in complete secrecy until 1956, when some research results were first made public by the Soviet Union. The second international Atoms-For-Peace Conference in Geneva in 1958 was characterized by broad exchanges of information on the principal trends of research in the control of nuclear fusion. The barriers of secrecy having been removed, further work on the problem produced fruitful cooperation among physicists of many countries. Nevertheless, all attempts to find a shortcut to the construction of a fusion reactor proved unsuccessful, and progress in this direction became slower than had been anticipated.

THE FUSION PROCESS

Two kinds of reactions. It is necessary to distinguish between two important types of fusion reactions. One of these types consists merely of a regrouping of nucleons into new nuclei, without involving conversions of protons to neutrons or vice versa. An example of such a reaction is the fusion of two deuterons:

$$d + d \rightarrow \begin{cases} {}^3\mathrm{He} + n \\ t + p \end{cases}, \qquad (1A)$$

in which d represents a deuteron (proton plus neutron), t a triton (proton plus two neutrons), p a proton, n a neutron, and ^{3}He, a nucleus of helium consisting of two protons plus one neutron. The two arrows indicate that this reaction may proceed in either of two directions: the formation of a nucleus of ^{3}He, a light isotope of helium, and neutrons, or the formation of tritons and protons. Both reaction routes are about equally probable. The second important type of fusion reaction does involve conversions between neutrons and protons. The simplest example of such a reaction is the synthesis of deuterium from hydrogen:

$$p + p \rightarrow d + e^+ + \nu. \qquad (2)$$

In this reaction one of the two protons is converted into a neutron with the simultaneous creation of a positron e^+ (a positive electron), and a neutrino ν (a particle without charge, having negligible mass and great penetrating power); that is, the process of fusion involves a radioactive decay with the emission of two light particles classified as leptons. Each type of fusion reaction has two characteristics: the energy equivalent (defined as the amount of energy released in a single elementary event), and the intensity of the reaction (being a measure of the number of elementary events occurring in a unit of volume of a mixture of reactants per unit time).

Energy yield. If the kinetic energy of the reacting nuclei is relatively small (as is true for all cases of real interest), the energy equivalent may be assumed to equal the sum of the kinetic energies of the products of the reaction. In very accurate calculations, however, the sum of the kinetic energies of the nuclei before the reaction occurs must be taken into account. In atomic and nuclear physics the energy released in elementary events is usually measured in electron volts. (One electron volt is the energy acquired by an electron, or by some other singly charged particle, on being accelerated by a potential difference of 1 volt; 1 electron volt $= 1.6 \times 10^{-12}$ erg $= 1.6 \times 10^{-19}$ joule.) In reaction 1A the release of energy for the route indicated by the upper arrow is 3,300,000 electron volts, while for the route indicated by the lower arrow it is 4,000,000 electron volts. To appreciate the significance of these quantities, it should be realized that if all the atoms in a single gram of deuterium were to react according to 1A, the energy released would amount to approximately 8×10^{10} joules. If, moreover, one takes into account the fact that the fusion of deuterium produces tritons and ^{3}He nuclei, which may enter with deuterons into further highly exothermal reactions, and if consideration is given to the energy released when the freed neutrons are captured in the materials of the container, the total amount of energy liberated is found to be five times larger than this value, reaching approximately 4×10^{11} joules per gram.

Fusion by nuclear bombardment. Fusion reactions can be observed in the laboratory by a standard technique in which a substance is bombarded with a stream of fast particles issuing from an accelerator. The reaction products are registered by the conventional detectors of nuclear radiation, such as Geiger counters, cloud chambers, and photographic emulsions. The reaction yield for any given reaction depends on sigma (σ), a quantity called "the effective cross section," which is defined as the probability that a reaction will occur when a single fast particle passes through a layer of the substance containing a single nuclear target per unit area. Thus, if n_0 fast particles pass through a thin layer of a substance in which there are N nuclear targets per square centimetre, the total number of fusion reactions would be $n_0 N\sigma$. The effective cross section for a given reaction depends on the kinetic energy, W, of the bombarding particle, and it is possible to establish experimentally the precise relationship between these two quantities by counting the number of elementary reaction events for different values of W.

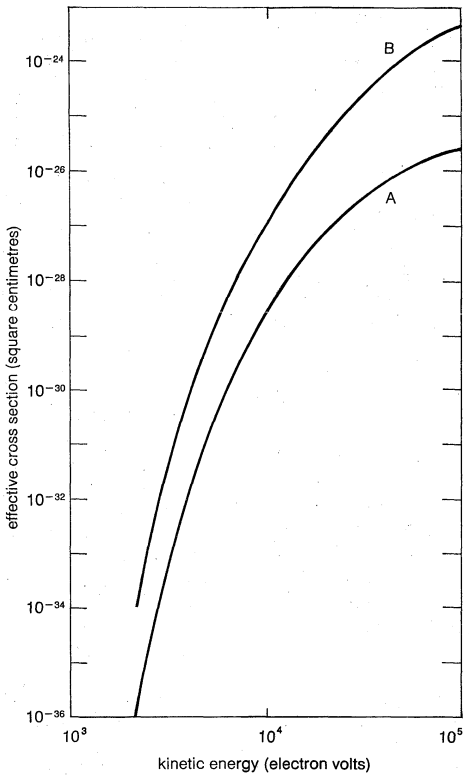

Figure 1: Experimental relationship between cross section of fusion reaction and the kinetic energy of mutual approach of nuclear particles. Curve A refers to reaction 1A for deuterium target; Curve B refers to reaction 1B for tritium target.

Effective cross sections. The results of such experiments are summarized in Figure 1. Curve A relates to reaction 1A, and here σ stands for the *overall* effective cross section, taking into account both possible routes of this reaction. Curve B relates to another reaction:

$$d + t \rightarrow {}^{4}\mathrm{He} + n \qquad (1B)$$

which is of practical interest. The energy equivalent (17,600,000 electron volts) for this reaction is quite high, and its effective cross section is, relatively speaking, very large. It is apparent from Figure 1 that, as the energy of the bombarding particle increases, the value of the effective cross section rises initially quite steeply; but at higher values of W the corresponding rise in σ is drastically retarded, if not stopped altogether. This behaviour may be accounted for in the following manner. A fusion reaction can occur only if two nuclei have succeeded in approaching one another within a distance of the order of

Nuclear forces

10^{-13} centimetre, because only when the distance between the nuclei is this small is it possible for the nuclear forces of attraction to overcome the electrostatic forces of repulsion due to the presence of positive charges on both nuclei. The probability that a bombarding nucleus will penetrate the potential barrier of electrostatic repulsion as it approaches a target nucleus rises very quickly with the increase in the energy of the relative motion of approach. This is expressed in the initial steepness of the rise of the value of σ, and holds strictly only as long as the kinetic energy of approach for the two nuclei remains well below the height of the potential barrier. But as the energy of the relative motion of approach becomes comparable to or exceeds the magnitude of the potential barrier, the increasing insignificance of the potential barrier as an obstacle to nuclear interaction is compensated for by other factors, such as, for example, the greatly reduced time span available for interaction while the two nuclei are separated by still no more than the extremely short distance in which the nuclear force is effective. Because the effect of electrostatic repulsion increases with the magnitude of the charges on the nuclei, the only fusion reactions occurring with appreciable probabilities when two nuclei approach each other with not very high kinetic energies are reactions between the lightest among nuclei; specifically, the nuclei of the various isotopes of hydrogen and helium.

The statements made concerning the dependence of σ on the kinetic energy of approach are, to some extent, also valid for reactions of type 2 accompanied by the emission of leptons. In this case, however, in order to react, not only must the nuclei involved have succeeded in approaching each other to within a distance of the order of 10^{-13} centimetre, but, in addition, one of the fundamental nuclear particles must undergo a radioactive conversion in the negligible time interval during which the nuclei are separated by no more than that distance—a very improbable event. For comparable values of W, therefore, the effective cross sections of reactions involving the conversion of fundamental nuclear particles are expected to be smaller by many orders of magnitude than the effective cross sections of reactions involving merely a regrouping of protons and neutrons. According to theoretical calculations for reaction 2, for example, the value of σ corresponding to values of W not exceeding 1,000,000 electron volts is less than 10^{-46} cm^2. This explains why a fusion reaction even as simple as reaction 2, representing the synthesis of deuterium from hydrogen, cannot in practice be observed in the laboratory.

Low intensities. Although it is quite possible to obtain useful information about elementary fusion events by bombarding a substance with fast nuclei, such bombardments are ineffective as a method of producing fusion reactions with appreciable intensities. The charged, fast particles, when passing through the substance, are greatly retarded by numerous collisions with atomic electrons. In such collisions an initially fast particle rapidly loses relatively large amounts of energy, and its free path in the substance becomes, therefore, very short. While covering its short, free path, the charged particle has only a very small chance of passing an atomic nucleus at a distance close enough for a fusion reaction to be possible. The probability for the occurrence of reaction 1A, for example, when a deuteron with a kinetic energy of the order of 10,000 electron volts is directed at a target of deuterium, is as low as approximately 10^{-11}. Even if W is increased to 1,000,000 electron volts, the probability for the occurrence of this reaction still remains negligible.

Requirements for intensive fusion reactions. From the point of view of usefulness as a source of power, the attainable intensity of fusion reactions and its control are of critical concern. Nuclear fusion processes may develop in a substance spontaneously, that is, without bombardment by fast particles from an external source, if the temperature of the substance is sufficiently high. Such spontaneous reactions occurring because of the high temperature are known as thermonuclear reactions. The higher the temperature of the substance the greater is the kinetic energy of its atomic nuclei in their chaotic motion. The fast-moving nuclei tend to collide with one another, and if in some such collision their kinetic energy of approach is sufficiently high by comparison with the potential barrier of electrostatic repulsion, a fusion reaction may be initiated. The total number of elementary fusion events occurring in a unit of volume of the substance per unit time is proportional to the square of the concentration of nuclei and rises very steeply with the temperature. Consider, for example, a rigid and closed container filled with deuterium and maintained at a pressure of one atmosphere while the temperature is gradually allowed to rise. Until the temperature has reached several hundred thousand degrees Kelvin, a detector will register no sign that a fusion reaction has yet occurred. But at a temperature of 1,000,000° the detector will register as many as about 10^8 elementary fusion events per second for each cubic centimetre of volume enclosed by the vessel, while at a temperature of 100,000,000° the yield will have increased to some 10^{21} fusion events per cubic centimetre per second, implying that in only 0.1 second all deuterons will have participated in reactions with release of nuclear energy.

Spontaneous fusion

Temperature dependence. At any given temperature, T, the atomic nuclei of any substance have a wide dis-

tribution of energies, which, for stationary conditions, is described by Maxwell's law. As long as the temperature is relatively low and the mean kinetic energy of the nuclei is no more than a fraction of the height of the potential barrier of electrostatic repulsion, fusion reactions can be initiated only by the relatively few nuclei whose energies correspond to the remote "tail-end" of the distribution and which, furthermore, happen to encounter one another while approaching from nearly opposite directions, because it is under these conditions that their kinetic energy of approach is greatest. In the region of moderately high temperatures, the yield, or the number of reaction events, increases extremely quickly as the temperature continues to rise. Eventually, with the approach to very high temperatures, nuclei belonging to an increasingly wider part of the energy distribution participate in the fusion process, but the growth of the yield declines. The mean value of the kinetic energies of all nuclei in the substance equals $\frac{3}{2}\,kT$ with k, the Boltzmann constant, equalling 1.38×10^{-16} erg/degree. When the mean kinetic energy reaches the same order of magnitude as the height of the potential barrier of electrostatic repulsion, the growth of the reaction yield practically ceases. At the very high temperatures needed to initiate thermonuclear reactions, nearly all the atoms of the substance are practically fully ionized; that is, they are stripped of all their electrons, resulting in a homogeneous mixture of charged particles, such as free electrons and bare atomic nuclei—all in rapid and randomly directed motion. In this state the substance is called a plasma, and high-temperature plasmas are the only natural medium for the generation of thermonuclear reactions. The fast-moving atomic nuclei of a high-temperature plasma are not retarded in their collisions with free electrons, because the mean kinetic energy is here the same for both types of particles.

Plasma

Predicting yield. It is possible to predict theoretically the yield of thermonuclear reactions for the fusion processes of most general interest. In conformity with the above arguments, the number g of elementary fusion events per second in one cubic centimetre of plasma would be expected to be $g = n_1 n_2 f(T)$, where n_1 and n_2 are the numbers of atoms per cubic centimetre of plasma of each of the two reacting nuclides respectively, while the factor $f(T)$ is some function of the temperature. In the case of a fusion reaction between nuclei of the same nuclide (as, for example, deuterium in reaction 1A), the product $n_1 n_2$ is to be replaced by $\frac{1}{2}n^2$. Figure 2 shows

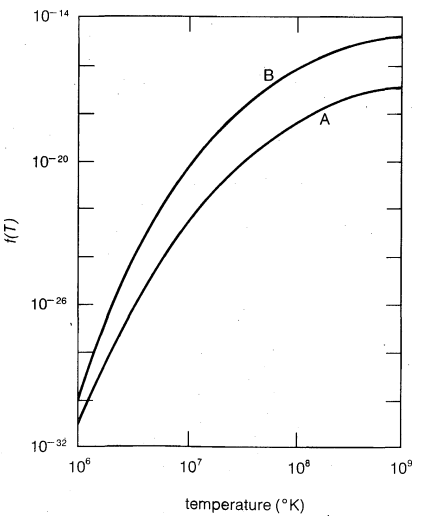

Figure 2: Theoretical relationship between intensity of thermonuclear reaction and temperature. Curve A refers to reaction 1A taking place in pure deuterium; curve B refers to reaction 1B in a mixture of deuterium and tritium.

the behaviour of $f(T)$ for two cases that are of greatest practical interest. Curve A applies to reactions taking place in pure deuterium, while curve B applies to a mixture of deuterium and tritium in which only reactions between different nuclides, as in 1B, are being considered. The effective cross section for reaction 1B is, within a broad range of collision energies, a hundred times greater than that for reaction 1A. It is this fact that accounts for the substantial difference in the behaviour of $f(T)$ for these two reactions.

SOURCES OF THERMONUCLEAR REACTIONS

Thermonuclear reactions and the energy output of stars. According to notions first advanced by Bethe, the energy emitted by the so-called normal stars, of which the sun is an example, derives mainly from sequences of thermonuclear reactions in which hydrogen is converted into helium, with four nuclei of hydrogen (four protons), contributing to the synthesis of a single nucleus of ^{4}He. The end result may be arrived at by several routes, the most important of which are two sequences of nuclear reactions known respectively as the hydrogen cycle and the carbon cycle. These two cycles together contribute most to the energy generated by a star at a stage of its evolution when it consisted mostly of hydrogen.

$$2(p + p \rightarrow d + e^+ + \nu)$$
$$2(d + p \rightarrow {}^3\mathrm{He} + \gamma)$$

(in which ν denotes a neutrino and γ denotes a gamma photon)

$$^3\mathrm{He} + {}^3\mathrm{He} \rightarrow {}^4\mathrm{He} + 2p$$

The hydrogen cycle. The hydrogen cycle begins with reaction 2, which produces deuterium. Two such reactions are required. On reacting with more hydrogen, each of the two deuteriums turns into ^{3}He accompanied by the emission of gamma rays. And, finally, the ^{3}He reacts with more ^{3}He to produce ^{4}He and more hydrogen. The intermediate products, ^{3}He and d, have disappeared, and the net effect of the complete cycle of three reactions is the fusion of four protons to form one nucleus of the heavier of the stable isotopes of helium. The last stage of this cycle requires two nuclei of ^{3}He, each of which had been produced in an independent reaction requiring a deuteron; and each of the two deuterons, in turn, had been produced in an independent reaction from two protons with the simultaneous creation of positrons. When calculating the energy balance of this cycle, therefore, one must also take into account the energy released in the annihilation of two positrons by the two extra electrons remaining after the conversion of hydrogen to helium. The total energy generated by the hydrogen cycle with the creation of a single nucleus of ^{4}He is 26,700,000 electron volts, and nearly all of this energy is initially converted into heat in the immediate vicinity of the points where the reactions occur. These reactions take place well within the deep interior of the star, from whence the thermal energy is slowly transported through the immense volume of the star to its surface by the relatively inefficient processes of thermal conduction. On reaching the surface, the thermal energy is converted to electromagnetic energy, which is radiated into space. Of the total amount of energy generated in a star by thermonuclear processes only about 2 percent is not involved in its heat balance. This energy is dissipated into space by neutrinos—particles that, because of their enormous penetration capacity, are not retained within the star for significant amounts of time. According to theoretical calculations, the hydrogen cycle contributes the greater share of the energy generated in the interior of stars when the temperatures are below 15,000,000 degrees.

Neutrinos

The carbon cycle. At higher temperatures the more rapid conversion of hydrogen to helium is accomplished mostly through the carbon cycle:

$^{12}\mathrm{C} + p \rightarrow {}^{13}\mathrm{N} + \gamma,$
$^{13}\mathrm{N} \rightarrow {}^{13}\mathrm{C} + e^+ + \nu$ (radioactive decay of the unstable ^{13}N nucleus),
$^{13}\mathrm{C} + p \rightarrow {}^{14}\mathrm{N} + \gamma,$
$^{14}\mathrm{N} + p \rightarrow {}^{15}\mathrm{O} + \gamma,$
$^{15}\mathrm{O} \rightarrow {}^{15}\mathrm{N} + e^+ + \nu$ (radioactive decay of the unstable ^{15}O nucleus),
$^{15}\mathrm{N} + p \rightarrow {}^4\mathrm{He} + {}^{12}\mathrm{C}.$

The nucleus of ^{12}C acts merely as a catalyst, and the net

effect is the fusion of four protons to form a single nucleus of ^{4}He, just as in the case of the hydrogen cycle. As expected, therefore, the total energy generated by the carbon cycle is found to be the same as for the hydrogen cycle. But here the part of the energy (6 percent) carried away by neutrinos is somewhat larger. Besides these two main processes of converting hydrogen to helium, there are others that will not be dealt with here. In old stars of high density, in which much of the hydrogen has already been converted to helium, fusion reactions producing heavier elements, such as carbon from helium, become increasingly more important. These processes occur at considerably higher temperatures than the carbon cycle, and the generation of energy per unit mass is lower.

Stellar energy. The rates at which energy is released by thermonuclear fusion processes in stars are characteristically low. In the sun, for example, the rate of heat generation per gram is a mere 2×10^{-7} watt. This is less by many orders of magnitude than the power generated in burning one gram of an organic substance, such as coal, in the furnace of an old-fashioned thermal power plant. Yet, despite this negligible rate at which nuclear energy is being released, the temperatures prevailing in the interior of stars are extremely high, ranging from 10,000,000° to 20,000,000°. This is due to the fact that, because of the huge dimensions of stars, the hot zones in their deep interior, where most of the fusion reactions occur, are very effectively thermally insulated.

It ought to be borne in mind that modern notions concerning nuclear fusion reactions in the interior of stars are speculative. Nevertheless, the thermonuclear fusion hypothesis is the only hypothesis capable of accounting for the origin of stellar energy within the framework of present knowledge of atomic and nuclear processes. In principle, at least, it is possible to put this hypothesis to an experimental test that would consist of registering the flux of neutrinos issuing from the nearest star, the sun. Neutrino fluxes from the sun can be intercepted by means of specialized, extremely bulky, and expensive apparatus in laboratories situated deep underground where they cannot be reached by any of the various types of other particles arriving at the surface of the earth from outer space. Such experiments have just begun, but their outcome will be critical. If it is indeed possible to detect neutrinos born in the interior of the sun, the experimental results will have corroborated one of the boldest physical hypotheses ever advanced to account for cosmic phenomena. Conversely, the proved absence of neutrino fluxes of the anticipated intensity would be an even more intriguing result, because it would force the postulation of entirely new types of processes involving the release of energy, and this could entail the revision of some of the most fundamental ideas of physics.

Hypothesis

The hydrogen bomb. The hydrogen bomb, or H-bomb as it has come to be known, is an instrument of destruction in which thermonuclear reactions of tremendous power are artificially stimulated. The explosion of such bombs is known to liberate energies of up to 10^{17} joules. Its design is, in principle at least, quite simple. The initial explosion of an atomic detonating device embedded in a substance containing deuterium, tritium, and ^{6}Li (the lighter isotope of lithium) raises the temperature to about 10,000,000° within microseconds. This practically instantaneous heating of the mixture of the three light nuclides gives rise to exothermic nuclear fusion reactions of considerable intensity that cause a further increase in the temperature. As a consequence, the reaction rate is sharply accelerated, so that, in an extremely short time interval, all of the many nuclei making up the bulk of the bomb have managed to react and thus to contribute to the release of the surplus nuclear energy contained in the bomb.

Atomic detonator

The time required for a considerable fraction of the total number of nuclei to participate in the fusion process is, at a given temperature, inversely proportional to the concentration of nuclei, or the density of the substance. It is therefore essential that the density be sufficiently high, implying that the explosive mixture must be in a condensed state. Otherwise, the nuclear explosive, after being ignited by the atomic detonator, would be scattered long before each atom could have an opportunity to participate in a nuclear reaction. The main nuclear processes occurring in the H-bomb are reactions between two deuterons (1A), reactions between deuterium and tritium (1B), and reactions involving the disintegration of lithium according to $^6\text{Li} + n \rightarrow {}^4\text{He} + t$, which compensate for the rapid depletion of tritium through reaction 1B. The disintegration of lithium is likewise exothermic. Its energy equivalent is 4,800,000 electron volts. The neutrons for this reaction derive initially from the fission of the heavy uranium nuclei in the explosion of the detonator, but subsequently they are supplied by reactions 1A and 1B.

The generation of energy by the explosion of a thermonuclear bomb is considerably enhanced if the bomb is encased in a shell of ordinary uranium. When this is so, the fast neutrons produced by reactions 1A and 1B will give rise to nuclear fission processes in the uranium envelope, which are accompanied by the release of energy at a rate of about 200,000,000 electron volts for each elementary fission event. Thus, thermonuclear bombs of this type operate through a complex sequence of reactions initiated by nuclear fission, continued through nuclear fusion, and terminated by fission once more. The additional nuclear fuel used in this case is an inexpensive isotope of uranium that is unsuitable for use with an ordinary atomic bomb.

Thermonuclear reactor. The explosion of a thermonuclear bomb, representing a sudden uncontrolled release of energy, cannot in practice be utilized directly to provide power for industry. Hence, the prospects for harnessing the vast amounts of energy, which are so readily available through nuclear reactions involving the light elements, assume critical importance. Because ordinary water contains about one deuteron for every 6,000 protons, and the separation of deuterium from water is a sufficiently simple matter, the oceans may be considered a practically inexhaustible source of nuclear energy. The problem then reduces to one of finding ways of exercising sufficient control over the rates or progress of thermonuclear reactions in high-temperature plasmas, so that the release of nuclear energy would be gradual and could be maintained at a level at which it may be conveniently transformed into electrical energy with maximum efficiency. Any system capable of accomplishing this task is called a thermonuclear reactor.

Inexhaustible source of fuel

BASIC REQUIREMENTS IN THERMONUCLEAR REACTORS

Two conditions. If a high-temperature plasma is to serve as fuel in a thermonuclear reactor, two principal conditions have to be met. The first condition is that the amount of energy released in the fusion reactions must exceed the plasma's losses of energy by radiation, which result from the emission of X-rays that accompanies the collisions of fast electrons with atomic nuclei. Because the plasmas in which nuclear fusion rates could be controlled most readily have relatively low densities, X-rays could easily escape. The energy carried off by X-rays is roughly proportional to T, in which T is the plasma temperature; but the energy released by fusion reactions increases with T according to its $\frac{5}{2}$ power and begins to exceed the radiation losses only above a certain definite value of T. A thermonuclear reactor can produce surplus energy only at a temperature higher than this threshold value, which for pure deuterium is about 3×10^8 degrees, while for a mixture of equal parts of deuterium and tritium, it is about 4×10^7 degrees.

Operating temperatures

The second condition that has to be satisfied in a thermonuclear reactor follows from the fact that energy is removed from the plasma not only by electromagnetic radiation but also through thermal conduction, as well as by streams of fast particles. The combined effect of all these factors on the energy balance of the plasma is taken into account by introducing the quantity τ, defined as the "mean lifetime" of a particle in the plasma. Because the thermal energy of the plasma is made up of the energy of motion of individual particles, τ is also a measure of the interval of time for which the plasma's thermal energy is preserved. A thermonuclear reactor will produce surplus

Mean lifetime

energy only if there is a sufficiently high probability that an atomic nucleus in the plasma during the time interval τ will experience a collision leading to a fusion reaction. The probability for such a collision is proportional to both τ and n, the concentration of particles in the plasma. Thus, the product $n\tau$ must be required to exceed a certain limit. The limiting value of $n\tau$ for pure deuterium is about 10^{16} particle-sec/cm^3, while for a mixture of equal amounts of deuterium and tritium it is only about 10^{14} particle-sec/cm^3—that is, two orders of magnitude smaller. Thus, a mixture of deuterium and tritium would be a much more effective nuclear fuel than pure deuterium. Tritium, however, is not available from natural sources, though small quantities of it could be prepared in ordinary atomic reactors. For this reason, the use of tritium as a component of a nuclear fuel would be feasible only if the thermonuclear reactor happened to be a breeder of that isotope. In principle at least, the breeding of tritium can be realized through a neutron-multiplication reaction (in which a highly energetic neutron on interacting with a nucleus causes the emission of two neutrons of lower energy), as well as through a reaction involving the capture of neutrons by ^{6}Li. But in practice it is deuterium that appears destined to play the major role as a fuel in thermonuclear power plants of the future.

Deuterium fuel

Problem of control. For the technical solution of the problem of effective control over nuclear fusion processes it is first necessary to find ways of heating a plasma to a temperature of the order of 10^8 degrees and, having once reached such a high temperature, to maintain this temperature for a sufficiently long time interval. These requirements represent the major obstacles to the design and construction of a practical thermonuclear reactor. A high-temperature plasma is an extremely efficient conductor of heat. Its thermal conductivity at a temperature of about 10^8 degrees is a million times greater than the thermal conductivity of ordinary metals at room temperature. In a thermonuclear reactor, therefore, the plasma must be effectively insulated from the walls of its container. This insulation is of critical importance because, in the absence of such insulation, all the energy imparted to the plasma as it is being heated will immediately be transmitted to the walls by the fast-moving particles of the plasma. It is possible to insulate a high-temperature plasma by means of a strong magnetic field whose lines of force permeate the plasma and surround it on all sides. In a magnetic field, the electrons and ions of a plasma are relatively free to move only in directions parallel to the lines of force. A charged particle moving perpendicular to the direction of a magnetic field is compelled to move in a circular path, the radius of which becomes smaller as the strength of the magnetic field increases. (For the sake of simplicity, only those portions of the plasma are being considered here in which the magnetic field is very nearly homogeneous.) In general, therefore, the trajectory of a charged particle would be a helix appearing to be wound over a magnetic line of force (Figure 3). It follows that, wherever

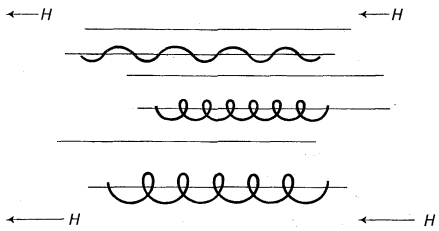

Figure 3: Trajectories of charged particles in homogeneous magnetic fields. Parallel straight lines are lines of force of a magnetic field with strength, H, constant in direction, but increasing toward left. Screwlike curves are paths of given charged particle in various regions of magnetic field (see text).

the lines of force run parallel to the boundaries of the plasma, the magnetic field acts as a barrier preventing the escape of the charged particles. This phenomenon is known as "magnetic thermal insulation." It can also be explained in macroscopic terms. Plasmas are strongly diamagnetic, implying that the strength of the magnetic field over the region occupied by the plasma is greatly reduced. Because of the displacement of the magnetic field by the plasma, the magnetic pressure outside the region occupied by the plasma exceeds the magnetic pressure inside the plasma, and it is this difference in magnetic pressure that prevents the plasma from spreading. During the early stages in the study of controlled fusion, it was anticipated that the principle of magnetic thermal insulation would rapidly lead to the realization of the objective—the construction of a thermonuclear generator. Soon, however, it became clear that, because of certain complicating phenomena in the behaviour of plasmas in magnetic fields, the practical application of magnetic thermal insulation would not be easy to accomplish. It was then realized that the solution of the technical aspects of the problem of controlling nuclear fusion would have to wait until the physical behaviour of high-temperature plasmas is more fully understood.

Magnetic thermal insulation

HIGH-TEMPERATURE PLASMAS

The efforts directed toward achieving control over nuclear fusion, as well as basic studies of properties of high-temperature plasmas per se, require the generation of plasmas with sufficiently high concentrations, n, of particles at extremely high temperatures, and the preservation of the thermal energy of such plasmas for considerable intervals of time τ. The separate values of τ and n are not as critical as the product $n\tau$.

Trends in research. *Mirror trap.* Several avenues of research are directed toward this common objective. One approach is based on the use of systems known as magnetic "mirror traps." The containment of the plasma in such devices depends on the motion of charged particles in nonuniform magnetic fields. A charged particle moving along a line of force in the direction of increasing field strength is compelled to slow down. But while its longitudinal velocity decreases, its speed of rotation about the line force increases, so that the total speed in its helical path remains constant. Therefore, the only change is in the angle between the direction of the velocity and the direction of the magnetic lines of force. If the velocity of a particle is initially directed at a sufficiently large angle to a line of force, the particle will, on approaching a stronger field region, rebound from it as though reflected from a mirror. It should thus be possible to confine all plasma particles between two "magnetic mirrors" in a system in which the magnetic field strength increases at either side of a relatively weak central region. The simplest example of a system designed to incorporate this principle is the device shown in Figure 4. Here, the

"Magnetic mirrors"

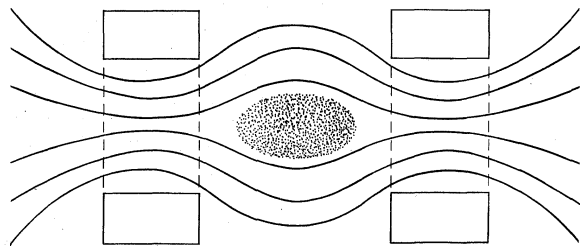

Figure 4: *Plasma trap of the open type employing a pair of magnetic mirrors.*

two magnetic mirrors confining the plasma to the space between them are created by a pair of coils that are arranged so that the current through them flows in the same direction. Such a system also offers a considerable choice in the method of generating the high-temperature plasma that it is designed to contain. The plasma within the magnetic trap may be created by such methods as injecting streams of fast particles, capturing streams of plasma, or high-frequency heating.

Closed magnetic trap. The second major trend of research is concerned with ways of generating and main-

taining a circular ring of plasma within the magnetic field of a toroid, an enclosure shaped like the inflated inner tube of a tire. In this case the bulk of the plasma would be free to flow along the strictly concentric magnetic lines of force which are wholly confined to the space within the toroid, as shown in Figure 5. Such devices are referred to as closed magnetic traps, as distinguished from the open magnetic (mirror) traps described above.

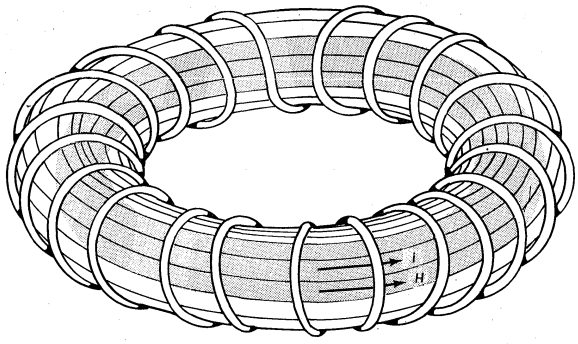

Figure 5: Closed-type plasma trap. Dotted area represents ring-shaped mass of plasma. Current *I*, circulating in plasma ring itself, produces a strong magnetic field of toroidal configuration (not shown). Current flowing in windings of toroid enveloping plasma creates a relatively weak ring-shaped magnetic field *H*, which helps suppress plasma's instabilities.

In the two types of magnetic trap mentioned so far, the bulk of the plasma must be in equilibrium with the magnetic forces acting on it, and all processes associated with the plasma must, therefore, be quasi-stationary. From the macroscopic point of view this means that in order for these traps, whether open or closed, to function properly, no dynamic processes such as would give rise to inertia forces may be associated with the plasma. In microscopic terms, the quasi-stationary behaviour of the plasma implies that the fast, charged particles, while they are still confined by the magnetic system, will perform thousands or tens of thousand of oscillations between the boundaries of the region occupied by the plasma. In traps for the quasi-stationary confinement of plasma, the magnetic fields either are constant or are changing only slowly with time.

Pinch principle. Apart from systems for the quasi-stationary confinement of plasma, much effort is also directed toward developing methods in which the plasma is heated very rapidly in the process of being compressed by a quickly rising magnetic field. This so-called fast-pinch principle is capable of leading to very high concentrations of energy in small volumes of space over very short intervals of time. The magnetic fields in these rapid-compression devices are of the impulse type, implying that they reach their maximum strength within a few microseconds. There are several approaches to achieving the rapid heating of a plasma in a rising magnetic field. The scheme that is most developed at present involves the so-called theta-pinch, or Θ-pinch, system. In such a system the plasma is generated by ionizing a gas in a tube placed inside a coil of low inductance.

When a powerfully charged capacitor is connected to the coil, the very quickly mounting current within the completed circuit gives rise to a magnetic field pulse inside the coil. This field compresses the plasma while simultaneously heating it to a high temperature within a time interval of no more than a few microseconds.

State of progress and prospects for the future. *Traps employing magnetic mirrors.* Initial research was concentrated chiefly on systems of the simplest type with two magnetic mirrors as shown in Figure 4. This method, however, failed to achieve a sufficiently long containment of a dense enough plasma at high temperatures. The lifetime of a plasma in such a trap is limited to tens of microseconds because the strength of the magnetic field, while increasing along the lines of force, is attenuated in radial directions, and the plasma, being diamagnetic, tends to move toward the weaker regions of the magnetic field. If a slight bulge accidently develops somewhere along the lateral surface of the plasma in the central part of the trap, the bulge will tend to grow in a radial direction. Thus, any minor chance disturbances are likely to produce tongues of plasma extending further and further into the surrounding space. In almost no time the plasma will spread throughout the volume of the container and disappear on contact with the container walls.

Plasma tongues

This illustrates the main problem encountered in nearly all experiments aimed at preserving very hot plasmas for significant intervals of time. So capricious is this substance that it seeks to cast off the shackles of magnetic thermal insulation and wriggle its way out of the magnetic trap. The main effort in research is now directed toward dealing with the various instabilities of plasmas.

The large-scale instabilities observed in open magnetic traps of the simplest type, for example, could be reduced by changing the configuration of the magnetic field. But a truly stable confinement of plasma can be achieved only by having the field strength increase in any and all directions away from the region occupied by the plasma. When this is the case, the plasma is said to be in a magnetic well. One of the more plausible methods of effecting a system that would satisfy this requirement is shown schematically in Figure 6. The magnetic field is produced not only by the two coils but also by linear current-carrying conductors that are disposed symmetrically with respect to the common axis of the coils. The current flowing in the linear conductors alternates direction and, if the current intensity is sufficiently high, the magnetic field strength increases in all directions away from the centre of such a system.

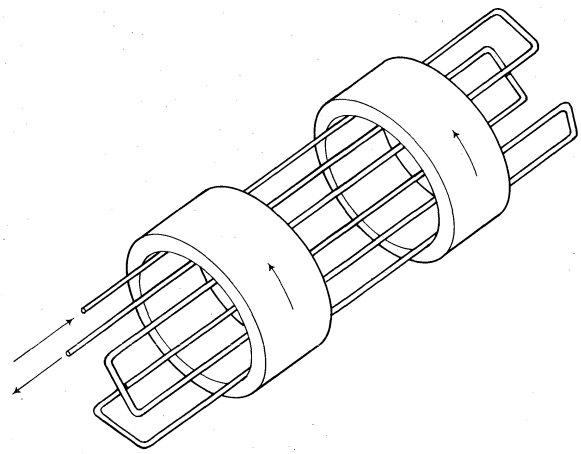

Figure 6: Advanced type of plasma trap, designed so that magnetic field strength increases in all directions away from central region. Short tubes represent a pair of coils wound in the same direction and are responsible for longitudinal increase in strength of magnetic field. Linear conductors, which carry current that alternates in direction, are responsible for radial increase in magnetic field strength. Arrows indicate direction of currents in coils and linear conductors, respectively.

The earliest experiments with such magnetic systems were carried out in the Soviet Union between 1961 and 1963. For the first time, it had become possible to maintain stable configurations of plasmas at temperatures of several tens of millions of degrees with concentrations of up to 10^{10} particles/cm^3, and it was then generally recognized that open traps with magnetic mirrors are feasible only in conjunction with a magnetic well design. All subsequent installations built in the U.S.S.R., the U.S., and Great Britain fulfill this requirement. In these installations it is now possible to produce stable plasmas with a temperature of about 10^7 degrees and with densities of up to 10^{13} particles/cm^3. The maximum values of the product $n\tau$ attainable in present-day mirror traps with strong magnetic fields range from 10^8 particle-sec/cm^3 to 10^9 particle-sec/cm^3. This, however, is still smaller, by as many as five orders of magnitude, than the minimum value of $n\tau$ necessary for the operation of a thermonuclear generator fuelled with a mixture of deuterium and tritium. The temperature also is still too low.

The earliest experiments

Realizing that only a few years ago the value of $n\tau$ in such systems was barely of the order of 10^4 particles-sec/cm^3, and considering the logarithm of $n\tau$ a measure of progress, it appears that half the route toward the ultimate goal via mirror-trap development has just about been covered. From the standpoint of future industrial utilization, however, traps with magnetic mirrors have a crucial drawback. Even if all types of plasma instability could be completely taken care of, such systems would suffer from a loss of particles along the lines of force, a disadvantage that cannot be eliminated in principle. In a trap with magnetic mirrors, it is possible to confine only those particles whose velocity vectors do not form too small an angle with the lines of force. Hence, if the direction of such a plasma particle's velocity has greatly changed as a result of its collisions with other particles, it may now be able to escape from the trap. The amount of energy carried away by the stream of particles from the trap because of collisions with other particles in the plasma would be likely to play a very important role in the energy balance of a future thermonuclear reactor. Rough estimates show that the reactor would have a positive energy yield only if a considerable part of the energy losses due to the escape of particles through the mirrors could be recovered. Because it is uncertain at present whether this is feasible, the future of thermonuclear reactors employing traps with magnetic mirrors also remains uncertain. That the principle of magnetic mirrors will eventually lead to the realization of the first thermonuclear reactor cannot yet be completely ruled out.

Closed magnetic traps. Systems employing closed magnetic traps fall into two groups. In the first group, the plasma is kept generally stable by the toroidal magnetic field due to a current circulating in the ring of plasma itself, while the more dangerous instabilities are supressed by a very strong externally generated field concentric with the ring of plasma. This latter field is produced by coils wound over the toroidal chamber that houses the plasma, as shown schematically in Figure 5. This is the method of plasma containment used in the Tokamak installations of the U.S.S.R. The heating of the plasma in such systems has been accomplished so far exclusively by the joule heat generated by the current flowing through the plasma. But, in principle, other methods of heating could also be used. With longitudinal magnetic field strengths of up to 35 kilogauss, it has now been possible, at the Tokamak installations, to obtain plasmas without appreciable signs of instability at electron temperatures in excess of 10^7 degrees, deuteron temperatures of about 5×10^6 degrees and densities of approximately 5×10^{13} particles/cm^3. With the mean lifetimes of particles reaching into the hundredths of a second, the product $n\tau$ becomes approximately 10^{12} particle-sec/cm^3. In the experiments at Tokamak, the stable plasma ring produces a long-lived neutron radiation that appears to be of thermonuclear origin.

The Tokamak installation

The other group of systems employing closed magnetic traps are the so-called stellarators. In stellarators the ring of plasma is maintained within the toroidal chamber by only an external field that has, however, a complex structure. The design is such that the lines of force are compelled to undergo what is known as a rotational transformation, amounting to having the lines of force wind continuously around the annular axis of the toroidal chamber as one moves along it. The investigation of the properties of plasmas in stellarators is a key element in the research program on controlled nuclear fusion in the United States. The complex geometry of the magnetic field, however, has made it very difficult to suppress the instabilities of the ring of plasma and, for this reason, it has not yet been possible to achieve in such systems the containment of plasmas for sufficiently long intervals of time.

Stellarator systems

In any event, the construction of thermonuclear power plants based on any one of the quasi-stationary closed-trap type of reactors would face tremendous technical difficulties because such high magnetic field strengths are required in conjunction with such large installations.

Impulse compression of plasma. The greatest interest in this line of research has for some years centred on systems of the Θ-pinch type, in which the plasma is compressed by a rapidly increasing external magnetic field. The study of such systems originated in the United States and then spread to a number of laboratories in Great Britain and the Federal Republic of Germany. With magnetic fields rising to 1×10^5 gauss within a few microseconds, it is now possible to produce plasmas at temperatures ranging from 1×10^7 degrees to 3×10^7 degrees and densities ranging from 10^{16} particles/cm^3 to 10^{17} particles/cm^3. The time interval for which such high temperatures can be maintained depends on the dimensions of the apparatus, that is, on the length of the coil in which the process of compression takes place. With coil lengths of about one metre, τ ranges from five to ten microseconds, and the product $n\tau$ reaches a value of about 10^{11} particle-sec/cm^3. The high temperatures, together with the high particle densities in these Θ-pinch systems, produce conditions that give rise to neutron radiation. If it were possible to overcome some of the difficulties of converting the open Θ-pinch system to a closed ring design, a manifold increase would be achieved in the duration of plasma confinement and this would make such a system highly promising.

The compression and simultaneous heating of plasmas can be accomplished by means other than that of an externally produced magnetic field. In the earlier stages of nuclear fusion studies, much interest was expressed in the possibility of producing high temperatures by the rapid compression of plasmas in what came to be known as linear pinch systems. In this case a filament of plasma is compressed in the course of a very short time interval by the magnetic field accompanying a strong current that flows through the plasma filament itself. It was found, however, that because of the instability of a plasma filament carrying a strong current, the values of τ in linear pinch systems tended to be very small. According to the criteria discussed above, therefore, a positive energy yield for a thermonuclear reactor based on the linear pinch system could be brought about only by creating a very dense plasma and passing a gigantic current through it. This, in turn, would imply the practically instantaneous concentration within the plasma of an enormous amount of energy, followed by its practically instantaneous liberation; that is, the process would assume the character of an intense explosion. Despite such discouraging implications, however, continued study has shown that, if the strictly cylindrical geometry of the system is replaced by a noncylindrical design, it is possible to obtain the formation of a plasma focus in the very small volume of approximately 0.01 cm^3 and to achieve within this focus a density of roughly 10^{19} particles/cm^3 at temperatures reaching some 10^7 degrees. Such a plasma focus can be maintained for about 10^{-7} seconds, so that the product $n\tau$ attains a value of 10^{12} particle-sec/cm^3. The plasma focus is an impulse source of intensive neutron radiation. Currently, experiments with plasma foci are being conducted in the U.S.S.R., the U.S., Great Britain, and Italy.

Linear pinch systems

Technological developments of recent years have opened up new avenues for producing high temperatures in plasmas by processes of extremely short duration. The impulse heating of plasmas to very high temperatures can be achieved, for example, by means of laser beams (see LASER AND MASER). In principle, at least, this offers the possibility of generating thermonuclear reactions of considerable intensity without the necessity for thermally insulating the plasma by magnetic fields. Modern laser technology makes it possible to produce well-focussed beams of light carrying large amounts of energy for time intervals shorter than 10^{-9} second. In such rapid heating, the energy losses of the plasma through thermal conduction and diffusion cannot play an appreciable role. Nevertheless, it can be anticipated that the explosive character of energy generation in any system employing this principle would lead to technical difficulties comparable to those expected in the case of cylindrical linear pinch systems.

Heating by laser beams

When can a solution to the problem of controlled fusion be expected? Perhaps only when mankind's need for new sources of power becomes so acute that all possible approaches are investigated.

Nuclear Reactor

A nuclear reactor is a device designed to permit self-sustaining and controlled nuclear fissions, with the object of generating heat, producing radioactive isotopes or plutonium, developing an intense field of nuclear radiation, or serving some other useful purpose. Nuclear fission (*q.v.*) is the phenomenon in which an atom of fissionable material disintegrates when struck by a neutron, producing two entirely different atoms and generating a large amount of heat. In the fission process, neutrons are also given off, and these neutrons can cause more atoms to fission, thus leading to the possibility of a chain reaction. In the atom bomb this chain reaction is uncontrolled; in a nuclear reactor it is very carefully controlled.

The amount of heat generated in the fission process is very large. If all the atoms in a pound (0.45 kilogram) of uranium-235 were to undergo fission, the heat produced would be equivalent to burning 1,500 tons of coal. This phenomenon is the basis of the major application of nuclear reactors: the production of large amounts of heat for electrical power generation.

Whenever nuclear fission occurs, the two atoms that are produced are radioactive, often intensely so. They may spontaneously release highly penetrating gamma rays (X-ray-like radiation) and generally less penetrating beta rays (electrons). A nuclear reactor, therefore, is potentially a source of heat, neutrons, and radiation.

This article is divided into the following sections:

NUCLEAR-REACTOR PRINCIPLES

The chain reaction. For a chain reaction to take place, it is necessary for at least one of the neutrons released during each fission to cause another fission to occur. This condition requires the release of a large number of neutrons because many escape the chain-reaction system altogether, and some, after collisions with atoms, become absorbed without causing fission.

The only atom found in nature capable of supporting a nuclear chain reaction is a rare isotope of uranium, uranium-235. Most of the atoms of which normal uranium is composed contain 238 particles in their nuclei. The 235 variety, which exists in the proportion of approximately one out of every 140 atoms, generally splits easily when a neutron collides with it. It is more likely to split if the neutron is moving at a relatively slow pace; faster neutrons tend to fly directly by without any effect. Neutrons released during fission have high speeds, so that one way to start a chain reaction is to find some means of slowing them down. A chain reaction can also be made more likely to occur by increasing the proportion of uranium-235 atoms in the fuel, a process known as enrichment. With sufficient enrichment, the chain reaction can occur without the slowing down of neutrons. Still another way to facilitate the chain reaction is to make the reactor core large enough to minimize the number of neutrons escaping its boundaries. For any particular reactor core there is a critical size below which the chain reaction cannot occur. This critical size decreases with the increasing enrichment in uranium-235. It may also be reduced by surrounding the core with a reflector, a material that reflects neutrons back into the core.

The critical core size

Finally, a chain reaction is more likely to be sustained if the number of neutrons captured by nonfissionable atoms is minimized. Certain kinds of atoms readily capture neutrons, particularly the slow ones. Materials composed of these atoms may have to be avoided insofar as possible. The nonfissionable portion of uranium, uranium-238, can absorb neutrons, particularly those at intermediate speeds, without producing fission. Fissions can occur with fast neutrons; nevertheless, this probability is so low that the number of neutrons supplied in this manner provide only a small contribution to the requirements of the chain reaction.

Moderation. The process by which neutrons are slowed down is called moderation. In the process, a moderator composed of light atoms with low-absorption cross sections is employed. The cross section may be thought of as the area surrounding the nucleus of the atom through which the neutron must pass to interact with the nucleus. When neutrons are released into the moderating material, they bounce from one atom to another, losing speed with each collision in a billiard-ball fashion. This action occurs only when the atoms with which they collide are small and do not absorb the neutrons. Deuterium, for example, is an excellent moderator because its atomic weight is low, only twice that of a neutron, and its absorption cross section is also low. Hydrogen is better from the standpoint of its mass, close to that of a neutron, but its absorption, or capture, cross section is somewhat higher than that of deuterium.

Slowing of neutrons. If uranium-238 is to be contained in the core of the reactor, the designer must consider its relatively high-absorption cross section at intermediate neutron speeds. For this reason the cores of reactors often consist of a lattice arrangement in which the uranium is spaced at regular intervals in the form of rods embedded in a moderator. This approach has led to the heterogeneous-reactor type in which the fuel is in the form of discrete rods or plates, allowing the neutrons released at high speeds to escape the uranium quickly and then bounce about in the moderator before re-entering the fuel rods. Neutron speeds are thus reduced to the point at which their chances of capture by a uranium-238 atom are reduced, and their chances of capture by a uranium-235 atom are increased.

Reactor control. There would be an excessive release of heat if the chain reaction were to proceed at too great a rate. To control the reaction, a material that has a high neutron-absorption cross section, such as cadmium or boron, is inserted in the core, often in the form of rods. The reactivity of the core increases when the rods, called control rods, are withdrawn. When the control rods are inserted as far as possible, the reaction is completely shut down, and any further chain reaction is prevented. Another method of control requires varying the amount of fuel, but in this case withdrawing the fuel rods reduces reactivity. Control of the reaction may also be achieved by varying the amount of a reflector or the amount of a moderator.

Control rods

Heat removal. Nuclear fission releases energy in the form of heat. If the power of the reactor and the rate at which fissions occur are kept low, the core may become only slightly warm, and no special provisions will be required to remove the heat. On the other hand, high power levels require elaborate heat removal systems inside the core. In these systems cooling fluids, such as water, gases, or liquid metals, are circulated through the core. The fluids must be composed of materials that have suitable nuclear properties so that not too many neutrons will be absorbed, and they must also have suitable flow and heat-transfer properties.

Shielding. To protect personnel in the vicinity of the reactor from radiation, a shield is installed around the core to absorb escaping neutrons and gamma rays from the fission and the fission fragments. The amount of shielding required depends on the power level at which the reactor is operated and the length of time during which the radioactive fission fragments accumulate. Some shielding is provided to protect various materials, the physical properties of which are affected by radiation.

NUCLEAR-REACTOR DEVELOPMENT

The first reactors. *Two atomic-bomb designs.* Even before the World War II atomic bomb project was organized in the United States as the Manhattan Project, two different ways to achieve a nuclear chain reaction had been considered. Later, these provided the basis for two different ways to make an atomic bomb, and both methods worked.

In one design, a chain reaction is achieved by separating the fissionable uranium-235 from the more abundant uranium-238. With a sufficient amount of enriched uranium (the critical mass), a chain reaction occurs if a moderator is not used (*i.e.*, without slowing down the neutrons to a point such that the probability of neutron-causing fission becomes much higher). By concentrating the fissionable material, they believed that they could accept the lower fission cross section, which allows neutrons to bypass atoms more easily without causing fission. When the chain reaction proceeds so rapidly that all or most of the atoms undergo fission before being blown apart, a nuclear weapon results. (See also NUCLEAR WEAPONS.)

The problems involved in separating uranium-235 are formidable. Their solution became one of the major accomplishments of the Manhattan Project. Success came first at a large gaseous diffusion plant at Oak Ridge, Tennessee. The separated uranium-235 was incorporated in the atomic bomb that was exploded at Hiroshima on August 6, 1945.

Another method for producing a chain reaction is the use of natural uranium with a moderator that takes full advantage of the high fission cross section of uranium-235 for slow neutrons. It was not recognized at first that this method could also lead to an atomic bomb because the pertinent discovery had not yet been made. Scientists knew that uranium-238 has a relatively high capture cross section for neutrons with intermediate speed and that the lattice design of fuel elements embedded in a moderator would minimize losses of neutrons into uranium-238. What had not been established was that the absorption of a neutron into uranium-238 leads to the formation of a new type of fissionable atom, one not normally found in nature. When a uranium-238 atom absorbs a neutron, it becomes uranium-239, which is unstable and emits an electron. It thus transmutes itself from uranium to another element, called neptunium, with an atomic number of 93 instead of 92. Neptunium, in turn, is also unstable, leading to a similar transmutation to plutonium, with an atomic number of 94. Because both reactions occur rapidly, the plutonium exists within a few days after the neutron has been absorbed by uranium-238. The plutonium isotope produced, plutonium-239, is relatively stable and fissionable. It releases approximately the same number of neutrons as does uranium-235; *i.e.*, between two and three on the average for each fission, and its fission cross section for slow neutrons is even higher than that for uranium-235.

With these discoveries it became apparent that the production of plutonium could be a substantial benefit to be gained through the capture of neutrons by uranium-238. For this purpose it would be necessary to design a reactor to favour such captures, but without using up so many neutrons that the chain reaction could not proceed.

Though a natural uranium chain reaction is a possible source of heat and radiation, it is too bulky to serve as the basis for an atomic bomb. It may, however, be used to produce plutonium, which then can be fabricated into a bomb without having to rely on uranium-235. The design and construction of a large plutonium-producing nuclear reactor, therefore, had a high priority during the early days of the Manhattan Project; it was plutonium, in fact that was employed in the first nuclear explosion in a nuclear-weapons test at Alamogordo, New Mexico, on July 16, 1945.

The Chicago pile. The world's first nuclear reactor was constructed in the United States at the University of Chicago under the direction of Enrico Fermi. It achieved criticality (a self-sustaining chain reaction) on December 2, 1942. The reactor consisted of 400 tons of graphite, six tons of uranium metal, and 50 tons of uranium oxide, with control rods made of cadmium. Instruments placed inside the pile measured neutron intensity. When the cadmium rods were withdrawn gradually, at a certain point the neutron intensity began to increase rapidly, signalling the start of a self-sustaining nuclear chain reaction. The cadmium rods were reinserted before any appreciable amount of heat developed and before the neutron and radiation levels became hazardous. It was later in the day that the historic news was transmitted by telephone from Arthur Holly Compton in Chicago to James B. Conant at Harvard University with the following guarded language: "Jim, you will be interested to know that the Italian navigator has just landed in the New World."

The world's first reactor

The experiment confirmed what had been expected: criticality was reached even more easily than anticipated. Plans were formulated for the construction of four other reactors in the U.S., and the work of harnessing the atom for peaceful purposes was underway.

Reactor types. *Thermal and fast reactors.* The long-run advantages of a reactor that operated with fast neutrons, without a moderator, had been recognized by 1946. With sufficient enrichment, criticality could be achieved despite the lower cross section for fission with fast neutrons. Because fissions produced by fast neutrons supply slightly more neutrons on the average, they provide extra neutrons beyond those required to keep the chain reaction going. Calculations showed that with sufficient uranium-238 in or near the core, the supply of neutrons that resulted from occasional fissions of uranium-238 would increase slightly.

More important, there would be a sufficent supply of the extra neutrons captured by the uranium-238 to produce plutonium faster than the uranium-235 was consumed. In other words, using one neutron per fission to cause the next fission, with allowances for escaping neutrons or losses caused by capture in structural materials, there would still be more than one neutron on the average remaining to be captured by uranium-238, which would then convert to plutonium-239. It thus became theoretically possible to consume uranium completely, thus tremendously increasing the value of uranium as a new source of energy.

To test these ideas, an experimental breeder reactor, the EBR-I, was built in Idaho by the Argonne National Laboratory. The reactor core was composed of fuel rods of highly enriched uranium-235, surrounded by a blanket of natural uranium to provide the fertile material in which the plutonium could be formed.

The breeder reactor

Operating successfully for the first time during 1951, the reactors demonstrated not only the feasibility of breeding but also the feasibility of generating electricity with nuclear power. Reactor heat was transferred with a liquid metal (a mixture of sodium and potassium, called NaK) to a steam generator that provided power for a small electric turbine.

The two reactor concepts, one making use of slow neu-

trons (generally referred to as thermal neutrons), and the breeder concept, utilizing fast neutrons, were forerunners of two fundamental classes of reactors: thermal reactors and fast reactors. Most of the wide variety of reactor types that have since been developed are of these two classes.

Thermal power reactors (Figure 1) have been developed to the point that they are commercially attractive as energy sources for large power plants, but, in the early 1970s, fast reactors had not yet reached that stage of development.

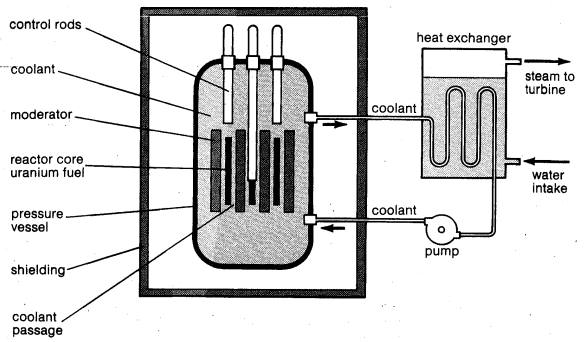

Figure 1: Components of a power reactor designed to generate high-pressure steam.

Plutonium-production reactors. The production of plutonium for military purposes was expanded in the United States after World War II with the construction of additional graphite-moderated reactors and a new series of large heavy-water reactors (HWR). (Heavy water is water in which the conventional hydrogen atoms have been replaced by deuterium, the hydrogen-2 isotope.) The heavy-water reactors were also used to convert lithium into tritium (the hydrogen-3 isotope) for use in thermonuclear weapons.

Materials-testing reactor. One of the early needs in reactor development was a materials-testing reactor that could supply a high flux of neutrons to test their effects on materials and thus provide necessary information for the design of other reactors. Neutron flux is the number of neutrons crossing a unit area each second.

Pressurized water was selected to serve as both moderator and coolant in the first materials-testing reactor. The fuel was highly enriched uranium embedded in aluminum, arranged in the form of parallel plates. Water was pumped through at high speeds to carry heat away, thus allowing the reactor to operate at a high power density with a correspondingly high neutron flux. The reactor was placed in full-scale operation in 1952.

Aircraft-propulsion reactor. The use of nuclear power for aircraft propulsion was proposed immediately after the end of World War II. The U.S. Air Force began a project known as Nuclear Energy for the Propulsion of Aircraft (NEPA); but controversy over the potential hazard began at once, and, as the complexities of the problem became more evident, the project was discontinued in 1951.

Responsibility for the design of an aircraft engine was shifted to the General Electric Company and the National Reactor Testing Station in Idaho where test facilities could be built. But in the end enthusiasm for the project was overcome by doubts about feasibility and safety. The goal of planes that could fly for long periods without refuelling did not seem to justify the development expense nor the hazards that would inevitably be associated with carrying nuclear reactors in airplanes, and the project was abandoned in 1961.

Reactors for a nuclear navy. The use of nuclear reactors for the propulsion of naval vessels has been highly successful. Although it was not directly involved in nuclear matters during World War II, the U.S. Navy was interested in nuclear energy before the establishment of the Manhattan Project as the result of research undertaken at the Naval Research Laboratory.

Nuclear energy for submarines

Studies of the use of nuclear reactors as a source of energy for submarine propulsion began in 1946. The potential advantages over oil as a fuel were obvious. With nuclear fuel, it would no longer be necessary to surface to recharge batteries, and the energy from uranium for a given bulk would be far higher than that from oil, thus making possible almost indefinite operation without refuelling.

Two submarine-propulsion projects were formulated, the submarine intermediate reactor and the submarine thermal reactor. The submarine-intermediate-reactor concept involved the use of enriched-uranium pins as fuel with liquid sodium as a coolant and with intermediate-energy neutrons. This concept was thought to have a long-range potential for breeding and electric-power generation as well as for submarine propulsion. It soon became clear, however, that the requirements for submarine propulsion are different from those for electric-power generation, and military requirements taking precedence, the reactor was designed solely for submarine propulsion. The "Seawolf," a submarine possessing the submarine-intermediate-reactor type of propulsion, was operated successfully from 1956 until it was shut down in 1959.

The concept was not adopted by the Navy because of the spectacular success of the water-cooled and -moderated reactors that had been achieved in the meantime by the submarine-thermal-reactor concept. Use of pressurized water both as coolant and moderator was advantageous because the Navy was thoroughly familiar with the material. Because operation at high pressure was required to achieve reasonable efficiency, new problems arose, centred on control, corrosion, fuel-element fabrication, and shielding. Materials had to be selected that would maintain their integrity under intense radiation by both gamma rays and neutrons and that would not themselves absorb too many neutrons. To provide the necessary compactness, it was necessary to use highly enriched uranium-235.

Homogeneous reactor. Another significant concept introduced immediately after World War II was that of the homogeneous reactor, in which uranium, usually in the form of uranyl sulfate, was mixed with a water moderator to form a slurry that was continuously circulated to remove fission products and plutonium, thus avoiding the problem of fuel fabrication. With pressurization, the system could become hot enough to be used as a source for the generation of electricity. One of the major difficulties was finding materials that could withstand the corrosiveness of the slurry. A small, homogeneous, experimental reactor was built and operated during 1952, and in February 1953, it became the second reactor to demonstrate the technical feasibility of converting nuclear to electrical energy.

Reactor development worldwide. During the early period after World War II, reactor development was also studied in other countries, notably the United Kingdom, Canada, France, and the Soviet Union.

With assistance from French and English scientists, Canada had a small, natural-uranium, heavy-water-moderated reactor operating at Chalk River, Ontario, in 1945. By 1947, another reactor, also using natural uranium and heavy water, was able to supply what were at that time extremely high neutron fluxes.

Later, this reactor was used by Argonne National Laboratory scientists to test materials for large, heavy-water-moderated plutonium- and tritium-production reactors. This second reactor was used to produce experimental quantities of uranium-233 from thorium as well as plutonium from uranium-238.

Reactor development in the United Kingdom

Before 1942, the United Kingdom had discussed with the United States the possibility of making atomic bombs. From that period until the close of the war, however, its role was essentially limited to the Canadian project and to some participation in the work at the Los Alamos Scientific Laboratory. Immediately after the war, the British, assigning a high priority on plutonium production for weapons development, planned to use graphite-moderated, air-cooled reactors. Two small reactors of

this type were operating for research purposes by 1948, and two plutonium-production reactors were operating successfully at Windscale by 1951, when it was decided to combine plutonium and power production in subsequent reactors, cooling them with carbon dioxide instead of air. The resulting series of Calder Hall reactors, as they were known, gave the United Kingdom an early lead in the commercial production of electric power and at the same time enabled it to build a stockpile of plutonium.

By 1948, France had a heavy-water-moderated natural-uranium reactor, similar to Canada's first, for research purposes. A plutonium-production policy similar to that of the United Kingdom was adopted; by 1956 the first of a series of reactors was being operated as a small, dual-purpose plant. This was air-cooled, but subsequent reactors of this type also switched to carbon dioxide.

NUCLEAR POWER DEVELOPMENTS TO 1962

Industrial participation. By 1950, certain industrial leaders in the United States were impatient to participate in the development of nuclear power. Industry proposed that an atomic-power plant be built with private funds, to produce power and plutonium at the same location. This proposal led to an "industrial participation program" in which the Atomic Energy Commission (AEC), the successor of the Manhattan Project, allowed industrial study teams to have access to pertinent classified information in order to "examine the economic and technical aspects of building this (dual-purpose) reactor in the next few years." A variety of concepts was considered, ranging from graphite moderation with sodium cooling, graphite moderation with helium cooling, homogeneous systems with uranium-233 production instead of plutonium, to a fast-breeder reactor. Although the dual-purpose-reactor concept was finally abandoned in the United States as the basis for starting a private nuclear power industry, the studies undertaken laid the foundation for extensive industrial participation in reactor development.

The work of one of the study teams led eventually to the Enrico Fermi fast-breeder reactor at Monroe, Michigan. Another team, proceeding without direct government assistance, purchased a boiling-water reactor (BWR) with an electrical-power capacity of 208,000 kilowatts, at Morris, Illinois. It became, in 1959, one of the earlier power-demonstration plants (see Table 1).

The dual-purpose concept was abandoned as a spur to power production because of the reluctance to combine military and commercial objectives. One reason for the abandonment was the fact that high-priority-plutonium requirements would affect the reactor design and reduce the efficiency for power production.

The British, however, took a different view. They decided to build graphite-moderated, carbon-dioxide-cooled reactors to produce plutonium, for military purposes, while at the same time utilizing the heat to generate electricity. As a result, they became the largest producers of electricity from nuclear fuel, but the plants were not economical when used entirely for the production of electricity.

The dual-purpose concept was revived by the United States in 1958, when the government authorized the design and construction of a new production reactor with plutonium production as its primary purpose, but with the by-product, heat, to be sold to an electric-utility company in the form of steam to operate an 800,000-kilowatt electric-power plant. In this instance, the purpose was to reduce the cost of plutonium production. The reactor first became critical in 1963, and in 1966 the adjacent Washington Public Power Supply System generating station began to produce electricity. In 1971, with a declining need for plutonium, shutdown of the reactor was under serious consideration.

"Atoms for peace." On December 8, 1953, President Eisenhower recommended the establishment of the International Atomic Energy Agency. Shortly thereafter, he recommended that the Atomic Energy Act of 1946 be amended to provide more encouragement to the peaceful application of atomic energy. In 1954 a new Atomic Energy Act was adopted, making it possible for nuclear reactors to be privately owned under suitable licensing arrangements. Nuclear materials, plutonium, uranium-233, and uranium-235, were to be leased for private use. Reactor development was encouraged in other ways for peaceful purposes, and international cooperation in all peaceful applications of atomic energy was likewise encouraged.

The power-reactor development program. During the same year, the Atomic Energy Commission announced a power-reactor development program centred on five reactor concepts: pressurized water, boiling water, sodium–graphite, homogeneous, and fast breeder.

Five reactor concepts

The first of these was a pressurized-water reactor to be built immediately at Shippingport, Pennsylvania, as a plant with 60,000 kilowatts of electrical power capacity with steam to be sold to an electric-power company. The technology was derived largely from experience with the submarine thermal reactor.

The concept of a boiling-water reactor was derived from experiments at the Argonne National Laboratory with a small reactor that had been allowed to boil the water surrounding the core on a continuous basis, thus suggesting the possibility of direct coupling to a steam turbine instead of using hot pressurized water from the reactor to produce steam in a boiler separate from the reactor. The experiment had shown that if the control rods were abruptly removed, thus causing a sudden power expansion, the boiling water became steam so rapidly that the moderating effect of the water was lost and the chain reaction came to a stop long before the fuel elements were damaged.

The homogeneous reactor was to be based upon earlier experience at Oak Ridge. It would be slightly larger, and would hopefully serve as a prototype for a still larger plant.

The sodium–graphite reactor was intended to combine the well-known graphite technology as the moderator with sodium cooling to achieve higher temperatures for more efficient power production, without the inconvenience of the high pressures associated with water cooling.

Finally, the potential advantages of a fast-breeder reactor were well recognized. With the success of the original experimental breeder reactor (EBR-I), it was decided that the Argonne National Laboratory should build a larger version (the EBR-II), also to be in Idaho at the National Reactor Testing Station. It would be scaled up to about 60,000 kilowatts of heat with an electrical production of about 15,000 kilowatts. It would be loaded first with uranium-235 and later with plutonium in order to enable it to produce larger amounts of plutonium in the uranium blanket.

By the end of the decade, each of these five experimental reactors was operating and another had been added. A small reactor moderated with organic material had been tried because of its potential for producing fairly high steam temperatures at relatively low pressures. A major disadvantage, however, was the low heat-transfer properties of the organic material and its tendency to decompose and polymerize (combine two or more small molecules into large ones).

Except for the homogeneous-reactor concept, each of the experimental reactors led to the design and construction of industrial prototypes or demonstration reactors. Some of these plants were large enough to produce a significant amount of power, but there was still no proof that the costs could be made competitive with power plants burning fossil fuels.

The European Atomic Energy Community. Prompted largely by a growing shortage of coal and oil, the six Common Market countries of Europe in March 1957, ratified the establishment of the European Atomic Energy Community (Euratom). Earlier, representatives from West Germany, France, and Italy had visited the United States and had discussed plans for a nuclear power program in Europe. Their report, "A Target for Euratom," noted the growing dependence of Europe on en-

Founding of Euratom

*Electrical output. †Thermal output.

ergy imports and the crisis that the threatened closing of the Suez Canal posed to obtaining oil from the Middle East. With rising fuel costs and rising demand for electric power, they were enthusiastic about the advent of nuclear power as a means by which Europe could become less dependent on fuel imports. They proposed that Euratom set a target of 15,000,000 kilowatts of installed nuclear power capacity to be built during the next ten years.

It appeared, therefore, that the conditions for nuclear-power development in Europe were more favourable than those in the United States and indeed that European experience might become a proving ground from which American power reactor development could benefit.

These expectations were not realized, partly because of the increasing availability of coal and the discovery of new oil and gas reserves. France had the beginnings of a nuclear-power industry based upon the dual-purpose graphite-moderated, carbon-dioxide-cooled-reactor approach. Italy opened negotiations to buy plants from both the United States and the United Kingdom and was the first to propose a nuclear-power plant of substantial size to be built under arrangements between Euratom and the United States. These initiatives, however, fell far short of what the Europeans had visualized. The Euratom proposal was dependent upon decisions by utility companies, and the uncertainties in the cost and availability of nuclear fuel, the complexities of nuclear-liability insurance, together with the high capital costs, discouraged the switch from fossil to nuclear fuels.

By 1962, five years after Euratom's founding, two firm Euratom power projects, and a third underway, provided altogether about 700,000 kilowatts of capacity. Obviously the earlier goal was not to be achieved, and there had been only a beginning in the development of an international market for nuclear-power equipment. During the same period, Japan, with its dependence on fuel imports, recognized the potential advantages of nuclear power and began to explore the possibility of purchasing both nuclear technology and equipment from the United States and from the United Kingdom.

Progress in reactor development. By 1962, 233 American-built nuclear reactors were being operated. Of these, 18 were directed toward electric-power production with half of them at the prototype stage. There were 21 test reactors and 116 research or teaching reactors, of which 37 were located in foreign countries. There were 42 naval propulsion reactors, with 51 more under construction. Thirteen large materials-production reactors were operating with plutonium as the primary product.

It was evident that substantial progress in reactor development had been made, but economically competitive nuclear-power plants had not yet been achieved. The nine prototype power reactors are described briefly in Table 1. In addition, experiments at various stages were underway with a variety of reactor concepts.

Boiling reactor experiment no. 5 (Borax-5). This was the fifth in a series of experimental reactors built to study boiling-water reactors and to demonstrate the feasibility of generating superheated steam with a nuclear reactor. In order to obtain the higher efficiencies associated with higher temperatures, saturated steam is produced in one set of fuel elements in the core and then recirculated through a second set in the same core to obtain the superheated steam.

Superheated-steam production

Experimental boiling-water reactor. This reactor was designed to experiment with gradually increasing power outputs. After having been designed to boil water at a rate of 20,000 kilowatts of heat, it was found to be possible to raise the level to more than 100,000 kilowatts. In addition, the reactor was used for experimentation with plutonium as a fuel.

Organic-moderated-reactor experiment. Organic compounds, such as diphenyl, were used both as moderator and coolant. Such compounds have the advantage of a relatively high boiling point, thus permitting higher temperatures without so much pressurization as required by water.

Heavy-water components-test reactor. This experimental pressurized heavy-water reactor was directed toward heavy-water-power-reactor development. Test irradiations were made of fuel elements composed of natural or slightly enriched uranium.

Plutonium-recycle-test reactor. This was a heavy-water-moderated and -cooled reactor with the cooling water circulated through pressure tubes. It had a heat capacity of 70,000 kilowatts, and its primary purpose was to test the use of plutonium as an alternate for uranium-235 as a fuel in power reactors.

NUCLEAR POWER DEVELOPMENTS AFTER 1962

Two years after 1962 forecasts of a growing need for nuclear energy to supplement fossil fuels, economically competitive nuclear power was signalled for the first time by the announcement of plans for the private financing and construction of large-scale nuclear-power plants that would produce electricity at lower costs than would be possible with fossil fuels. The first of these was a boiling-water reactor at Oyster Creek, New Jersey, with an elec-

trical capacity of 515,000 kilowatts. This was followed by many other orders for large plants, both boiling-water and pressurized-water types, some ranging up to the 1,000,000-kilowatt range.

By the end of March 1971, 20 nuclear-power plants with a combined capacity of 8,121,000 kilowatts were licensed for operation in the United States. An additional 55 plants with a combined capacity of 46,221,000 kilowatts were under construction, including one of the high-temperature, gas-cooled type. Applications for the construction of 25 more plants had been filed. In 1964 the U.S. Atomic Energy Act was amended to provide for a gradual transition from government to private ownership of nuclear fuel for power plants. A variety of projects directed toward power reactors with higher ratios of conversion of uranium to plutonium and with higher thermal efficiencies was supported for a while. By the end of the decade, with the growing commercial acceptance of the water reactors, the AEC shifted its top priority in reactor development to fast breeders. Most of the other programs involving different reactor concepts were either abandoned or placed on standby.

Economically competitive nuclear power

Thermal reactors. *Pressurized-water reactors (PWR).* The first reactor of this type was the submarine thermal reactor (STR) built in Idaho in 1953, which had led directly to the first nuclear-powered submarine, the USS "Nautilus." As the name implies, a pressurized-water reactor is both cooled and moderated by water under high pressure, thus permitting high temperatures. As indicated in Figure 2A, the hot water is pumped from a pressurized vessel containing the nuclear core to a steam generator in which heat is exchanged to produce the steam that drives a turbogenerator.

The fuel is arranged in a lattice, usually enriched in commercial reactors to 3 to 4 percent of uranium-235, and fabricated in the form of rods composed of uranium dioxide pellets. Although uranium dioxide has the disadvantage of a relatively low heat conductivity, it was chosen as the preferred chemical form of the fuel because of its resistance to radiation damage, thus increasing the time that the fuel may be left in the reactor. Both stainless steel and a zirconium alloy have been used for fuel cladding (a coating designed to contain fission products released in the fuel). They both do well in keeping fission products within the fuel, even though the accumulation of gaseous fission products causes pressures to build up.

Fuel enrichment depends on various factors, such as the size of the core, the power level at which the reactor is operated, the amount of moderation (particularly in relation to the total amount of fuel), the diameter of fuel elements, the nature of the cladding, the length of time the fuel remains in the reactor, and the fuel-cycle costs, including the credit derived from plutonium production.

The diameter of the rods influences the rate at which heat can flow from the fuel through the cladding to the pressurized water, which in turn determines the power level at which the reactor can safely operate. In determining the rod diameter, consideration is given to the maximum allowable temperature in the centre of the fuel rod (about 4,800° F, 2,650° C) and the temperature gradient through the rod and the cladding to the pressurized water. The space between the fuel and the cladding is filled with helium to facilitate the heat flow. The rod diameter also affects the speed of neutrons within the uranium, and, therefore, the proportion that is absorbed in the uranium-238 and produces plutonium.

Reactor shielding

The shielding of the reactor must keep heat losses and radiation levels external to the reactor down to acceptable levels. In addition to thermal shielding, neutrons and gamma rays must be absorbed. Typically, a "core barrel" also serves to confine the coolant flow within the core region, and is enclosed in a thermal shield, a pressure vessel, a water shield against neutrons, and a blanket of reinforced concrete for gamma-ray absorption; there may be a second concrete blanket, and, finally, the containment wall. In the newer pressurized-water reactors, fuel burnup has been improved to the point that fuel assemblies may be left in the reactor for years before refuelling is required.

Boiling-water reactors (BWR). These reactors have much in common with the pressurized-water reactors (Figure 2B). The main difference is that the intermediate steam generator is omitted, and steam is supplied directly from boiling water in the reactor core. Less pressurization

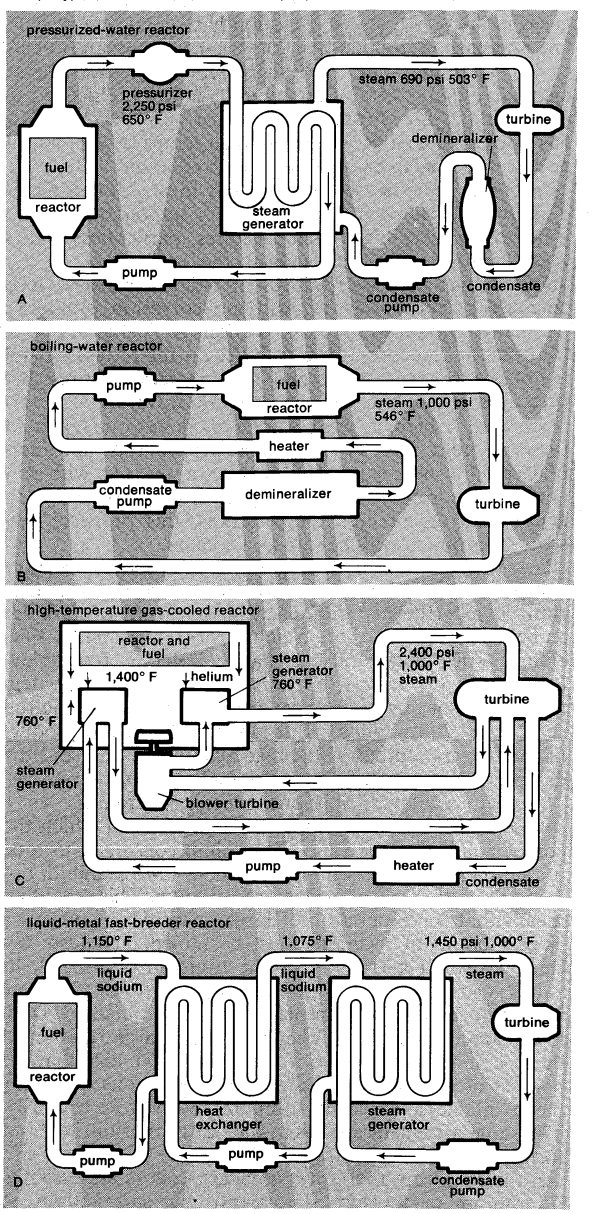

Figure 2: Nuclear-reactor systems of greatest importance for central-station power (see text).

is needed because the water is allowed to boil, and less pumping is needed because of the large amount of heat absorbed by boiling water. An excellent safety feature is the increase in steam production that results from an increase in power level, thus reducing the water volume and lessening its moderating ability, a condition that in turn reduces the reactivity. In other words, an inadvertent power increase tends to be self-correcting.

High-temperature gas-cooled reactors (HTGR). The conversion of heat to electricity can be accomplished more efficiently if the heat can be generated at higher temperatures, thus decreasing the percentage of the total heat that must be rejected. One of the obvious advantages of a nuclear reactor for power production is that it can be brought to as high a temperature as the materials of which it is made will permit. Limiting factors include melting, change of shape, and corrosion. These effects are sometimes exaggerated under irradiation; and if the ma-

terials deteriorate to the point that they interfere with the flow of heat out of the reactor as fast as it is produced, then the temperature of the reactor may increase to unacceptable levels.

The use of gas as a coolant is one method of achieving high temperatures, even though its heat-transfer properties are generally less favourable than liquids (Figure 2C). At higher pressures, the heat-transfer properties of gases improve. Most consideration has been given to helium and carbon dioxide. Air has been tried because of its easy availability, but its heat-transfer properties are so ineffective that excessive amounts of power are needed to circulate the air through the reactor. Furthermore, air has poor chemical properties at high temperatures, and it becomes radioactive under neutron irradiation.

Carbon dioxide is used, particularly in the United Kingdom and in France, in power reactors, although its chemical properties at higher temperatures, particularly under intense radiation, tend to be unsatisfactory.

Helium has the disadvantage of being expensive. It is chemically inert, however, with no corrosion problems; its neutron-absorption cross section is negligible; it is transparent, thus providing visibility during refuelling and maintainance operations; and at high temperatures and pressures its heat-transfer properties improve.

Graphite as a moderator

Graphite, which is used as the moderator in each of these reactors, has good mechanical properties and thermal stability and is a good conductor of heat with low neutron absorption. Although graphite is chemically reactive with air at high temperatures, this property presents no problem with helium as a coolant.

The fuel in the high-temperature gas-cooled reactors consists of highly enriched uranium, together with thorium as a fertile material, each in the forms of carbides embedded in pyrocarbon, a dense form of graphite. Fuel elements of this general type have a potential for achieving very high burnups, in the range, perhaps, equivalent to 500,000 megawatt-days per metric ton (one metric ton = about 2,200 pounds). Burnup is equal to the product of the thermal output of the reactor in megawatts and the days of operation divided by the fuel load in metric tons.

Breeder reactors. Without breeding, uranium as a source of energy is limited. Even in reactors in which the conversion ratio (the ratio of uranium consumed to total uranium employed) is improved, there is no possibility of using more than a few percent of uranium. This condition means that for generation of large quantities of power, a large amount of uranium must be mined, and also, because so small a fraction of the uranium is utilized, its value is so low that it is not economical to use the more abundant but more expensive uranium obtained from low-grade ores. On the other hand, if a large fraction of the uranium is consumed, it becomes so valuable that the poorest ores may be mined economically, thus extending the available and usable uranium reserves enormously. The same argument applies to the use of thorium reserves through conversion to uranium-233.

In the long run, therefore, breeder reactors are essential if uranium or thorium is to contribute substantially to meeting the world's energy needs.

Liquid-metal fast-breeder reactors. The concept that was receiving greatest emphasis in the 1970s is a liquid-metal fast-breeder reactor (LMFBR) operating on the uranium–plutonium cycle. With liquid-metal cooling, higher temperatures and therefore higher efficiencies are obtainable. Sodium has been selected as the coolant because it has favourable heat-transfer properties, a low-absorption cross section for neutrons, and its atoms are heavy enough so as not to slow down the neutrons, thus allowing the reactor to become a fast reactor (Figure 2D).

The fuel is expected to be plutonium diluted by uranium, providing a use, at least for start-up, of the plutonium produced by thermal water reactors. Oxides of uranium and plutonium rather than their metallic forms are used because of their better resistance to radiation damage.

Fast-fuel-test facility

The second experimental breeder reactor (EBR-II), originally intended as an experimental prototype, was used instead as a facility for testing fuels and materials in a fast neutron flux. During the early 1970s a larger fast-fuel-test facility (FFTF) was being built at Hanford, Washington, in order to provide a higher flux capability for fuels and materials testing.

Gas-cooled fast-breeder reactors. This reactor represents an extension of the technology of the high-temperature gas-cooled reactor, but it differs in the absence of graphite as a moderator and in its use of the uranium–plutonium cycle instead of the uranium-233–thorium cycle. The core of the reactor is composed of metallic-clad pins of mixed uranium–plutonium oxide fuel. It has helium cooling with a potential for being used to drive gas turbines directly instead of working through a heat exchanger to supply steam.

The breeding ratio may be high enough so that the doubling time (*i.e.*, the time required to produce an amount of new fuel equivalent to the amount contained in the reactor and its associated fuel cycle at the outset) will turn out to be only about ten years.

One of the questions about this concept centres on the safety problem in avoiding excessive heating in the event that the helium cooling is accidentally interrupted. Even though the chain reaction in a reactor is stopped, the temperature of the fuel elements can increase because of the heat produced through the absorption of intense gamma rays from fission products. Other questions centre on the performance of the metallic cladding of the fuel elements at high temperatures.

The molten-salt reactor. An experiment has been performed as a step toward a molten-salt breeder reactor that would operate on the thorium–uranium-233 cycle and therefore need not be a fast reactor in order to breed. The fuel is a mixture of lithium-7 fluoride, beryllium fluoride, zirconium tetrafluoride, uranium tetrafluoride, and thorium fluoride.

The circulating molten fuel enters the reactor at 1,175° F (635° C) and leaves at 1,225° F (663° C). The molten-salt mixture is stable at these high temperatures and under the intense radiation, and it has a low vapour pressure, thus avoiding pressurization problems. There are, however, some substantial engineering problems associated with the circulation of intensely radioactive fluid at high temperatures.

Power reactors worldwide. The original Euratom target of 15,000,000 kilowatts of electrical capacity in its six member countries by 1967 was not realized. Instead, by 1971 it turned out to be a little more than 3,000,000, with about half of this capacity in France. By this time, the United Kingdom had more than 5,000,000 kilowatts. On a worldwide basis, the total capacity was approximately 20,000,000 kilowatts, with more than half of this total of installed capacity being outside of the United States. Aside from the United States, 48 plants were operating, of which twelve had been built by U.S. companies. Great Britain was the early leader in the development of nuclear-fueled electric-power plants, largely because its shortage of hydroelectric sources and problems with cost and availability of fossil fuels made nuclear power attractive.

In the early 1970s nuclear production of electric power was becoming competitive in many areas and promised certain advantages, such as less air pollution, and a large number of nuclear installations were in the planning or construction stage all over the world. A listing of these power reactors showing their types and capacities in kilowatts (electric) is given in Table 2.

Gas-cooled reactors. The program of the United Kingdom was still the largest in 1971 in terms of total electricity having been produced, with its reliance on gas-cooled graphite-moderated technology using natural uranium as fuel. Two reactors of this type have been sold to other countries, one to Japan and one to Italy.

Capital costs for this reactor type are high, but this disadvantage is partially offset by the building of reactors of high capacity and the achievement of high-load factors. In the early 1970s, advanced gas-cooled reactors were being built with slightly enriched uranium fuel instead of natural uranium, thus permitting a substantial reduction in reactor size. With this enrichment, it was also possible

Table 2: Nuclear Power Reactors in Countries Outside the U.S. (1971)

country and plant	type	capacity (kW)

to switch to an oxide form of fuel rather than using natural uranium, with stainless-steel cladding to enclose the fuel elements instead of a magnesium alloy. These switches permit higher temperature operation and higher fuel burnups, both of which help to reduce costs.

The so-called Dragon Project located at Winfrith in the United Kingdom is a cooperative venture of 12 European countries with participation by the United States, Euratom, and the European Nuclear Energy Agency. It produces no electricity, but it has operated successfully at a power level of 20,000 kilowatts of heat.

CANDU reactors

Heavy-water reactors. The Canadian interest in heavy-water reactors (HWR) has led to a Canadian Deuterium Uranium (CANDU) series of power reactors, the first of which was located at Douglas Point, in Canada.

The use of deuterium instead of hydrogen in the moderator has the advantage of a lower neutron-absorption cross section, permitting the use of natural uranium in the oxide form. Furthermore, with a better neutron economy, the lattice of fuel elements may be more widely spaced, thus permitting the use of zirconium-alloy pressure tubes in which heavy water as a coolant is confined. The hot heavy water is pumped through annular channels surrounding the cylindrical fuel elements placed in these tubes.

The use of heavy water as a moderator was also being studied in the 1970s in Sweden and West Germany (using pressure vessels instead of tubes), in France (carbon dioxide cooling through pressure tubes), in the United Kingdom (boiling light water in pressure tubes), and in a Euratom project (organic cooling). Other varieties may be considered, including the use of enriched uranium or plutonium or uranium-233 as fuel.

Light-water reactors. During the early 1970s both pressurized- and boiling-water reactors were being built in about equal numbers in many countries throughout the world. In spite of the disadvantages of requiring enriched fuel, of making inefficient use of the fuel, and of operating at inefficient temperatures, widespread recognition was being given to their economic and environmental advantages over fossil-fuelled plants. In competition with the United States, a manufacturing capability for light-water reactors was developing in France, Western Germany, and the Soviet Union.

Fast-breeder reactors. There is widespread interest in other countries in breeder reactors. Prototypes have been built in the United Kingdom, in the Soviet Union, and in France. Second generation plants are in the Soviet Union, with 150,000 kilowatts of electrical output, and in the United Kingdom with 250,000 kilowatts. Others are being planned in France, West Germany, Japan, and Italy.

NUCLEAR-REACTOR SAFETY PROBLEMS

A nuclear reactor is not a bomb and thus does not present a bomb-type hazard; nevertheless, the problem of safety is critical. It is simplified by certain self-controlling features of reactors; *e.g.*, the fact that any increase in temperature in a boiling-water or pressurized-water reactor reduces the reactivity—that is, tends to shut down the reactor, thus providing an inherent stability.

Nuclear excursions. The possibility of a nuclear excursion, involving a substantial release of radioactive materials, nevertheless remains. A loss of coolant is conceivable. The loss would immediately stop the chain reaction, but the heat residue could melt the fuel, releasing a large volume of radioactivity. Coolant systems are designed to make the probability of such an accident extremely remote, and an emergency coolant is provided in the form of automatically sprayed borated water. In the very remote possibility of both coolant and emergency-coolant systems failing, further engineering safeguards must be provided. These include back-up devices for rendering harmless any fission products released and surrounding the entire reactor, in addition to the normal shielding, with a steel shell strong enough to contain any scale of accidental radiation fallout. The reactor plant is always placed in an area remote enough to further minimize danger to the nearest community.

Emergency safeguards

Coolant purification. During normal power-reactor operation, there may be some leakage of slight amounts of fission products and perhaps of radioactive corrosion products into the coolant circulating through the core. All reactors, therefore, provide for the removal of such materials by a coolant-purification system. Also, in pressurized-water reactors using boron as a burnable poison, there may be some tritium production in the water coolant resulting from the absorption of neutrons in boron. Although all of these materials are normally completely contained in the reactor, it is difficult to completely prevent leakage. In some cases some of the fission products, such as the inert gases krypton and xenon, are vented high into the air through stacks after a holdup period that allows the short-lived isotopes to decay. Similarly, the tritium in pressurized-water reactors, chemically identical to water after combining with oxygen, may be released to a small extent in the external cooling water.

REACTORS IN OTHER APPLICATIONS

Besides the reactors built for electric-power production and to propel nuclear submarines, many reactors throughout the world serve other purposes. In every case, some use is made of either heat or radiation or both.

Research, training, and test reactors. Reactors may be designed and used for research and test purposes, in which case neutrons escaping from the core are used directly. The gamma rays released from fission fragments may be used more conveniently after the fission fragments have been removed from the core.

Research reactors are usually small compared to power reactors. Many of them on university campuses are used for training and educational purposes and to provide neutrons for research in many areas in the physical and the biological sciences. Larger research reactors are found in national laboratories, in which the greater expenses associated with operating at the higher power levels needed to obtain higher neutron fluxes are justified.

Test reactors require relatively high neutron fluxes because their primary purpose is to test the effects of neutrons on materials, particularly those being considered for use within a power reactor. Materials sometimes deteriorate after long exposure to high neutron fluxes. In a test reactor it is possible to study these effects without waiting for the actual reactor operation. These tests can be particularly important in regard to the possible use of various types of nuclear fuel for power reactors.

Small power reactors. In addition to the large installations that provide electric power commercially from central stations, small-scale nuclear electric plants have become practical, particularly in places too inaccessible for convenient refuelling with more conventional fuels.

Nuclear ships. Many naval surface vessels, such as the U.S. aircraft carrier "Enterprise," are nuclear fuelled. The demonstration of nuclear propulsion for merchant ships undertaken in the 1960s by the United-States-built "Savannah," powered by a pressurized-water reactor, proved a technical success but an economic failure, because it was not possible to operate the ship without a subsidy. The demonstration, however, is significant, and other nonmilitary applications of nuclear power at sea have been developed, notably the Soviet ice-breaker "Lenin." West Germany has built the merchant ship "Otto Hahn," equipped with a pressurized-water reactor to provide power for propulsion, and Japan was building its first nuclear-powered merchant ship in the early 1970s.

Desalinization. In a number of places in the world freshwater is scarce and expensive to import, but seawater is at hand. Nuclear power may provide the most economical means for operating desalinization plants. Consideration is being given to dual-purpose plants in which part of the heat could be used for electric-power production.

Rocket propulsion. Small nuclear reactors were being developed in the 1970s to provide auxiliary sources of heat and electricity for space flights; more ambitious was research directed at producing a nuclear engine for rocket propulsion. Major research and development activities were aimed at early applications—for example, for space shuttle transportation—and at advanced fission and fusion concepts. (See also ROCKETS AND MISSILE SYSTEMS.)

NUCLEAR FUEL

Most uranium ores contain less than 1 percent of uranium, usually in the form of uranium oxide. After the mining and milling of the ore, the uranium must be concentrated and then converted to uranium hexafluoride if it is to be put through an enrichment process in a gaseous diffusion plant. Having achieved the desired enrichment, it is then converted to the metal or to the oxide or to whatever chemical form is desired and fabricated into the required shape together with the needed cladding. After installation in the reactor, some portion of the uranium will be consumed, leaving fission products, the remaining uranium-238, and the plutonium that has been formed. After the optimum burnup time, the spent fuel is removed and transported to a chemical-processing plant in which the fission products and the plutonium are removed, leaving unused uranium to be converted back to uranyl hexafluoride for re-enrichment and re-use. The fission products in some cases have value as radiation sources and may be regarded as by-products that can be used as nuclear fuel. If not, they must be stored as radioactive wastes. The plutonium is a by-product. A simplified outline of this total fuel cycle is shown in Figure 3.

Fission products as by-products

Drawing by D. Meighan

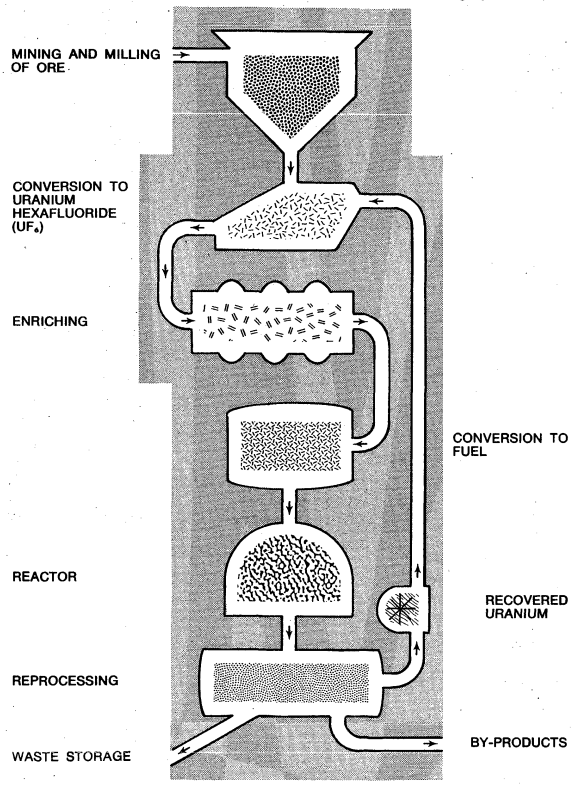

Figure 3: Basic steps in the preparation and processing of fuel for nuclear reactors.

Sources of uranium and thorium. The highest grade uranium ores available to the Western countries, containing from 1 to 4 percent uranium, are found in the Katanga Province of the Republic of the Congo and in Canada. Medium-grade ores in range of 0.1 to 0.5 percent uranium are found in many parts of the world. One of the more significant lower grade ores is found in the South African gold-ore residues. In the United States, extensive phosphate fields, oil shales, and uraniferous lignites contain large amounts of uranium with a concentration of 0.01 percent or less. Uranium is present in seawater in large amounts, but at extremely low concentrations.

Large deposits of thorium ores are found in India, Canada, and Brazil in monazite-bearing sands. Lesser amounts occur in Australia, Madagascar, South Africa, and the United States.

During purification, the uranium oxide is usually converted first to a nitrate and then to uranium dioxide. If the fuel product is to be enriched, it may be converted first to uranium tetrafluoride, commonly referred to as green salt, and then converted further to uranium hexafluoride. The latter is a gas at temperatures above 56.5° C (133.7° F) at atmospheric pressure and may therefore be fed through the gaseous diffusion process.

Monazite ore may contain as much as 1 to 5 percent of thorium dioxide. The extraction and purification of thorium as a nitrate is carried out in a manner analogous to that for uranium. It may then be converted first to thorium tetrafluoride and then reduced to the metal or converted to the oxide.

Enrichment of uranium. Enrichment requires the separation of the isotopes of uranium-238 and uranium-235. They are chemically identical and differ only in that uranium-238 has a slightly greater mass.

The principle of the gaseous diffusion separation process is to allow the uranium in gaseous form (uranium hexafluoride) to diffuse through a porous barrier. On the average, the lighter molecules have a slightly greater speed in order that their kinetic energies may be the same as the heavier molecules. These lighter molecules come in contact with the walls of the container more frequently than the heavier molecules and therefore are more likely to encounter a pore and pass through the barrier. Each barrier has hundreds of millions of pores per square inch with the average pore diameter being about 0.000002 inch (0.00005 millimetre).

The difference in penetration is very small because the masses of the two molecules are so nearly the same. Nevertheless, it is possible to obtain desired enrichments by arranging the barriers in a cascade so that the effect is multiplied over and over again. Thousands of barrier stages are used with high pressure on one side and low pressure on the other. The uranium hexafluoride enters at about the middle of the cascade. As the gas moves through the cascade from high pressure to low pressure in each stage, it becomes more enriched. The gas moving in the other direction contains increasing proportions of uranium-238. A pump is required between each stage; thus the pumping capacity of the plant and the electric-power requirements for the pumps are substantial. Because it has been the major source of enriched uranium since that first developed by the Manhattan Project, gaseous diffusion technology is well developed.

Another process receiving serious consideration and a great deal of experimentation is the use of a high-speed centrifuge. Centrifugal forces cause the heavier atoms to gravitate toward the periphery of a spinning centrifuge, thus producing some enrichment in the gas remaining near the centre. One of the major difficulties is the construction of centrifuges that will themselves withstand the strong centrifugal forces.

Fabrication and preparation of the fuel. For homogeneous reactors, the fuel is in the form of a fluid, and there is no need for fabrication or cladding. It must merely be in the proper chemical form.

Fuel types

For heterogeneous reactors, fuel is used in many different chemical forms and shapes and with different types of cladding. The fuel should have a high thermal conductivity, be resistant to radiation damage, be chemically stable (particularly with respect to the coolant in the event of leakage through the cladding), and it should be easy to fabricate. Uranium has been used in the form of a pure metal, as a constituent of an alloy, in the form of its oxide, its carbide, and in other forms. Each has its advantages and disadvantages with respect to particular reactor types. Uranium metal corrodes in water and changes its shape with irradiation. Uranium dioxide has far better radiation resistance, thus allowing higher burnup, but its thermal conductivity is low. Uranium carbide has high thermal conductivity, favourable mechanical properties, and excellent dimensional stability under irradiation.

Fuel cladding must have a low neutron-absorption cross section if it is used in thermal reactors. It must be mechanically strong (to withstand possible outside pressures or inner pressures caused by the accumulation of gaseous fission products). It must be radiation-resistant and able to withstand attacks by both the fuel and the coolant at the temperatures existing in the reactor. Materials that have been used include aluminum, magnesium, stainless steel, zirconium, graphite, and various carbides. In most cases, some bonding material is used to improve the thermal contact between the fuel and the cladding.

Fuel burnup. The revenue-producing portion of the fuel cycle occurs in the period when the fuel is within the reactor. In general, the longer it can stay inside the reactor, the more the other costs of the cycle are offset. The limits on burnup are determined by changes in the reactivity of the reactor and by the physical condition of the fuel. The accumulation of fission products that absorb neutrons and the reduction in the amount of fissionable material (uranium-235, uranium-233, or plutonium-239), thus diminishing the supply of neutrons, could eventually bring the chain reaction to a stop. The production of plutonium (or uranium-233) would be an offsetting factor helping to maintain reactivity. In most cases, however, radiation damage to the fuel elements would make them unusable before they reached the point at which reactivity is too low. The fuel or cladding may change shape or become corroded or brittle or deteriorate in other ways, so that the heat flow to the coolant is interrupted or fission products may escape into the coolant.

Fuel reprocessing. When the fuel elements are first removed from the reactor, they must be allowed to cool long enough for the radioactivity of the fission products to decay to acceptable levels, a process usually involving their immersion in water for a month or so. The chemical-separation process, even after this cooling-off period, has to be carried out under conditions of intense radioactivity.

After being transported in suitably constructed radiation-resistant containers, the fuel is taken to a chemical-separation plant in which the jacket may first be removed mechanically, or the fuel may be dissolved with its jacketing still in place, depending upon the fuel and the circumstances. Great care is taken to make certain that at no time is there a large enough quantity of fissionable material accumulated to allow a chain reaction to occur. Separation of the uranium and plutonium may be carried out by one of three general methods: (1) aqueous processes with the principal separation being accomplished by solvent extraction techniques; (2) volatility methods depending on the distillation of uranium hexafluoride; and (3) pyrometallurgical (or melt-refining) processes, such as those that provide for removal of impurities as oxides. Other procedures based upon liquid-metal or fused-salt extraction, metal distillation, zone melting, and electrorefining have been studied.

Fuel dejacketing

Radioactive-waste disposal. The disposal of the highly radioactive wastes that remain as liquid residues after removal of the uranium and plutonium and any fission products having practical value represents one of the more difficult problems in the fuel cycle. Some of the radioactive fission products, notably strontium-90 and cesium-137, are long-lived, and it is difficult to store them in such a way that they will not escape into the ground or water and thus become a hazard.

For the short term, large underground tanks have proved satisfactory with mechanisms built into them to carry away the heat caused by the radioactivity; but with the accumulation of ever-increasing amounts of fission products, other methods are being considered. One promising method is to prepare the material for permanent storage in deep salt mines. The material must be reduced to solid form, and the salt mine must be sufficiently deep and meet certain geological criteria that will guarantee no disturbance for thousands of years to come.

Gaseous fission product wastes are also troublesome. Iodine, krypton, and xenon, the most important examples, are liberated when the fuel is dissolved. The last two, being inert, are sometimes released into the atmosphere, but they can also be adsorbed in carbon or silica gel at low temperatures and then stored.

Fuel management. High burnups are generally desirable, and various procedures may be followed that affect not only burnup but the total cost of the fuel cycle. The advantages and disadvantages of various procedures, together with the interactions between various portions of the cycle, are complex, requiring sophisticated computer techniques to find the best procedures.

Instead of loading and unloading the total core as a unit (batch irradiation), it may be desirable to load part of the fuel in a zone toward the outside of the core and then, after a certain period of operation, to use this partial batch to replace a previous partial batch in a central region. In this way, the extra enrichment needed by the fresh fuel to obtain a long burnup is compensated by the fission-product poisons that have accumulated in the old fuel in the central region.

There are some variations in the nuclear-fuel cycle with different reactor types, and in every instance the complex of interactions between its several components must be

considered. In addition to the pattern of moving batches of fuel within the reactor, the enrichment of the fuel may be varied, plutonium may or may not be recycled for use as a fuel, the size of each batch loaded into the reactor may be varied, the power level may be lowered to increase the life of the fuel, and neutron-control poisons may be used in different ways.

(P.N.P.)

Nuclear Weapons

Nuclear weapons derive their enormous explosive force from either the fission or fusion of atomic nuclei. Their significance may best be appreciated by the coining of the words kiloton (1,000 tons) and megaton (1,000,000 tons) of TNT equivalent to describe their blast effect. For example, the first nuclear fission bomb, the one dropped on Hiroshima, Japan, in 1945, released energy equalling 20,000 tons (20 kilotons) of chemical explosive from less than 100 pounds of uranium. Fusion, or thermonuclear, bombs (H-bombs) have given yields ranging up to 60 megatons. The first nuclear weapons were bombs delivered by aircraft; warheads for ballistic missiles have come to be by far the most important nuclear weapons. Smaller tactical, or battlefield, nuclear weapons have been developed; they include artillery projectiles, howitzer shells, and demolition munitions.

The basic principle of nuclear fission weapons involves the assembly of a sufficient amount of the uranium isotope uranium-235 or of the plutonium isotope plutonium-239 to "go supercritical"—that is, for neutrons (which cause fission and are in turn released during fission) to be produced at a faster rate than they can escape from the assembly. There are two ways in which a subcritical assembly of fissionable material can be rendered supercritical and made to explode. The subcritical assembly may consist of two parts, each of which is too small to have a positive multiplication rate; the two parts can be shot together by a gun-type device. Alternatively, a spherical subcritical assembly surrounded by a shell of chemical high explosive may be compressed into a supercritical one by igniting the explosive.

The basic principle of the thermonuclear, or fusion, weapon is to produce ignition conditions in a thermonuclear fuel, such as deuterium, an isotope of hydrogen with double the weight of normal hydrogen, or lithium deuteride. The sun may be considered a thermonuclear device; its main fuel is deuterium, which it consumes in its core at temperatures of 10,000,000° to 20,000,000° C (18,000,000° to 36,000,000° F). To achieve comparable temperatures in a weapon, a fission device is used.

There are no insurmountable scientific or technological difficulties in designing and building either a fission or a fusion weapon. In the early 1970s, five nations, the United States, the Soviet Union, the United Kingdom, France, and China, had tested and stockpiled both types of weapons, and many other nations were capable of producing them, although the Non-Proliferation Treaty of 1970 made the process more difficult for signatory nations.

For a detailed explanation of the basic processes, see NUCLEAR FISSION; NUCLEAR FUSION.

FISSION WEAPONS

Following the discovery of artificial radioactivity in the 1930s, the Italian physicist Enrico Fermi performed a series of experiments, exposing many elements to low-velocity neutrons. He obtained more than 400 new radioactive substances, but nearly all were isotopes of the exposed elements—that is, the same elements chemically but with a different atomic mass. When he exposed thorium and uranium, however, he encountered a striking exception: chemically different radioactive products resulted, indicating that new elements had been formed, rather than merely isotopes of the original elements. Fermi concluded that he had produced elements beyond uranium (element 92), the last element in the periodic table; he called them transuranic elements and named two of them ausenium (element 93) and hesperium (element 94). During the autumn of 1938, however, at the very moment when Fermi was receiving the Nobel Prize for his work, Otto Hahn and Fritz Strassmann of Germany were discovering that one of the "new" elements was actually barium (element 56).

The mystery of uranium fission

The Danish scientist Niels Bohr visited the United States in January 1939 and carried with him the explanation given by the Austrian refugee scientists Lise Meitner and her nephew Otto Frisch. A new process explained Hahn's surprising data. Low-velocity neutrons caused the uranium nucleus to fission, or break apart into two smaller pieces the combined atomic numbers of which equalled that of uranium, for example, the two elements barium and krypton. Much energy was released in the process. This news set off experiments at many laboratories. Bohr worked with John Wheeler at Princeton; they postulated that the uranium isotope uranium-235 was the one undergoing fission; the other isotope, uranium-238, merely absorbed the neutrons. It was discovered that neutrons were produced during the fission process; on the average, each fissioning atom produced more than two neutrons. If the proper amount of material were assembled, these free neutrons might create a chain reaction. Under special conditions, a very fast chain reaction might produce a very large release of energy; in short, a weapon of fantastic power might be feasible.

Development of the fission bomb. The possibility that such a weapon might first be developed by Nazi Germany alarmed many scientists and was drawn to the attention of Pres. Franklin D. Roosevelt by Albert Einstein, then living in the United States. The President appointed an Advisory Committee on Uranium; it reported that a chain reaction in uranium was possible though unproved. Chain-reaction experiments with carbon and uranium were started in New York at Columbia University, and in March 1940 it was confirmed that the isotope uranium-235 was responsible for low-velocity neutron fission in uranium. The Advisory Committee on Uranium increased its support of the Columbia experiments and arranged for a study of possible methods for separating the uranium-235 isotope from the much more abundant uranium-238. (Normal uranium contains approximately 0.7 percent uranium-235, most of the remainder being uranium-238.) The centrifuge process, in which the heavier isotope is spun to the outside, as in a cream separator, at first seemed the leading candidate, but at Columbia a rival process was proposed, diffusion of gaseous uranium hexafluoride through barriers, or filters; more molecules containing the lighter isotope, uranium-235, would pass through the filter than those containing the heavier isotope, slightly enriching the mixture on the far side. It was calculated that a sequence of several thousand stages would be needed to enrich the mixture to 90 percent uranium-235; the total barrier area would be many acres.

During the same summer of 1940, Edwin McMillan and

The discovery of neptunium and plutonium

Philip Abelson of the University of California at Berkeley discovered element 93, named neptunium; they inferred that this element would decay into element 94. The Bohr and Wheeler fission theory suggested that one of the isotopes, mass number 239, of this new element might also fission under low-velocity neutron bombardment. The cyclotron at the University of California in Berkeley was put to work to make enough element 94 for experiments; by mid-1941, element 94 had been firmly identified and named plutonium, and its fission characteristics had been established. Low-velocity neutrons did cause it to undergo fission, and at a rate much higher than that of uranium-235. The Berkeley group, under Ernest Lawrence, was also considering producing large quantities of uranium-235 by turning one of their cyclotrons into a super mass spectrograph. A mass spectrograph employs a magnetic field to bend a current of uranium ions; the heavier ions (uranium-238) bend at a larger radius than the lighter ions (uranium-235), allowing the two separated currents to be collected in separate receivers.

In the spring of 1941 a review committee reported that a nuclear explosive probably could not be available before 1945; a chain reaction in natural uranium was probably 18 months off; it would take at least an additional year to produce enough plutonium for a bomb; it would take three to five years to separate enough uranium-235. Further, it was held that all of these estimates were optimistic. In late June 1941 President Roosevelt established the Office of Scientific Research and Development under the direction of the United States scientist Vannevar Bush; a British committee simultaneously recommended pushing their uranium-235 bomb project at maximum speed.

In the fall of 1941 the Columbia chain-reaction experiment with natural uranium and carbon yielded negative results. A review committee concluded that boron impurities might be poisoning it by absorbing neutrons. It was decided to transfer all such work to the University of Chicago and repeat the experiment there with high-purity carbon. At Berkeley, the cyclotron, converted into a mass spectrograph (now called a calutron), was exceeding expectations in separating uranium-235, and it was enlarged to a ten-calutron system with a total ion current of one ampere, capable of producing a tenth of an ounce of uranium-235 per day.

The move toward actual production

The U.S. entry into World War II in December 1941 was decisive in providing funds for a massive research and production effort for obtaining fissionable materials. In May 1942 the momentous decision was made to proceed simultaneously on all promising production methods. Bush decided that the army should be brought into the production plant construction activities. The Corps of Engineers opened an office in New York City and named it the Manhattan Engineer District Office. After considerable argument over priorities, a workable arrangement was achieved with the formation of a three-man policy board chaired by Bush and the appointment of Gen. Leslie Groves head of the Manhattan Engineer District. Groves arranged contracts for a gaseous diffusion separation plant, a plutonium production facility, and a calutron pilot plant, which might be expanded later. The day before the success of Fermi's chain-reaction experiment on December 2, 1942, Groves signed the construction contract for the production reactors. Many problems were still unsolved: the diffusion barrier had not yet been demonstrated as practical. Berkeley had been successful with its empirically designed calutron, but the Oak Ridge pilot plant contractors were understandably uneasy about the rough specifications available for the massive separation of uranium-235, which was designated Y-12 (for yttrium-12) effort. Plutonium chemistry was almost unknown; in fact, it was not known whether plutonium gave off neutrons during fission, or how many.

Meantime, as part of the reorganization in June 1942, J. Robert Oppenheimer became the director of Project Y, the group that was to design the actual weapon. The effort was spread over several locations; in the fall, Groves and Oppenheimer chose a laboratory site in New Mexico, the former Los Alamos Ranch School some 90 miles (140 kilometres) north of Albuquerque. By July two essential and encouraging pieces of experimental data had been obtained—plutonium did give off neutrons in fission, more than uranium-235; and the neutrons were emitted in a short time compared to that needed to bring the weapon materials into a supercritical assembly. The theorists contributed one discouraging note: their estimate of the critical mass for uranium-235 had risen over threefold, to something between 50 and 100 pounds.

The emphasis during the summer and fall of 1943 was on the gun method of assembly: the projectile, a subcritical piece of uranium-235 (or plutonium-239), would be placed in a gun barrel and fired into the target, another subcritical piece of uranium-235. After the mass was joined (now supercritical), a neutron source would be used to start the chain reaction. A problem developed with the plutonium gun. In manufacturing plutonium-239 from uranium-238 in a reactor, some of the plutonium-239 absorbs a neutron and becomes plutonium-240. This material undergoes spontaneous fission, producing neutrons. Some neutrons will always be present in a plutonium assembly and cause it to begin multiplying as soon as it goes critical, before it reaches supercriticality; it will then explode prematurely and produce comparatively little energy. The gun designers tried to beat this problem by achieving higher projectile speeds, but they lost out in the end to a better idea—the implosion method.

The implosion technique

In April 1943 a Project Y physicist, Seth Neddermeyer, proposed to assemble a supercritical mass from many directions, instead of just two as in the gun. In particular, a number of shaped charges placed on the surface of a sphere would fire many subcritical pieces into one common ball at the centre of the sphere. John von Neumann, a U.S. mathematician who had had experience in shaped-charge, armour-piercing work, supported the implosion method enthusiastically and pointed out that the greater speed of assembly might solve the plutonium-240 problem. U.S. physicist Edward Teller suggested that the converging material might also become compressed, offering the possibility that less material would be needed. By late 1943 the implosion method was being given an increasingly higher priority; by July 1944 it had become clear that the plutonium gun could not be built. The only way to use plutonium in a weapon was by the implosion method.

By 1944 the Manhattan Project was spending money at a rate of over $1,000,000,000 per year. The situation was likened to a nightmarish horse race; no one could say which of the horses (the calutron plant, the diffusion plant, or the plutonium reactors) was likely to win or whether any of them would even finish the race. In July 1944 the first Y-12 calutrons had been running for three months but were operating at less than 50 percent efficiency; the main problem was in recovering the large amounts of material that reached neither the uranium-235 nor uranium-238 boxes and, thus, had to be rerun through the system. The diffusion plant was far from completion, the production of satisfactory barriers remaining the major problem. The first reactor at Hanford, Washington, had been turned on in September, but it had promptly turned itself off. Solving this problem, which proved to be caused by absorption of neutrons by one of the fission products, took several months. These delays meant almost certainly that the war in Europe would be over before the weapon could be ready. The ultimate target was slowly changing from Germany to Japan.

In April 1945, two weeks after he had become president, Harry Truman was briefed on the status of the project: the uranium-235 gun design had been frozen, but sufficient uranium-235 would not be accumulated until around August 1. Enough plutonium-239 would be available for an implosion assembly to be tested in early July; a second would be ready in August. Several B-29s had been modified to carry the weapons; support construction was under way at Tinian, in the Mariana Islands, 1,500 miles south of Japan.

The test of the plutonium weapon was named "Trinity"; it was fired before dawn on July 16, 1945. The theorists' predictions of the energy release ranged from the equiva-

lent of 1,000 tons of TNT to an optimistic 5,000 tons. Instead the test produced an energy, or yield, equivalent to 20,000 tons of TNT.

The bombing of Hiroshima

A single B-29 bomber flew over Hiroshima, Japan, on August 6, 1945, at 8:15 in the morning, local time. The untested uranium-235 gun assembly was air burst 2,000 feet (600 metres) above the city to eliminate local fallout. Hiroshima had been chosen because it was a port of embarkation, a convoy assembly site, and the site of an army headquarters, as well as a manufacturing centre. Two-thirds of the city area was destroyed. The second weapon, a duplicate of the plutonium-239 implosion assembly tested in "Trinity," was scheduled to be dropped on Kokura on August 11; a third was being prepared in the U.S. for possible use in late August or early September.

To avoid bad weather, the schedule was moved up two days to August 9. The B-29 spent 45 minutes over Kokura without sighting its aim point; it then proceeded to the secondary target of Nagasaki. About 50 percent of that city's area was destroyed. The next day, Radio Tokyo broadcast Japan's tentative acceptance of the Potsdam terms of surrender.

Fission weapon programs outside the U.S. Scientists in several countries performed experiments in connection with nuclear reactors and fission weapons during World War II, but no country other than the U.S. carried its projects as far as separating uranium-235 or manufacturing plutonium-239. In Paris, Jean-Frédéric Joliot-Curie and two colleagues had measured the number of neutrons emitted during fission and concluded that a chain reaction was possible. Another French researcher introduced the concept of critical mass and calculated that a sphere of several tons of pure uranium might produce a self-sustaining reaction. During the fall of France in June 1940, Joliot-Curie's two colleagues reached England with the world's entire supply of heavy water (400 pounds) and continued their chain-reaction experiments at Cambridge.

The British weapon project started informally, as in the U.S., among university physicists. In April 1940 a short paper of Professors Frisch and Rudolf Peierls, expanding on the idea of critical mass, estimated that a super weapon could be built using several pounds of pure uranium-235 and that this amount of material might be obtainable from a chain of diffusion tubes. A group known as the MAUD Committee was set up in the Ministry of Aircraft Production. This committee's feasibility report, in July 1941, caused the U.S. to propose a joint production effort, but the British felt they were far ahead and were cool toward the proposal. A year later, when the British wished to merge the two projects, the U.S. was moving rapidly and had lost interest in a joint effort. A number of British scientists did join the weapon design effort at Los Alamos. By 1943 the separate British project was abandoned.

Soviet nuclear beginnings

In the Soviet Union the news of Joliot-Curie's experiments had excited great interest. Igor Kurchatov and others at Leningrad started studies on nuclear reactors and, by late 1940, felt ready to approach the government for the necessary funds to build one. The German attack in July 1941 focussed most physicists' attention on more immediate problems. One of Kurchatov's students observed the gradual disappearance of articles on fission physics from the U.S. journals; in May 1942 he wrote an impassioned plea to several outstanding U.S.S.R. physicists and the State Defense Committee that the chain reaction experiments should continue, that nuclear weapons should not be written off. A government review committee, including leading Soviet scientists, recommended that the work be continued at a high priority with Kurchatov in charge.

A Uranium Institute with a few dozen physicists was established in Moscow; studies were started on nuclear reactors, on the separation of the uranium isotopes by barrier diffusion, and on the ballistic problems of gun assembly. Uranium metal and carbon of sufficient purity, however, did not become available until after World War II. The Soviet government then expanded the effort and set a national goal of highest priority to produce a nuclear weapon. The first Soviet chain-reaction experiment went critical on Christmas 1946; the first nuclear weapon was tested on August 29, 1949. The time between the two events, two and a half years, was the same as that between Fermi's successful experiment in Chicago and the "Trinity" test at Alamogordo.

In Germany the War Office also received an enthusiastic letter, in April 1939, advocating nuclear weapon development. By the time the war had started, Germany had a special office for the military application of nuclear fission; chain-reaction experiments with uranium and carbon were being planned, and ways of separating the uranium isotopes were under study. Some measurements on carbon, later shown to be in error, led the physicist Werner Heisenberg to recommend that heavy water be used, instead, for the moderator. This dependence on scarce heavy water was a major reason why the German experiments never reached a successful conclusion. The isotope separation studies were oriented toward low enrichments (about 1 percent uranium-235) for the chain reaction experiments; they never got past the laboratory apparatus stage, and several times these prototypes were destroyed in bombing attacks. As for the fission weapon itself, it was a rather distant goal, and practically nothing but "back-of-the-envelope" studies were done on it.

German difficulties

The French and Chinese nuclear weapon projects were postwar efforts. Some French scientists had worked in exile during the war in Britain and Canada and returned to work for the Commissariat à l'Energie Atomique. This French effort, however, was aimed at energy production; not until 1954 was a section for military applications formed. The first French plutonium production reactor went on line in 1956; the first nuclear weapon was tested in 1960.

The Chinese program started in 1958 with a slightly enriched uranium reactor, which was part of a technical aid program provided by the Soviet Union. When that aid program was stopped a year or two later, foreign intelligence experts estimated it would be the early 1970s before China could produce enough plutonium to test a weapon. China's first test bomb (1964), however, contained no plutonium at all—it used uranium greatly enriched in uranium-235. China continued to move rapidly. Its second test bomb was dropped from an airplane; its fourth was delivered by a missile. Its sixth test was a multimegaton thermonuclear device. While there were only five known nuclear powers as the 1970s began, there were rumours that several other countries (such as India and Israel) had completed all the necessary research, development, and production of materials and lacked only the final credential, a proof test, to be considered nuclear powers.

THERMONUCLEAR WEAPONS AND THEIR DEPLOYMENT

The United States project. The U.S. Super project started from a conversation in early 1942 between Fermi and Teller. Fermi suggested that the explosion of a fission weapon could be used to start something similar to the reactions in the Sun. Teller undertook to analyze the thermonuclear processes in some detail and presented his work several months later to a summer study group of theoretical physicists in Berkeley. They concluded that a weapon based on the thermonuclear fusion of deuterium was indeed possible. Oppenheimer made a special trip east to arrange for experimental studies, and as the news leaked to physicists at Berkeley and Chicago, several volunteered for the new laboratory at Los Alamos out of interest in the Super project.

The project's first and most obvious requirement, however, was a working fission weapon. It was suggested that the addition of tritium (an isotope of hydrogen with three times the normal weight) could lower the required ignition temperature, because the reaction rate of a deuterium–tritium mixture was many times larger than the rate for pure deuterium. Tritium, then, seemed to be a necessity. Groves made arrangements for a pilot plant operation to manufacture tritium from lithium in the experimental reactor at Oak Ridge (tritium is produced when a neutron is captured by the lithium-6 isotope of lithium). The net effect of a review in 1944, however, was to delay further work on the Super until after the war.

Even after the war, the Super continued to be a low-priority program, behind testing and stockpiling fission weapons. The test of the Soviet Union's first fission weapon on August 29, 1949, provoked a vigorous debate among United States scientists and political and military leaders. The Atomic Energy Commission was divided; the majority recommended against the development of the Super at that time. The General Advisory Committee had concluded that the theoretical studies were incomplete, that success might require large amounts of tritium, but that an imaginative and concerted attack on the problem had a better than even chance of producing a fusion weapon within five years. They observed that such a superweapon could not be confined to military targets and hoped that its development could be avoided.

The Joint Chiefs of Staff also made a study but did not recommend a high-priority program to build a Super, although it did urge a speedy determination of feasibility and some prudent plans for long lead-time production items. The Joint Committee on Atomic Energy of the U.S. Congress was strongly in favour of the Super. On January 31, 1950, President Truman made his decision that work on the Super would proceed.

The production facilities for thermonuclear materials were pushed steadily. By the end of 1950, a pilot plant for the production of heavy water was completed, and a Savannah River (South Carolina) site was selected for building up to six dual reactors capable of producing either tritium or plutonium. The Super theoretical studies went less smoothly.

The H-bomb and the computer

The development of thermonuclear weapons, which because their energy comes from "burning" the deuterium isotope of hydrogen came to be known as hydrogen bombs, or H-bombs, was intimately associated with electronic computers. The calculations needed in early 1950, however, were larger than any existing computer could handle. Drastically simplified calculations, suitable for available computers, showed that Super appeared to be marginal, that much more tritium would be required than previously believed.

In the spring of 1951, a new approach was mapped, and a Pacific test of thermonuclear principles proved successful. By fall Los Alamos had gone on a six-day work week to ensure that the first device test would be completed before the end of 1952. On the morning of November 1, 1952, the test was successful, obliterating a small island and leaving a wave-washed crater more than a mile in diameter.

Control agreements. When a nation becomes a nuclear power, it often issues an extensive statement about its weapon programs; most nuclear powers have been more reticent about their first thermonuclear test. The Soviet Union tested its first thermonuclear device on August 12, 1953; the United Kingdom tested its first on May 15, 1957. The larger yields of the thermonuclear explosions and the increasing pace of nuclear testing made the world aware of the fallout problem—that is, the danger to life of the radioactive products given off during a nuclear explosion, the total of which was building up at an increasing rate.

During 1958 the Soviet Union accepted a U.S. offer to convene a conference of technical experts on the problem of supervising a ban on testing. A temporary moratorium on testing went into effect on October 31, 1958, while the talks continued. It lasted almost three years, until the Soviet Union resumed atmospheric testing on September 1, 1961, conducting over 30 tests, including one with a yield of 60 megatons, before the U.S. resumed testing at Christmas Island some eight months later. The talks themselves had continued, punctuated by the atmospheric testing episode and the Cuban missile crisis of October 1962. In June 1963 Pres. John F. Kennedy announced that three-power talks (the United Kingdom, the U.S., and the U.S.S.R.) would resume in Moscow. The result was the Moscow Treaty, or the partial Nuclear Test-Ban Treaty, which became effective on October 10, 1963. It bans nuclear weapon tests in the atmosphere, in outer space, and under water. The treaty does not specifically prohibit testing in any other environment, provided the explosion does not cause radioactive debris to be present outside the territorial borders of the tester. Any signatory power can withdraw by giving three months notice. France and the People's Republic of China did not sign, China testing its first fission weapon about a year later. Five tests later, on June 17, 1967, it tested its first thermonuclear weapon. France continued its atmospheric tests in the South Pacific and achieved its first thermonuclear weapon on August 24, 1968.

In the spring of 1966, the U.S. Senate passed a resolution in support of negotiations for a non-proliferation treaty to prevent the further spread of nuclear weapons. The negotiations were formally carried out under the auspices of an Eighteen-Nation Disarmament Committee (ENDC). In January 1968, the U.S. and the U.S.S.R. submitted a draft treaty to the ENDC. The treaty, formally called a Treaty on the Non-Proliferation of Nuclear Weapons, was opened for signature on July 1, 1968, at London, Moscow, and Washington. It went into effect on March 5, 1970, when it had been ratified by the three depository nations (the U.K., U.S., U.S.S.R.) and 40 other nations. The nuclear weapon states agreed not to assist any nonnuclear weapon states to obtain or produce nuclear explosives in any way; they would, however, make available the potential benefits of peaceful applications of nuclear explosions for such industrial or civil-engineering uses as the stimulation of gas fields or the construction of harbours and canals. The nonnuclear weapon states agreed not to produce nuclear explosives and to allow inspection of their nuclear reactors and nuclear-materials production facilities to insure that no source or special fissionable material was being diverted for possible weapons use. These safeguard procedures were being worked out in the early 1970s. Several countries, including China, France, India, Israel, Japan, South Africa, and Spain, had not yet ratified the treaty.

The Non-Proliferation Treaty

Deployment of nuclear weapons. The main role played by nuclear weapons has been a strategic one—to support a country's doctrine of deterrence. In the U.S. this doctrine has ranged from so-called massive retaliation in the 1950s to mutual deterrence in the 1970s. Most new nuclear powers have chosen the long-range heavy bomber as their first nuclear weapon carrier. Early carriers were simply modified versions of existing aircraft; later planes were specifically designed for the long ranges, high speeds, and other characteristics thought necessary.

Several developments, such as reliable guidance systems, were needed before the intercontinental ballistic missile (ICBM) became militarily attractive. As missile design improved, with solid propellants replacing the operationally awkward liquid propellants and with guidance that reduced the warhead yield requirement, great progress was also made in producing higher thermonuclear yields per pound of warhead weight, as well as in reducing the overall size. The fleet ballistic missile system of the U.S. Navy, started in 1956, saw the first Polaris submarine, the nuclear-powered "George Washington," become operational on November 15, 1960. The sixth Polaris submarine conducted an operational test, including the detonation of the warhead, near Christmas Island in May 1962. The Minuteman missile system of the U.S. Air Force, started in 1958, saw its first squadron become operational in early 1963. In the early 1970s new versions of the Polaris and Minuteman were deployed, capable of carrying multiple, independently targetable reentry vehicles (MIRV).

The Soviet Union deployed its nuclear weapons in a pattern similar to that of the U.S., except for the early postwar years when it built a large, intermediate-range ballistic missile (IRBM) force, targeted for western Europe. For many years, the U.S.S.R. ICBM force lagged behind the U.S.; strategic parity with the U.S. for ICBM's was attained in 1969. At that time, the U.S. estimated the Soviet ICBM threat at about 300 SS-9s, capable of carrying 25 megatons each, and 700 SS-11s, a Minuteman-like missile using a storable liquid propellant. In the early 1970s, the Soviet Union also had a number of Polaris-like submarines.

The United Kingdom and France have selected a sub-

marine-launched ballistic-missile system as their main nuclear deterrent force. The U.K. deployed four, and France planned to deploy five, Polaris-like submarines in the mid-1970s. In addition, France was emplacing 18 IRBM's in silos in Haute-Provence.

In the early 1970s, China had made no statements on the method it would use in the deployment of its nuclear stockpile. Its fourth nuclear weapon test was delivered by a missile. U.S. estimates were that the Chinese would be capable of producing up to 25 ICBM's by 1975.

Just as there have been efforts to control the testing and proliferation of nuclear weapons, there have been efforts to control nuclear weapon delivery systems. In January 1969, the Soviet Union announced that it stood ready to begin talks with the U.S. on the limitation and reduction of strategic nuclear delivery systems, including defensive systems. Strategic arms limitation talks (SALT) opened in Helsinki, Finland, on November 17, 1969, and continued into the early 1970s.

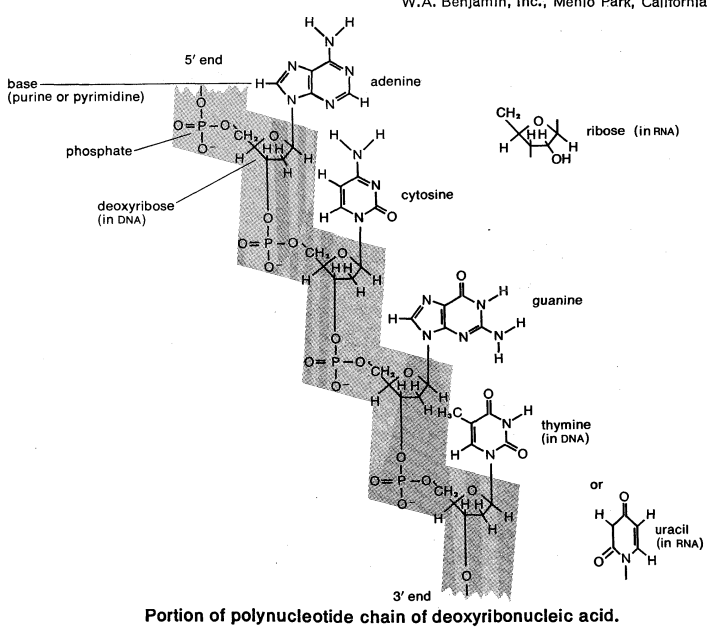
Nucleic Acid

Nucleic acids are of interest because they provide the genetic material of the cell and, by directing the process of protein synthesis, determine its inherited characteristics (see GENE). Nucleic acids are naturally occurring complex phosphorus compounds, acidic in character, and capable of being broken down chemically to yield phosphoric acid, sugars, and a mixture of organic bases (purines and pyrimidines). About 1868 nuclei isolated from pus cells were found to contain an unusual phosphorus compound, which was named nuclein. In later years, complex phosphorus-containing acid materials were also isolated from a wide variety of cells; these appeared to be chemically similar to nuclein and came to be called nucleic acids.

There are two classes of nucleic acids: ribonucleic acids (RNA) and deoxyribonucleic acids (DNA). Both RNA and DNA are macromolecules (giant molecules) that can be distinguished from each other by their base and sugar contents. DNA, a major constituent of chromosomes in the nuclei of all cells, is also found in other cellular components (*e.g.*, mitochondria, chloroplasts). RNA is present in both the nucleus and cytoplasm of many cells. The bulk of cytoplasmic RNA is associated with ribosomes, small particles composed of RNA and proteins that are the site of protein synthesis.



Portion of polynucleotide chain of deoxyribonucleic acid.

General features of nucleic acids. Nucleic acids are polynucleotides, long chain compounds consisting of repeating structural units called nucleotides. Each nucleotide contains a pentose (or five-carbon) sugar, a purine or pyrimidine base, and a phosphate residue. The pentose sugar is ribose in RNA and 2-deoxyribose in DNA (see CARBOHYDRATE); the major purine and pyrimidine bases are adenine, guanine, cytosine, and thymine (or uracil in RNA). For further information about the chemical properties of purine and pyrimidine bases and nucleotides, see NUCLEOTIDES.

Enzymatic breakdown of nucleic acids results in the release of nucleotide units in which a phosphate residue is attached to the deoxyribose sugar at one of two possible positions on the sugar molecule. These internucleotide linkages are known as phosphodiester bonds. The internucleotide linkage is the same in RNA.

It was the fact that adenine and thymine are present in approximately equal amounts in DNA, as are guanine and cytosine, together with information from X-ray crystallography of DNA that led Nobel Prize winners J.D. Watson and F.H.C. Crick to postulate that the DNA molecule consists of two chains or strands of polynucleotides coiled around each other to form a double helix, the bases of one strand being paired with complementary bases of the other by hydrogen bonds: adenine paired with thymine and cytosine with guanine. RNA has unequal proportions of the four bases and, in addition, contains unusual bases (*e.g.*, pseudouridine, various methylated purines).

Nucleic acids can be separated from other cellular constituents by treating a tissue with cold acid. Most of the contents of the tissue go into solution, but both RNA and DNA are insoluble in cold acid and can be removed from the mixture. RNA and DNA, in turn, can be separated by treatment with alkali; in this case, RNA is broken down by the alkali into nucleotide units, but DNA remains unchanged. If acid is added to this mixture, DNA precipitates (comes out of solution), and the RNA nucleotide units remain in solution.

The DNA found in cell nuclei (as chromosomes) and in other cell components usually is bound to proteins called histones. The protein bound to the DNA in sperm cells is known as protamine. Bacterial DNA is not associated with protein. DNA–protein complexes from animal tissues, known as deoxyribonucleoproteins, are molecules of very high molecular weight (from 10,000,000 to more than 100,000,000 times the weight of a hydrogen atom). Approximately 25 to 50 percent of the dry weight of this complex is nucleic acid.

Characteristics of DNA. *Physical properties.* Many of the physical properties of DNA depend on the methods used to purify it. If, for example, fragmentation of DNA molecules by either mechanical means or enzymes is avoided, DNA preparations of very high molecular weight (*e.g.*, 120,000,000), corresponding to a chromosome or to the entire nucleic acid complement of a virus or a bacterium, can be obtained. Solutions of such preparations are viscous, and almost any manipulation (*e.g.*, stirring) can break the molecules into fragments of lower molecular weight.

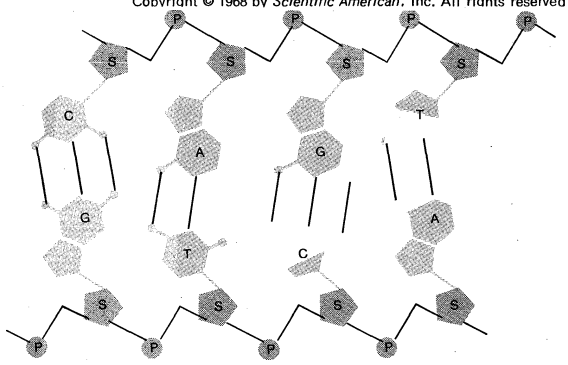
Because of their purine and pyrimidine base content, DNA preparations absorb ultraviolet light. If a solution of DNA is heated to a critical temperature, it absorbs more ultraviolet light and becomes less viscous because the orderly helical structure of the molecules breaks down. DNA molecules become irregularly coiled structures during this process, which is called thermal denaturation of DNA. The melting temperature at which thermal denaturation takes place is dependent on the base composition of the DNA molecule. DNA molecules with a high content of guanine and cytosine, for example, are more stable at high tem-

peratures than those high in adenine and thymine because the hydrogen bonding between guanine and cytosine is stronger. At temperatures slightly above the melting temperature, the two strands of DNA separate. If the DNA solution is cooled slowly, sometimes recombination of the strands and partial restoration of the double helix occurs.

If a concentrated salt solution is spun in a centrifuge at high speed for a long period of time, an equilibrium is eventually attained in which the concentration, and, therefore, the density, of the salt solution increases gradually from the top of the tube to the bottom. If the salt solution also contains DNA, these molecules migrate to the level in the tube in which the density of the salt solution equals their own. This is an important method for determining with great precision the density of nucleic acids and for separating DNA molecules of different densities. The density of DNA molecules with a high proportion of guanine and cytosine is slightly greater than that of molecules with a lower proportion of these bases. Denaturation also causes a slight increase in density. Although DNA usually is double-stranded, there are single-stranded forms (for example, the small bacterial virus designated ϕX 174), which do not show the denaturation phenomena of the double-stranded molecules.

Importance of hydrogen bonds

Structure. The long polynucleotide chains that comprise DNA molecules would form flexible threadlike molecules, instead of coils, were it not for cross-links (hydrogen bonds) between bases of each chain. Measurements indicate that the space between DNA chains agrees with values calculated for hydrogen bond linkage of a purine base to a pyrimidine base (the space is too small for two purines and too large for two pyrimidines). Three cross-links occur between a guanine residue (purine base) and its complementary base, cytosine (a pyrimidine), in two complementary chains; on the other hand, two cross-links occur between adenine (purine base) and its complementary base, thymine (a pyrimidine). Each purine base is linked to its complementary pyrimidine base in the opposite chain by either two or three hydrogen bonds.



DNA structure.
(C) Cytosine. (T) Thymine. (A) Adenine. (G) Guanine.
(P) Phosphate. (S) Deoxyribose (sugar).

The sugar molecules (deoxyribose in DNA) are linked by phosphodiester bonds to form the backbone of each DNA chain. The bases, with their large hydrophobic (water-hating) surfaces, are stacked together on the inside of the molecule like a pile of coins. These two complementary chains coil around each other to form a double helix. In other words, DNA resembles a spiral staircase in which the bases are the steps and the sugar phosphate residues are the bannisters. The DNA molecule derives stability not only from hydrogen bonding between base pairs in complementary chains but also from hydrophobic "base-stacking forces" between neighbouring bases on the same chain. The DNA of mammalian chromosomes and DNA-containing viruses generally consist of long unbranched double helical threads of the type described above. The DNA of many viruses (including ϕX 174) and of mitochondria, however, are circular, and, in some cases, there is evidence that such cyclic double helices are twisted into a supercoiled form. A single break in either chain of the helix releases the molecule, and an untwisted structure results.

Base sequence. The biological function of DNA molecules, whether single- or double-stranded, cyclic or unbranched, is to provide a genetic message encoded in a sequence of purine and pyrimidine bases. Although there are ways to determine the sequences of the units in some macromolecules like proteins (see PROTEIN), it is extremely difficult to do so for DNA molecules, which generally are of much higher molecular weight. In addition, nucleic acids are composed of fewer kinds of units (*i.e.*, the purine and pyrimidine nucleotides) than are found in proteins (*i.e.*, about 20 amino acids). It is also more difficult to obtain a single molecule of pure DNA than it is to purify proteins. Progress has, however, been made in the base sequence determination of the relatively small DNA of the ϕX 174 virus, which contains about 5,500 nucleotide units; thus far it has been possible to obtain only statistical evidence about the order in which these nucleotides are arranged. The usual experimental approach takes advantage of the fact that the purine bases of DNA are removed by acid, while the pyrimidine bases retain their original positions in the molecule. Pyrimidine nucleotides have been shown to occur frequently in clusters.

Laboratory synthesis of DNA. Experiments with living cells have tended to confirm the hypothesis that DNA is synthesized by a process in which the two strands of an existing molecule separate while new complementary strands are synthesized using the old strands as templates, or patterns. For a detailed discussion of the biosynthesis of DNA, see GENE. The product of DNA synthesis in the cell is the formation of two molecules, each containing one strand from the original DNA and a newly synthesized complementary strand.

Enzymes purified from mammalian and bacterial cells catalyze the synthesis of DNA in the test tube. The reaction takes place only in the presence of the nucleoside triphosphates of the four bases (adenine, cytosine, guanine, and thymine) and preformed DNA, which serves as a template. That the product has the same nucleotide sequence as the template has been demonstrated by the technique of "nearest neighbour frequency analysis." One of the four nucleotides contains radioactive phosphorus. During DNA synthesis these radioactive phosphorus residues form internucleotide links with nucleotides next to them in the newly forming chain. The newly synthesized DNA is degraded with enzymes that split the radioactive phosphorus from the molecule to which it was originally attached. The result is that the radioactive phosphorus becomes part of the structure of the nucleotide nearest the nucleotide originally labelled. In this way it is possible to determine the frequency with which particular pairs of nucleotides are neighbours in polynucleotide chains. Such nearest neighbour frequencies vary markedly from one DNA source to another and are specific for each kind of DNA. Generally, the DNA produced by the DNA-synthesizing enzyme in the test tube cannot be shown to possess the biological activity of the template.

Nearest neighbour frequency analysis

When single-stranded circular DNA of the virus ϕX 174 is used as a template for DNA synthesis, however, a complementary (or $-$) strand is formed along the original (or $+$) strand. The free ends of the new (or $-$) strand can be joined by an enzyme to form a cyclic double-stranded molecule. If the cyclic double-stranded molecules are broken with another enzyme, random single breaks occur in a proportion of the molecules in either strand. The broken molecules can be eliminated leaving a number of intact synthetic cyclic ($-$) strands. When these are tested, they are found to be capable of infecting susceptible cells and of giving rise to a new generation of normal virus particles.

Characteristics of RNA. *Physical properties.* Most DNA molecules share a common genetic function and structural pattern. RNA molecules, however, perform several functions in the cell, and their properties vary correspondingly. Three types of RNA have been studied chemically: ribosomal RNA (rRNA), transfer (soluble or adaptor) RNA (tRNA), and viral RNA. Messenger RNA (mRNA), despite its biological importance, has not yet been the subject of extensive chemical investigation. The RNA's of some viruses (*e.g.*, reovirus, wound tumour virus) have

properties in common with DNA, including a double helical structure and a critical melting temperature. Other viral RNA's (*e.g.*, tobacco mosaic virus) and ribosomal RNA, however, have less sharp melting characteristics and lack a complete double helical structure; instead the polynucleotide chains are folded back on themselves to provide small regions of base pairing and, therefore, hydrogen bonding and some helical sections. The small tRNA molecules are thought to be folded similarly into a cloverleaf structure, with regions of hydrogen bonding between base pairs forming hairpin-like helical sections.

The molecular weights of RNA molecules vary according to their type and source. Ribosomal particles, for example, contain a large fraction of the RNA in a cell; these particles can be split into two unequal subunits. The main component of ribosomal RNA from the larger of the subunits has a molecular weight of about 1,000,000; the RNA from the smaller subunit has a molecular weight of about 800,000. Ribosomes also contain RNA's of lower molecular weight (about 60,000). Transfer RNA is the smallest type of RNA molecule; its molecular weight varies from about 25,000 to 30,000. The molecular weights of messenger RNA molecules vary over a wide range.

Structure and base sequence. Research involving RNA structure has centred around tRNA (the type of RNA to which amino acids are attached during protein biosynthesis), the smallest nucleic acids (70 to 80 nucleotide units). The different tRNA molecules (each of the approximately 20 amino acids has at least one specific tRNA) in the cell can be separated and purified. In addition to their small size, tRNA molecules are distinguished from other forms of nucleic acids by their relatively high content of minor nucleotides (*e.g.*, pseudouridine, methylated bases). The relative ease with which these minor nucleotides can be identified has been useful in sequence determinations. By using enzymes that catalyze different specific reactions for various lengths of time on one type of tRNA, fragments of the polynucleotide are produced and can be separated and analyzed to determine the sequence of nucleotides in the intact molecule.

Laboratory synthesis of RNA. It has been suggested that RNA is synthesized in the living cell by a process in which one of the two strands of a DNA molecule is used as a template (or pattern) for the formation of a complementary strand of RNA. For detailed discussion of the biosynthesis of RNA, see GENE. Enzymes found in microorganisms and in animal tissues can catalyze the synthesis of RNA in the test tube. This synthesis occurs provided that a mixture of the proper nucleoside triphosphates and a small quantity of DNA are present. The composition of the newly synthesized RNA corresponds exactly to that of the DNA template (with uracil replacing thymine), and nearest neighbour sequence analysis indicates a similar correspondence in base sequence. In certain cases, a hybrid double helical molecule, which may form from template DNA and the RNA product, indicates an exact correspondence in structure between primer and product. In animal and bacterial cells infected with RNA viruses, the RNA of the virus acts as a template for the synthesis of more RNA.

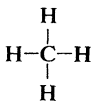
Nucleotides

Nucleotides are organic chemical compounds composed of nitrogen-containing units joined to sugar and phosphate units. They are of importance in biology as the structural groups composing nucleic acids, long chainlike molecules that may contain more than 1,000,000 nucleotides and that make up the fundamental genetic material responsible for storage and replication of hereditary information in living cells. Several nucleotides belong to a class of compounds called coenzymes, substances that act in conjunction with compounds called enzymes that catalyze (speed up) chemical reactions in biological systems; a few nucleotides are starting materials in biological systems from which compounds of other classes are synthesized.

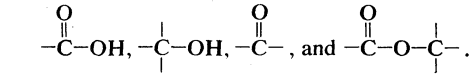
Discovery of the nucleotides

The chemistry of nucleotides has been studied since 1847, when a German chemist, Justus von Liebig, isolated inosinic acid from a meat extract, but nucleic acids were not obtained until more than 20 years later, and their relationship to nucleotides was made clear only after 1900. The first discovery of a nucleotide coenzyme occurred in 1904. The study of nucleotides has been greatly facilitated by the introduction of such analytical techniques as spectroscopy and chromatography about the middle of the 20th century.

General considerations. Understanding of nucleotides is based on knowledge of the structure of organic compounds, which are classified into families that have similar molecular structures and, as a result, comparable properties. All organic compounds have as their basic structural feature chains or rings of carbon atoms linked together by bonds, of a type called covalent, that result from sharing electrons between each pair of atoms. Each carbon atom has the capacity to form four such bonds with other carbon atoms or atoms of other elements. Empirical formulas for compounds are written with the symbol for an element representing a single atom and a subscript indicating the number of such atoms in the molecule; for example, methane has one carbon and four hydrogen atoms: CH_4. Structural formulas indicate the actual disposition of the atoms relative to one another in the molecule, each covalent bond being represented by a line between the relevant symbols:



Most chemical reactions of organic compounds involve only one or two of the numerous atoms and bonds, while the rest of the structure does not change. The unaffected part is called a radical (represented by the symbol R), a molecular fragment that is given a name derived from that of the compound formed by bonding a hydrogen atom to it; *e.g.*, the methyl radical, CH_3, is named from methane, CH_4. There are also tightly knit groups of atoms, called functional groups, that form part of an organic molecule without losing their characteristic properties in chemical reactions, whatever kind of molecule they are attached to. The most important of these are the carboxylic acid group, the hydroxyl group, the carbonyl group, and the ester group, for which formulas are written respectively:



When small organic molecules bond with one another to form chains, the repeating unit is called a monomer, or subunit, and the chain, or macromolecule, a polymer. Several kinds of monomers may also bond together in a re-

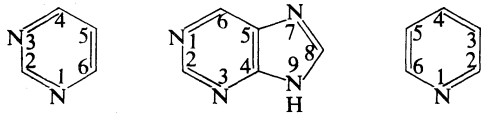
peating pattern to form polymers of varied classifications. Nucleic acids belong to a class of polymers, the subunits of which are nucleotides, themselves composed of three subunits.

The formation of nucleic acids in plant and animal cells is a process of joining a very large number of nucleotides end to end. The reaction is catalyzed by enzymes called polymerases.

Chemistry of the nucleotides and related compounds.

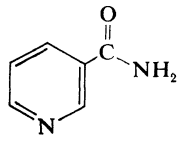
Nitrogen bases

Composition. The nitrogen-containing bases combined with sugar and phosphate units in the naturally occurring nucleotides are derivatives, and so named, of members of three families of heterocyclic compounds: the pyrimidines, purines, and pyridines. The derivatives have formulas in which one or more hydrogen atoms in a pyrimidine, purine, or pyridine structure has been replaced by simple radicals or functional groups, usually amino (NH_2), hydroxyl (OH), or methyl (CH_3). The most abundant of these nitrogen bases are the pyrimidines cytosine, thymine, and uracil; the purines adenine and guanine; and the pyridine nicotinamide. The structures of these compounds are represented by structural formulas in which the symbols for the elements are joined by single lines for single covalent bonds and two lines for double bonds. In a ring or cyclic structure the carbon atoms are at the corners of the ring but are not shown; noncarbon atoms, however, are. Hydrogen atoms attached to ring carbons also are not shown. The same rules are followed with multiple ring structures. Carbon atoms are shown in all chains attached to the rings. Ring positions are numbered for purposes of nomenclature and identification of bond positions. The parent ring systems of the nucleotides are shown as:

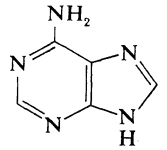


pyrimidine purine pyridine

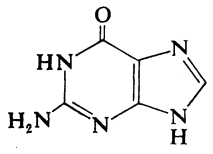
Major nitrogen bases formed from the nucleotides are:



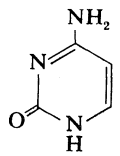
nicotinamide



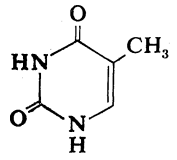
adenine



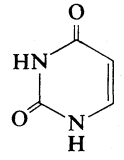
guanine



cytosine



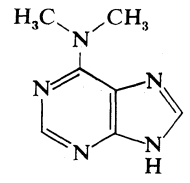
thymine



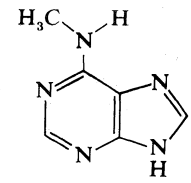
uracil

Certain nitrogen bases occur only in nucleotides present in a few specific nucleic acids; these rarer bases have the structures shown below.

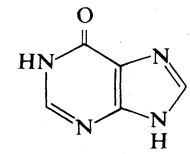
The purines and pyrimidines related to the nucleotides are crystalline, high-melting solids. They do not absorb light in the visible region of the spectrum (hence, are colourless), but their characteristic absorption of ultraviolet light is of great value for analytical determinations.



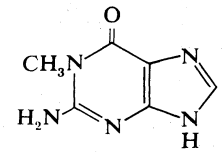
6-dimethylaminopurine



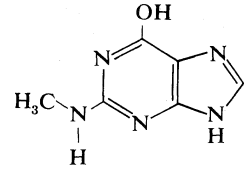
6-methylaminopurine



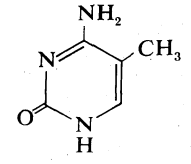
hypoxanthine



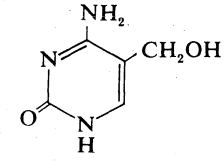
1-methylguanine



2-methylamino-6-hydroxypurine



5-methylcytosine



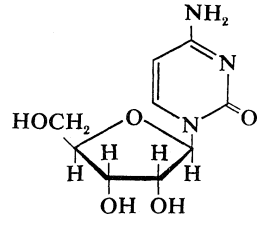
5-hydroxymethylcytosine

The purines and pyrimidines exhibit similar chemical behaviour because the properties of the pyrimidine ring are not much affected by the presence of the second ring of the purines.

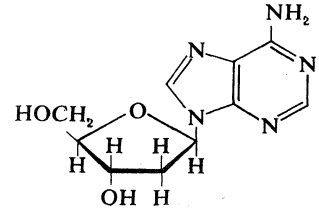
The nitrogen bases can all be prepared from simpler compounds in the laboratory. Pyrimidines are usually synthesized from urea and a second component that furnishes the three carbon atoms that occupy positions designated 4, 5, and 6 in the product. Purines are commonly made from pyrimidines that have amino groups at positions 4 and 5; these amino groups become the nitrogen atoms at positions 7 and 9 of the purine structure.

Several compounds analogous in structure to purine and pyrimidine bases have been synthesized, and their effects on biological systems have been studied. Small variations in the molecular structure can exert profound influences upon processes such as the formation of proteins or of deoxyribonucleic acids (DNA's), often because the modified compound cannot undergo some essential chemical reaction.

Relationship to nucleosides. Nucleosides are compounds in which one of the nitrogen bases is combined with a sugar unit, but the phosphate portion of the nucleotides is absent. The nucleosides are named as derivatives of the bases: for example, cytidine is composed of



cytidine
(a ribonucleoside)

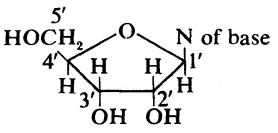


deoxyadenosine
(a deoxyribonucleoside)

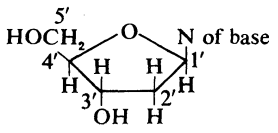
cytosine and the sugar ribose. Nucleosides can be decomposed into their constituent bases and sugars by hydrolysis; that is, a reaction with water in which a chemical bond is broken and the products are the parts of the original molecule—formerly connected by the bond that was hydrolyzed—now combined with the parts of a water molecule (a hydrogen atom and a hydroxyl group). The sugars that are obtained by the process of hydrolysis of nucleosides are usually the five-carbon compounds ribose or 2-deoxyribose.

Sugars

It has been found that the sugar is always present as a five-membered ring for which the structures are shown as:



ribose group

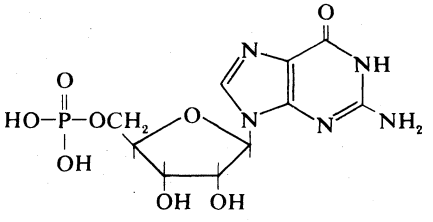


deoxyribose group

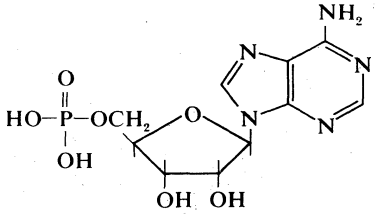
Laboratory preparation of nucleosides requires prior conversion of the sugar into a "protected" form that can combine with a nitrogen base only at position 1′ of the sugar ring. After the base–sugar bond has been formed, the protecting modifications are removed.

Structure of nucleotides. The constitution of nucleotides as three-part molecules was originally established by experiments in which the two chemical bonds joining the three units were broken by hydrolysis. The point at which the sugar is linked to the phosphate group may be determined by studies of the compounds in which these components remain bound together. It has been found that the location of this linkage may change during the chemical treatments used to isolate the nucleoside but that, in natural polynucleotides (nucleic acids), phosphate ester bonds extend from the 3′ position of one nucleotide to the 5′ position of the next.

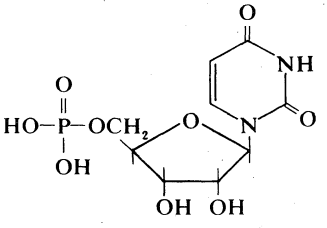
The structures of the nucleotides that make up most of the repeating units in ribonucleic acids (RNA's) are:



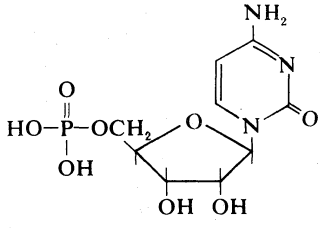
guanylic acid
(guanosine 5′-phosphate, GMP)



adenylic acid
(adenosine 5′-phosphate, AMP)

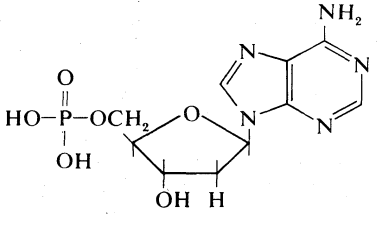


uridylic acid
(uridine 5′-phosphate, UMP)

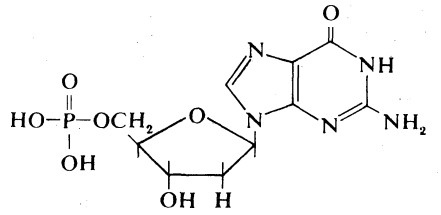


cytidylic acid
(cytidine 5′-phosphate, CMP)

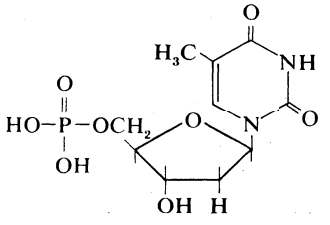
Those most common in DNA's are:



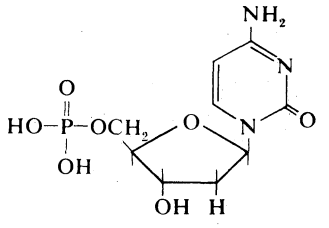
deoxyadenylic acid
(deoxyadenosine 5′-phosphate, dAMP)



deoxyguanylic acid
(deoxyguanosine 5′-phosphate, dGMP)



thymidylic acid
(thymidine 5′-phosphate, dTMP)



deoxycytidylic acid
(deoxycytidine 5′-phosphate, dCMP)

The nucleotides that serve as coenzymes or as the actual physiological building blocks in synthesis of nucleic acids often are esters (when an acid and an alcohol react they form water and an ester) not of phosphoric acid but of condensed relatives of it, pyrophosphoric or triphosphoric acids. They are named as derivatives of the nucleosides.

Laboratory conversion of a nucleoside to a nucleotide is most successful when both the nucleoside and the phosphate unit are employed in modified forms. The nucleoside must be altered so that only one of the two or three hydroxyl groups is available for reaction, while the compound used to introduce the phosphate unit must be capable of reacting with one hydroxyl group but no more. A variety of techniques has been developed for carrying out these difficult syntheses.

Oligonucleotides. An oligonucleotide is a compound in which a small number of nucleotides are joined together by the same kind of chemical linkages as those present in nucleic acids: phosphoric ester groups exist between 3′ and 5′ positions of sugar units. Oligonucleotides may be obtained either by partial hydrolysis of nucleic acids or by combining mononucleotides.

Decomposition of a nucleic acid into oligonucleotides is preferably effected by using enzymes because these substances hydrolyze specific sugar–phosphate bonds without inducing other reactions. Bovine pancreatic ribonuclease, for example, hydrolyzes some of the ester linkages in RNA's and does not act upon DNA's at all. Ribonucleases of differing specificities have been used in determination of the sequence of nucleotide units in RNA's. Such determinations in DNA's, however, are much more difficult because no suitable enzymes have been discovered.

Synthesis of oligonucleotides

Oligonucleotides can be synthesized by treating mononucleotides with reagents that induce the formation of phosphate diesters. Such reactions proceed satisfactorily with deoxyribonucleotides, which possess only one hydroxyl group that can react in this fashion; in ribonucleotides, however, there are two hydroxyl groups of similar reactivity and part of the product contains phosphate links between 2′ and 5′ positions. The desired result can be attained with ribonucleotides only when the 2′ hydroxyl group can be excluded from the reaction, as by prior conversion to an unreactive form from which it can be regenerated after formation of the 3′–5′ phosphate diester bond.

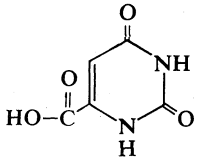
Oligonucleotides with specific base sequences often can be synthesized by enzyme action more easily than by chemical methods. Polymerase enzymes incorporate nucleotide 5′-triphosphates into a copy of a preformed oligonucleotide added to the reaction mixture.

Biological functions of nucleotides. Nucleotides are very widely distributed, apparently being present in all

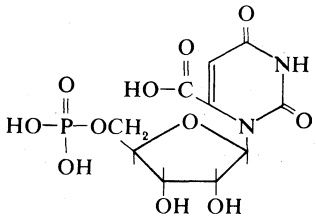
known life forms. Viruses contain DNA's or RNA's, although they are capable of replication only inside the cells of host organisms, utilizing nucleotides available there. Nucleotides have the same functions—those of coenzymes and of starting materials for nucleic acid synthesis—in all plants and animals, from the simplest to the most complex, and they are built up and broken down by processes that vary only in details throughout the same range.

Biological synthesis

In the biological synthesis of the pyrimidine nucleotides, ammonia, carbon dioxide, and the amino acid aspartic acid are utilized in the assembly of the pyrimidine ring of orotic acid, which is then attached to the ribose phosphate unit to produce orotidine 5′-phosphate, from which all the other pyrimidine nucleotides are formed. The structure is:

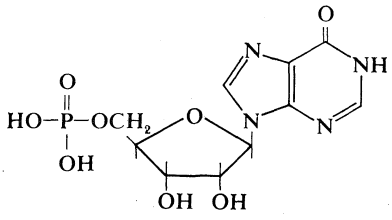


orotic acid



orotidine 5′-phosphate

The precursor (in the sequence of reactions in the organism) of the purine nucleotides is inosinic acid,

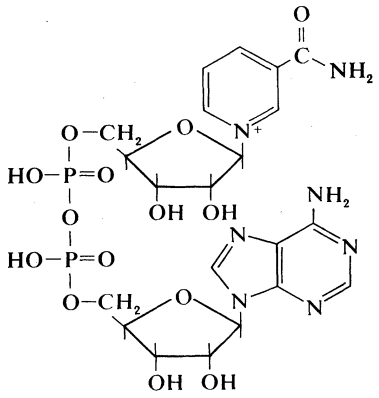


inosinic acid

which is built up from ribose phosphate by stepwise addition of the atoms of the five-membered ring, then those of the six-membered ring.

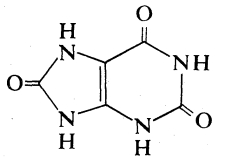
Transformations of orotidine 5′-phosphate or inosinic acid into other nucleotides involve three major classes of reactions: (1) The monophosphates are converted into diphosphates and triphosphates by the action of adenosine 5′-triphosphate, or ATP, which is generated during metabolism of carbohydrates. (2) Ribonucleotides are converted to deoxyribonucleotides by removal, through the action of an enzyme, of an oxygen atom from the ribose ring. (3) Groups such as amino, hydroxyl, and methyl are introduced into the pyrimidine and purine rings by replacement of hydrogen atoms or of other groups.

The important pyridine nucleotide, nicotinic acid ribonucleotide, is utilized in the synthesis of the coenzyme nicotinamide adenine dinucleotide (NAD+), in which the structure is:



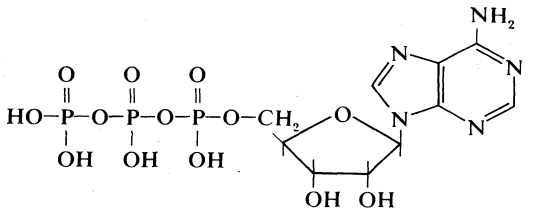
nicotinamide adenine dinucleotide, NAD+

Metabolic breakdown. Conversion of the purine and pyrimidine nucleotides to simpler compounds by reactions occurring in the living organism follows separate routes, after cleavage of the bond between the sugar and the nitrogen base. The pyrimidine bases are decomposed in the body by hydrogenation (addition of hydrogen) and hydrolysis reactions to ammonia, carbon dioxide, and the amino acids β-alanine or β-aminoisobutyric acid. The purines are converted into uric acid, which is excreted by man and other primates. In other species, uric acid is broken down into a series of simpler compounds, including allantoin, allantoic acid, urea, glyoxylic acid, ammonia, and carbon dioxide.



uric acid

Nucleotides as coenzymes. Several nucleotides perform essential roles as coenzymes, the function of which often is to drive physiological reactions more nearly to completion. Adenosine 5′-triphosphate, ATP, is one of the most important coenzymes, participating in syntheses of fats, carbohydrates, proteins, and nucleotides. Its structure is:



adenosine 5′-triphosphate (ATP)

Other nucleotide coenzymes are involved in interconversions among carbohydrates and in the synthesis of membranes and cell walls and of phospholipids, which are essential in the oxidation of organic substances to carbon dioxide.

NAD+ and flavin adenine dinucleotide (FAD) participate in oxidation–reduction reactions, in which hydrogen and oxygen atoms are exchanged between compounds. Coenzyme A transfers groups, such as acetyl (CH_3CO, derived from acetic acid), from one compound to another in the formation of fatty acids, isoprenoids, and steroids. Adenosine 3′, 5′-phosphate (cycloadenylic acid or cyclic AMP) activates the enzyme phosphorylase kinase, one of the substances controlling the interconversion of glucose and glycogen, a storage form of sugar. Cyclic AMP also regulates release of the hormone insulin from the pancreas.

Cyclic AMP

Nucleotides as starting materials. The utilization of nucleotides as starting materials for synthesis of other classes of compounds is exemplified by formation of the amino acid histidine from ATP and of the folic acid coenzymes from the compound GMP.

Formation of nucleic acids from nucleotides by polymerases requires the presence of a metal ion (usually magnesium), a preformed nucleic acid, and the four appropriate nucleoside triphosphates. The nucleic acid is a chain of nucleoside monophosphate units, the remaining two phosphate units of each triphosphate appearing as the inorganic pyrophosphate ion.

Nucleus, Atomic

An atom, according to one definition, consists of a nucleus surrounded by electrons, the nucleus being a small and relatively heavy object at the centre, about which the electrons gyrate. In this model the atom can be compared to the solar system, the nucleus corresponding to the Sun and the electrons to the revolving planets, except that the solar system is flat with all the planetary orbits in almost the same plane, whereas the electrons in the atom orbit in all planes creating a sphere of effectiveness.

From the point of view of massive substance, the atom is almost all nucleus; the mass of the nucleus is about 4,000 times that of all the electrons together. The nucleus is electrically positively charged, the electron is negatively charged, and in a normal atom all of the electrons together have the same amount of charge as the nucleus so that, since the charges exactly balance, the whole atom is electrically neutral, with a charge of zero. The chemical properties of atoms are determined by the numbers of their electrons of which they may have more or less than normal. The variety of atoms found in nature, explained by the number of different kinds of nuclei, is the basis for the great variety of chemical substance.

Composition of the nucleus

A nucleus consists of protons and neutrons, called nucleons. The proton is positively charged, whereas the neutron has no charge. A neutron and proton have almost equal masses; hence the net charge or atomic number of a nucleus depends on the number of its protons, and the nuclear mass depends on the total number of its nucleons. The nucleons cling together to form a nucleus because of a strong, attractive force known as a nuclear force, one nucleon exerts on another close to it. There also exist opposing repulsive forces arising from the nuclear force (at extremely close range) and from the electrostatic force due to the positive charges on the protons. Nucleons also display much weaker magnetic fields, which can be attractive or repulsive.

Individual nucleons spin on their own axes and circulate vaguely about a common nuclear centre in orbits. These orbits have various energies and are ordered in shells, being arranged according to the laws of quantum mechanics. The shape of a nucleus as a whole is spherical or distorted into an oblate ellipsoid like a tangerine or a prolate ellipsoid like a lemon. It can vibrate, rotate, and change its shape, phenomena that can be identified because of the change in the total energy of the nucleus. Nuclei can change into one another through the process of radioactivity, and certain very heavy nuclei can split into two parts of almost equal size, known as a fission reaction.

Knowledge of atomic nuclei facilitates many practical applications of their properties and enriches other fields of study. One nucleus is said to be an isotope of another if it has the same nuclear charge, and thus the same chemical properties, but a different mass. A rare isotope introduced into one stage of a chemical or other process may be retrieved at another and thus serve as a tracer to indicate the path of the process. Radioactivity, which results from nuclear activity, can be used to treat cancer or, as a poison in the environment, can cause cancer. The energy released by causing interactions among nuclei is, on a weight basis, millions of times greater than that released in chemical reactions, and thus nuclear energy poses unprecedented vistas and threats to mankind. Laboratory studies of nuclei may provide explanations for the processes that release these same energies in stars, thus supporting theories of cosmic evolution.

HISTORICAL BACKGROUND

Since practically all of the mass of an atom is in its nucleus, the early chemical discoveries of the nature of atoms turned out to constitute knowledge about nuclei. In this sense some of the first information about nuclei came from the work of the English chemist John Dalton, who in 1803 proposed an atomic theory of atoms and compounds; of the Italian physicist Amedeo Avogadro, who in 1811 elucidated the number of atoms in a given volume of atoms and thus provided the first basis for determining what turned out to be nuclear masses; and of the Russian chemist Dmitry Ivanovich Mendeleyev, whose periodic table of the elements (1869) classified elements by atomic weights and like properties. After later recognition of the existence of nuclei, it could be inferred that nuclei are composed of "building blocks" of nearly equal mass, now recognized to be protons and neutrons.

Other paths that led more directly to the recognition that an atom has a central nucleus surrounded by electrons began in 1879 with the study of electrical discharges through low-pressure gases. Such discharges excited fluorescence; *i.e.*, produced the delayed emission of light from crystalline materials. While investigating this radiation, the French physicist Henri Becquerel in 1896 discovered radioactivity, a much more energetic and penetrating radiation emitted spontaneously from, in that case, uranium. Study of this new phenomenon in heavy elements was taken up most vigorously by two other French physicists, Pierre and Marie Curie, who in 1898 isolated radium and showed that it has a family of radioactive daughters with individual radiations that could be identified by their penetrations and the lifetimes over which they decay in intensity. Subsequent work traced other radioactive families and showed that different paths of radioactive evolution can lead to atoms with different radiations but the same chemical properties, suggesting isotopes of the same element. Such energetic rays, so different from the light rays ordinarily emitted by atoms, hinted that there must be some special part of the atom capable of emitting them. The radiations consist of alpha particles (later shown by the British physicist Sir Ernest Rutherford to be identical with helium nuclei); beta rays, or streams of electrons; and gamma rays, or electromagnetic radiations, which, like X-rays, resemble ordinary light but are more energetic and penetrating.

Discovery of radioactivity

In 1897 an English physicist J.J. Thomson discovered that what were called cathode rays in the Crookes tube were in reality negatively charged particles generated at the cathode, or negative terminal, coasting past the positive terminal, or anode. After a series of experiments, he concluded that these particles always have the same ratio of electric charge (designated e) to mass (m): e/m. These particles came to be called electrons. Years later, in 1910, Thomson discovered that the so-called canal rays —that is, the rays that appear behind the negative terminal from a discharge in neon gas—consist of ionized atoms (atoms lacking one or more electrons) with different masses, in this case of two different mass numbers, 20 and 22. He thus established the existence of isotopes, atoms of the same chemical element having the same chemical properties but different mass, and confirmed that the nonintegral mass numbers of some elements, in the case of neon 20.2, are due to mixtures of isotopes.

The nuclear age may be said to have started in 1911 when Rutherford definitely established the existence of an extremely small and massive particle within the atom—its nucleus. He did so by letting alpha particles from radium impinge on thin foils of various metals and observing how the particles are deflected by counting the scintillations they produced when they hit a fluorescent screen. From these observations he calculated that the massive cores had diameters about $1/10{,}000$ of the diameter of the whole atom. This, in turn, led a Danish physicist, Niels Bohr, to posit the planetary nature of the atom, with electrons circulating in orbits about a nucleus, and to invent the idea of quantization (according to which only certain discrete orbital energies are possible) of those orbits based on the fundamental quantum constant that Max Planck, the German physicist, had discovered in radiation in 1900 and Einstein had applied in 1905 to the photoelectric effect. New vistas of theoretical physics were opened, and in 1925 the physicists Erwin Schrödinger of Austria and Werner Karl Heisenberg of Germany discovered what is known as wave mechanics or

The Bohr atom

quantum mechanics, which constituted a drastic revision of the laws of classical mechanics as applicable to small systems and provided the basis of modern theories of atomic and nuclear structure in which orbits are more nebulous than in Bohr's theory.

The simplest atom is hydrogen, with only one electron, and its nucleus consists of an elementary particle called the proton, a particle with mass 1,836 times that of the electron and a positive electric charge equal to that of the electron but opposite in sign.

For a time it was thought that the nucleus must consist of protons and electrons, the particles then known, but there were difficulties. In 1932 the British physicist Sir James Chadwick discovered the neutron, an uncharged particle with almost the same mass as the proton (about a tenth of a percent more). The serious study of nuclei as assemblages of protons and neutrons then began.

GENERAL PROPERTIES OF NUCLEI

Mass and electric charge. Nuclear masses are derived by measuring the masses of atoms or molecules and making a correction for the mass of the electrons contained in them. These masses can be measured by means of deflections in combined electric and magnetic fields in an instrument known as a mass spectrograph. It is found that the masses of nuclei differ from one another very nearly by integral or whole multiples of a fundamental unit, the nuclear mass unit, that is very slightly less than the mass of a proton or neutron. Thus each kind of nucleus is assigned a mass number (A) and its mass is said to be A mass units. For example, the mass number of one of oxygen's isotopes is 16, which is the sum of the neutrons and protons in this isotope's nucleus; its mass is 16 mass units.

Atomic and mass numbers

The electric charges of various nuclei also differ from one another by integral multiples of a fundamental unit, in this case, the electron charge. Because atoms are electrically neutral, the positive nuclear charge (or number of protons) is exactly compensated for by the negative charge of the same number of electrons. Each kind of atom, or each element in the periodic table, is assigned what is called its atomic number Z, denoting both the number of electrons of the neutral atom and the electric charge on its nucleus in units of the proton charge. (For example, oxygen has eight protons and, therefore, is of atomic number 8.) Thus each kind of nucleus is characterized by a charge number, Z (for oxygen, 8), and a mass number, A (for oxygen, 16). Since each element also has a chemical name abbreviated into a chemical symbol, it is customary to designate a nucleus by its chemical symbol preceded by a superscript A and a subscript Z. For example, helium, as it occurs in nature, has a charge number $Z = 2$ and a mass number $A = 4$ and is denoted as helium-4 or ${}^{4}_{2}\mathrm{He}$; an oxygen nucleus is represented by ${}^{16}_{8}\mathrm{O}$.

Nuclei with all values of Z from 1 to 92 (except Z = 43 and 61) occur in the earth's crust, and others (up to $Z = 105$) have been made in the laboratory. For each value of Z (charge number), there may be several values of A (mass number), and nuclei with the same Z but different A are known as isotopes of one another, the word isotope implying equal atomic number. Almost all elements have more than one isotope, those with an odd Z usually having two and those with even Z frequently have more, up to a maximum of ten for tin (Z = 50). Altogether, natural elements have about 350 isotopes. Such is the great variety of nuclei that nature has provided.

Stable isotopes

A chemical element as it occurs in nature is in general a mixture of isotopes, and the relative abundance of the various isotopes in the mixture is very nearly constant, no matter where on earth the element may occur. In many elements, one isotope is considerably more abundant than the others, and the chemical atomic weight of the mixture is very nearly the atomic number of that isotope. In ordinary carbon compounds, for example, there are about 90 atoms of the common isotope carbon-12 for every atom of the rare isotope carbon-13, and the resulting chemical atomic weight of the mixture is 12.011. Because they arise from mixtures of isotopes, chemical atomic weights are not always close to integers.

Apart from the light isotope of hydrogen, ${}^{1}_{1}\mathrm{H}$, the mass numbers A of the fairly light nuclei are either equal to or very slightly larger than twice their atomic numbers Z. Beyond the light nuclei this ratio gradually increases until, for the heaviest natural nuclei, such as the heavy isotope of uranium, uranium-238, A is about 2½ times Z. This trend is displayed in Figure 1, in which $A-Z$ is plotted against Z for all the natural isotopes and $A-Z$ is shown to start out about equal to Z and to increase to about 1½ times Z.

From R.R. Roy and B.P. Nigam, *Nuclear Physics* (1967); John Wiley & Sons, Inc.

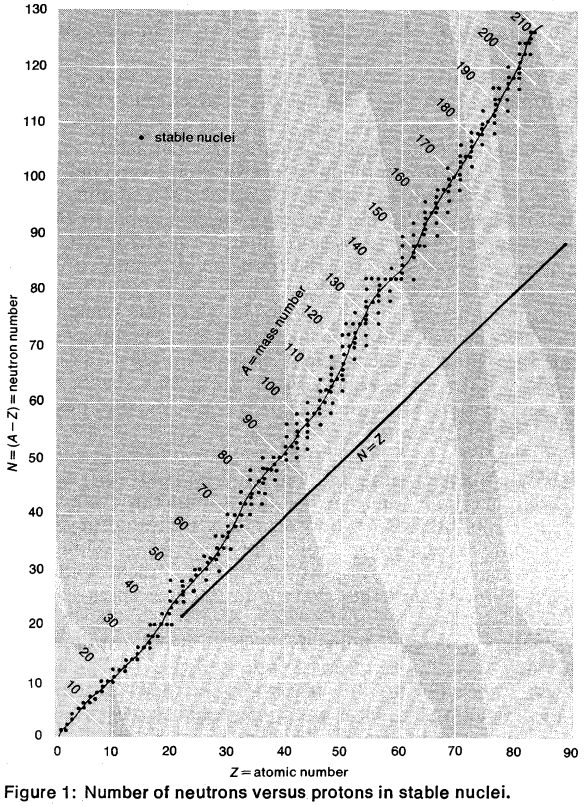

Figure 1: Number of neutrons versus protons in stable nuclei.

The size of nuclei. The radius of a typical atom is about 10^{-8} centimetre—$1/100{,}000{,}000$ of a centimetre. The radii of nuclei are a little less than 10^{-12} centimetre. Thus nuclear radii are roughly 10^{-4}, or $1/10{,}000$, of the radii of atoms. Atomic sizes vary periodically throughout the periodic table of elements, but heavy atoms are in general only slightly larger than moderately light elements. In sharp contrast to this, nuclear sizes increase very regularly with the mass of the nucleus. The volume of a nucleus is, in fact, directly proportional to its mass, so that it is possible to speak of "nuclear matter," the stuff that nuclei are in effect made of, as having a constant density. In this respect, a nucleus is indeed quite like a water droplet.

Nuclei, for the sake of defining an average radius, may be considered approximately spherical, the volume of a nucleus being proportional to the cube of its radius. What is observed by means of scattering of alpha particles (helium nuclei), or more recently of high-energy electrons, from nuclei, is that the nuclear mass is proportional to the radius cubed, and since volume is proportional to the radius cubed, the mass of a nucleus is directly proportional to its volume.

Nuclear angular momentum. One of the intriguing properties of an electron, proton, or neutron, tiny "elementary" particles that they are, is that each seems to be spinning like a top and has an angular momentum (a term describing the persistence of rotation of a body). In quantum mechanics, the unit of angular momentum is Planck's universal constant divided by two pi; *i.e.*, Planck's constant divided by the ratio of the circumference of a circle to its radius, or $h/2\pi$, in which h is Planck's constant (equal to 6.626×10^{-27} erg-sec). Elec-

tron, proton, and neutron spins are equal to one-half this unit of angular momentum and are referred to as spin-½ particles. A spin is said to have a certain orientation, meaning that it can spin in one direction or the other about its axis of rotation.

Nuclear spin

Many nuclei have angular momentum arising from both the spins and the orbital motions of its components. Because of the way it was discovered, this nuclear angular momentum is known as nuclear spin, though it is more complicated than the spinning of a top. Nuclear spin is called I; its value for a particular kind of nucleus is either an integer or half-integer (½, 1, 3/2, 2, etc.) and the magnitude of the spin is I times the unit of angular momentum.

Since electron spins and nuclear spins are both angular momenta arising from some sort of circulation of electrically charged matter, both behave as tiny magnets. The strength of a small magnet is called its magnetic moment. It is largely through the influence of their associated magnetic moments that electron spins and nuclear spins affect atomic spectra; *i.e.*, the energy of spectroscopic lines arising from electron transitions in the atom. When those electrons responsible for the total angular momentum of an atom dip in close to the nucleus, they create an average magnetic field at the nucleus in which the nucleus can assume one or more (in some cases, $2I + 1$, thus indicating the value of the nuclear spin I) different states of slightly different energies, visible in atomic spectroscopy as a hyperfine structure pattern (splitting of lines into further components).

Nuclei with even mass number and even charge number have no nuclear spin, and hence the spin is zero. The very few light nuclei that have a mass number even and a charge number odd (even isotopes of lithium, boron, and nitrogen) have integer 1 or 3 for their spins. Almost all nonvanishing nuclear spins are those of nuclei with odd mass number, and they have odd-integral spins varying all the way from ½ to 13/2.

Nuclear magnetic moments. The magnetic moment of a nucleus—*i.e.*, its strength as a magnet—is measured (with some difficulty) by observing its energy in an external magnetic field. This energy is equal to the projection of a vector, representing the magnetic moment, along the field multiplied by the strength of the magnetic field. A common way of portraying energy states of a molecule, atom, or nucleus is by means of a series of parallel horizontal lines, called energy levels. Thus the energy of a state is represented by the height of its level, and the energy difference of two states is proportional to the separation of their two energy levels. When there is a pattern of equally spaced energy levels formed by the quantization of a nuclear spin in an external magnetic field, what is observed is the energy jump between two adjacent levels.

Quantized magnetic moment

Ever since the late 1920s, measurements of nuclear magnetic moments have been made by measuring the energy spacings in hyperfine structure. The strong magnetic field at the nucleus, due to the electrons, takes the place of an external magnetic field, but this cannot be measured directly and can be determined theoretically only with limited accuracy; so magnetic moments for many nuclei have been determined by this method to an accuracy of only about 10 percent. The more accurate and more modern methods involve nuclear magnetic resonance (see MAGNETIC RESONANCE).

The accuracy of the nuclear resonance method is greater than that of the hyperfine method because the magnetic field being used is accurately known, since it is being supplied by an external magnet, and because the energy jump is induced by radio waves whose frequency can be precisely determined. The energy jumps between successive energy levels made by different orientations of the nuclear spin in the field are accordingly much smaller than those of hyperfine structure.

Nuclear magnetic resonance, the mechanism by which the radio waves cause the energy jump, can be described in a rather pictorial manner. The nuclear spin with its magnetic moment is acted on by the pull of an external magnetic field in the same way that a spinning top is acted on by the pull of gravity, and it precesses around the direction of the magnetic field, describing a cone just as does the axis of a top. In the nuclear case, the frequency of precession is characteristic of the nuclear spin and magnetic moment, and the angle of the cone and corresponding energy are quantized—that is, they can have only certain values depending on the permitted values of the nuclear spin projection. A child's swing also has a natural frequency, and if one pushes it repeatedly at just the right times in "resonance" with its frequency, the swing goes higher and higher. In the case of a top, if one pushes its axle in the direction it is precessing, say to the north when it is at its easternmost position, with just the right frequency, it gradually rises towards a vertical position as it precesses, absorbing energy. In the case of a nuclear spin, the magnetic field of the radio wave pushing on its magnetic moment similarly with the right frequency, in resonance with its precession, can cause it to change its cone angle with the field, jumping from one quantized angle to the next. Energy will be absorbed from the radio wave, indicating the magnetic moment involved.

Measured values of nuclear magnetic moments, sorted out according to values of the associated nuclear spin, are plotted in Figure 2 for nuclei with odd mass number and odd charge number and for nuclei with odd mass number and even charge number. The unit in which nuclear magnetic moments are measured is the magnetic moment or nuclear magneton, equal to the product of the electron charge and Planck's constant, divided by the product of four pi, the mass of the proton, and the velocity of light, or $eh/4\pi Mc$, in which M is the proton mass, e is electron charge, c is the velocity of light, and h is Planck's constant.

Shapes of nuclei and their electric quadrupole moments. A dumbbell with a positive electric charge on one end and a negative charge on the other is a simple illustration of an electric dipole moment. It is turned in

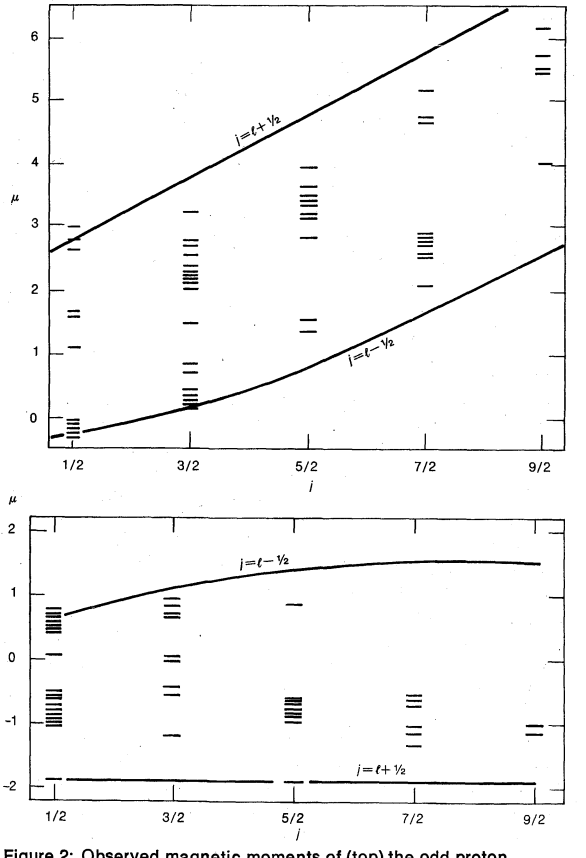

Figure 2: Observed magnetic moments of (top) the odd proton nuclei (having an odd number of protons and an even number of neutrons) and (bottom) the odd neutron nuclei. In each graph, the two lines give the calculated values for a single nucleon, with spin either parallel or antiparallel to the orbital angular momentum.

Example of quadrupole moment

one direction by a uniform electric field just as a compass needle is turned by a magnetic field. An electric quadrupole moment is illustrated by a dumbbell with equal positive charges on both ends. A uniform electric field pulls equally on both ends and does not tend to turn it. An inhomogeneous electric field, one whose strength is not uniform with direction, does pull harder on one end than the other, and thus the energy of an electric quadrupole moment in an inhomogeneous field depends on its orientation. Rotating it by 90° can take the quadrupole moment from a position of minimum energy to a position of maximum energy.

Some nuclei are spherical and have no electric quadrupole moment. Some are elongated like a football and have a positive electric quadrupole moment, like that of the positively charged dumbbell. Some are flattened like a doorknob and have a negative electric quadrupole moment.

An atom with electron orbits confined near one plane has an inhomogeneous electric field at the nucleus, and this makes the energy depend on the orientation of nuclear spin in a different way for the electric quadrupole moment than for the magnetic moment. The quadrupole moment thus modifies the pattern of the atom's hyperfine structure. These effects are small, and it is difficult to do more than estimate how inhomogeneous these fields are; so measurements of electric quadrupole moments deduced from this effect are not accurate.

When a beam of heavy ions (atoms that are charged due to the absence of one or more electrons) such as neon nuclei is allowed to impinge on target nuclei and then scatter, the inhomogeneity of the average field at the target nucleus can be calculated. Such transitory fields from passing ions twist on the quadrupole moment and make a target nucleus rotate, exciting quantized rotations. From the amount of excitation, the quadrupole moment can be determined. The quadrupole moment also helps the nucleus in the excited state radiate and jump back down to the nonrotating state. Measurement of the lifetime of the excited state is thus another way of measuring quadrupole moments.

NUCLEAR STRUCTURE AND FORCES

Nuclear components. Nuclei are made up of nucleons —protons and neutrons—having nearly equal masses. In terms of the mass unit, adjusted to make the mass of the carbon-12 atom exactly 12, and in terms of the electron mass m, their masses are shown in the Table. The mass of

Nucleon Masses

	atomic mass units	electron mass units
neutron mass	1.00867	1838.6
proton mass	1.00728	1836.1
(electron mass)	0.00055	1

the neutron is thus equal to the total mass of a proton plus about 2½ electrons. The neutron, being electrically neutral, has the total electric charge of a proton plus one electron. In respect to mass and charge, then, a neutron is equivalent to a proton and an electron with 1½ electron masses, or 1.5 m left over. According to the equivalence of mass and energy (energy is equal to the product of mass and the velocity of light squared), the mass left over is equivalent to the energy $1.5\ mc^2 = 0.78$ MeV. (The usual nuclear unit of energy is a million electron volts, 1 MeV, or the energy involved in transporting an electron through a potential difference of 1,000,000 volts, and $mc^2 = 0.511$ MeV, in which c is the velocity of light.)

Mass–energy equivalence

Because of this extra mass, a neutron is the unstable form of the nucleon, and when it is alone in free space it lives on the average only about 17 minutes before it becomes a proton and an electron flying energetically apart. At the same time there is emitted an elusive chargeless and nearly massless particle known as a neutrino. The maximum energy of the electron as it flies away is $1.5\ mc^2$, but it practically always has less energy because the neutrino carries away some. This process of changing into a proton and electron is known as beta decay. Neutrons in nuclei may or may not be stable. When neutrons do decay in a large number of similar nuclei, there is emitted a stream of electrons known as beta particles or beta rays—one of the three kinds of radioactivity of heavier nuclei.

Whether or not a neutron undergoes beta decay depends on its environment. If it is bound in a nucleus so tightly that the total energy of the nucleus would be increased by more than $1.5\ mc^2$ if the neutron should become a proton, then the decay is energetically unfavourable and does not take place. This is why neutrons, unstable in free space, can last forever as constituents of stable nuclei. Not only can a neutron emit an electron to become a proton if the energetic situation is favourable but the reverse process can also take place; a proton bound in a nucleus can emit a positive electron, or positron as it is called, and a neutrino to become a neutron bound in the nucleus.

Nucleons and statistics

A nucleon may be either a proton or a neutron and when bound in a nucleus may change from either form to the other depending on the energies involved in the transformation. Nucleons are the fundamental building blocks of nuclei. A nucleus with mass number (A) and charge number (Z) is composed of A nucleons, Z of which are protons and $A-Z$ or N of which are neutrons. When a neutron changes to a proton, emitting an electron, A remains constant and Z changes to $Z+1$. When the reverse process takes place with emission of a positron, A remains constant and Z decreases by one.

In several situations in which quantized aggregates of particles, such as nuclei, tend to settle in low quantized states (low energy levels), their behaviour depends markedly on whether they contain an even number or an odd number of spin-½ particles. One manifestation of their behaviour influences the statistical behaviour of condensing gases. Nuclei with an even number of particles are said to obey Bose–Einstein statistics; those with an odd number obey Fermi–Dirac statistics (see THERMODYNAMICS, PRINCIPLES OF), which keeps them from all moving in the same way or occupying the same low state of motion. By observations it is shown that the nucleus of nitrogen-14, or ^{14}N, obeys Bose–Einstein statistics and should have an even number of particles. Before the discovery of the neutron in 1932, one of the historic difficulties was the presumption that this nucleus must contain 14 protons and 7 electrons to make the positive charge come out equal to 7; but then the nucleus would have an odd number of particles making it inconsistent with Bose–Einstein statistics and demanding Fermi–Dirac statistics. Now one may consider that there are only nucleons present in a nucleus, and in the case of nitrogen-14, 7 protons and 7 neutrons, an even number of particles. One may think of each neutron as virtually a proton plus an electron and a neutrino, because in beta decay in a nucleus, an electron and neutrino are created as a neutron becomes a proton.

Mass defect and binding energy. Particles attracting one another tend to assemble into a state of lowest possible internal energy while giving off external energy, the way water attracted by gravity flows down through a mill to a level of lower energy while supplying energy to the mill. The energy of a nucleus is said to be zero when its nucleons are separated too far apart to interact and the internal energy of a normal nucleus is thus negative, the lowest or most negative energy attainable. The positive measure of this negative energy is called the binding energy, equal to the amount of external energy given off in the binding process. If two nuclei can be combined to make lower internal energy, external work can be done. According to the equivalence of mass and energy, not only the energy but also the mass of the bound nucleons is less than that of the separated nucleons, the missing mass being called the mass defect of the nucleus. Thus the mass of a nucleus is somewhat less than the sum of the masses of its parts. With the unit adjusted to make the mass of the carbon-12 nucleus, $^{12}_{6}C$, exactly equal to 12 nuclear mass units, the nucleons each have a mass greater than one mass unit by almost 1 percent, as already described, and so 12 of them have a total mass greater than

12 units by that percentage and mass defect of $^{12}_{6}C$ is somewhat less than 1 percent of its mass.

A heavy nucleus with many nucleons bound together naturally has more binding energy than a light nucleus with few nucleons. In fact, through most of the range of nuclear masses, the internal energy is almost, but not quite, directly proportional to the number of nucleons, so that the binding energy per nucleon is nearly constant. This is shown in Figure 3, in which the internal energy

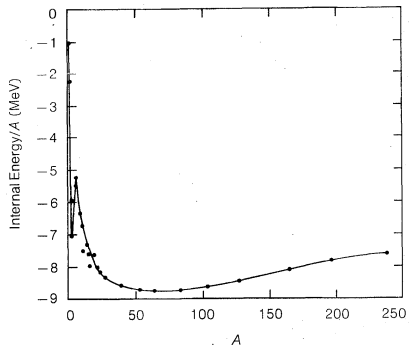

Figure 3: Energy per nucleon by which the nucleons are bound together to make nuclei of various mass numbers A.

per nucleon is plotted against the nucleon number, A, of the nucleus. Aside from minor fluctuations, the curve is seen to be quite flat for the intermediate-mass nuclei from $A = 100$ to 150 and it rises at both ends, quite gradually toward the heavy-nucleus end and more sharply for light nuclei in the region $A < 10$. For most nuclei the binding energy is about $A \times 8$ MeV, or 8 million electron volts per nucleon.

Nuclear energy levels: properties of nuclear states. Many nuclei are spherical, and nucleons in them have orbital motions and spins similar to those of electrons in atoms. The shapes of the orbits are different because there is no central attracting body at the centre. The nucleus has a more sharply defined surface or boundary, and the orbits may more nearly resemble those of a ball rolling or bouncing around the inside of a spherical enclosure, but the angular momentum of the nucleus is quantized just as in atoms. A nucleon also has spin like an electron, and each nucleon has an orbital angular momentum (l) and a spin angular momentum (s).

Nuclear shells

The shell configuration in nuclear physics is a useful concept for the orderly grouping of nucleons—protons and neutrons—that compose a nucleus. Unlike the atom, which has only one kind of particle, the electron, circling about a central field of force, the nucleus has two kinds of particles, the proton and neutron, moving about inside a force field, and therefore the grouping of particles is different in nuclear shells than in atomic shells. In nuclei of increasing atomic number and mass, the orbital and spin angular momenta are important to the way in which nuclear shells can be occupied. According to the Pauli exclusion principle, every particle in any one shell must have its own set of quantum numbers. The quantum number l, representing orbital angular momentum, is useful in assigning nucleons to shells. A shell may contain a maximum number of protons equal to $2(2l + 1)$. It is then called a closed shell of protons, and similarly for a shell of neutrons. The quantity $2(2l + 1)$ is equal to two for quantum number l equal to zero, six for $l = 1$, and so on. In the first shell the orbital angular momentum l is zero and the shell is closed for two protons and two neutrons, as shown by helium-4 (symbolized as $^{4}_{2}He$); and in the second shell it is one, and hence the shell becomes closed for either six protons or six neutrons, or doubly closed for protons and neutrons. The oxygen-16 nucleus, $^{16}_{8}O$, is extremely stable, having a helium-4 nucleus for an inner shell, and thus being doubly closed for both shells.

To illustrate how shells are filled as the number of nucleons increases, hydrogen-2, the deuteron, has one proton and one neutron in the first shell. A second neutron of opposite spin can be added, giving hydrogen-3, the triton. If hydrogen-4 were to exist, the third neutron could not be placed in the same shell as it would then be identical to one of the other neutrons and thus would have to occupy another shell. Helium-3, the mirror nucleus to hydrogen-3, has its first shell occupied by two protons of opposite spin and one neutron. Lithium-5 (which is unstable) contains the helium-4 shell for a core and requires a second shell for its third proton.

A nucleus ordinarily exists in its lowest energy, or ground, state but, under certain experimental conditions, it can be excited to have more energy in a higher state. The energies are discrete or individually distinct, being quantized usually in quite complicated ways. Some of the low states in nuclei having only one nucleon outside of closed shells are relatively simple. Oxygen-17, $^{17}_{8}O$, has one neutron in a third shell, outside of the first two closed shells of oxygen-16, in which the quantum number l can take two values, $l = 0$ and $l = 2$.

When the neutron spin s in a nuclear shell points in approximately the same direction as the orbital angular momentum of the neutron, the total angular momentum, given by the quantum number (j) of the neutron is: $j = l + \frac{1}{2}$. On the other hand, when s points approximately backward along l, $j = l - \frac{1}{2}$. Such a pair of states is known as a doublet with this value of l. The force that gives rise to the energy difference between the two states of the doublet is known as "spin–orbit coupling." If one could poise two gyroscopes at different angles on the point of a needle and if one could stretch a rubber band between the outer ends of their axles, the two gyroscopes would precess around a common direction. Spin–orbit coupling is roughly analogous to the rubber band and makes the spin and orbital angular momenta precess about the direction of the total angular momentum (j) in a similar fashion. The spin–orbit coupling for a neutron or a proton makes the state $j = l + \frac{1}{2}$, lower than the other member of the doublet, and indeed lower usually by several million electron volts (MeV).

Spin–orbit coupling

The energy states of oxygen-16 and oxygen-17, up to an excitation energy of 7 MeV, are shown in Figure 4. The ground state of oxygen-16 has nuclear angular momentum $I = 0$. This is an instance of the general rule that all

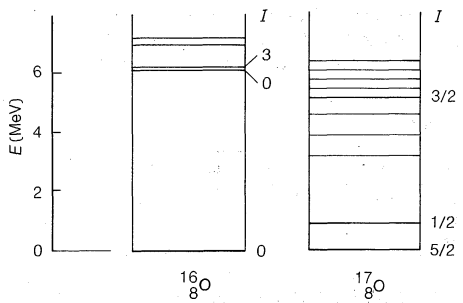

Figure 4: Energy levels of two isotopes of oxygen, contrasting a closed-shell nucleus with its neighbour.

nuclei with even proton number and even neutron number, or even–even nuclei, as they are called, have a nuclear angular momentum equal to zero. Thus the total angular momentum of the additional neutron in oxygen-17 is the total angular momentum of that nucleus. The ground state (zero energy) of $^{17}_{8}O$ is one with $l = 2$ and $I = j = \frac{5}{2}$ or $l + \frac{1}{2}$. The companion state of the doublet, with $l = 2$ and $I = \frac{3}{2}$, has an energy of 5.1 million electron volts (MeV). The other single-neutron state, with $l = 0$ and $I = \frac{1}{2}$ lies between them with the energy of 0.9 million electron volts. These three single-neutron states are indicated by heavy lines in the figure. They appear prominently in experiments known as stripping reactions in which a nucleus may acquire a nucleon that is stripped from a passing deuteron. But most nuclear states are more complicated than this and even the relatively simple nucleus oxygen-17 has many more complicated states. These are in some way related to the excited states of oxygen-16.

It is characteristic of closed-shell nuclei that the ground

state is particularly stable and farther separated from the first excited state than in other nuclei. Whereas the ground state is spherical, the excited states of oxygen-16 have a collective deformation similar to that encountered in the ground states of many heavier nuclei, deformations that involve lifting either two or four nucleons from the supposedly closed second ($l = 1$) shell into higher states with quantum number $l = 0$ or 2. In some of these states the deformation rotates, and in oxygen-17 these rotations combine with the angular momentum of the odd neutron to make a great variety of excited states. This is typical of the complexities found in excited states of nuclei.

Even the three simple single-nucleon states of oxygen-17 involve a little of this excitation from the closed second shell, as is manifest in the effective charge of a neutron needed to account for the magnitude of its electric quadrupole moment, even though a neutron has no charge. As the extra neutron swims almost freely through a sea of other nucleons, so to speak, it seems to drag some of the other nucleons along with it to a small extent. It retains the angular-momentum properties of a neutron, but in other ways the state differs slightly from that of a pure neutron and in this situation it is sometimes called a quasi-neutron, one kind of quasi-nucleon.

When there are two nucleons (or, more precisely, quasi-nucleons) outside of closed shells, their spin and orbital angular momenta can add up in two characteristic simple ways known as (LS) coupling and (jj) coupling or in some more complicated intermediate manner. (LS) coupling, common in atomic spectra, is encountered in nuclei only in the two lithium isotopes lithium-6 and lithium-7 and their immediate neighbours. It nevertheless provides an example of important symmetries in nuclear states.

Lithium-6 has two nucleons, a proton and a neutron, in the second shell in addition to the first closed-shell helium ($^4_2$He) core. Their two spins (designated $s = \frac{1}{2}$) can add up to make a total spin angular momentum of one or zero (designated $S = 1$ or 0). Similarly, the two vectors representing the two orbital angular momenta ($l = 1$) can add up to make a total orbital angular momentum of zero, one, or two ($L = 0$, 1, or 2), all in the usual angular momentum units. Hence the name (LS) coupling. When the total spin is one ($S = 1$), for one value of L these add up as vectors in such a way that they make three states with total nuclear angular momentum: L minus one, L itself, or L plus one ($I = L - 1$, L, or $L + 1$). They are known as a triplet for this value of the total orbital momentum (L), and if the spin–orbit coupling is weak, they are clustered together with only slightly different energies. With total spin equal to zero ($S = 0$), for one value of L there is only a single state, known as the singlet, with nuclear angular momentum equal to the total orbital angular momentum ($I = L$).

(LS) coupling

These two-nucleon states are described mathematically by wave functions, the nature of which cannot be described here (see MECHANICS, QUANTUM) other than to state that they are quantities whose value depends on where the two nucleons are and in which of two possible quantized directions the spins point (say up or down). If the positions of the two nucleons in space are interchanged—if the first nucleon takes the place of the second, and vice versa—the function may either remain unchanged or just change sign, say from positive to negative, and is accordingly called either symmetric or antisymmetric in space exchange. If the total angular momentum quantum number is even, it is symmetric, and if it is odd, it is antisymmetric in space exchange. The function is also either symmetric or antisymmetric in respect to interchanging which spin vector belongs to which nucleon. If the total spin is one it is symmetric and if it is zero it is antisymmetric in spin exchange.

A rule of the Pauli principle states that if the two nucleons are identical (either both neutrons or both protons) the function must be antisymmetric (that is, the function changes sign) on interchange with respect to both space and spin of the two nucleons.

This limitation does not apply when the two nucleons are a neutron and a proton, as in lithium-6, $^6_3$Li, but it does in the similar helium-6 nucleus, $^6_2$He, having two

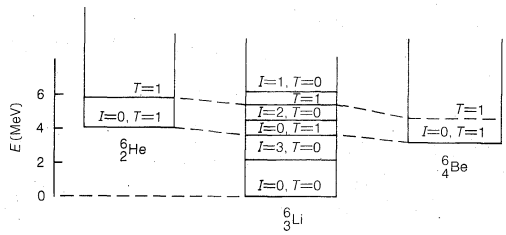

Figure 5: The energy levels of three nuclei with $A = 6$, relative to the ground state of ^{6}Li after subtraction of the calculated electrostatic energy. The isospin $T = 1$ levels exist in all three nuclei.

neutrons outside the closed shell. The low energy levels of these two nuclei are shown side by side in Figure 5 and it is seen that, because of this limitation, helium-6 has fewer states than lithium-6. In fact, instead of three triplets and three singlets it has only two singlets (the notation is as follows: $S = 0$ and $L = 0$ and 2) and one triplet with $S = 1$, $L = 1$, a total of five states in place of twelve. Nevertheless, they are the same states of motion as the corresponding states in lithium-6 and are observed to have very nearly the same energy separations. The other neighbour, beryllium-6, or $^6_4$Be, in which each of the two nucleons with orbital angular momenta equal to one are protons, is similar to helium-6 and is also depicted.

The variety of values of S, and the accompanying symmetries, arise from the existence of two spin vectors, each of which has a quantized up-or-down part (again in angular momentum units), designated as $+ \frac{1}{2}$ for up and $- \frac{1}{2}$ for down, and in addition, a small and indefinite sideways part. In the quantized system these values of $- \frac{1}{2}$ and $+ \frac{1}{2}$ add up in such a way either that $S = 0$, with the up-and-down part equal to zero, or that $S = 1$, with the up-and-down part, called M_S, either $M_S = 1$, 0, or -1. The values $M_S = 1$ or -1 correspond simply to having both spins up or both down, and interchanging them changes nothing, so these states are symmetric. When one nucleon spin is up and one down, they may combine their sideways parts in such a way as to make the total spins equal to one (which is symmetric) or equal to zero (which is antisymmetric).

The mathematical result of all this is that two quantities, each quantized to have two values, are combined into four other quantities, three of which are symmetric and one of which is antisymmetric. A similar situation is encountered in describing the dichotomy of the nucleon, which may be either a proton or a neutron. Quite separately from spin, its neutronness or protonness may be described mathematically as exactly analogous to spin up and spin down. In this analogy isobaric spin, or isospin for short, takes the place of real spin. Two nuclei or two nucleons are isobars of one another if they have the same mass number but different charge number. Isobaric spin up or down indicates which of its isobars a nucleon is, neutron or proton. When there are two nucleons, the two possible states of each combine in a way that is described as having total isospin T (analogous to the total spin, S) either one or zero, so that the combined state is symmetric for isospin equal to one and antisymmetric for isospin equal to zero. Completing the analogy, there are three isospin-equal-one states, either both neutron, both proton, or one of each, and one isospin-zero state with one neutron and one proton. This means that isospin-equal-one states can exist in the three isobars $^6_2$He, $^6_3$Li, and in $^6_4$Be, whereas the $T = 0$ state can exist only in $^6_3$Li. They form an isobaric triplet and an isobaric singlet, respectively.

Isobaric spin

A generalization of the Pauli principle says that a nuclear state must be antisymmetric in simultaneous exchange of any two nucleons in space, spin, and isospin. Since two changes of sign mean no change, this means that it must either be antisymmetric in all three or antisymmetric in one and symmetric in the other two. In lithium-6 there are isospin-one states that are antisymmetric in space and spin (which permits them to exist also in the other isobars) and isospin-zero states that are symmetric in space and spin. Thus in lithium-6 the isospin quantum number

of each state, isospin one or zero, indicates something about the symmetry of the state, and specifically whether or not it has such a symmetry in space and spin as to permit it to exist in the two isobaric nuclei, helium-6 and beryllium-6.

Symmetry may be summarized as requiring that no two nucleons in the same nucleus can behave in exactly the same way. If they are both protons or both neutrons and have the same spin direction, then the function whose magnitude describes where they may be in space is antisymmetric. This means that it changes sign when the position of the two particles is interchanged and becomes small when they are close together. Thus, they are seldom close together to take full advantage of the attractive force between them, and the energy of such a state is not as low as that of a state of the opposite symmetry, such as is permitted for a proton and a neutron.

The (LS) coupling scheme occurs only in a few of these light nuclei, but isospin has significance also for heavier nuclei, even those with many more neutrons than protons. In heavier nuclei, isobaric analogue states occur when a highly excited nucleus will have level spacings and other properties very similar to those of fairly low states in a neighbouring nucleus.

In most nuclei the (jj) coupling scheme prevails because spin–orbit coupling has a stronger influence on the orientation of the spin and orbital angular momentum vectors than have the attractive forces between the nucleons that hold them together in the nucleus. If there are two nucleons outside closed shells, for example, each nucleon has a spin (s) and orbital (l) that add up to its total nucleon angular momentum denoted by j (or $j = l + s$) and the nuclear momenta of the two nucleons (j_1 and j_2) add up to make the total nuclear angular momentum I for the nucleus. The two single-nucleon angular momenta are half-integral and add up to the nuclear angular momentum that may take all integral or whole values for the various states (from $j_1 - j_2$, if j_1 is the larger or they are equal, to $j_1 + j_2$, which makes $2j_2 + 1$ states altogether: for example, if $j_1 = 9/2$ and $j_2 = 5/2$, the sum is 7 and the difference is 2; the values of the states are 7, 6, 5, 4, 3, and 2, or 6 altogether as given by the expression $2j_2 + 1$).

There is an attractive force between two nucleons if they are close together but not if they are far apart on opposite sides of the nucleus. That is, the nucleon–nucleon interaction is short-ranged and attractive. Nucleon orbital angular momentum is something like that of a gyroscope: the mass distribution is near a plane and the orbital angular momentum vector is along an axis at right angles to the plane. Because the spin is usually considerably smaller than the orbital vector, which is the greater part of the total nucleon moment, the nucleon, as it circulates, is almost always near the plane through the centre of the nucleus and at right angles to the total nucleon angular momentum. When the two nucleon angular momenta are equal and they have exactly opposite directions so as to add up to make the total nuclear angular momentum equal to zero, the two nucleons are almost in the same plane and frequently close together to interact strongly. This makes the energy of the state in which $I = 0$ lower than that of all the others. Such nucleons are said to be paired, and the lowering of the energy is called pairing energy. It is responsible for the fact that all even–even nuclei have a total nuclear angular momentum equal to zero ($I = 0$).

Pairing energy

The (jj) coupling shell model. The average potential-energy well in which a nucleon moves in a typical nucleus is flat on the bottom and rises steeply at the sides. A parabola, symmetrical about a vertical axis, its vertex at the bottom, is a very simple function that has such a shape. In it the potential energy is proportional to the square of the distance from the vertex. A particle moving in a parabolic potential is known as a harmonic oscillator and has the special feature that quantized energy levels are equally spaced at intervals that differ by an amount equal to Planck's constant times the frequency with which a classical or nonquantized particle would vibrate in the potential well, namely, $h\nu$. A clock pendulum swinging through a small arc is an example of a one-dimensional harmonic oscillator, for its circular arc is almost the same as the part of a parabola for small angles. The potential energy of a nucleon in a spherical nucleus is approximated by a three-dimensional harmonic oscillator, with potential energy proportional to the square of the distance from the centre of the nucleus. The energy levels form a regularly spaced ladder, but each energy may correspond to several states. This ladder is shown in the left-hand column of Figure 6.

From D.R. Inglis, *Physics Today* (June 1969)

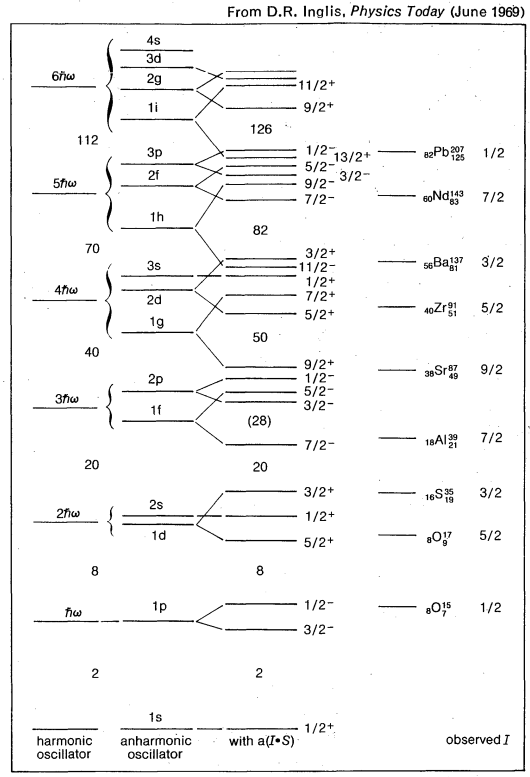

Figure 6: Energy level scheme for a single nucleon with strong spin–orbit coupling. In second column, letters s, p, d, f, g, etc. correspond to orbital angular momentum quantum numbers $l = 0, 1, 2, 3, 4, 5$, etc.

A better approximation would be a potential curve that is flatter on the bottom, rises more steeply, but then levels off at the energy of the separated nucleon. Such a potential tends to make the energy lower for states with higher orbital angular momentum (l) values that tend to concentrate near the edge. The rung of the ladder at two times Planck's constant times the frequency (written as $2h\nu$), for example, has two states, one with $l = 0$ and one with $l = 2$. With the flat-bottomed potential these are split apart, the latter state being lower, as shown in the second column for this and other cases.

Spin–orbit coupling modifies the energy further, splitting each level of orbital angular momentum (l) into two levels (written: $j = l + 1/2$ and $l - 1/2$). These splittings are distinctly larger for the larger l-values, as shown in the third column.

Each of the states in the third column can be filled with neutrons and again with the same number of protons. In the second column, the states are bunched in groups according to the oscillator levels of the first column, a large value being at the bottom of each group. In the top half of the figure, the spin–orbit splittings are so large that the higher total angular momentum (j) falls down into the next lower group, but still the levels fall into groups with large spaces between. The nuclei with levels just filled up to these spaces are especially stable, and a nucleon added to it has smaller than average binding energy. The number of neutrons, say, required to fill up through the last highest level below each of these spaces is known as a magic number, and these numbers, indicated in the spaces in the third column, are 2, 8, 20, 50, 82, and 126.

Magic numbers

Because of the pairing energy, which is especially

effective between like nucleons, an even number of protons, for example, has a total angular momentum zero and if there is just one neutron in addition to closed shells or one neutron short of closing the last shell, the total nuclear angular momentum is that due to that one particle or nucleon vacancy, called a hole. This is borne out perfectly by the observed ground-state angular momentum I, as shown in the last two columns of the figure. In many cases single-particle excited states corresponding to the nearby particle or hole levels in the diagram are observed. Such observations are testimony to the fact that the roundness of closed shells keeps these nuclei nearly spherical. For the ground states and simplest excited states of nuclei, such as these in the immediate vicinity of the magic-number closed shells, the (jj) coupling shell model works extremely well (with the exception of atomic masses equal to 6 and 7).

The general trend (but not the exact values) of the magnetic moments plotted in Figure 2 can be explained in terms of the (jj) coupling shell model with the magnetic moment ascribed to the single odd nucleon. The unit of these magnetic moments is the nuclear magneton, the magnetic moments of a proton circulating in a nuclear orbit with $l = 1$. It is equal to the product of the proton charge and Planck's constant divided by 4π times the product of the proton mass and the velocity of light, or $eh/4\pi Mc$, in which e is charge, h is Planck's constant, M is the mass, and c is the velocity of light. The spin of a proton is more richly endowed with magnetic moment than is the orbit, the proton spin magnetic moment being 2.79 nuclear magneton units, almost as great as that of an orbit with orbital angular momentum equal to three ($l = 3$), although the spin angular momentum is only one-half ($S = \frac{1}{2}$). When the spin points almost forward (along l to make $j = l + \frac{1}{2}$), the magnetic moment associated with spin angular momentum is large, as indicated by the upper solid line of Figure 2A. When the spin points almost backward (to make $j = l - \frac{1}{2}$), the spin magnetic moment tends to cancel out much of the orbital magnetic moment and the total is smaller, as indicated by the lower solid line in Figure 2A. In the case of a single neutron that carries no net charge around with it in its orbit, the orbit contributes no magnetic moment and the spin magnetic moment is negative, — 1.91 nuclear magnetons; so the total moment is positive when the spin points backward and negative when it is forward along l, as indicated by the upper and lower lines of Figure 2B. It is a remarkable sign of some simplicity in nuclei that the observed magnetic moments in Figure 2 fall into two groups, not on theoretical lines but between them in such a way that each group seems to belong to the $j = l \pm \frac{1}{2}$ of the nearest theoretical line. These data include both simple and more complex nuclei. For the simple nuclei with one nucleon or hole aside from closed shells, the discrepancy between theory and observation seems to verify that one is dealing with quasi-nucleons rather than with pure nucleons. For the other nuclei, the simple trend suggests that they are not as complex as one might expect and that the magnetic moment is contributed preponderantly by one quasi-nucleon.

The collectively deformed model. When two nucleons outside closed shells pair together and have their orbits almost in the same plane, they have little effect on the closed shells. When several pairs all attract each other and populate one region, they help each other exert a pull on the closed shells and deform them, partially exciting nucleons from the closed shells to higher states in the process. Such a cooperative or collective deformation of the nucleus may make it resemble either an oblate ellipsoid, flattened like a doorknob, or a prolate ellipsoid, elongated like a watermelon. In either case the nucleus, with a definite nonspherical shape, can rotate like a football tumbling end over end. A round nucleus does not rotate as a whole, just as the water in a bucket does not immediately rotate when the bucket is spun.

Rotational energy

The deformation of nuclei was first recognized by the ladders of rotational energies, similar to those already known in molecules, to which their quantized rotations give rise. The angular momentum of the rotation is an integer, usually expressed in angular momentum units, and the energy of rotation is proportional to one-half the product of the angular momentum and itself plus one, or $\frac{1}{2} I (I + 1)$. For even–even nuclei deformed in an ellipsoidal shape, this quantum number is an even integer 0, 2, 4, etc., which means that when these values are substituted into the foregoing expressions, the rotational energies are proportional to 0, 3, 10, 21, as shown by the characteristic pattern in Figure 7.

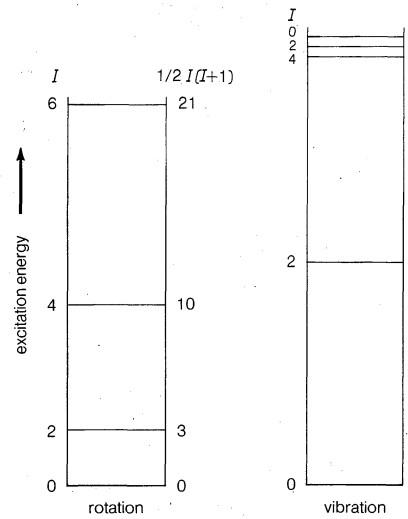

Figure 7: Patterns of the first few energy levels of collective excitation of an even–even nucleus.

The energy scale of the pattern is inversely proportional to the moment of inertia of the nucleus. Moment of inertia is a measure of the inertia involved in making a body rotate and is large for a flywheel, for example. If the internal structure of the nucleus were rigid it would have a relatively large moment of inertia and the spacing between the first two rotational states would be small, about ($\frac{1}{20}$) MeV. If, instead, the matter inside the nucleus were to behave like a liquid, it would move relatively little with the rotation, just as the water in an elliptical bucket does when the bucket is started rotating. This makes for a small moment of inertia, and spacing between the states is perhaps ten times as large as the rigid value. The observed situation in actual nuclei is about midway between these extremes, as may be explained in terms of the quantized orbits and the pairing energies of the nucleons that make up the nuclear fluid.

Nucleus analogous to a liquid droplet

A normally spherical nucleus is something like a liquid drop kept round by surface tension, and the vibrations of its surface are quantized, the second vibrational state having about twice the energy of the first. The nuclear surface tension is strong enough so that the first vibrational state is somewhat higher than the first rotational state of a typical deformed nucleus. Indeed, the heavy even–even nuclei with neutron number between 88 and 116, and again between 137 and 144, have exceptionally low first excited states and a ratio of second to first excitation energy near 3.33, indicating that these nuclei are permanently deformed and rotate, whereas those nearer the magic numbers 82 and 126, which do not have as many nucleons apart from closed shells to deform them, appear to be spherical, having the ratio nearer to two, characteristic of surface vibrations.

The simplest and most prevalent shape of a permanently deformed nucleus is ellipsoidal, with a circular cross section at right angles to an axis of symmetry. The nucleon orbits in such a nucleus are somewhat different from those in spherical nuclei. The deformation exerts a torque on the nucleon but none about the symmetry axis. The part of the angular momentum along this axis is quantized with a special quantum number (K), its different values corresponding to different energies. An even number of nucleons pair together to make this total quantum number equal to zero, and an odd mass nucleus has

several states with these quantum numbers that are half-integral because of the nucleon's one-half spin. With each of these, the nucleus can rotate collectively, and for each there is a band of states of increasing total angular momentum and energy. Two such bands observed in the fairly light aluminum-25 nucleus are shown in Figure 8.

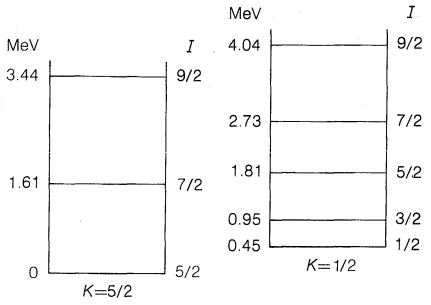

Figure 8: Two typical rotation bands in the odd-proton nucleus aluminum-25. The angular momentum *I* of lowest state of each band is due to internal nucleon motion, and in the states above it the nucleus is similar but rotates as a whole.

Deformation energies

The way the energy levels of an individual nucleon in a deformed nucleus vary with the deformation can be calculated approximately. The result is shown in Figure 9 for the lower levels. With a deformation (δ) equal to zero, the states are those of the spherical shell model and show gaps at the magic numbers 8, 20, 50, etc. As the deformation increases either in the prolate direction (positive deformation) or the oblate direction (negative deformation), the levels spread apart and eventually cross each other to make a complex pattern. The lines that slope upward with prolate deformation, for example, represent those states with angular momentum almost parallel to the nuclear axis, and thus a nucleon orbit in a plane almost perpendicular to the axis, in the direction that is squeezed by the deformation to raise the energy. The structure of intermediate and heavy deformed nuclei can be represented well by thinking of putting nucleons in

From D.R. Inglis, *Physics Today* (June 1969)

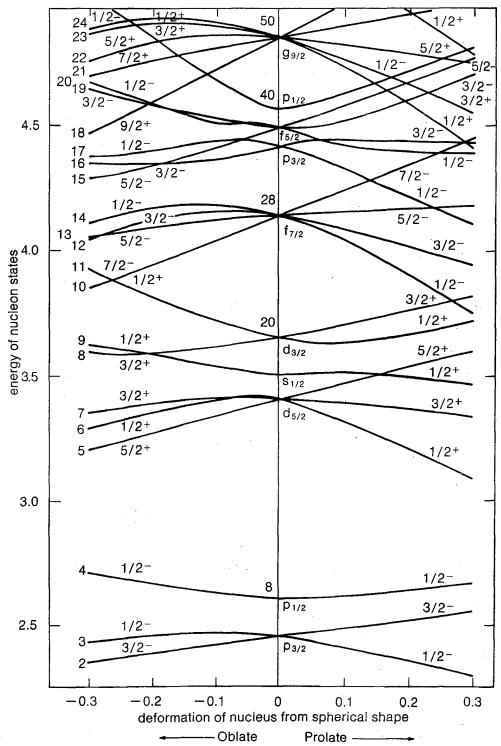

Figure 9: Energy levels of a single nucleon in a nucleus with an elliptical deformation from spherical shape. At the central line where the deformation vanishes, the levels converge to those of Figure 6.

these states, starting from the bottom, with two neutrons and two protons to a state as far as they go, with a given deformation. For an odd mass nucleus, the value of the quantum number K of the lone last nucleon is the total angular momentum of the nuclear ground state. Excited states of the nucleus are then formed by lifting nucleons from the topmost filled levels to nearby unfilled levels, accounting quite successfully for observed excited states.

Nuclear binding forces. The best understood part of the total force acting between nucleons is the electrostatic repulsion that one proton exerts on another. It is the same as the force between two electrons, giving rise to a potential energy inversely proportional to the separation or distance between the two protons. Since nuclear sizes are well-known and the potential varies slowly with separation, the contribution of repulsion to the energy of a nuclear state can be reliably calculated.

The energy levels of the three nuclei with atomic mass six have been plotted in Figure 5 after making allowance for the energy repulsion. It is remarkable that in this and similar situations the energies caused by all other interactions between the nucleons match up almost exactly between the neighbouring nuclei. From this, it may be concluded that the specific nuclear interactions, as they are called (those apart from electrostatic interaction), are practically the same between any two nucleons, be they two protons, two neutrons, or one of each.

The specific nuclear interactions that hold the nucleons together are short-ranged, strong, and attractive. The dependence on the separation may be represented approximately by a potential energy curve resembling a well with a radius or range of about 10^{-13} centimetre and a depth of roughly 50 million electron volts. That is, two nucleons interact quite strongly, but only when they are close together, their interaction being cut off much more abruptly than is the electrostatic interaction. This accounts for the abrupt change of particle density at the surface of a nucleus as compared with an atom.

The saturation property

Beyond these simple facts, nuclear forces are considered to be complicated in detail and no description of them is unique. A salient feature is the saturation property, which means, in effect, that one nucleon can interact with only about three other nucleons at a time. A phenomenological representation of this fact has been widely used to simplify calculations of nuclear structure. This formality describes the interactions as interchanging the identity of the two nucleons, interchanging mainly their positions but also to some extent their spins. It exploits the symmetry properties of the nuclear wave function to give the desired saturation, making a strong attraction when the function is symmetric in the interchange of the positions of the two nucleons and a weak repulsion when it is antisymmetric. (Because the Pauli principle strictly limits the degree to which it is symmetric, only a few neighbouring nucleons attract each other.) The more detailed and physical theories of nuclear interactions explain the important role of symmetrics. In its simplest form, the Pauli principle says that no two nucleons can behave in just the same way. They interact strongly only if they are similar (and symmetric) in space coordinates, but then they must differ in either spin or isospin. There are only two possible projections of spin, ½ and −½, and similarly two of isospin; so a group of four nucleons can differ from each other in either spin or isospin, and this is the number that can interact strongly with each other. A dramatic example is the exceptional stability of helium-4 and the fact that a fifth nucleon is not bound in helium-5.

The saturation property is responsible for the constant density of nuclear matter. Without it, each of the nucleons in a heavy nucleus would be attracted by all the other nucleons, and they would all crowd into a small space within about the range of nuclear forces of each other and thus would have an enormous binding energy, roughly proportional to the atomic mass number squared, rather than to the first power, in spite of the increased kinetic energy associated with this crowding.

Mesons in nucleons

More detailed theories of nuclear interactions are based on the fact that, in high-energy experiments, nucleons may be made to emit other particles known as mesons.

This has some similarity to the way they emit electrons in beta decay but involves much higher energies, 10^8 or 10^9 electron volts, and much stronger interactions between the nucleon and the emitted particle. Indeed, the building block of nuclei, the nucleon, may itself be considered to contain a whole host of mesons associated with it.

In all quantized systems, when particles are confined in a small space, the kinetic energy is high. When they are somehow permitted to spread out, the energy is lowered. When two atoms are brought together and their outer electrons can spread over both atoms, the energy is lowered and the atoms are bound in a molecule. Similarly, when two nucleons are close together, their mesons can spread over both and the energy is lowered, leading to an attractive interaction between the nucleons. When two atoms are pushed so close together that their closed shells overlap appreciably, the energy is raised and the atoms repel each other. Nuclear forces are rather generally considered similarly to include a very strong and very short range repulsion, though this is not certain. They may instead be markedly dependent on the relative momentum of the two interacting nucleons.

Particles have associated with them a length known as the de Broglie wavelength; that is, their shortest wavelength when they are moving with the speed of light. The wavelength lambda (λ) is equal to Planck's constant h divided by the mass m of the particle, 2π, and the velocity c of light, that is, $\lambda = h/2\pi mc$. For the pi meson with a mass 273 times that of an electron, this length is 1.4×10^{-13} centimetre, essentially equal to the range of the nuclear forces for which it is mainly responsible.

The pi meson has no spin, but the heavier rho meson and omega meson do have spin, and their participation in the interaction process leads to strong spin–orbit coupling. Any particle with spin, carried around in an orbital motion, has spin–orbit coupling because of the relativistic precession of the spin's coordinate system accelerated in the orbital motion. For the bare nucleon spin, however, this effect is much too weak and is apparently greatly enhanced by the spin-carrying mesons being accelerated between the two nucleons. The meson exchange also contributes to another part of the interaction known as a tensor interaction. This depends on the direction of the spins relative to the line between the two nucleons. If it is positive when the two spins point in the same direction at right angles to this line, it is negative when they are parallel to it.

Meson exchange

Such meson theories suggest the form but do not yet reliably give the magnitude of various terms of the nuclear interaction. Detailed calculations of nuclear structure thus assume a complicated form of interaction and, after determining the magnitude of the various terms by fitting some of the available experimental data, go on to calculate other results that may be compared with other experiments to test the consistency of the analysis.

NUCLEAR PHENOMENA AND REACTIONS

Radioactivity and the region of stable nuclei. Both alpha and beta radioactivity (see RADIOACTIVITY) help to determine which nuclei are present in nature. The region of stable nuclei is indicated in Figure 1, in which the number of neutrons is plotted against the number of protons. Light nuclei have about equal numbers of protons and neutrons, whereas the heavy nuclei have a considerable neutron excess, with about 1½ times as many neutrons as protons. This can be understood in terms of the specific nuclear interaction being the same between all nucleons, the positive potential energy of the electric repulsion between protons, and the freedom of nucleons through beta decay to be either neutrons or protons, whichever makes the energy lower. Without the electric energy, the protons and neutrons would be equal in number because neutrons and protons separately fill the various nucleon states, starting with the lowest. Equal numbers of protons and neutrons fill the states up to the same level, but to make the neutron number greater than the proton number, nucleons would have to be lifted to a higher level, increasing the total kinetic energy. The addition of the positive electric energy between protons, however, tends to make it energetically advantageous to change protons to neutrons and counterbalances some of the excess kinetic energy and makes it favourable to have a limited neutron excess. The electric effect is unimportant in light nuclei in which each proton is repelled by only a few others, but it is increasingly important in heavier nuclei, making the graph in Figure 1 curve upward until the excess of neutrons over protons is about one-half the proton number for the heaviest nuclei. The nuclei, sufficiently stable to be present in nature, end at proton number 92 and nuclear number 238, because in that vicinity the increasing electric repulsion makes nuclei too unstable mainly against alpha decay, and also against spontaneous fission (see NUCLEAR FISSION).

Spontaneous fission

The increase of electric energy toward the heavier nuclei is also responsible for the upward curvature of the graph of energy per nucleon in Figure 3. The fact that this internal energy per nucleon is lower for nucleon number 100 or 140 than for 240 means that a nucleus with nucleon number about 240 can separate into those two fragments with a decrease of the total internal energy, the excess energy going largely into the kinetic energy with which they fly apart, propelled by the electric repulsion between the fragments. This is the act of fission, made possible as demonstrated by the shape of the curve in Figure 3. In addition, one or more neutrons, called prompt neutrons, are released at the time of fission.

The two fission fragments have the neutron–proton ratio about the same as that in the original nucleus. Because of the curvature of the region of stable nuclei in Figure 1, this means that they have neutron excesses considerably greater than those of the stable nuclei of the same mass number. They get rid of this difference in neutron excess by a series of beta disintegrations, the first relatively energetic and short-lived, with a half-life of a few seconds, and the last with a half-life that may be measured in years. The original fission fragments thus decay to the mostly radioactive fission products, such as the ecologically troublesome strontium-90 with a half-life of 28.1 years, that either were dispersed in the atmosphere from nuclear weapons tests or that must be carefully disposed of from power reactors. Some, such as iodine-131, are useful as sources of radiation for medical therapy or diagnosis and for tracer and monitoring techniques in science and industry.

Part way down the chains of beta decay from some fission fragments a neutron is emitted. Since beta decay is inherently slower than neutron emission, there are a few delayed neutrons in addition to the prompt neutrons from the fragments preceding beta decay, a fact of importance for the stability of the chain reaction in a power reactor.

Nuclear reactions. The first nuclear reaction induced by an incident particle was observed by Rutherford in 1919 when he let natural alpha particles hit nitrogen nuclei and observed that protons were emitted. This was the first artificial transmutation of elements, changing nitrogen to oxygen.

First observed nuclear reaction

Nuclear reactions are powerful tools for learning about the properties of nuclear states, such as energies, angular momenta, the extent to which states may be single-particle states, and the way nucleons may be partially correlated into alpha-particle-like clusters at the surface of a nucleus. In laboratory investigations, nuclear reactions are induced either by neutrons from nuclear research reactors, nuclear bombs, or by charged particles, such as protons, deuterons (^{2}H), tritons (^{3}H), and helium nuclei (^{3}He and ^{4}He), accelerated to precisely known energies in electrostatic accelerators, linear accelerators, or cyclotrons. In addition to such light-particle reactions, there are heavy-ion reactions such as those induced by carbon nuclei, requiring higher energy acceleration of the heavier projectile to overcome the higher barrier of the electric repulsion.

Neutron bombardment for nuclear reactions has the advantage that it encounters no potential barrier at all, and neutrons with energies with a fraction of an electron volt or a little more can be used, their energies determined by time-of-flight methods, to pick out the energies of very narrow and closely clustered states of heavy nu-

clei at an excitation energy equivalent to the neutron's binding energy.

A greater variety of experiments is possible with charged particles, their energies being commonly varied over a wide range from under a million electron volts to ten times that or more. Precisely defined energies of nuclear states are seen in two ways. As the bombarding energy is varied slowly, resonances are observed; that is, a certain reaction takes place at just the right bombarding energy but not at nearby energies, making a peak if one plots a curve of the intensity. The bombarding energy is said to be in resonance with the energy of a state of the compound nucleus, the nucleus made when the projectile enters the target nucleus. With the bombarding energy fixed to cause the reaction, a second significant energy is that of the outgoing particle, which may be observed to have several precisely defined values corresponding to several states of the final nucleus composed of the target nucleus plus bombarding particle and minus the outgoing particle, the total energy being divided between kinetic energy of the particle and the excitation energy of the final nucleus. The highest energy product particles are those that leave the final nucleus in its ground state. They may have either more or less energy than had the incoming projectile, the reaction being called exoergic or endoergic, depending on whether the final nucleus and outgoing particle together have more or less binding energy than the target nucleus and projectile.

Resonance energy

The uncertainty principle in the quantum domain states not only that position and momentum together are uncertain but also that energy and time together are uncertain, or that a state cannot have a precisely defined energy unless it lasts a long time. In some reactions, the sharpness of the resonances indicates that the states of the product nucleus have relatively long lifetimes (though perhaps only microseconds). This means that the projectile does not retain its energy in the state so as to be able to come right out again, but rather that the excitation energy is divided up among many nucleons, producing what is known as a compound nucleus. Only after some time will the excitation energy be concentrated in the projectile particle, causing it to be re-emitted, or in the product particle of the reaction observed.

There is another class of reactions in which the projectile, such as a deuteron or triton, as it flies by the target nucleus is either stripped of one or more of its nucleons, which are deposited in the target to make the product nucleus, or picks up one or more nucleons from the target as it goes by. These "stripping" and "pick-up" reactions do not show sharp resonances, there being no compound nucleus involved; but there are sharply defined energies of the outgoing particles, corresponding to states of the product nucleus, when the bombarding energy is definite.

Stripping

A typical stripping reaction is the reaction in which an incident deuteron drops its neutron into the target nucleus and the remaining proton flies off at an angle from the incident direction. The deuteron has internal kinetic energy, and in it the proton and neutron in the deuteron have equal and opposite internal momentum at any instant as they vibrate back and forth past each other. When the neutron joins the target nucleus at the nuclear surface, its internal momentum from the deuteron helps determine its angular momentum in the product nucleus, and at the same time the equal and opposite internal momentum of the proton contributes to the angle at which the proton flies off. Thus, observation of the angular distribution of the protons is useful in determining the angular momentum of the nuclear state formed.

In still more refined observations of reactions, either the incident particle or the outgoing particle is polarized, meaning that its spin direction is determined. By such means not only the orbital angular momentum but also the total angular momentum of the neutron in the final state may be determined.

There are reactions with more than one outgoing particle. For example, in the reaction in which one proton, at incident energies of 200 to 400 million electron volts, knocks out another proton from the nucleus, the angular distributions of the two outgoing protons, observed simultaneously, indicate the momentum distribution of a proton before it was plucked from a low closed shell within the nucleus. (An electron can similarly be used to knock out a proton.)

Among the peculiar properties of heavy-ion reactions, such as a carbon-12 nucleus hitting another carbon-12 nucleus, is the apparent formation of temporary states associated with the contact of the two surfaces, perhaps resembling molecular vibrations, before complete amalgamation of the two heavy nuclei. This has some similarity to one aspect of the fission of uranium (see NUCLEAR FISSION). Fission is a neutron-induced reaction in which the target nucleus flies apart into two almost equal fragments. It may be described in terms of a potential barrier. The fission barrier, however, is such that quantized vibrations of the almost-separated fragments give rise to quasi-stationary states that manifest themselves in regularly spaced groups of sharp resonances.

Heavy-ion reactions

Interaction of nuclei with electromagnetic radiation. A straight radio antenna is a dipole radiator. The electrons that constitute an electric current rush back and forth, determining which end is positive and which negative; and the consequent electric and magnetic fields around it are propagated out into space, most strongly in the plane at right angles to the antenna. Electric quadrupole radiation may be produced by placing two antennas end to end and making their currents go always in opposite directions, so that both outer ends are positive at one instant, both inner ends at another. The radiations from the two cancel each other in some directions and add in others, so together they radiate most strongly in the direction midway between the antenna direction and the plane at right angles to it. In a plane that includes the antenna direction, this makes a four-lobed rosette radiation pattern.

Gamma rays are extremely high frequency electromagnetic radiation, and nuclei, as they make transitions from one state to another, can emit or absorb either dipole or quadrupole radiation in quantized amounts of energy called photons. As in the case of atoms emitting lower frequency photons as visible light (see ATOMIC STRUCTURE), the energy of a photon is determined by the energy difference of the quantized states involved, and the energy is equal to Planck's constant times the frequency, or $h\nu$.

Nuclear states have another property called parity, which is formally defined in terms of symmetry but may be described by saying that a state has even or odd parity according to whether the sum of the angular momentum quantum numbers of all the nucleons in it is even or odd. Electric dipole radiation is emitted when there is a change of parity between initial and final state, electric quadrupole radiation when there is no change in parity. In a nucleus that is essentially a closed shell and a single proton, called a one-proton state, strong dipole radiation is emitted when the orbital angular momentum quantum number l changes from zero to one, for example. Much weaker quadrupole radiation could be emitted if it were to change from zero to two. A proton in an orbit has a back-and-forth motion like that of the electrons in an antenna; but in a quantized system such as the nucleus, it radiates only when there is a change in this motion. The intensity of the electric dipole radiation emitted can be calculated when a proton changes from one orbit to the next. Even for nuclei with proton outside a closed shell the observed electric dipole radiation is considerably weaker than calculated, indicating that there are no pure one-nucleon states. When the orbital quantum number changes by two, electric quadrupole radiation is possible but is much weaker still. There is also magnetic dipole radiation corresponding to having the spin magnetic moment flip alternately up and down, as well as higher magnetic and electric multipoles.

Parity

When all the nucleons of a nucleus move collectively with a change of nuclear shape, however, the situation as far as radiation is concerned is quite different because the nucleons cooperate systematically in causing the radiation. A prolate nucleus may vibrate between a longer and shorter ellipsoidal shape, for example. The motion of the positive charge inward and outward at the two ends,

always moving in opposite directions, is analogous to the case of the two antennas, and like them it emits electric quadrupole radiation. Because many protons move together and because the intensity of radiation is proportional to the square of the strength of the electric field involved, the intensity of this radiation is in many cases considerably stronger than the electric dipole radiation from a single proton. This enhancement applies to radiations from changes of either vibration or rotation quantum numbers of deformed nuclei, a fact that facilitates the study of the properties of such states.

It already has been stated that when nuclei make transitions from one state to another they can emit high-energy quanta called gamma rays. The most accurate observations of gamma-ray energies are made with a bent-crystal spectrometer in studies analogous to those of atomic spectroscopy with a diffraction grating.

When a slow neutron is absorbed with a binding energy of about eight million electron volts, the nucleus is excited by the same amount, and this energy is emitted usually in a cascade of several gamma rays as transitions are made down a ladder of states. Similar cascades occur when deformed nuclei are excited to high rotational states by heavy-ion bombardment. Beta decay (the emission of electrons or positrons by an excited nucleus) produces a daughter nucleus, which itself gamma decays, thus giving rise to a whole series of beta–gamma cascades. In these various cascades, two successive radiations may usefully be investigated at the same time in a coincidence experiment. The frequency of the coincidence is dependent on the angle between the two rays, and any slight time delay recorded from the first to the second emission indicates the half-life of the intermediate state between them. This angular correlation gives information about the multipolarity of the radiations and the angular momenta and parities of the three states involved.

Beta decay cascade

Excitations caused by nuclear forces in nuclear reactions also are often followed by gamma emission, and studies of the angular correlation between the deflection angle and the gamma-ray pattern can be revealing. A striking example is observed in the inelastic scattering of alpha particles from such nuclei as magnesium-24, $^{24}_{12}Mg$ (nuclei with just enough nucleons to make up internal alpha particles), exciting the nucleus from the nonrotating ground state to the first excited state, which rotates with a nuclear spin equal to two. The angular distribution of the subsequent quadrupole gamma radiation has a rosette pattern, the orientation of which rotates backward as the deflection angle of the alpha-particle detector is increased.

Excitation of nuclear rotations and vibrations by the electric field of bombarding ions may also be looked upon as an interaction of the nucleus with electromagnetic radiations, an absorption process because the rapidly varying electric field of the passing ion may be analyzed as a superposition of radiations of various multipolarities and gives information supplementing that obtained from radiation.

Number Games and Other Mathematical Recreations

Mathematical recreations comprise puzzles and games that vary from naive amusements to sophisticated problems, some of which have never been solved. They may involve arithmetic, algebra, geometry, theory of numbers, graph theory, topology, matrices, group theory, combinatorics (dealing with problems of arrangements or designs), set theory, symbolic logic, or probability theory. Any attempt to classify this colourful assortment of material is at best arbitrary. Included in this article are the history and the main types of number games and mathematical recreations and the principles on which they are based. Details, including descriptions of puzzles, games, and recreations mentioned in the article, will be found in the references listed in the bibliography.

At times it becomes difficult to tell where pastime ends and serious mathematics begins. An innocent puzzle requiring the traverse of a path may lead to technicalities of graph theory; a simple problem of counting parts of a geometric figure may involve combinatorial theory; dissecting a polygon may involve transformation geometry and group theory; logical inference problems may involve matrices. A problem regarded in medieval times as very difficult may prove to be quite simple when attacked by the mathematical methods of today.

Mathematical recreations have a universal appeal. The urge to solve a puzzle is manifested alike by young and old, by the unsophisticated as well as the sophisticated. An outstanding English mathematician, G.H. Hardy, observed that professional puzzle makers, aware of this propensity, exploit it diligently, knowing full well that the general public gets an intellectual kick out of such activities.

The relevant literature has become embarrassingly extensive, particularly since the beginning of the 20th century. Some of it is repetitious, but surprisingly enough, successive generations have found the older chestnuts to be quite delightful, whether dressed in new clothes or not. Much newly created material is continually being added. Over 300 books and monographs appeared between 1925 and 1970, exclusive of reprints and new editions. Even more voluminous is the literature in mathematical and educational journals and in periodicals devoted exclusively to recreational mathematics, including the former magazines *Sphinx* (Belgium, 1931–1939) and *Recreational Mathematics Magazine* (U.S., 1961 to 1964) and the current periodicals *Journal of Recreational Mathematics* (U.S.) and *Pythagoras* (The Netherlands, England, and U.S.).

History

EARLY HISTORY

Men have always taken delight in devising "problems" for the purpose of posing a challenge or providing intellectual pleasure. Thus, many mathematical recreations of early origin that have reappeared from time to time in new dress seem to have survived chiefly because they appeal to man's sense of curiosity or mystery. A few survived from the ancient Greeks and Romans: little was known about them during the Dark Ages, but a strong interest in such problems arose during the Middle Ages, stimulated partly by the invention of printing, partly by enthusiastic writers of arithmetic texts, and partly by the rivalry and disputations among early algebraists and scholars. Such activities were most prominent on the Continent, particularly in Italy and Germany. Notable contributors included Rabbi ben Ezra (1140), Fibonacci (Leonardo of Pisa; 1202), Robert Recorde (1542), and Geronimo Cardano (1545), among others.

Kinds of problems. The problems in general were two kinds: those involving the manipulation of objects, and those requiring computation. The first required little or no mathematical skill, merely general intelligence and ingenuity, as for example, so-called decanting and difficult crossings problems. A typical example of the former is how to measure out one quart of a liquid if only an eight-, a five-, and a three-quart measure are available. Difficult crossings problems are exemplified by the dilemma of three couples trying to cross a stream in a boat that will hold only two persons, with each husband too jealous to leave his wife in the company of either of the other men. Many variants of both types have appeared over the years.

Manipulation of objects and computation

Some examples. Problems involving computation also took on a variety of forms; some were as follows:

Finding a number. Think of a number, triple it, and take half the product; triple this and take half the result; then divide by 9. The quotient will be one-fourth the original number.

"God-Greet-You" problems. For example, in "God greet you, all you 30 companions," someone says: "If there were as many of us again and half as many more, then there would be 30 of us." How many were there?

The chess-board problem. How many grains of wheat are required in order to place one grain on the first square, 2 on the second, 4 on the third, and so on for the 64 squares?

The lion in the well. This is typical of many problems dealing with the time required to cover a certain distance at a constant rate while at the same time progress is hindered by a constant retrograde motion. "There is a lion in a well whose depth is 50 palms. He climbs $^1/_7$ of a palm daily and slips back $^1/_9$ of a palm. In how many days will he get out of the well?

Courier problems. These are typified by the movements of bodies at given rates in which some position of these bodies is given and the time required for them to arrive at some other specified position is demanded.

PIONEERS AND IMITATORS

The 17th century produced books devoted solely to recreational problems not only in mathematics but frequently in mechanics and natural philosophy as well. The first important contribution was that of the Frenchman Claude-Gaspar Bachet de Méziriac, one of the earliest pioneers in this field, who is remembered for two mathematical works: his *Diophanti*, the first edition of a Greek text on the theory of numbers (1621), and his *Problèmes plaisans et delectables qui se font par les nombres* (1612). The latter passed through five editions, the last as late as 1959; it was the forerunner of similar collections of recreations to follow. The emphasis was on arithmetic rather than geometric puzzles. Among the outstanding problems given by Bachet were questions involving number bases other than ten; card tricks; watch-dial puzzles depending on numbering schemes; the determination of the least number of weights which would enable one to weigh any integral number of pounds from one pound to 40, inclusive; and difficult crossings or ferry problems.

Books and collections

In 1624 a French Jesuit, Jean Leurechon, writing under the pen name of van Etten, published *Récréations mathématiques*. This volume struck the popular fancy, passing through at least 30 editions before 1700 despite the fact that it was based largely on the work of Bachet, from whom he took the simpler problems, disregarding the more significant portions. Yet it did contain some original work, and it served as a model for others, including Mydorge and Schwenter. The first English edition (1633) bore the title: *Mathematicall Recreations, or a Collection of Sundrie Problemes, extracted out of the Ancient and Moderne Philosophers, as Secrets in Nature, and Experiments in Arithmeticke, Geometrie, Cosmographie, Horologographie, Astronomie, Navigation, Musicke, Opticks, Architecture, Staticke, Machanicks, Chimestrie, Waterworkes; Fireworks, etc. Not vulgarly made manifest untill this Time. . . . Most of which were written first in Greeke and Latine, lately compiled in French, by HENRY VAN ETTEN Gent. And now delivered in the English Tongue with the Examinations, Corrections, and Augmentations* [*translated by William Oughtred*].

The rising tide of interest was exploited by French mathematicians Claude Mydorge, whose *Examen du livre des récréations mathématiques* was published in 1630, and Denis Henrion, whose *Les Récréations mathématiques avec l'examen de ses problèmes en arithmétique, géométrie, méchanique cosmographie, optique, catoptrique*, etc., based largely upon Mydorge's book, appeared in 1659. Leurechon's book, meanwhile, had found its way into Germany, to be imitated by Daniel Schwenter, a professor of Hebrew, Oriental languages, and mathematics, who assiduously compiled a comprehensive collection of recreational problems based on a translation of Leurechon's book, together with many other problems that he himself had previously collected. This work appeared posthumously in 1636 under the title *Deliciae Physico-mathematicae oder Mathematische und Philosophische Erquickstunden*. Immensely popular, Schwenter's book was enlarged by two supplementary editions in 1651–53. For some years thereafter Schwenter's enlarged edition was the most comprehensive treatise of its kind, although in 1641–42 the Italian Jesuit Mario Bettini had issued a two-volume work called *Apiaria Universae Philosophiae Mathematicae in Quibus Paradoxa et Nova Pleraque Machinamenta Exhibentur*, which was followed in 1660 by a third volume entitled *Recreationum Mathematicarum Apiaria Novissima Duodecim. . . .* And in 1665 one Johann Mohr in Schleswig published an imitation of Schwenter under the title of *Arithmetische Lustgarten*.

In England, somewhat belatedly, William Leybourn, a mathematics teacher, textbook writer, and surveyor, in 1694, published his *Pleasure with Profit: Consisting of Recreations of Divers Kinds, viz., Numerical, Geometrical, Mechanical, Statical, Astronomical, Horometrical, Cryptographical, Magnetical, Automatical, Chymical, and Historical*. The title page further states that the purpose of the book was to "recreate ingenious spirits and to induce them to make farther scrutiny into these sublime sciences, and to divert them from following such vices, to which Youth (in this Age) are so much inclined." Much of the volume is conventional textbook material, for most of Leybourn's published works grew out of his teaching.

18TH AND 19TH CENTURIES

The 18th century saw a continuation of this interest. Published in England were volumes by Edward Hatton, Thomas Gent, Samuel Clark, and William Hooper. In 1775 Charles Hutton published five volumes of extracts from the *Ladies' Diary* dealing with "entertaining mathematical and poetical parts." On the Continent there appeared several writers, including: Christian Pescheck, Abat Bonaventura, the Dutch writer Paul Halcken, and A.H. Guyot's four volumes of *Nouvelles Récréations physiques et mathématiques*, etc. (1769, 1786). But by far the outstanding work was that of Jacques Ozanam, the precursor of books to follow for the next 200 years. First published in four volumes in 1694, his *Récréations mathématique et physiques* went through many editions; based on the works of Bachet, Mydorge, Leurechon, and Schwenter, it was later revised and enlarged by Montucla, then translated into English by Charles Hutton (1803, 1814) and again revised by Edward Riddle (1840, 1844).

The work of Ozanam

The first half of the 19th century produced only a moderate number of lesser writers on mathematical recreations, but the second half of the 19th century witnessed a rising crescendo of interest, culminating in the outstanding contributions of Édouard Lucas, C.L. Dodgson (Lewis Carroll), and others at the turn of the century. Lucas' four-volume *Récréations mathématiques* (1882–94) became a classic. The mathematical recreations of Dodgson included *Symbolic Logic* and *The Game of Logic; Pillow Problems* and *A Tangled Tale*, 2 vol. (1885–95).

20TH CENTURY

Among the more colourful figures at the turn of the 20th century was an American, Sam Loyd, or rather two Loyds, father and son. Tremendously successful in making puzzles, the elder Loyd sold his weekly puzzle column to a national syndicate for years, and, in addition, created or adapted hundreds of mechanical puzzles fashioned of cardboard, wood, and metal that were also financially rewarding. When he died in 1934 at the age of 60, it was estimated that Loyd II had produced at least 10,000 puzzles.

In Germany, Hermann Schubert published *Zwölf Geduldspiele* in 1899 and the *Mathematische Mussestunden* (3rd ed., 3 vol.) in 1907–09. Between 1904 and 1920 Wilhelm Ahrens published several works, the most significant being his *Mathematische Unterhaltungen und Spiele* (2 vol.) with an extensive bibliography.

Among British contributors, Henry Dudeney, a contributor to the *Strand Magazine*, published several very pop-

ular collections of puzzles that have been reprinted from time to time (1917–67). Although the first edition of W.W. Rouse Ball's *Mathematical Recreations and Essays* appeared in 1892, it soon became a classic, largely because of its scholarly approach. After passing through ten editions it was revised by the Canadian professor H.S.M. Coxeter in 1938; it is still a standard reference.

Outstanding work was that of Maurice Kraitchik, editor of *Sphinx* and author of several well-known works published between 1900 and 1942.

Modern shift in emphasis

About the middle third of the 20th century, there was a gradual shift in emphasis on various topics. Up to that time interest had focussed largely on numerical curiosities; simple geometric puzzles; arithmetical story problems; paper folding and string figures; geometric dissections; manipulative puzzles; tricks with numbers and with cards; magic squares; those venerable diversions concerning angle trisection, duplication of the cube, squaring the circle, and the elusive fourth dimension. Interest began to swing toward more mathematically sophisticated topics: cryptograms; recreations involving modular arithmetic, numeration bases, and number theory; graphs and networks; lattices, group theory; topological curiosities; packing and covering; flexagons; manipulation of geometric shapes and forms; combinatorial problems; probability theory; inferential problems; logical paradoxes; fallacies of logic; paradoxes of the infinite.

Types of games and recreations

ARITHMETIC AND ALGEBRAIC RECREATIONS

Number patterns and curiosities. Some of the properties of the natural numbers when operated upon by the ordinary processes of arithmetic reveal rather remarkable patterns, affording pleasant pastimes. For example:

$1 \times 8 + 1 = 9$	$3 \times 37 = 111$	$(1)^2 = 1$
$12 \times 8 + 2 = 98$	$6 \times 37 = 222$	$(11)^2 = 121$
$123 \times 8 + 3 = 987$	$9 \times 37 = 333$	$(111)^2 = 12321$
$1234 \times 8 + 4 = 9876$	$12 \times 37 = 444$	$(1111)^2 = 1234321$
etc.	etc.	etc.

Another type of number pleasantry concerns multigrades; *i.e.*, particular identities between sets of numbers and their powers—*e.g.*,

$1^n + 6^n + 8^n = 2^n + 4^n + 9^n$ (for $n = 1$ or 2);
$36^2 + 37^2 + 38^2 + 39^2 + 40^2 = 41^2 + 42^2 + 43^2 + 44^2$.

An easy method of forming a multigrade is to start with a simple equality *e.g.*, $1 + 5 = 2 + 4$—then add, for example, 5 to each term: $6 + 10 = 7 + 9$. A second order multigrade is obtained by "switching sides" and combining, as shown below:

$$1^n + 5^n + 7^n + 9^n = 2^n + 4^n + 6^n + 10^n \quad (n = 1 \text{ or } 2).$$

On each side the sum of the first powers (S_1) $= 22$, and of the second powers (S_2) $= 156$.

Ten may be added to each term to derive a third-order multigrade:

$$11^n+15^n+17^n+19^n=12^n+14^n+16^n+20^n \quad (n=1 \text{ or } 2).$$

Switching sides and combining, as before:

$1^n + 5^n + 7^n + 9^n + 12^n + 14^n + 16^n + 20^n$
$= 2^n + 4^n + 6^n + 10^n + 11^n + 15^n + 17^n + 19^n$
In this example $S_1 = 84$, $S_2 = 1{,}152$, and $S_3 = 17{,}766$ ($n = 1$, 2, or 3).

This process can be continued indefinitely to build multigrades of successively higher orders. Similarly, all terms in a multigrade may be multiplied or divided by the same number without affecting the equality. Many variations are possible, palindromic multigrades that read the same backward and forward, for example, and prime-number multigrades.

Narcissistic numbers

Other number curiosities and oddities are to be found. Thus, narcissistic numbers are numbers that can be represented by some kind of mathematical manipulation of their digits. One such manipulation occurs when a whole number, or integer, is the sum of the nth powers of its digits; *e.g.*, $153 = 1^3 + 5^3 + 3^3$, which is called a perfect digital invariant. On the other hand, a recurring digital invariant is illustrated by:

$$55:5^3 + 5^3 = 250;$$
$$250:2^3 + 5^3 + 0^3 = 133;$$
$$133:1^3 + 3^3 + 3^3 = 55.$$

(From *Mathematics on Vacation*, Joseph Madachy; Charles Scribner's Sons.)

A variation of such digital invariants would be:

$$165{,}033 = 16^3 + 50^3 + 33^3.$$

Another curiosity is exemplified by a number that is equal to the nth power of the sum of its digits:

$$81 = (8 + 1)^2 = 9^2;$$
$$4913 = (4 + 9 + 1 + 3)^3 = 17^3.$$

An automorphic number is an integer whose square ends with the given integer, as $(25)^2 = 625$, and $(76)^2 = 5776$. Strobogrammatic numbers are numbers that read backwards after having been rotated through 180°; *e.g.*, 69, 96, 1001.

It is not improbable that such curiosities should have suggested intrinsic properties of numbers bordering on mysticism.

Digital problems. The problem of the four n's calls for the expression of as large a sequence of integers as possible, beginning with 1, representing each integer in turn by a given digit used exactly four times. The answer depends upon the rules of operation that are admitted. Two partial examples are shown.

Problem of the four n's

For four "1s":

$1 = 1 + \frac{1}{1} - 1$
$2 = 1 + 1 + 1 - 1$
$3 = 1 + 1 + \frac{1}{1}$
$4 = 1 + 1 + 1 + 1$
$5 = (1 + 1 + 1)! - 1$
etc.

For four "4s" it would be possible to have:

$1 = (4 \div 4) \cdot (\frac{4}{4})$
$2 = \frac{4}{4} + \frac{4}{4}$
$3 = \frac{4}{4} + 4/\sqrt{4}$
$4 = \sqrt{(4)(4)} \cdot (\frac{4}{4})$
$5 = \sqrt{4} + \sqrt{4} + \frac{4}{4}$
etc.

(In M. Bicknell & V. Hoggatt, "64 Ways to Write 64 Using Four 4's," *Recreational Mathematics Magazine*, No. 14, Jan.–Feb. 1964, p. 13.)

Obviously, many alternatives are possible; *e.g.*, $7 = 4 + \sqrt{4} + 4/4$ could also be expressed as $4!/4 + 4/4$, or as $44/4 - 4$. The factorial of a positive integer is the product of all the positive integers less than or equal to the given integer; *e.g.*, "factorial 4," or $4! = 4 \times 3 \times 2 \times 1$. If the use of factorial notation is not allowed, it is still possible to express the numbers from 1 to 22 inclusive with four "4s"; thus $22 = (4 + 4)/.4 + \sqrt{4}$. But if the rules are extended many additional combinations are possible.

A similar problem requires that the integers be expressed by using the first m positive integers, $m > 3$ ("m is greater than three"), allowing a finite number of operational symbols used in elementary algebra. For example, using the digits 1, 2, 3, and 4:

$2 = 4 - 3 + 2 - 1$
$4 = \sqrt{4} + 3 - 2 + 1$
$6 = \sqrt{4} + 3 + 2 - 1$
$8 = \sqrt{4} + 3 + 2 + 1$
$9 = 4 + 3 + (2 \cdot 1).$

Such problems have many variations; for example, over 100 ways of arranging the digits 1 to 9, *in order*, to give a value of 100 have been demonstrated.

All of these digital problems require considerable ingenuity, but, in reality, they involve little significant mathematics.

Cryptarithms. These are mathematical problems usually calling for addition, subtraction, multiplication, or division in a set of operations in which the digits have been replaced by letters of the alphabet or some other symbols. The term "crypt arithmetic" was introduced in 1931, when the following multiplication problem appeared in the former Belgian journal *Sphinx:*

$$\begin{array}{r} ABC \\ DE \\ \hline FEC \\ DEC \\ \hline HGBC \end{array}$$

An analysis of the puzzle suggested the general method of solving a relatively simple cryptarithm:

1. In the second partial product D $\times$ A = D, hence A = 1.
2. D $\times$ C and E $\times$ C both end in C; since for any two digits 1–9 the only multiple that will produce this result is 5 (zero if both digits are even, 5 if both are odd), C = 5.
3. D and E must be odd. Since both partial products have only three digits, neither D nor E can be 9. This leaves only 3 and 7. In the first partial product E $\times$ B is a number of two digits, while in the second partial product D $\times$ B is a number of only one digit. Thus E is larger than D, so E = 7 and D = 3.
4. Since D $\times$ B has only one digit, B must be 3 or less. The only two possibilities are 0 and 2. B cannot be zero because 7B is a two digit number. Thus B = 2.
5. By completing the multiplication, F = 8, G = 6, and H = 4.
6. Answer: 125 $\times$ 37 = 4,625.

(From *150 Puzzles in Cryptarithmetic* by Maxey Brooke; Dover Publications, Inc., New York, 1963. Reprinted through the permission of the publisher.)

Such puzzles had apparently appeared, on occasion, even earlier; in recent years they have become quite popular. Alphametics refers specifically to cryptarithms in which the combinations of letters make sense, as in one of the oldest and probably best known of all alphametics:

$$\begin{array}{r} SEND \\ +\ MORE \\ \hline MONEY \end{array}$$

Unless otherwise indicated, convention requires that the initial letters of an alphametic cannot represent zero, and that two or more letters may not represent the same digit. If these conventions are disregarded, the alphametic must be accompanied by an appropriate clue to that effect. Some cryptarithms are quite complex and elaborate, and have multiple solutions. Electronic computers have been used for the solution of such problems.

Paradoxes and fallacies. Mathematical paradoxes and fallacies have long intrigued mathematicians. A mathematical paradox may be described as a mathematical conclusion so unexpected that it is difficult to accept even though every step in the reasoning is known to be valid. A mathematical fallacy, on the other hand, is an instance of improper reasoning leading to an unexpected result that is patently false or absurd. The error in a fallacy generally violates some principle of logic or mathematics, often unwittingly. Such fallacies are quite puzzling to the tyro, who, unless he is aware of the principle involved, may well overlook the subtly concealed error. A sophism is a fallacy in which the error has been knowingly committed, for whatever purpose. If the error introduced into a calculation or a proof leads innocently to a *correct* result, the result is a "howler," often called an illegal operation or "making the right mistake."

Many paradoxes arise from the concepts of infinity and limiting processes. For example, the infinite series

$$1 + \tfrac{1}{2} + \tfrac{1}{4} + \tfrac{1}{8} + \ldots$$

appears at first glance to have a continually greater "sum" the more terms are included, although the sum actually can never be equal to 2, although it approaches nearer and nearer to 2 as more terms are included. On the other hand, the series

$$1 + \tfrac{1}{2} + \tfrac{1}{3} + \tfrac{1}{4} + \tfrac{1}{5} + \tfrac{1}{6} + \ldots$$

is divergent and has no limit, the "sum" becoming ever larger the more terms are taken. Another paradox is the fact that there are just as many even natural numbers as there are even and odd numbers all together, thus contradicting the notion that "the whole is greater than any of its parts." This seeming contradiction arises from the properties of collections containing an infinite number of objects. Since both are infinite, they are for both practical and mathematical purposes equal.

Zeno's paradoxes

The so-called paradoxes of Zeno (*c.* 450 BC) are, strictly speaking, sophisms. Thus, in the case of Achilles and the tortoise: Achilles, who could run ten yards per second, competed with a tortoise that ran five yards per second; the tortoise was to have a handicap of ten yards. Zeno claimed that Achilles could never catch the tortoise; his argument being based on the "fact" that whenever Achilles reached a point where the tortoise had just been, the tortoise would have moved ahead. Obviously, Zeno did not believe what he claimed; his interest lay in locating the error in his argument. The same observation is true of the three remaining paradoxes of Zeno, the *Dichotomy*, "motion is impossible"; the *Arrow*, "motionless even while in flight"; and the *Stadium*, or "a given time interval is equivalent to an interval twice as long." Beneath the sophistry of these contradictions lie subtle and elusive concepts of limits and infinity, only completely explained in the 19th century when the foundations of analysis became more rigorous and the theory of transfinite numbers had been formulated.

Common algebraic fallacies usually involve a violation of one or another of the following assumptions:

1. If $a = b$, then $a/k = b/k$, provided $k \neq 0$.
2. If $a > b$, then $ka > kb$, provided k is positive.
3. If a is nonnegative, then $\sqrt{a^2} = +a$.

Three examples of such violations follow:

A. Solve: $6x - 18 = 4x - 12$
Factoring: $3(2x - 6) = 2(2x - 6)$
Dividing by $(2x - 6)$: $3 = 2$

B. Since $+1/-1 = -1/+1$, then $\sqrt{+1}/\sqrt{-1} = \sqrt{-1}/\sqrt{+1}$, and so $(\sqrt{+1})(\sqrt{+1}) = (\sqrt{-1})(\sqrt{-1})$, hence $+1 = -1$

C. Given two positive numbers, a and b:

then,	also,
$a > -b$	$b > -a$
$b > -b$	$a > -a$
Multiplying: $ab > b^2$	$ab > a^2$
Or $a > b$	$b > a$

Thus a is both greater than b and less than b.

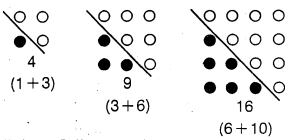
An example of an illegal operation or "lucky boner" is:

$$\tfrac{16}{64} = \tfrac{16}{64} = \tfrac{1}{4}.$$

Polygonal and figurate numbers. Among the many relationships of numbers that have fascinated man are those that suggest (or were derived from) the arrangement of points representing numbers into series of geometrical figures. Such numbers, known as figurate or polygonal numbers, appeared in 15th-century arithmetic books and were probably known to the Chinese as early as 2,000 years ago; but they were of especial interest to the ancient Greek mathematicians. To the Pythagoreans (*c.* 500 BC) numbers were of paramount significance; everything could be explained by numbers, and numbers were invested with specific characteristics and personalities. Among other properties of numbers, the Pythagoreans recognized that numbers had "shapes." Thus the triangular numbers, 1, 3, 6, 10, 15, 21, etc., were visualized as points or dots arranged in the shape of a triangle. Each triangular number is the sum of all successive numbers from 1 on up to some point.

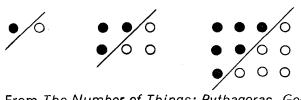
The "shapes" of numbers

Square numbers are the squares of natural numbers, such as 1, 4, 9, 16, 25, etc., and can be represented by squares. Inspection reveals that the sum of any two adjacent triangular numbers is always a square number.

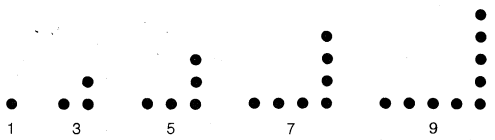


From *The Number of Things: Pythagoras, Geometry and Humming Strings* by Evans G. Valens, copyright © 1964 by Evans G. Valens; published by E.P. Dutton & Co., Inc., and used with their permission

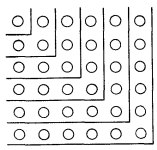
Oblong numbers are the sums of successive even numbers. It is notable that each oblong number is the product of two successive numbers; *e.g.*, $6 = 2 \cdot 3$; $12 = 3 \cdot 4$; $20 = 4 \cdot 5$; etc. The sum of any two equal triangular numbers forms an oblong number (see below).



The gnomons are all the odd numbers, represented by a right angle, or a carpenter's square (see below). Gnomons were useful to the Pythagoreans. They could build



up squares by adding gnomons to smaller squares and from such a figure could deduce many interrelationships: thus $1^2 + 3 = 2^2$, $2^2 + 5 = 3^2$, etc: or $1 + 3 + 5 = 3^2$, $1 + 3 + 5 + 7 = 4^2$, $1 + 3 + 5 + 7 + 9 = 5^2$, etc. (see below). Indeed, it is likely that Pythagoras first



realized the famous relationship $a^2 + b^2 = c^2$ by contemplating the properties of gnomons and square numbers, observing that any odd square can be added to some even square to form a third square. Thus

$$3^2 + 4^2 = 5^2, \text{ where } 3^2 = 4 + 5;$$
$$5^2 + 12^2 = 13^2, \text{ where } 5^2 = 12 + 13,$$

and in general, $a^2 + b^2 = c^2$, where $a^2 = b + c$. This is a special class of Pythagorean triples (see below).

Besides these, the Greeks also studied numbers having pentagonal, hexagonal, and other shapes. Many relationships can be shown to exist between geometric patterns and algebraic expressions.

Polygonal numbers constitute a subdivision of a class of numbers known as figurate numbers. Examples would be the arithmetic sequences

$$1, 2, 3, 4, \ldots r$$
and $$1, 3, 5, 7, \ldots (2r - 1).$$

When new series are formed from the sums of the terms of these series, the results are, respectively,

$$1, 3, 6, 10, \ldots$$
and $$1, 4, 9, 16, \ldots$$

These series are not arithmetic sequences but are seen to be the polygonal triangular and square numbers. Polygonal number series can also be added to form three-dimensional figurate numbers called pyramidal numbers.

The significance of polygonal and figurate numbers lies in their relation to the modern theory of numbers. Even the simple, elementary properties and relations of numbers often demand sophisticated mathematical tools. Thus it has been shown that every integer is either a triangular number, the sum of two triangular numbers, or the sum of three triangular numbers; *e.g.*, $8 = 1 + 1 + 6$; $42 = 6 + 36$; $43 = 15 + 28$; $44 = 6 + 10 + 28$.

Pythagorean triples. The study of Pythagorean triples as well as the general theorem of Pythagoras leads to many unexpected byways in mathematics. A Pythagorean triple is formed by the measures of the sides of an integral right triangle; *i.e.*, any set of three positive integers such that $a^2 + b^2 = c^2$. If a, b, and c are relatively prime—*i.e.*, if no two of them have a common factor—the set is a primitive P. triple.

A formula for generating all P. triples is

$$a = p^2 - q^2, b = 2pq, c = p^2 + q^2,$$

in which p and q are relatively prime, p and q are neither both even nor both odd, and $p > q$. By choosing p and q appropriately, for example, primitive P. triples such as the following are obtained:

p	q	(*a*) $p^2 - q^2$	(*b*) $2pq$	(*c*) $p^2 + q^2$
2	1	3	4	5
3	2	5	12	13

The only primitive triple that consists of consecutive integers is 3, 4, 5.

Characteristic properties of primitive triples

Certain characteristic properties are of interest:

1. Either a or b is divisible by 3.
2. Either a or b is divisible by 4.
3. Either a or b or c is divisible by 5.
4. The product of a, b and c is divisible by 60.
5. One of the following: a, b, $a + b$, $a - b$ is divisible by 7.

It is also true that if n is any integer, then $2n + 1$, $2n^2 + 2n$, and $2n^2 + 2n + 1$ form a P. triple for every value of n.

Some of the properties of P. triples were known to the ancient Greeks; *e.g.*, that the hypotenuse of a primitive triple is always an odd integer. It is now known that for an odd integer R to be the hypotenuse of a primitive triple, a necessary and sufficient condition is that every prime divisor of R be of the type $4k + 1$ (k is any positive integer $\neq 0$).

Perfect numbers and Mersenne numbers. Most numbers are either "abundant" or "deficient." In an abundant number, the sum of its proper divisors (*i.e.*, including 1, but excluding the number itself) is greater than the number; in a deficient number, the sum of its proper divisors is less than the number. A perfect number is an integer that equals the sum of its proper divisors. For example, 24 is abundant, its divisors giving a sum of 36; 32 is deficient, giving a sum of 31. The number 6 is a perfect number, since $1 + 2 + 3 = 6$; so is 28, since $1 + 2 + 4 + 7 + 14 = 28$. The next two perfect numbers are 496 and 8,128. The first four perfect numbers were known to the ancients. Indeed, Euclid suggested that any number of the form $2^{n-1}(2^n - 1)$ is a perfect number whenever $2^n - 1$ is prime, but it was not proved until the 18th century when the Swiss mathematician L. Euler proved that every even perfect number must be of the form $2^{n-1}(2^n - 1)$, where $2^n - 1$ is a prime.

Numbers of the form $2^n - 1$ are called Mersenne numbers after French mathematician Marin Mersenne; they may be prime (*i.e.*, having no factor except itself or 1) or composite (composed of two or more prime factors). A necessary though not sufficient condition that $2^n - 1$ be a prime is that n be a prime. Thus, all even perfect numbers have the form $2^{n-1}(2^n - 1)$ where both n and $2^n - 1$ are prime numbers. Until comparatively recently only 12 perfect numbers were known. In 1876, French mathematician Edouard Lucas found a way to test the primality of Mersenne numbers. By 1952 R.M. Robinson had applied Lucas' test and, by means of electronic digital computers, had found the Mersenne primes for $n = 521$, 607, 1,279, 2,203 and 2,281, thus adding five more perfect numbers to the list of 12 already known. By 1971 there were 23 known perfect numbers.

It is known that to every Mersenne prime there corresponds an even perfect number and vice versa. But two questions are still unanswered: Are there any odd perfect numbers? Are there infinitely many perfect numbers?

Many remarkable properties are revealed by perfect numbers. All perfect numbers, for example, are triangular. Also, the sum of the reciprocals of the divisors of a perfect number (including the reciprocal of the number itself) is always equal to 2. Thus

$$\text{for 6: } \tfrac{1}{1} + \tfrac{1}{2} + \tfrac{1}{3} + \tfrac{1}{6} = 2$$
$$\text{for 28: } \tfrac{1}{1} + \tfrac{1}{2} + \tfrac{1}{4} + \tfrac{1}{7} + \tfrac{1}{14} + \tfrac{1}{28} = 2$$

Fibonacci numbers. This sequence of numbers first became known in 1202 when Leonardo of Pisa, also called

Fibonacci, published *Liber abaci.* The sequence results from a recreational problem: "How many pairs of rabbits can be produced from a single pair in one year if it is assumed that every month each pair begets a new pair which from the second month becomes productive?" Thus

Month:	1	2	3	4	5	6	7	8	9	10	11	12
No. of pairs:	1	1	2	3	5	8	13	21	34	55	89	144

The second row represents the first 12 terms of the Fibonacci sequence, in which each term (except the first two) is found by adding the two terms immediately preceding; in general, $x_n = x_{n-1} + x_{n-2}$, a relation that was not recognized until about 1600.

Over the years, and especially in the middle decades of the 20th century, the properties of the Fibonacci numbers have been extensively studied, resulting in a very considerable literature. Their properties appear to be inexhaustible; for example, $x_{n+1} \cdot x_{n-1} = x_n^2 + (-1)^n$. Another formula for generating the Fibonacci numbers is attributed to Lucas:

$$x_n = \frac{1}{\sqrt{5}}\left\{\left(\frac{1+\sqrt{5}}{2}\right)^n - \left(\frac{1-\sqrt{5}}{2}\right)^n\right\}.$$

Lucas also created and discussed the Lucas series

$$1, 3, 4, 7, 11, 18, \ldots$$

The ratio $(\sqrt{5}+1):2 = 1.618\ldots$, designated as Φ, is known as the golden number; the ratio $(\sqrt{5}-1):2$, the reciprocal of Φ, is equal to $0.618\ldots$. Both these ratios are related to the roots of $x^2 - x - 1 = 0$, an equation derived from the Divine Proportion of the 15th century Italian mathematician Lucas Pacioli, namely, $a/b = b/(a+b)$, when $a < b$, by setting $x = b/a$. In short, dividing a segment into two parts in mean and extreme proportion, so that the smaller part is to the larger part as the larger is to the entire segment, yields the so-called Golden Section, an important concept in both ancient and modern artistic and architectural design. Thus, a rectangle the sides of which are in the approximate ratio of 3:5 ($\Phi^{-1} = 0.618\ldots$), or 8:5 ($\Phi = 1.618\ldots$), is presumed to have the most pleasing proportions, aesthetically speaking.

The Golden Section

$$\Phi = (\sqrt{5}+1)/2 \qquad \Phi^4 = (3\sqrt{5}+7)/2$$
$$\Phi^2 = (\sqrt{5}+3)/2 \qquad \Phi^5 = (5\sqrt{5}+11)/2$$
$$\Phi^3 = (2\sqrt{5}+4)/2 \qquad \Phi^6 = (8\sqrt{5}+18)/2$$

The above exhibits one of many interrelations between the Fibonacci and the Lucas numbers; the successive coefficients of the radical $\sqrt{5}$ are Fibonacci's 1, 1, 2, 3, 5, 8, while the successive second terms within the parentheses are Lucas' 1, 3, 4, 7, 11, 18.

If a golden rectangle ABCD is drawn and a square ABEF is removed, the remaining rectangle ECDF is also a golden rectangle. If this process is continued and circular arcs are drawn, the curve formed approximates the

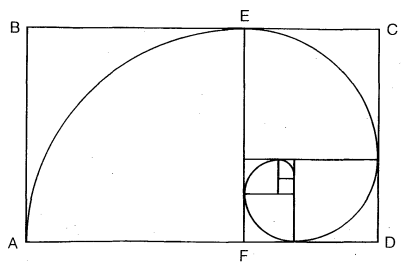


Figure 1: The golden rectangle.

logarithmic spiral, a form found in nature. The logarithmic spiral is the graph of the equation $r = k^\theta$, in polar coordinates, where $k = \Phi^{2/\pi}$. The Fibonacci numbers are also exemplified by the botanical phenomenon known as phyllotaxis. Thus, the arrangement of the whorls on a pinecone or pineapple, of petals on a sunflower, and of branches from some stems follows a sequence of Fibonacci numbers or the series of fractions.

$$\tfrac{1}{1}, \tfrac{1}{2}, \tfrac{2}{3}, \tfrac{3}{5}, \tfrac{5}{8}, \tfrac{8}{13}, \text{ etc.}$$

These relationships form the basis of the theory of dynamic symmetry that has been applied to the fine arts as well as to living forms. (For an excellent treatment of the Fibonacci numbers, see V.E. Hoggatt, *Fibonacci and Lucas Numbers*, 1969.)

Magic squares. A magic square is a square formed by numbers or letters in particular arrangements that were once thought to have magical properties. In arithmetical magic squares the numbers are arranged so that the sum of every column, of every row, and of the two main diagonals is the same.

A standard magic square of any given number contains the sequence of natural numbers from 1 to the square of that number. Thus the magic square of three contains the numbers 1 to 9 in three rows: 4, 9, 2; 3, 5, 7; and 8, 1, 6. The earliest magic square known, it can be traced back to about 2000 BC in China; it does not appear elsewhere until centuries later. For examples and discussion of magic squares composed of letters and words see BOARD AND TILE GAMES; for the mathematical theory of arithmetical magic squares, or Latin squares, see COMBINATORICS AND COMBINATORIAL GEOMETRY.

GEOMETRIC AND TOPOLOGICAL RECREATIONS

Optical illusions. The creation and analysis of optical illusions may involve mathematical concepts and geometric principles such as the areas of similar figures being proportional to the squares of their linear dimensions. Some involve physiological or psychological considerations, such as the fact that when making visual comparisons, relative lengths are normally more accurately perceived than relative areas.

For treatment of types of optical illusions and the sources of their illusory effects, including unorthodox use of perspective, distorted angles, deceptive shading, unusual juxtaposition, equivocal contours or contrasts, colour effects, chromatic aberration, and after images, see the article ILLUSIONS AND HALLUCINATIONS.

Geometric fallacies and paradoxes. Some of the more widely exhibited geometric fallacies include "proofs": (1) that every triangle is isosceles (*i.e.*, has two equal sides); (2) that every angle is a right angle; (3) that if ABCD is a quadrilateral in which $\overline{AB} = \overline{CD}$, then AD must be parallel to BC; and (4) that every point in the interior of a circle lies on the circle.

The explanations of fallacious proofs in geometry usually include one or another of the following: faulty construction; violation of a logical principle, such as assuming the truth of a converse, or confusing partial inverses or converses; misinterpretation of a definition, or failing to take note of "necessary and sufficient" conditions; too great dependence upon diagrams and intuition; being trapped by limiting processes and intuition—*e.g.*, in concluding that in Figure 2, as more and more "teeth" are

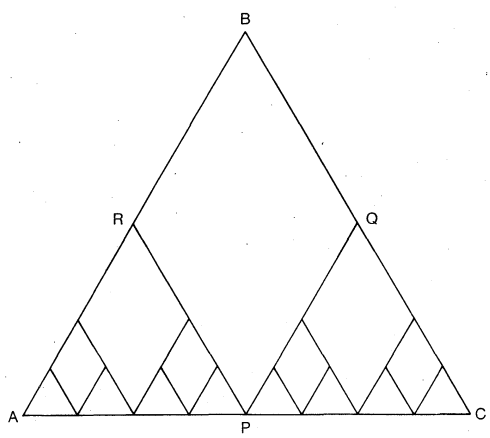

Figure 2: The constant zigzag (see text).

taken, the sawtooth zigzag from A to C approaches more and more nearly the length of AC, whereas actually, if P, Q, R are midpoints of the sides of an equilateral triangle ABC, it always equals $2 \times \overline{AC}$.

Some geometric curves, such as the so-called snowflake curve, a closed curve of infinite length but having a finite interior, furnish genuine paradoxes rather than fallacies. More unbelievable still (but true) is the space-filling curve; in seeming defiance that a curve is "one-dimensional" and thus cannot fill a given space, it can be shown that the curve suggested in various stages in Figure 3, when completed, will ultimately pass through *every* point in the square. In fact, by similar reasoning, the curve can be made to fill completely an entire cube.

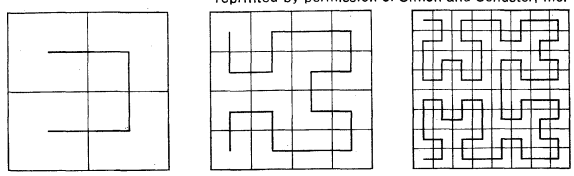

Figure 3: The space-filling curve (see text).

Tangrams; mazes. One of the oldest of Oriental amusements, a tangram is a set of geometric shapes, called *tans*, usually of wood or tile, that can be arranged to represent all sorts of objects, animals, people, and so on. The seven-piece set cut from a square is of Chinese origin; a Greco-Roman version, the loculus of Archimedes, or the stomachion, consisted of 14 pieces cut from a rectangle of which the length is twice its width.

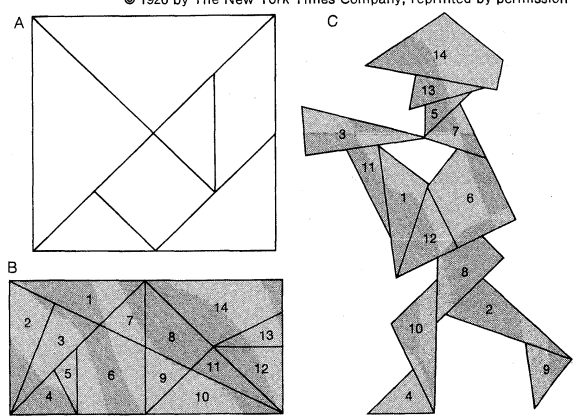

Figure 4: (A) Seven-piece tangram. (B) Fourteen-piece tangram. (C) Pied Piper made from B.

Whereas a tangram involves no mathematical principles, a maze presents a topological situation; the map of a maze is a topological invariant. A maze having only one entrance and one exit can be solved by placing one hand against either wall and keeping it there as it is traversed; the exit can always be reached in this manner, although not necessarily by the shortest path. If the goal is within the labyrinth, the "hand-on-wall" method will also succeed, provided that there is no closed circuit; *i.e.*, a route that admits of complete traverse back to the beginning (Figure 5).

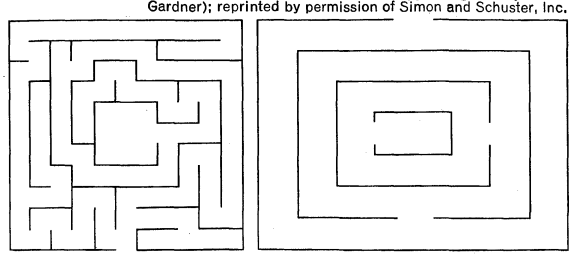

Figure 5: *Examples of mazes.*
(Left) "Simply connected" maze.
(Right) "Multiply connected" maze (see text).

If there are no closed circuits—*i.e.*, no detached walls—the maze is "simply connected"; otherwise the maze is "multiply connected." A classic general method of "threading a maze" is to designate a place where there is a choice of turning as a node; a path or node that has not yet been entered as a "new" path or node; and one that has already been entered as an "old" path or node.

The procedure is as follows:

1. Never traverse a path more than twice.
2. When arriving at a new node, select either path.
3. When arriving at an old node or at a dead end by a new path, return by the same path.
4. When arriving at an old node by an old path, select a new path, if possible; otherwise, an old path.

Ironically, while recreational interest in mazes has diminished, two areas of modern science have found them to be of value: psychology and communications technology. The former is concerned with the learning behaviour of men and animals, the latter with improved design of computers.

Geometric dissections. Geometric dissection problems involve the cutting of geometric figures into pieces that can be arranged to form other geometric figures; for example, cutting a rectangle into parts that can be put together in the form of a square and vice versa. Interest in this area of mathematical recreations began to manifest itself towards the close of the 18th century when Montucla called attention to this problem. As the subject became more popular, greater emphasis was given to the more general problem of dissecting a given polygon of any number of sides into parts that would form another polygon of equal area. Then, in the early 20th century, interest shifted to finding the *minimum* number of pieces required to change one figure into another.

Theory of equidecomposable figures

According to a comprehensive theory of equidecomposable figures outlined about 1960, two polygons are said to be equidecomposable if it is possible to dissect, or decompose, one of them into a finite number of pieces that can then be rearranged to form the second polygon. Obviously, the two polygons have equal areas.

According to the converse theorem, if two polygons have equal areas, they are equidecomposable.

In the method of complementation, congruent parts are added to two figures so as to make the two new figures congruent. It is known that equicomplementable figures have equal areas, and that if two polygons have equal areas, they are equicomplementable. As the theory advanced, the relation of equidecomposability to various motions such as translations, central symmetry, and, indeed, to groups of motions in general, was explored. Studies were also extended to the more difficult questions of dissecting polyhedra.

On the "practical" side, the execution of a dissection, such as converting the Greek cross or the tau cross into a square (Figure 6) requires the use of ingenious procedures such as the parallelogram slide, the quadrilateral slide, rational and step dissections, strip dissections, and tessellations, as described by H. Lindgren (see *Bibliography*).

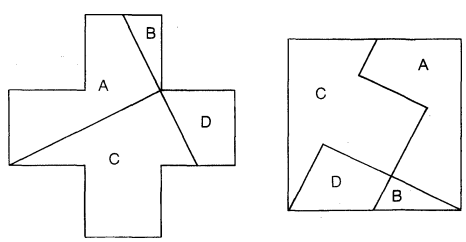

Figure 6: Greek cross converted by dissection into a square.

A quite different and distinctly modern type of dissection deserves brief mention, the so-called squaring the square, or squared rectangles. Thus, the problem of subdividing a square into smaller squares, no two of which are alike, long thought to be unsolvable, has been solved

by means of network theory. In this connection, a squared rectangle is a rectangle that can be dissected into a finite number of squares; if no two of these squares are equal, the squared rectangle is said to be perfect. The order of a squared rectangle is the number of constituent squares. It is known that there are no perfect rectangles of orders less than 9, and that there are exactly two perfect rectangles of order 9. The dissection of a rectangle or a square into unequal squares has been a comparatively recent development; that is, since about 1940.

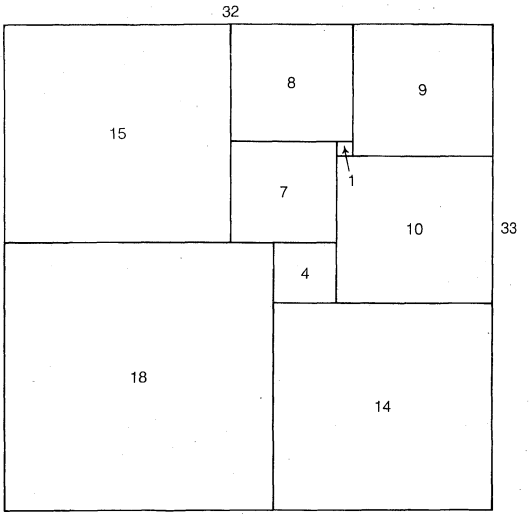

Figure 7: Squared rectangle (see text).

Graphs and networks. The word "graph" may refer to the familiar curves of analytic geometry and function theory, or it may refer to simple geometric figures consisting of points and lines connecting some of these points; the latter are sometimes called linear graphs, although there is little confusion within a given context. Such graphs have long been associated with puzzles.

If a finite number of points are connected by lines (Figure 8A), the resulting figure is a graph; the points, or corners, are called the vertices, and the lines are called the edges. If every pair of vertices is connected by an edge, the graph is called a complete graph (Figure 8B). A

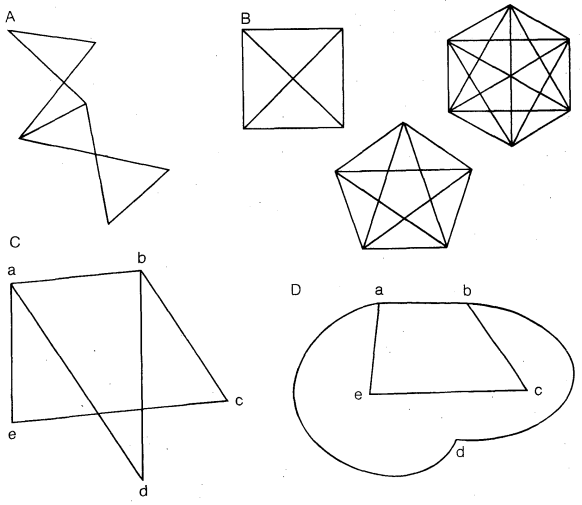

Figure 8: *Examples of linear graphs.*
(A) Graph. (B) Complete graphs. (C) Nonplanar graph.
(D) Nonplanar graph transformed into equivalent planar graph.

planar graph is one in which the edges have no intersection or common points except at the edges. (It should be noted that the edges of a graph need not be straight lines.) Thus a nonplanar graph can be transformed into an equivalent, or isomorphic, planar graph, as in Figures 8C and 8D. An interesting puzzle involves the problem of the three wells. Here (Figure 9) A, B, and C represent three neighbours' houses, and R, S, and T three wells. It is desired to have paths leading from each house to each well, allowing no path to cross any other path. The proof that the problem is impossible depends on the so-called Jordan Curve theorem that a continuous closed curve in a plane divides the plane into an interior and an exterior region in such a way that any continuous line connecting a point in the interior with a point in the exterior must intersect the curve. Planar graphs have proved useful in the design of electrical networks.

Problem of the three wells

From *Graphs and Their Uses*, by Oystein Ore. Copyright © 1963 by Yale University. Reprinted by permission of Random House, Inc.

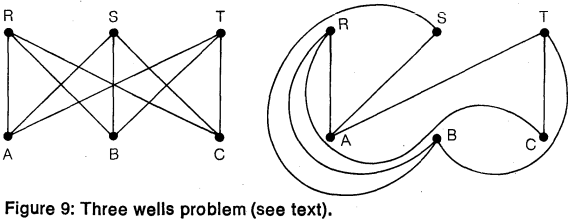

Figure 9: Three wells problem (see text).

A connected graph is one in which every vertex, or point (or, in the case of a solid, a corner), is connected to every other point by an arc; an arc denotes an unbroken succession of edges. A route that never passes over an edge more than once, although it may pass through a point any number of times, is called a path.

Modern graph theory (in the sense of linear graphs) had its inception with the work of Euler in connection with the Königsberg bridge problem, and was, for many years, associated with "unicursal curves"; *i.e.*, figures that can be drawn with one stroke of the pencil. The city of Königsberg (now Kaliningrad) embraces the banks and two islands of the river Pregel; seven bridges connect the islands with the mainland. The problem was: Could a person leave home, take a walk, and return, crossing each bridge just once? Euler showed why it is impossible.

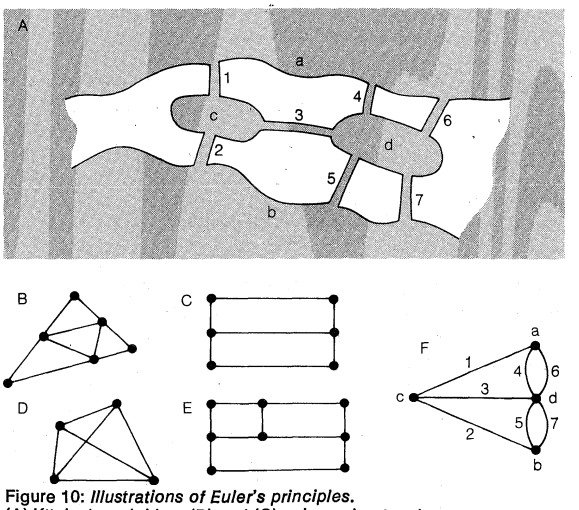

Figure 10: *Illustrations of Euler's principles.*
(A) Königsberg bridge. (B) and (C) unicursal networks.
(D) and (E) noncursal networks. (F) network corresponding to Königsberg bridge problem.

Briefly stated, Euler's principles (that apply for any closed network) are as follows:

1. The number of even points—*i.e.*, those in which an even number of edges meet—is of no significance.

2. The number of odd points is always even; this includes the case of a network with only even points.

3. If there are *no odd points*, the network is unicursal; one can start at any point and finish at the same point.

4. If there are *exactly two odd points*, the network is unicursal; one can start at either of the odd points and finish at the other odd point.

5. If there are *more than two odd points*, the network cannot be traced in one continuous path; if there

are $2n$ odd points and no more, it can be traced in n separate paths.

Thus Figure 10B and Figure 10C are unicursal; Figures 10D and 10E are not; Figure 10F shows a network corresponding to the K. bridge problem, in which the points represent the land areas and the edges the seven bridges.

Networks are related to a variety of recreational problems that involve combining or arranging points in a plane or in space. Among the earliest was a puzzle invented by an Irish mathematician, Sir William Rowan Hamilton (1859), which required finding a route along the edges of a regular dodecahedron that would pass once and only once through every point. In another version, the puzzle was made more convenient by replacing the dodecahedron by a graph isomorphic to the graph formed by the 30 edges of the dodecahedron (Figure 11). A Hamilton circuit is one that passes through each point exactly once but does not, in general, cover all the edges; actually, it covers only two edges at each vertex. The route shown in heavy lines is a Hamilton circuit.

The Hamilton circuit

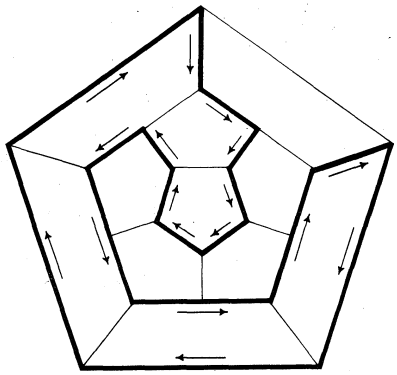

Figure 11: Hamilton circuit.

Graph theory, being a branch of mathematics known as combinatorial topology, lends itself to a variety of problems involving combinatorics: for example, designing a network to connect a set of cities by railroads or by telephone lines; planning city streets or traffic patterns; matching jobs with applicants; arranging round-robin tournaments such that every team or individual meets every other team or individual.

Map colouring problems. Although geographers have long known that maps depicting subdivisions of areas can be coloured in such a way that any two subdivisions having a common boundary show different colours and no more than four distinct colours are used, the celebrated "four-colour map problem" bears little or no relation, historically, to cartography. A political map, in fact, is rather different. The mathematical question was originally framed in 1850 and publicized in 1878. Essentially, the problem is: How many colours are needed to colour any map so that no two regions sharing a common border (edge) will have the same colour? Are four colours both necessary and sufficient? In short, is it possible to construct a map for which five colours are necessary? No one knows. It seems likely that four colours are necessary and sufficient; this has never been proved. It is still a conjecture, not a theorem. That is not to say that the problem has been neglected; the literature is extensive.

The four-colour problem

Some of the salient results may be stated briefly. To begin with, the surface of a sphere is topologically equivalent to a plane. The following basic theorems have been established:

1. Any map on the plane can be coloured with two colours if, and only if, all of its points are even.

2. If the surface of a sphere is divided into regions, each of which has an even number of edges, and if three countries meet at each point, then the map can be coloured with exactly three colours.

3. If the surface of a sphere is divided into regions, each of which shares its boundaries with three neighbouring regions, then the map can be coloured with three or fewer colours.

4. A map can always be coloured in five or fewer colours.

5. Any map with fewer than 38 regions can be coloured with four or fewer colours.

But the general four-colour theorem still remains unproved.

Flexagons. A flexagon is a polygon constructed from a strip of paper or thin metal foil in such a way that the figure possesses the property of changing its faces when it is "flexed." First discussed in 1939, flexagons have become a fascinating mathematical recreation. One of the simplest flexagons is the trihexaflexagon, made by cutting a strip of suitable material and marking off 10 equilateral triangles. By folding appropriately several times and then gluing the last triangle onto the reverse side of the first triangle, the resulting model may be "flexed" so that one of the faces "disappears" and another face takes its place.

As mathematicians experimented with flexagons, they came up with hexaflexagons (19 triangles), tetraflexagons, hexahexaflexagons, tetrahexaflexagons, pentahexaflexagons and even decahexaflexagons, the latter having 10 faces and 82 variations.

MANIPULATIVE RECREATIONS

Puzzles involving configurations. One of the earliest puzzles and games that require arranging counters into some specified alignment or configuration was Lucas' Puzzle: three black counters and three white counters are placed in a row, leaving a blank space between them. The object is to move the black pieces from the left end to the right end and the white to the left end; black pieces can be moved only to the right and the white only to the left. A counter may move to an adjacent square or it may jump over one of the opposite colours. Variations of the puzzle use nine squares with four counters of one kind and four of another, and so on. For n counters of each kind the number of required moves is $n(n + 2)$.

Lucas' puzzle and Ticktacktoe

A similar puzzle uses eight numbered counters placed on nine positions. The aim is to shift the counters so that they will appear in reverse numerical order; only single moves and jumps are permitted.

Well known, but by no means as trivial, are games for two players, such as Ticktacktoe and its more sophisticated variations, one of which calls for each player to begin with three counters (3 black, 3 white); the first player places a counter in any cell, except the center cell, of a 3 $\times$ 3 diagram; the players then alternate until all the counters are down. If neither has won by getting three in a row, each, in turn, is permitted to move a counter to an adjacent square, moving only horizontally or vertically. Achieving three in a row constitutes a win. There are many variations. The game can be played on a 4 $\times$ 4 diagram, each player starting with four counters; sometimes diagonal moves are permitted. Another version is played on a 5 $\times$ 5 pattern.

Another interesting modification, popular in Europe, is variously known as Mill or Nine Men's Morris, played with counters on a board consisting of three concentric squares and eight transversals (for details see BOARD AND TILE GAMES).

Another game of this sort is played on a diamond-shaped board comprised of tessellated hexagons, usually 11 on each edge, where by "tessellated" we mean fitted together like tiles to cover the board completely. Two opposite edges of the diamond are designated "white"; the other two sides, "black." Each player has a supply of black or white counters. The players alternately place a piece on any vacant hexagon; the object of the game is for each player to complete an unbroken chain of his pieces between the sides designating his colour. Though the game does not end until one of the players has made a complete chain, it may meander across the board; it cannot end in a draw because the only way one player can block the other is by completing his own chain. The game was created by Piet Hein in 1942 in Denmark,

where it quickly became popular under the name of Polygon. It was invented independently in the United States in 1948 by John Nash, and a few years later one version was marketed under the name of Hex.

In addition to the aforementioned varieties of a class of games that can be loosely described as "three in a row" or "specified alignment" many others also exist, such as three- and four-dimensional Ticktacktoe and even a computer Ticktacktoe. The game strategy in Ticktacktoe is by no means simple; an excellent mathematical analysis is given in F. Schuh (see *Bibliography*).

Chessboard problems. Recreational problems posed with regard to the conventional chessboard are legion. Among the most widely discussed is the problem of how to place eight queens on a chessboard in such a way that none of the queens is attacking any other queen; the problem interested the great German mathematician C.F. Gauss (*c.* 1850). Another group of problems has to do with the knight's tour; in particular, to find a closed knight's tour that ends at the starting point, that does not enter any square more than once, but that passes through all the squares in one tour. Problems of the knight's tour are intimately connected with the construction of magic squares. Other chessboard problems are concerned with determining the relative values of the various chess pieces; finding the maximum number of pieces of any one type that can be put on a board so that no one piece can take any other; finding the minimum number of pieces of any one type that can be put on a board so as to command all cells; and how to place 16 queens on a board so that no three of them are in a straight line.

The Fifteen Puzzle. This is perhaps one of the best known of all puzzles. Invented by one Sam Loyd about 1878, it is also known as the Boss Puzzle, Jeu de Taquin, and Diablotin. It became popular all over Europe almost at once and literally created a rage. It consists essentially of a shallow square tray that holds exactly 15 small square counters numbered from 1 to 15, and one square blank space. With the 15 squares initially placed in random order and with the blank space in the lower right-hand corner, the puzzle is to rearrange them in numerical order by sliding only, with the blank space ending up back in the lower right-hand corner. It may overwhelm the reader to learn that there are more than 20,000,000,000,000 possible different positions that the pieces (including the blank space) can assume. But in 1879 two American mathematicians proved that only one-half of all possible initial arrangements, or about 10,000,000,000,000, admitted of a solution. The mathematical analysis is as follows. Basically, no matter what path it takes, as long as it ends its journey in the lower right-hand corner of the tray, any numeral must pass through an even number of boxes. In the normal position of the squares, regarded row by row from left to right, each number is larger than all the preceding numbers; *i.e.*, no number *precedes* any number smaller than itself. In any other than the normal arrangement, one or more

Solving the Fifteen Puzzle

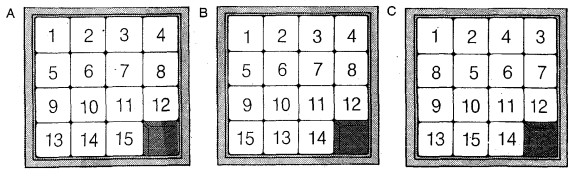

Figure 12: (A) Fifteen Puzzle with no inversions. (B) With two inversions. (C) With five inversions.

numbers will precede others smaller than themselves. Every such instance is called an inversion. For example, in the sequence 9, 5, 3, 4, the 9 precedes three numbers smaller than itself and the 5 precedes two numbers smaller than itself, making a total of five inversions. If the total number of *all* the inversions in a given arrangement is *even*, the puzzle can be solved by bringing the squares back to the normal arrangement; if the total number of inversions is *odd*, the puzzle cannot be solved. Thus, in Figure 12B there are two inversions, and the puzzle can be solved; in Figure 12C there are five inversions, and the puzzle has no solution. Theoretically, the puzzle can be extended to a tray of $m \times n$ spaces with $(mn - 1)$ numbered counters. In recent years, a "31" puzzle, as well as others, has been obtainable.

The Tower of Hanoi. This puzzle is believed to have been put out in 1883 by Lucas, under the name of M. Claus. Ever popular, made of wood or plastic, it still can be found in toy shops. It consists essentially of three pegs fastened to a stand and of eight circular disks, each having a hole in the centre. The disks, all of different radii, are initially placed on one of the pegs, with the largest disk on the bottom and, in order of decreasing radii, the smallest on top. The task is to transfer the individual disk from one peg to another so that no disk ever rests on one

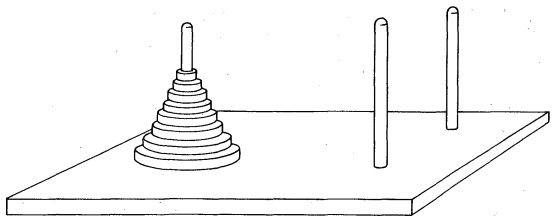

Figure 13: Tower of Hanoi.

smaller than itself, and, finally, to transfer the tower; *i.e.*, all the disks in their proper order, from their original peg to one of the other pegs. It can be shown that for a tower of n disks, there will be required $2^n - 1$ transfers of individual disks to shift the tower completely to another peg. Thus for 8 disks, the puzzle requires $2^8 - 1$, or 255 transfers. In a more imaginative version, the original "needle" (peg) was a tower with 64 disks, requiring $2^{64} - 1$, or 18,446,744,073,709,551,615 transfers; this is exactly the same number required to fill an 8×8 checkerboard with grains of wheat, 1 on the first square, 2 on the second, 4 on the next, then 8, 16, 32, etc. With no interruptions and no mistakes, it would take many thousands of millions of years to transfer the tower.

Polyominoes. The term designating this popular and relatively recent mathematical recreation was introduced in 1953. A polyomino is a simply connected set of equal-sized squares; *i.e.*, shapes consisting of congruent squares, each joined together with at least one other square along an edge. The simpler polyomino shapes are shown in Figure 14A. Somewhat more fascinating are the pentominoes, of which there are exactly 12 forms (Figure 14B). Asymmetrical pieces, which have "different shapes" when they are flipped over, are counted as one.

Manipulating squares and cubes

From Martin Gardner, *The Scientific American Book of Mathematical Puzzles and Diversions* (copyright © 1959 by Martin Gardner); reprinted by permission of Simon and Schuster, Inc.

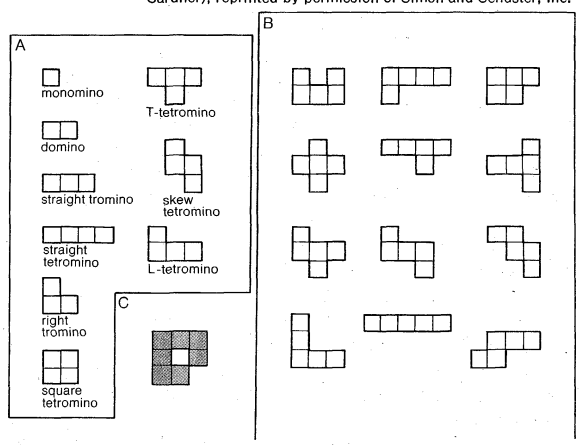

Figure 14: *Shapes made of squares.* (A) Monomino and simple polyominoes. (B) Pentominoes. (C) Heptomino with interior "hole."

The number of distinct polyominoes of any order is a function of the number of squares in each, but, as yet, no general formula has been found. It has been shown that there are 35 types of hexominoes, and 108 types of hep-

tominoes, if the dubious heptomino with an interior "hole" is included.

Recreations with polyominoes include a wide variety of problems in combinatorial geometry, such as forming desired shapes and specified designs; covering a chessboard with polyominoes in accordance with proscribed conditions; etc. Two illustrations may suffice.

The 35 hexominoes, having a total area of 210 squares, would seem to admit of arrangement into a rectangle 3×70, 5×42, 6×35, 7×30, 10×21, or 14×15; however, no such rectangle can be formed.

Another interesting problem is found in the question: Can the 12 pentominoes, together with one square tetromino, form an 8×8 checkerboard? A solution of the problem was shown around 1935. It is not known how many solutions there are, but it has been estimated to be at least 1,000. In 1958, by use of a computer, it was shown that there were 65 solutions in which the square tetromino is exactly in the centre of the checkerboard.

Soma Cubes. These were created by Piet Hein of Denmark, also known for his invention of the mathematical games known as Hex and Tac Tix. Hein stumbled upon the fact that all the irregular shapes that can be formed by combining no more than four congruent cubes joined at their faces can be put together to form a larger cube. There are exactly seven such shapes, as shown in Figure 15. No two shapes are alike, although the last two are mirror images of each other. The fact that these seven pieces (comprising 27 "unit" cubes) can be reassembled to form one large cube is indeed remarkable.

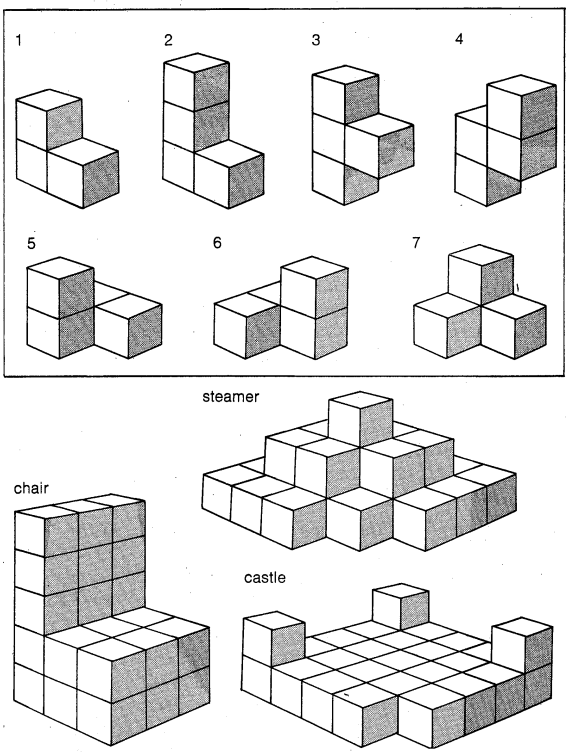

Figure 15: *Soma Cubes.*
(Top) The seven basic pieces. (Bottom) Examples of some of the shapes that can be built from Soma pieces.

Many interesting solid shapes can be formed from the seven Soma Cubes, shapes resembling, for example, a sofa, a chair, a castle, a tunnel, a pyramid, and so on. Even the reassembling of the seven basic pieces into a large cube admits of more than 230 essentially different solutions.

As a recreation, the Soma Cubes are fascinating. With experience, people often find that they can solve Soma problems mentally. Psychologists who have used them find that the ability to solve Soma problems is roughly correlated with general intelligence, although there are some strange anomalies at both ends of the distribution of intelligence. In any event, people playing with the cubes do not appear to want to stop; the variety of interesting structures possible seems endless.

Coloured squares and cubes. There is a wide variety of puzzles involving coloured square tiles and coloured cubes. In one, the object is to arrange the 24 three-colour patterns, including repetitions, that can be obtained by subdividing square tiles diagonally, using three different colours, into a 4×6 rectangle so that each pair of touching edges is the same colour and the entire border of the rectangle is the same colour.

More widely known perhaps is the 30 Coloured Cubes Puzzle. If six colours are used to paint the faces there result 2,226 different combinations. If from this total only those cubes that bear all six colours on their faces are selected, a set of 30 different cubes is obtained; two cubes are regarded as "different" if they cannot be placed side by side so that all corresponding faces match. Many fascinating puzzles arise from these coloured squares and cubes; many more could be devised. Some of them have appeared commercially at various times under different names, such as the Mayblox Puzzle, the Tantalizer, and the Katzenjammer. Stimulating discussions may be found in British combinatorial analysis authority Maj. P.A. MacMahon's original monograph *New Mathematical Pastimes* (1921); in F. Winter's *Spiel der 30 Bunten Würfel* (1934), and in T.H. O'Beirne's *Puzzles and Paradoxes* (1965), pp. 112–129.

A revival of interest in coloured-cube problems has been aroused by the appearance of a puzzle currently known as Instant Insanity consisting of four multicoloured unit cubes, each of which has its faces painted white, red, green, and blue, in a definite scheme. The puzzle is to assemble the cubes into a $1 \times 1 \times 4$ prism such that all four colours appear on each of the four long faces of the prism. Since each cube admits of 24 different orientations, there are 82,944 possible prismatic arrangements; of these only two are the required solutions.

Nim; Wythoff's Game; Tac Tix. A game so old that its origin is obscure, Nim lends itself nicely to mathematical analysis. In its generalized form, any number of objects (counters) are divided arbitrarily into several piles. Two people play alternately; each, in turn, selects any one of the piles and removes from it all the objects, or as many as he chooses, but at least one object. The player removing the last object wins. Every combination of the objects may be considered "safe" or "unsafe"; *i.e.*, if the position left by a player after his move assures a win for that player, the position is called safe. Every unsafe position can be made safe by an appropriate move, but every safe position is made unsafe by any move. To determine whether a position is safe or unsafe, the number of objects in each pile may be expressed in binary notation. If each column adds up to zero or an even number, the position is safe. For example, if at some stage of the game, the number of objects in each pile respectively is 4, 9, 15, in binary notation:

"Safe" and "unsafe" positions

$$\begin{array}{rr} 4 \rightarrow & 1\ 0\ 0 \\ 9 \rightarrow & 1\ 0\ 0\ 1 \\ 15 \rightarrow & 1\ 1\ 1\ 1 \\ \hline & 2\ 2\ 1\ 2 \end{array}$$

Since the second column from the right adds up to 1, an odd number, the given combination is unsafe. A skillful player will always move so that every unsafe position left to him is changed to a safe position.

A similar game is played with just two piles; in each draw the player may take objects from either pile or from both piles, but in the latter event he must take the same number from each pile. The player taking the last counter is the winner.

Games such as Nim make considerable demands upon the player's ability to "translate" decimal numbers into binary numbers and vice versa. Since digital computers operate on the binary system, however, it is possible to program a computer (or build a special machine) that will play a "perfect" game. This was done by E.U. Condon and an associate in 1940 in the invention of the

automatic Nimatron that was exhibited at the New York World's Fair. In still another version, developed by Piet Hein, the objects are arranged in a square formation.

Games of this sort seem to be widely played the world over. The game of Pebbles, also known as the game of Odds, is played by two people who start with an odd number of pebbles placed in a pile. Taking turns, each player draws one, or two, or three pebbles from the pile. When all the pebbles have been drawn, the player who has an odd number of them in his possession wins.

Predecessors of these games in which players distribute pebbles, seeds, or other counters into rows of holes under varying rules have been played for centuries in Africa and Asia. These games, known as Mancala games, are covered in the article BOARD AND TILE GAMES.

PROBLEMS OF LOGICAL INFERENCE

Logical puzzles. Under this heading are included challenging questions that, in general, do not involve numerical or geometrical considerations but call for deductive inferences based chiefly on logical relationships. Such puzzles are not to be confounded with riddles, which frequently rely upon deliberately misleading or ambiguous statements, a play on words, or some other device intended to "catch" the unwary. Logical puzzles do not admit of a standard procedure or generalized pattern for their solution and are usually solved by some trial and error method. This is not to say that the guessing is haphazard; on the contrary, the given facts (generally minimal) suggest several hypotheses, some of which may need to be rejected if found inconsistent, until, by substitution and elimination, the solution is finally reached. The use of various techniques of logic may sometimes prove helpful, but in the last analysis, success depends largely upon that elusive capacity called ingenuity. For convenience, logic problems are arbitrarily grouped in the following categories.

Solution of logical problems

The brakeman, the fireman, and the engineer. This puzzle, which dates back to at least the early 1920s, is used as a prototype for the first category of logic problems. In the intervening years it has become quite popular, the more recent versions being considerably more complicated. Three railway employees named Smith, Robinson, and Jones, are brakeman, fireman, and engineer, but not respectively, who live in the state of New York. Three businessmen, similarly named, also live in the state. The businessman Robinson and the brakeman live in Albany, the businessman Jones and the fireman live in Rochester, while the businessman Smith and the engineer live halfway between these two cities. The brakeman's namesake earns $3,500 a year; the engineer earns one-third as much as the businessman living nearest him. The railway man Smith beats the fireman at billiards. What is the engineer's name?

Overlapping groups. This crude designation suggests problems of the following sort. Among the members of a high-school language club, 31 were studying French; 26 were studying French and Spanish; 23, German; 36, Spanish; 11, French and German; 28, German and Spanish; two, French, German, and Spanish. How many members are there in the club, and how many are studying exactly two languages?

Truths and lies. Another favourite kind of logical inference puzzle concerns truths and lies. One variety is as follows: Some of the natives of a certain South Pacific island are pure-blooded and the rest are half-breeds, but they all look alike. The pure-blooded always tell the truth, but the half-breeds always lie. A visitor to the island, meeting three natives, asks them whether they are full-blooded or half-breeds. The first native mutters something inaudible. The second, pointing to the first, says, "He says that he is pure-blooded." The third, pointing to the second, says, "He lies." Knowing beforehand that only one of the natives is a half-breed, the visitor concludes what each of the three is.

In a slightly different type, four men, one of whom was known to have committed a certain crime, made the following statements when questioned by the police:

Archie: Dave did it.
Dave: Tony did it.
Gus: I didn't do it.
Tony: Dave lied when he said I did it.

If only one of these four statements is true, who was the guilty man? On the other hand, if only one of these four statements is false, who was the guilty man? (From 101 *Puzzles in Thought and Logic* by C.R. Wylie, Jr.; Dover Publications, Inc., New York, 1957. Reprinted through the permission of the publisher.)

Difficult crossings. These, as mentioned under *History* above, also are known as ferrying problems. Perhaps one of the oldest is that of the jealous husbands, one version of which was given about 1612 as follows: Three couples wish to cross a river, in a boat that will hold only two persons, in such a way as never to leave a woman in the company of a man unless her husband also is present. The original solution required 11 crossings. With two married couples, five passages are required. With four married couples, the problem has no solution. On the other hand, if the boat holds three persons, the problem can be solved for four couples. The use of graphs (networks) can facilitate the solution of such problems.

The problem of the jealous husbands

Many similar problems appeared in the writings of medieval mathematicians. Alcuin (*c.* 732–804), for example, gives the problem of a man and a wife and two children with a boat that can hold the man *or* his wife *or* the children. Alcuin also gives the problem of the man crossing a stream with a wolf, a goat, and a bundle of cabbages, the boat being so small that he can take only one of them at a time; he cannot leave the wolf alone with the goat nor the goat alone with the cabbages. A slightly different version is that of the man with a fox, a goose, and some corn who must cross a river and can take only one at a time. He cannot leave the goose with the corn to take the fox over and he cannot leave the fox alone with the goose. He can do it in six crossings, on two of which he will be empty-handed. Some wag has suggested that if the goose accompanies him each time—swimming beside the boat—only three crossings will be needed.

Logical paradoxes. Highly amusing and often tantalizing, logical paradoxes generally lead to searching discussions of the foundations of mathematics. As early as the 6th century BC, the Cretan prophet Epimenides allegedly observed that "All Cretans are liars," which, in effect, means that "All statements made by Cretans are false." Since Epimenides was a Cretan, the statement made by him is false, so that all statements made by Cretans are *not* false. Thus the initial statement is self-contradictory. A similar dilemma was given by an English mathematician, P.E.B. Jourdain, in 1913, when he proposed the card paradox. This was a card on one side of which was printed:

"The sentence on the other side of this card is TRUE."

On the other side of the card the sentence read:

"The sentence on the other side of this card is FALSE."

The barber paradox, offered by Bertrand Russell, was of the same sort: The only barber in the village declared that he shaved everyone in the village who did not shave himself. On the face of it, this is a perfectly innocent remark until it is asked "Who shaves the barber?" If he does not shave himself, then he is one of those in the village who does not shave himself and so is shaved by the barber, namely, himself. If he shaves himself, he is, of course, one of the people in the village who is not shaved by the barber. The self-contradiction lies in the fact that a statement is made about "all" the members of a certain class, when the statement or the object to which the statement refers is itself a member of the class. In short, the Russell paradox hinges on the distinction between those classes that are members of themselves and those that are not members of themselves. Russell attempted to resolve the paradox of the class of all classes by introducing the concept of a hierarchy of logical types but without much success. Indeed, the entire problem lies close to the philosophical foundations of mathematics.

The barber paradox

Miscellaneous problems. A considerable number of problem types do not lend themselves to ready classification. Some of them involve numerical considerations; all of them require some "inventive" use of logical faculty. Thus the classic problem of determining the least number of weights that would make possible the weighing of any number of pounds from one to 40 inclusive was first discussed by a mathematician who gave two solutions: (1) the series of weights 1, 2, 4, 8, 16, 32, and (2) the series 1, 3, 9, 27, depending on whether the weights may be placed only in one scalepan or in either scalepan. The problem was generalized in 1886, when it was shown that when any weight may be placed in either scalepan, and it is required (a) that no other weighings are possible and (b) that each weighing is to be possible in only one way, then there are eight possible sets of weights with which any number of pounds (one to 40 inclusive) may be accomplished. In seven of these solutions, some of the weights are equal (*e.g.*, 1, 3, 9, 9, 9, 9), but an earlier solution (1, 3, 9, 27) is one of the eight possible solutions, and is not only the one with the least number of weights but also the only one in which all the weights are different.

Weighing problems

Another type of recreation consists of detecting a false coin in a collection of otherwise identical coins by repeated weighings on a balance, with or without weights. The classic problem is a twelve-coin problem, which permits three weighings for 12 coins, where the false coin may be overweight or deficient in weight. The problem dates from about 1945; since then, various versions have become more sophisticated, and an extensive literature has been accumulated.

So-called decanting problems, or problems of partitioning liquids in vessels of specified capacity, made their appearance in 1484; they are still hardy perennials among mathematical recreations. In one version it is required to pour four quarts of wine from a full jug with a capacity of eight quarts, using only two empty jugs of five and three quarts capacity, respectively. Another is to partition 24 quarts into three equal parts, using only vessels with capacities of 5, 11, 13, and 24 quarts respectively. One solution of the first problem is as follows: Starting with the eight-quart jug full and the five-quart and three-quart jugs empty (8, 0, 0), the five-quart jug is filled from the eight-quart jug, leaving in it three quarts and leaving the three-quart jug still empty (3, 5, 0). Then the three-quart jug is filled from the five-quart jug giving 3, 2, 3; the three-quart jug is emptied into the eight-quart jug giving 6, 2, 0; and the two quarts in the five-quart jug are poured into the three-quart jug for 6, 0, 2. Next the five-quart jug is filled from the six quarts in the eight-quart jug giving 1, 5, 2; one quart from the five-quart jug is added to the two already in the three-quart jug giving 1, 4, 3; and, finally, the contents of the three-quart jug are added to the one quart in the eight-quart jug to solve the problem, 4, 4, 0.

Decanting problems

Other miscellaneous recreations involving imagination, visualization, or intuition more than mathematical ideas might include the jar of bacteria, the converging cyclists and the three smudged foreheads. In the first of these, a jar contains a single bacterium, which reproduces by simple division to produce two offspring every minute, at which rate it will fill the jar in exactly one hour. How full will the jar be after 59 minutes?

In the second instance, two cyclists are pedalling toward each other along a straight road at the rate of 12 miles an hour. When they are six miles apart, a dragonfly alights on one bicycle and forthwith flies toward the other, shuttling back and forth at the rate of 20 miles an hour until the two cyclists meet. How far did the dragonfly travel during that time?

The problem of the smudged faces is once more an instance of pure logical deduction. Three travellers were aboard a train that had just emerged from a tunnel, leaving a smudge of soot on the forehead of each. While they were laughing at each other, and before they could look into a mirror, a neighbouring passenger suggested that although no one of the three knew whether he himself was smudged, there was a way of finding out without using a mirror. He suggested: "Each of the three of you look at the other two; if you see at least one whose forehead is smudged, raise your hand." Each raised his hand at once. "Now," said the neighbour, "as soon as one of you knows for sure whether his own forehead is smudged or not, he should drop his hand, but not before." After a moment or two, one of the men dropped his hand with a smile of satisfaction, saying: "I know." How did that man know that his forehead was smudged?

A final example might be the paradox of the unexpected hanging, a remarkable puzzle which first became known by word of mouth in the early 1940s. One form of the paradox is the following: A prisoner has been sentenced on Saturday. The judge announces that "the hanging will take place at noon on one of the seven days of next week, but you will not know which day it is until you are told on the morning of the day of the hanging." The prisoner, on mulling this over, decided that the judge's sentence could not possibly be carried out. "For example," said he, "I can't be hanged next Saturday, the last day of the week, because on Friday afternoon I'd still be alive and I'd know for sure that I'd be hanged on Saturday. But I'd know this *before* I was told about it on Saturday morning, and this would contradict the judge's statement." In the same way, he argued, they could not hang him on Friday, or Thursday, or Wednesday, Tuesday, or Monday. "And they can't hang me tomorrow," thought the prisoner, "because I know it today!"

The paradox of the unexpected hanging

Careful analysis reveals that this argument is false, and that the decree can be carried out. The paradox is a subtle one. The crucial point is that a statement about a future event can be known to be a true prediction by one person but not known to be true by another person until *after* the event has taken place.

A rather different sort of a paradox is illustrated by the embarrassment of the executioner who is to do away with the prisoner. The condemned man is permitted to make one last statement before he is executed: if that statement is false, he is to be hanged; if it is true, he is to be beheaded. After a moment's thought, the prisoner makes a statement, whereupon the embarrassed executioner does nothing. What did the condemned man say?

Number Theory

Number theory is a branch of mathematics concerned with the properties of integers, or whole numbers, such as 0, ± 1, ± 2, $\cdots$. These properties have been the object of fascination and investigation for thousands of years; interest in the natural numbers is as old as civilization itself. In this article some of the more elementary notions and examples are given first, the more sophisticated ideas following.

This article is divided into the following sections:

Elementary and algebraic number theory

ELEMENTARY THEORY OF NUMBERS

Divisibility and prime numbers. An integer a is said to be divisible by another integer b, not 0, if there is a third integer c such that $a = bc$. Thus 6 is divisible by 3 since the integer 2 exists for which $6 = 2 \cdot 3$. If this is the case, b is said to be a divisor or factor of a, and the fact is expressed by the notation $b|a$. If a and b are two integers, not both zero, the notation (a, b) is used for the greatest integer d that is a factor of both a and b. The integer d is known as the greatest common divisor of a and b. It was known to the 4th-century-BC Greek mathematician Euclid that integers x and y exist with the property that $ax + by = d$, d being the greatest common divisor of a and b.

Definition of prime

An integer p that is greater than 1, but has no positive divisors other than 1 and p, is said to be prime. Thus the first few prime numbers are 2, 3, 5, 7, 11, 13, 17, $\cdots$. An integer greater than one that is not prime is called composite. A fundamental theorem of arithmetic states that every integer greater than one may be written as a product of primes in a unique way (apart from rearrangements of the factors). Thus $666 = 2 \cdot 3 \cdot 3 \cdot 37$ but has no different expression as a product of primes except for the order of the factors. This result is a simple consequence of another of Euclid's theorems: if a prime p divides ab, then either p/a or p/b can itself be deduced from the theorem of Euclid mentioned above.

Euclid also knew that there are infinitely many prime numbers, and his proof is much quoted as an example of mathematical reasoning and an example of mathematical beauty revealed in elegance and simplicity. It runs as follows: If it be supposed, on the contrary, that there is only a finite number of primes and they are denoted by $p_1, p_2, \cdots, p_n$, then the number N that is a product of primes plus 1 (see Box, equation 1) is not divisible by any p_i (for which the subscript i is a number between 1 and n, possibly including 1 and n) and so must be divisible by a prime other than these (which may of course be N itself). This contradicts the hypothesis that there are no other primes.

The sieve of Eratosthenes. The first problem after the proof that infinitely many primes exist is that of finding some way of exhibiting all primes up to any given number n.

About 250 BC, a contemporary of the Greek mathematician Archimedes named Eratosthenes of Cyrene proposed the following procedure, which is now called the sieve of Eratosthenes. If it is required to find all primes less than 200, all the numbers up to 200 are written down (see 2). Every second integer after 2 is not a prime, every third after 3 is not, every fifth after 5 is not a prime, and so forth; these are struck out (see 3). The striking out of every 2nd, 3rd, and 5th has been illustrated. On the face of it, this seems like a laborious task, but in fact, this sieving is surprisingly efficient. It is efficient because it is only necessary to sieve by primes 2, 3, 5, 7, 11, 13, because 13 is the largest integer that is less than or equal to the square root of the number 200. The reason for this is that in general any integer n which is not a prime must have a prime factor $\leq \sqrt{n}$.

This simple principle has been refined, modified, and generalized into an extremely powerful tool in the theory of numbers.

(1) $N = p_1 p_2 \cdots p_r + 1$

(2) 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, $\cdots$, 197, 198, 199, 200

(3) 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, $\cdots$, 196, 197, 198, 199, 200

(4) $F_n = 2^{2^n} + 1$

(5) $\begin{cases} F_0 = 3, & F_1 = 5, & F_2 = 17, & F_3 = 257 \\ F_4 = 65{,}537 \end{cases}$

(6) $M_p = 2^p - 1$

(7) $\begin{cases} 6 = 1 + 2 + 3 \\ 28 = 1 + 2 + 4 + 7 + 14 \end{cases}$

(8) $2^{p-1}(2^p - 1)$

Fermat and Mersenne primes. The Fermat numbers F_n, for non-negative integer n, are defined by taking the 2^nth power of 2 and adding the number 1 (see 4). In 1640 a French mathematician, Pierre de Fermat, noted that the first five such numbers were all prime (see 5) and he was led to conjecture that F_n was prime for all n.

The 18th-century Swiss mathematician Leonhard Euler was able to show, however, that F_5 is composite. F_n is now known to be composite for all values of n from 5 to 16 and for several higher values. No further Fermat prime beyond F_4 has been discovered, and it is now thought that the total number of such primes is finite. The Fermat primes have an interesting connection with the classical problem of constructing a regular polygon by Euclidean methods (*i.e.*, by the use of straightedge and compass). The ancients knew that regular polygons of $2^k m$ sides could be constructed by such methods when $m = 3$ or 5. In 1796 the German mathematician Carl Friedrich Gauss proved—at the age of 18—that such constructions were possible if and only if m is a product of distinct Fermat primes.

The Mersenne numbers M_p are constructed from a prime p by taking the pth power of 2 and subtracting the number 1 (see 6). The French mathematician Marin Mersenne gave in 1644 a list of primes p for which he conjectured M_p was prime. Several mistakes have been found in this conjecture, though it was not until 1886 that the first error was discovered. A few very large primes of this form are known. In particular, in 1963, it was shown that $M_{11,213}$ is prime. Mersenne primes also have a connection with the ancient problem of perfect numbers. A number is said to be perfect if it is equal to the sum of its positive factors other than itself; examples are easily constructed (see 7). It was known to Euclid that if a number now called Mersenne is a prime then a certain power of two times this number is perfect (see 8). Euler showed that all even perfect numbers are of this type. Whether there exist any odd perfect numbers remains an unsolved problem.

Bernoulli numbers. The Swiss mathematician Jakob I Bernoulli introduced, in his *Ars conjectandi* (1713; "The Conjectural Arts"), an important sequence of numbers known as Bernoulli numbers. The nth Bernoulli number is denoted by the symbol B_n and the first few numbers

are simply expressed (see 9). The numbers of odd orders, other than B_1, are zero. The numbers of even order, other than B_0, alternate in sign.

One definition of Bernoulli numbers is a symbolic one (see 10), in which after expansion of the nth power of the sum $(B + 1)$, powers of B are degraded into subscripts. Thus B_3 is obtained by expanding a 4th power (see 11). In this way B_3 is obtained in terms of Bernoulli numbers of lower order. This is only one example of a host of recursion formulas for generating these numbers.

Historically the first definition of Bernoulli numbers was that given by Bernoulli himself. Bernoulli's approach was to re-express the sum of a common power of a finite number of successive integers as a linear combination of successive powers of a common integer. Terms in the re-expression provided the Bernoulli numbers as coefficients (see 12). Another definition of B_n, given in terms of an explicit formula, was due to Euler, who made a striking independent discovery of the numbers in 1748 (see 13).

The Bernoulli numbers have several applications in number theory—in particular in work on Fermat's last theorem. Perhaps the most famous property of B_n is expressed in the Von-Staudt-Clausen theorem (see 14) that expresses the $2n$th Bernoulli number as the difference between an integer and the sum of reciprocals of primes that exceed by 1 as divisor of $2n$. The 12th Bernoulli number provides an example (see 15).

Fermat's last theorem. Fermat's last theorem, an example of an unsolved theorem in number theory, concerns the equation (see 16) for which x, y, z, and n are nonzero integers. This is an example of a Diophantine equation (named after Diophantus of Alexandria, who lived about AD 250)—an equation the solutions of which are required to be integers.

The above equation can be solved when $n = 2$; for example, it is satisfied by the integers 3, 4, and 5 because $3^2 + 4^2 = 5^2$. Fermat's theorem states that if n is an integer greater than 2, there is no solution for this equation in nonzero integers. He wrote (*c.* 1637)—on the margin of his copy of the works of Diophantus—"I have discovered a truly remarkable proof which this margin is too small to contain." Although he proved it for $n = 4$, the general proof remains undiscovered. Leonhard Euler produced an incomplete proof for $n = 3$ in 1770, the missing steps being filled in by later mathematicians.

Attempts to prove Fermat's last theorem

To prove the theorem in general, it is sufficient to demonstrate the impossibility of a similar equation in which the common power is any odd prime greater than 3 (see 17). In 1823 Adrien-Marie Legendre of France showed that this was the case when the power is 5, and a countryman of his, Gabriel Lamé, in 1839 proved it for a power of 7. Many efforts were made to extend proofs to other powers, and in 1850 Ernst Eduard Kummer of Germany showed that the equation $x^p + y^p = z^p$ cannot be solved for positive integers x, y, and z if p is a prime that does not divide the numerators of $B_2, B_4, \cdots, B_{p-3}$, these being Bernoulli numbers. The criteria developed by Kummer have been used with a digital computer to show that Fermat's last theorem is true for all exponents less than 25,000.

The theorem has been attacked by many mathematicians and has acquired a unique reputation because of the great difficulties it presents. Some mathematicians think that Fermat's statement was incorrect, though it may be that the theorem will never be proved or disproved.

Residue classes and congruence. If m denotes a given positive integer, every integer a can be written uniquely in the form (see 18) in which q, an integer, denotes the quotient of a on division by m, and r, the remainder, takes one of the m values $0, 1, 2, \cdots, m - 1$. If two integers a and b have the same remainder on division by m, they are said to be congruent modulo m, written $a \equiv b \bmod m$. This is equivalent to the assertion $m|(a - b)$. The set of integers congruent to a given integer modulo m is called a residue class. Clearly there are m such residue classes.

Euler introduced the symbol $\varphi(m)$ to denote that number of positive integers a not exceeding m that are such that $(a, m) = 1$; if $(a, m) = 1$, a and m are said to be relatively prime. It is possible to prove that if $(m, n) = 1$, $\varphi(mn) = \varphi(m)\varphi(n)$; and that if p is a prime, $\varphi(p^r) = p^{r-1}(p - 1)$. These facts enable the calculation of $\varphi(m)$ for any given m. If $a \equiv b \bmod m$, $(a, m) = (b, m)$. In particular, an obvious meaning may now be attached to the term residue class modulo m, relatively prime to m. There are $\varphi(m)$ such residue classes.

Euler's theorem states that if $(a, m) = 1$, then $a^{\varphi(m)} \equiv 1 \pmod m$. This generalized a theorem of Fermat, who found that if p is prime and does not divide a then $a^{p-1} \equiv 1 \pmod p$.

$$(9)\quad \begin{cases} B_0 = 1, & B_1 = -\frac{1}{2}, & B_2 = \frac{1}{6} \\ B_3 = 0, & B_4 = -\frac{1}{30}, & B_5 = 0, \quad B_6 = \frac{1}{42} \\ B_7 = 0, & B_8 = -\frac{1}{30}, & B_9 = 0, \quad B_{10} = \frac{5}{66} \end{cases}$$

$$(10)\quad B_n = (B + 1)^n$$

$$(11)\quad (B + 1)^4 = B_4 + 4B_3 + 6B_2 + 4B_1 + B_0$$

$$(12)\quad \begin{cases} 1^k + 2^k + 3^k + \cdots + (N-1)^k = \\ \qquad \frac{1}{k+1}\left\{B_0 N^{k+1} + B_1\binom{k+1}{1}N^k + \cdots + \right. \\ \qquad \left. + B_k\binom{k+1}{k}N\right\} \\ \text{in which } \binom{n}{m} = \dfrac{n!}{m!(n-m)!} \end{cases}$$

$$(13)\quad B_{2n} = \frac{2(-1)^{n-1}(2n)!}{(2\pi)^{2n}}\left(1 + \frac{1}{2^{2n}} + \frac{1}{3^{2n}} + \frac{1}{4^{2n}} + \cdots\right)$$

$$(14)\quad B_{2n} = A_n - \frac{1}{p_1} - \frac{1}{p_2} - \cdots - \frac{1}{p_k}$$

$$(15)\quad B_{12} = -\frac{691}{2730} = 1 - \frac{1}{2} - \frac{1}{3} - \frac{1}{5} - \frac{1}{7} - \frac{1}{13}$$

$$(16)\quad x^n + y^n = z^n$$

$$(17)\quad x^l + y^l + z^l = 0$$

$$(18)\quad a = qm + r$$

$$(19)\quad \{1, a, a^2, \cdots, a^{\varphi(m)-1}\}$$

It may happen that for a given number m there exists a number a with the property that the set of certain powers of number a (see 19) contains precisely one number from each of the $\varphi(m)$ relatively prime residue classes modulo m. In such a case a is said to be a primitive root modulo m. Gauss showed that primitive roots exist when (and only when) m is 2, 4, p^k, or $2p^k$ for some odd prime p.

Three further theorems concerning congruences may be mentioned: (1) The Chinese remainder theorem, so called from its being known to the Chinese in the 1st century AD: If $m_1, \cdots, m_k$ are k positive integers, each pair of which are relatively prime, and if $r_1, r_2, \cdots, r_k$ are any k integers, then there exists an integer x satisfying the k congruences: $x \equiv r \pmod{m_1}, \cdots, x \equiv r_k \pmod{m_k}$. Moreover, any two such integers x are congruent modulo $m_1 \cdots m_k$. (2) Lagrange's theorem, named after the 18th-century French mathematician Joseph-Louis Lagrange: If p is a prime and $f(x)$ a polynomial of degree n with integer coefficients, then the congruence $f(x) \equiv 0 \bmod p$ is satisfied by at most n incongruent integers x. (3) Wilson's theorem, named after the 18th-century English mathematician John Wilson: If p is a prime, then $1 \cdot 2 \cdot 4 \cdots (p - 1) \equiv -1 \pmod p$.

Quadratic residues. If m is a positive integer, then an integer a that is relatively prime to m is said to be a quadratic residue of m if there exists an integer x satisfying $x^2 \equiv a \pmod{m}$. The most interesting case is when m is an odd prime p. In this situation $(p-1)/2$ of the positive integers not exceeding $p-1$ are quadratic residues of p and the remaining $(p-1)/2$ are not (they are known as quadratic non-residues). Numerous interesting results about quadratic residues are known; for example, -1 is a quadratic residue of an odd prime p if, and only if, $p \equiv 1 \bmod 4$; if $p \equiv 3 \bmod 4$, there are more quadratic residues in the first half of the interval from 1 to $p-1$ than in the second. The most striking and important of such theorems, however, is the law of quadratic reciprocity, which was first proved by Gauss, although its truth had been conjectured both by Euler and Legendre. It may be stated simply as follows: if p and q are different odd primes, then p is a quadratic residue of q if, and only if, q is a quadratic residue of p, unless both p and q are congruent to 3 modulo 4, in which case p is a quadratic residue of q if, and only if, q is a quadratic non-residue of p. A more succinct statement of this important law may be obtained by employing Legendre's symbol $(a|p)$, which is defined to equal 1 if a is a quadratic residue of p, -1 if a is not a quadratic residue, and 0 if $p|a$ (see 20).

$$(20)\qquad (p|q)(q|p) = (-1)^{\frac{1}{2}(p-1)\frac{1}{2}(q-1)}$$

$$(21)\qquad b_0 + \cfrac{a_1}{b_1 + \cfrac{a_2}{b_2 + \cfrac{a_3}{b_3 + \ddots}}}$$

$$(22)\qquad \frac{A_0}{B_0} = \frac{b_0}{1}, \quad \frac{A_1}{B_1} = \frac{b_0 b_1 + a_1}{b_1}, \quad \frac{A_2}{B_2} = \frac{b_0 b_1 b_2 + a_1 b_2 + a_2 b_0}{b_1 b_2 + a_2}, \quad \cdots$$

$$(23)\qquad \xi = [\xi] + \cfrac{1}{[\xi_1] + \cfrac{1}{[\xi_2] + \cdots}}$$

Continued fractions. A continued fraction is an expression of a form composed of a number plus a fraction in which the denominator of the fraction is again a number plus a fraction (see 21), which may or may not terminate. If it does terminate, it has an obvious meaning. If not, and the sequence (see 22), obtained by cutting off the continued fraction at successive stages, converges to a limit V, the continued fraction is said to converge, and to have the value V. (Plainly, for this to happen, B_n must be non-zero for sufficiently large n.)

Convergent fractions

The continued fraction is said to be simple if each $a_i = 1$ and each b_i $(i > 0)$ is a positive integer (b_0 is allowed to be an integer).

A simple continued fraction is always convergent. Every real number has an expansion as a simple continued fraction. To obtain the continued fraction expansion of a real number, symbolized by the Greek letter xi, ξ, it is necessary to write $[\xi] + \theta_1$, in which $[\xi]$ denotes the greatest integer not exceeding ξ, and $0 \leq \xi_1 < 1$. If $\theta_1 = 0$, the process terminates. Otherwise the proof continues with $\xi_1 = 1/\theta_1$ and then $\xi_1 = [\xi]_1 + \theta_2$ with $0 \leq \theta_2 < 1$. If $\theta_2 = 0$, the process terminates. If not, $\xi_2 = 1/\theta_2$ and the process goes on as before. In this way an expansion for ξ (see 23) is obtained. It may be shown that the expansion terminates if, and only if, ξ is rational, and otherwise it is periodic if, and only if, ξ is a quadratic surd. (Ed.)

ALGEBRAIC NUMBER THEORY

Whereas ordinary number theory is the study of the integers, $0, \pm 1, \pm 2, \cdots$, in algebraic number theory larger collections of numbers are studied. A number is algebraic if it is a root of a polynomial equation with integral coefficients; if the highest power of the variables has coefficient 1, the number is called an algebraic integer. For instance, $\sqrt{2}$ is an algebraic integer because it satisfies the equation $x^2 - 2 = 0$; so is $1 + \sqrt{3}$ in view of the equation $x^2 - 2x - 2 = 0$, which it satisfies; and the five roots of $x^5 - x + 2 = 0$ are all algebraic integers, although it is not possible to exhibit a simple formula for them.

Since about 1830, when the formal study of algebraic numbers began, evidence has multiplied that algebraic number theory is the best road to take in the search for a better understanding of ordinary numbers and a deeper insight into the mysteries they hold. In addition, it has been applied to nearly every other branch of mathematics.

Early history. For brevity certain standard symbols are used in this article, beginning with Z, the symbol for the set of ordinary integers $0, \pm 1, \pm 2, \cdots$. Such integers belong to this set and are said to lie in Z.

The simplest system of algebraic numbers going beyond this set is the set of all numbers of the form $a + ib$, in which a and b are in Z (*i.e.*, they are integers) and i is the square root of -1. These complex numbers are added and multiplied in the natural way, subject to the rule that $i^2 = -1$. For instance, $(2 + 3i) + (4 - 7i) = 6 - 4i$, and $(2 + 3i)(4 - 7i) = 8 - 14i + 12i - 21i^2 = 29 - 2i$. These numbers, first studied in depth in 1828 by Gauss, are called the Gaussian integers in his honour. The symbol $\mathfrak{G}$ is used for the set of Gaussian integers.

Gaussian integers

An illustration of the power of algebraic number theory lies in the proof that the equation $x^2 + 1 = y^3$ has in Z only the solution $x = 0$, $y = 1$. In other words, the only integers satisfying the equation are these values. This assertion was made by Euler in 1738 after he sketched a proof of a similar theorem. The first complete proof was given in 1875 by Pepin.

In the proof facts about $\mathfrak{G}$ are used to obtain information about Z, and the vital tool required for the proof is that in $\mathfrak{G}$, as in Z, numbers can be uniquely expressed as a product of primes. (Primes in $\mathfrak{G}$ may be defined in a similar way to primes in Z.) While this is true in $\mathfrak{G}$, it must be accompanied by a precaution concerning units (numbers that divide 1). In Z the only units are 1 and -1, and the ambiguity introduced is easily avoided by confining attention to positive numbers. On the other hand, in $\mathfrak{G}$, there are four units, ± 1 and $\pm i$, and it is necessary to accept the complication that primes of $\mathfrak{G}$ come in indistinguishable quadruplets. These primes are readily catalogued by observing the factors, lying in $\mathfrak{G}$, of primes in Z. Number 2, for example, becomes $i(1-i)^2$, with $1 - i$ a prime.

If n is an integer, $1, 2, 3, \cdots$, then primes of Z that can be expressed in the form $(4n - 1)$, such as $3, 7, 11, \cdots$, remain prime in $\mathfrak{G}$. Primes in Z of the form $(4n + 1)$, such as $5, 13, 17, \cdots$, have factors in $\mathfrak{G}$ that are two primes. Thus $5 = (2 + i)(2 - i)$, etc.

In this way a neat proof may be obtained of the theorem that any prime in Z of the form $4n + 1$ is uniquely expressible as a sum of two squares. This was stated by Fermat and proved by Euler.

The equation $x^2 + 1 = y^3$ has the form $(x + i)(x - i) = y^3$. It is first necessary to dispose of the possibility that $x + i$ and $x - i$ have a common factor. If this were the case, the common factor would divide their difference, $2i$, and it would follow that y is even and x is odd. This is quite impossible because $x^2 + 1$ would then be twice an odd number, whereas y^3 would be divisible by 8.

Unique factorization then yields the result that $x + i$ is a cube in $\mathfrak{G}$ (there is fortunately no difficulty with

units, because the equation $i = (-i)^3$ shows that all units in $\mathfrak{G}$ are cubes). If $x + i = (a + bi)^3$, then the equations $x = a^3 - 3ab^2$ and $1 = b(3a^2 - b^2)$ follow. Thus $b = \pm 1$, $1 = \pm(3a^2 - 1)$, $3a^2 = 0$ or 2, $a = 0$, $x = 0$. A similar method will show that $x^2 + 2 = y^3$ has in Z only the solutions $x = \pm 5$, $y = 3$; this is historically interesting as one of a number of statements made without proof by Fermat; it was not until 1875 that a complete proof was given, again by Pepin. For this problem unique factorization for numbers of the form $a + b\sqrt{-2}$ is required.

The first substantial study of algebraic number theory was made by Gauss in the memoir of 1828 mentioned above. In it he used $\mathfrak{G}$, the Gaussian integers, to break into new territory in the study of biquadratic (fourth power) residues in Z. For instance, it may be asked when the integer 2 is a biquadratic residue of a prime p, this meaning that there exists x with $x^4 - 2$ divisible by p. The question is not interesting if p has the form $4n - 1$, for then any quadratic residue is a biquadratic residue. For p of the form $4n + 1$, Gauss discovered the following criterion: 2 is a biquadratic residue of p if, and only if, p can be expressed in the form $a^2 + 64b^2$. As an illustration, the first prime having this form is $73 = 3^2 + 64(1^2)$, and indeed $25^4 - 2 = 390{,}623$ is divisible by 73. Again, here is a theorem stated wholly within Z; Gauss proved it by a skillful, detailed development of the properties of $\mathfrak{G}$.

Kummer's attempt to prove Fermat's last theorem

The next major advance in algebraic number theory was achieved by Kummer in his investigation of Fermat's last theorem. The problem is to prove the impossibility of solving $x^n + y^n = z^n$ in Z for $n \geq 3$. Kummer's method was to rewrite the equation in the form $(x + y) \cdot (x + uy) \cdot \cdots \cdot (x + u^{n-1}y) = z^n$, in which $u = e^{2\pi i/n} = \cos(2\pi/n) + i \sin(2\pi/n)$ is a primitive nth root of unity. For instance, when $n = 3$, $u = (-1 + \sqrt{-3})/2$, and the equation reads $(x + y)(x + uy)(x + u^2y) = z^3$. The problems that must now be overcome are precisely those encountered above in the study of the equation $x^2 + 1 = y^3$—units, relative primeness, and unique factorization. The difficulties concerning units and relative primeness were formidable, but Kummer mastered them completely. In his first work, however, he overlooked the need to prove unique factorization. The error was pointed out by the German mathematician Peter Gustav Lejeune Dirichlet. Because the first instance of non-uniqueness occurs at $n = 23$, it is not easy to exhibit the failure in connection with Fermat's last theorem. It is simpler to observe the phenomenon of non-uniqueness in an example in which the calculations are slight. The set of numbers $a + b\sqrt{-5}$ are considered in which a and b range over Z, the ordinary integers. There are two factorizations of 6 (see 24). It is easy to check that 2, 3, and $1 \pm \sqrt{-5}$ are all primes. Units play no role here because the only units are ± 1. Hence factorization is not unique in this case.

Despite the error that spoiled his proof, Kummer did not abandon the project. He had the novel, ingenious idea of restoring unique factorization by inventing additional "ideal numbers." By his new method Kummer made a great deal of progress on Fermat's last theorem, but did not arrive at a complete proof—nor did the numerous mathematicians who followed up his program. Computations based on Kummer's ideas, however, have shown $x^n + y^n = z^n$ to be impossible up to $n = 25{,}000$ (Richard M. Pollack and John L. Selfridge, 1964).

Foundations. In a systematic study of algebraic number theory, a basic role is played by the concept of a field (*i.e.*, a set of numbers in which the operations of addition, subtraction, multiplication, and division can be performed). The set $\mathfrak{Q}$ of rational numbers forms a field. On adjoining to $\mathfrak{Q}$ an algebraic number u, a typical algebraic number field, $\mathfrak{F} = \mathfrak{Q}(u)$, is obtained. The set $\mathfrak{R}$ of algebraic integers lying in $\mathfrak{F}$ is a collection admitting addition, subtraction, and multiplication (but not division); such a set is called a ring. In this ring uniqueness of factorization into primes may fail, as noted above in the case $\mathfrak{F} = \mathfrak{Q}(\sqrt{-5})$. Unique factorization may be restored by a method of the German mathematician Richard Dedekind by introducing ideals. An ideal in $\mathfrak{R}$

Rings

(24) $$6 = 2 \cdot 3 = (1 + \sqrt{-5})(1 - \sqrt{-5})$$

(25) $$6 = (2, 1 + \sqrt{-5})(2, 1 - \sqrt{-5}) \times (3, 1 + \sqrt{-5})(3, 1 - \sqrt{-5})$$

is a subset of $\mathfrak{R}$ that is closed under addition and subtraction and, furthermore, admits multiplication by any element of $\mathfrak{R}$. The most obvious example of an ideal is a principal ideal $x\mathfrak{R}$, consisting of all multiples of an element x of $\mathfrak{R}$. If every ideal is principal, then factorization is unique and the introduction of ideals is superfluous: this is, for instance, the case for Z, the integers, and $\mathfrak{G}$, the Gaussian integers. When factorization is not unique, so that there exist nonprincipal ideals, something valuable has been accomplished by the introduction of ideals, for Dedekind proved that every ideal is uniquely a product of prime ideals. (In the ring $\mathfrak{R}$ of algebraic integers in an algebraic number field, a prime ideal $\mathfrak{P}$ can be defined very simply as one admitting no factorization into ideals except the trivial factorization $\mathfrak{P} = \mathfrak{P}\mathfrak{R}$.) In the example $6 = 2 \cdot 3 = (1 + \sqrt{-5}) \cdot (1 - \sqrt{-5})$ of non-unique factorization given above, uniqueness is restored when the factors are decomposed further into prime ideals (see 25). Here the notation $(2, 1 + \sqrt{-5})$ denotes the ideal generated by 2 and $1 + \sqrt{-5}$; *i.e.*, the set of all numbers $2x + (1 + \sqrt{-5})y$ with x and y in the ring.

Class group and class number. It is possible, in a useful way, to measure the extent of the departure from unique factorization by an invariant called the class number. Crudely speaking, the larger the class number, the greater the failure of factorization to be unique.

The class number is essentially a measure of the number of nonprincipal ideals. To state this precisely, it is convenient to use fractional ideals—*i.e.*, ideals that may contain algebraic numbers that are not integers. These fractional ideals form a group under multiplication, with the principal ideals as a subgroup. The quotient group is called the class group. (For basic information on group theory see ALGEBRAIC STRUCTURES.) An important theorem of a Lithuanian-born mathematician, Hermann Minkowski, asserts that the class group is finite. The number of elements in the class group is the class number.

The class number is 1 precisely when unique factorization holds. Thus the class number of $\mathfrak{G}$ is 1, whereas the class number of $\mathfrak{Q}(\sqrt{-5})$ must exceed 1 (it can be shown to be 2). It is in general a difficult computation to find the class number of an algebraic number field, and its value oscillates unpredictably from one field to another. The case of quadratic field has been most thoroughly explored. (A quadratic algebraic number field $\mathfrak{Q}(\sqrt{m})$ is one obtained from the rational numbers $\mathfrak{Q}$ by adjoining a square root of a number m; m can be taken to be square-free [*i.e.*, to have no square factors other than 1], and the field is called real or imaginary according as m is positive or negative.) In his *Disquisitiones Arithmeticae* ("Discussions on numbers") Gauss listed nine imaginary quadratic fields with class number 1, given by $-m = 1, 2, 3, 7, 11, 19, 43, 67$, and 163. Gauss conjectured that these were all. There was no progress on this problem until 1934, when H. Heilbronn and E. Linfoot proved that there was at most one more. Computations by the U.S. mathematician D.H. Lehmer showed that a 10th field, if it existed, would have an enormous value for $-m$. Finally, in 1967 another U.S. mathematician, Harold M. Stark, proved that Gauss was right: the list of nine fields is complete. At about the same time, and independently, A. Baker developed methods that reduced the problem to a finite amount of computation. In retrospect it was recognized that in 1952 K. Heegner had made an attempt on the problem that could have been completed by techniques already known at that time.

Real and imaginary fields

This theorem of Heegner and Stark has an intriguing connection with an elementary question concerning primes. The question goes back to Euler, and the connection was

observed by G. Rabinovich in 1911. Euler had asked: when is it true for a prime p that $x^2 + x + p$ is prime for all the values 0, 1, 2, $\cdots$, $p - 2$? (It is fruitless to attempt to go higher than $x = p - 2$, for when x is set equal to $p - 1$, $x^2 + x + p$ takes the value p^2.) Euler gave the example 41, and there are five easily discovered smaller primes that work: 2, 3, 5, 11, and 17. If these six numbers are multiplied by 4 and 1 is subtracted, the numbers 7, 11, 19, 43, 67, and 163, the six largest values of $-m$ for fields of class number, are obtained. (The three values 1, 2, 3 are too small for there to be a connection with Euler's question.) It follows in fact from the theorem of Heegner and Stark that 41 is the last prime enjoying Euler's property.

For real quadratic fields (those of the form $\mathfrak{Q}(\sqrt{m})$ with m positive) numerical evidence indicates that the class number 1 occurs with great frequency. Gauss conjectured that there are an infinite number of real quadratic fields with class number 1, but this remains unsettled.

It is known that the class number of an algebraic number field can be arbitrarily large. One way of exhibiting large class numbers appears in Gauss's *Disquisitiones*. It is a consequence of a theorem of his on duplication of genera that the class number of the field $\mathfrak{Q}(\sqrt{m})$ is divisible by 2^{k-1} if the integer m has k or more distinct odd prime factors.

Dirichlet discovered a connection between the class numbers of certain quadratic fields and quartic fields. Given a square-free positive integer m, the quadratic fields $\mathfrak{Q}(\sqrt{m})$ and $\mathfrak{Q}(\sqrt{-m})$ can be formed, and in addition the field $\mathfrak{Q}(\sqrt{m}, \sqrt{-m})$ obtained by adjoining both $\sqrt{m}$ and $\sqrt{-m}$ to the rational numbers. Dirichlet's theorem asserts that the class number of $\mathfrak{Q}(\sqrt{m}, \sqrt{-m})$ is either the product of the class numbers of $\mathfrak{Q}(\sqrt{m})$ and $\mathfrak{Q}(\sqrt{-m})$ or else half that number. This result was the starting point for a considerable amount of subsequent research.

Units. In the ring $\mathfrak{R}$ of integers of an algebraic number field $\mathfrak{J}$, an element u of $\mathfrak{R}$ is called a unit if there exists an element v in $\mathfrak{R}$ with $uv = 1$. At least the numbers 1 and -1 are units; for some fields there are no other units. In a special category are those units u having the property that some power u^n is equal to 1; these are called roots of unity.

Dirichlet's unit theorem

In 1846 Dirichlet found a decisive theorem concerning the units of an arbitrary algebraic number field. This theorem gives a formula for the number of units, other than roots of unity, that are independent in a reasonable sense. $\mathfrak{J}$ is allowed to equal $\mathfrak{Q}(x)$ and is supposed to be n-dimensional over $\mathfrak{Q}$ so that the irreducible equation for x has degree n. Of the n roots of this equation, some are real and some imaginary, the imaginary ones coming in pairs; r_1 is written for the number of real roots and r_2 for the number of pairs of imaginary ones, so that $n = r_1 + 2r_2$. Dirichlet's formula for the number of independent units is $r_1 + r_2 = 1$.

Quadratic fields furnish simple illustrations for Dirichlet's unit theorem. If the field is imaginary, then $r_1 = 0$ and $r_2 = 1$, so that $r_1 + r_2 - 1 = 0$ and there are no units other than roots of unity. If the field is real, then $r_1 = 2$ and $r_2 = 0$, so that $r_1 + r_2 - 1 = 1$. There is then one basic unit called the fundamental unit, and all others are powers of it or their negatives. Stated in direct terms, this is the assertion about the equation named after the 17th-century English mathematician John Pell, $x^2 - Dy^2 = 1$, with D a non-square positive number. There is a solution in integers other than the trivial ones $x = \pm 1$, $y = 0$, and all solutions are obtainable in a simple way from a certain basic solution. As an illustration, if $D = 2$, the basic solution of $x^2 - 2y^2 = 1$ is given by $x = 3$, $y = 2$. If x^*, y^* is any solution, then $x^* + y^*\sqrt{2} = \pm(3 + 2\sqrt{2})^m$ for some m. Dirichlet's theorem can be viewed as a far-reaching generalization of the theory of the Pell equation.

The discriminant. If $\mathfrak{J}$ is an n-dimensional algebraic number field and $\mathfrak{R}$ its ring of integers, then there exists for $\mathfrak{R}$ an integral basis over the ring Z of ordinary integers. This is a set $u_1, \cdots, u_n$ of elements of $\mathfrak{R}$ with the property that every element of $\mathfrak{R}$ is uniquely a linear combination of the u's with coefficients in Z. For example, the numbers 1, i form an integral basis for the Gaussian integers. Now every member of $\mathfrak{J}$ has n conjugates that do not necessarily lie in $\mathfrak{J}$. When $u_{i1}, \cdots, u_{in}$ is written for the conjugates of u_i, d is the n by n determinant formed from the n^2 elements u_{ij}. It can be seen that $D = d^2$ lies in Z and that D does not depend on the choice of the integral basis; D is called the discriminant of $\mathfrak{J}$. The discriminant plays an important role in determining the properties of $\mathfrak{J}$.

A quadratic field $\mathfrak{Q}(\sqrt{m})$ serves as a simple illustration. If $m \equiv 2$ or 3 (mod 4), then an integral basis consists of 1 and $\sqrt{m}$, and $D = 4m$. If $m \equiv 1$ (mod 4), the elements 1 and $(1 + \sqrt{m})/2$ form an integral basis, and D turns out to equal m.

Some facts about the discriminant follow. Of these, the first is due to the Swiss mathematician Ludwig Stickelberger, the second to Dedekind, the third to the 20th-century Norwegian-born U.S. mathematician Oystein Ore, and the remaining three to the 19th–20th-century Lithuanian-born mathematician Herman Minkowski. (1) $D \equiv 0$ or 1 (mod 4); (2) the only primes in Z that acquire as factors multiple powers of prime ideals in $\mathfrak{R}$ (they are called the ramified primes) are those that divide D; (3) $2D$ is a multiple of the number of roots of unity in $\mathfrak{J}$; (4) D is never equal to 1 or -1; (5) there are only a finite number of fields with a given discriminant; (6) D becomes large with n; for example, there exists an absolute constant c such that $D > e^{cn}$.

The Zahlbericht and Hilbert's problems. At the invitation of the German Mathematical Society, the German mathematician David Hilbert prepared a report on algebraic number theory, published in 1897 and reprinted in his collected works. While initially planned as a joint project with Minkowski, he completed it alone. It was really a full length treatise, and in a masterful way it covered virtually all work in the field up to that date. Known as the "Zahlbericht" (number report), it became the "Bible" for all workers in the field. It fixed the notation, the names for the main concepts, and the style of proof used.

In 1900, at the International Mathematical Congress in Paris, Hilbert proposed 23 problems that he considered would be significant for research in the 20th century. The importance he attached to algebraic number theory is attested by three of the problems (the 9th, 11th, and 12th) being entirely in that field, and another (the 8th) partly so. These problems will be mentioned again below.

Hensel's p-adic numbers. As 20th-century work on algebraic number theory got under way, an important innovation was made by the German mathematician Kurt Hensel. Inspired partly by congruences to powers of primes that abound in number theory, and partly by an analogy with the power series that occur in algebraic function theory (see below), he conceived the idea of forming power series in a prime p. A typical p-adic number formed in this way can be written as a sum of powers of p with coefficients a_k (see 26) in which each coefficient a_i lies in the range $0 \leq a_i \leq p - 1$. If $a_{-1} = a_{-2} = a_{-3} = \cdots = 0$, the number is called a p-adic integer. This is just like a number written in the scale of p, except for the novelty that the digits are allowed to run on forever to the left. Addition and multiplication of p-adic numbers follow the usual rules of arithmetic. Such numbers could also be formed to the base 10, but there is then the serious disadvantage that divisors of zero occur—*i.e.*, there exist two non-zero 10-adic numbers the product of which is 0.

A simple illustration of the efficiency of using p-adic numbers is the statement that -1 has a square root in the 5-adic numbers. It is easily proved by an approximation procedure that is systematized once for all in a lemma (auxiliary proposition) named after Hensel. From this an infinite number of statements about ordinary integers may be deduced: for every n there exists an integer x such that $x^2 + 1$ is divisible by 5^n.

Out of Hensel's p-adic numbers there developed a major branch of modern algebra called valuation theory.

Quadratic forms and the Hasse principle. A quadratic form is an expression of the form $\Sigma\, a_{ij}\, x_i\, x_j$, the x's being variables. The earliest work on quadratic forms concerned the case in which the coefficients a_{ij} were ordinary integers. Eventually it was realized that it clarifies matters to study first the case of rational coefficients. This was the subject of a brilliant paper by Minkowski in 1890 in which he gave a complete classification of rational quadratic forms, which took advantage of virtually everything that had been done during the 19th century on integral quadratic forms. With this triumph fresh in his mind, Hilbert thought it timely in his 11th problem to ask for a classification of quadratic forms over an arbitrary algebraic number field.

The solution to Hilbert's 11th problem

The solution was given by the German mathematician Helmut Hasse in 1923, and the method was an impressive application of Hensel's p-adic numbers. Hasse first recast Minkowski's theorem in a new, attractive way. The field $\mathfrak{Q}$ of rational numbers can, for each prime p, be regarded as forming part of the field of p-adic numbers (say $\mathfrak{Q}_p$), and also part of the field $\mathfrak{R}$ of real numbers. The theorem states that two quadratic forms over $\mathfrak{Q}$ are equivalent (meaning that it is possible to pass from one to the other by a change of variable) if, and only if, they are equivalent over each $\mathfrak{Q}_p$ and over $\mathfrak{R}$. In this form the result is ready for a natural generalization to any algebraic number field, a generalization that Hasse succeeded in proving by a method, called the Hasse principle, that is regarded as a passage from local to global data. For the field of rational numbers, the local information is given one prime at a time, the field of real numbers being treated as a prime "at infinity." For a general algebraic number field, the primes are replaced by prime ideals, and there are usually several primes at infinity.

The Hasse principle has had other successes (for instance, in associative algebras and in algebraic groups), but for polynomial equations of degree higher than two it may fail. A simple example was given by the Norwegian Ernst Selmer in 1951: the equation $3x^3 + 4y^3 + 5z^3 = 0$ admits a nontrivial solution over the p-adic numbers for every p and also a solution over the real numbers, but it has no solution over the rational numbers.

Class field theory and reciprocity. A portion of algebraic number theory unites virtually everything that is known into a highly sophisticated structure. Two algebraic number fields $\mathfrak{F}$ and $\mathfrak{L}$ are studied, with $\mathfrak{L}$ an extension of $\mathfrak{F}$. Information is sought about how ideals behave in the passage from $\mathfrak{F}$ to $\mathfrak{L}$. The object is to classify the possibilities for $\mathfrak{L}$ in terms of readily computed objects in $\mathfrak{F}$. For a given $\mathfrak{F}$, there is a particularly important field $\mathfrak{L}$ that enjoys numerous special properties with respect to $\mathfrak{F}$: for instance, its dimension over $\mathfrak{F}$ is equal to the class number of $\mathfrak{F}$, and every ideal in $\mathfrak{F}$ becomes principal in $\mathfrak{L}$. The field $\mathfrak{L}$ is called the class field of $\mathfrak{F}$, the origin of the name class field theory.

There is a close relation between class field theory and reciprocity. In its original form, reciprocity referred to quadratic residues computed in the ring of ordinary integers and asserted the following: if p and q are odd primes, then p is a quadratic residue of q if, and only if, q is a quadratic residue of p, unless both p and q have the form $4n + 3$, in which case the behaviour is opposite. In his 9th problem, Hilbert asked for two advances to be made: squares were to be replaced by arbitrary nth powers, and the context was to be broadened to any algebraic number field.

Artin's reciprocity theorem

Many mathematicians (including Hilbert himself) made partial contributions until the climax in 1927, when Austrian-born Emil Artin discovered a definitive version of reciprocity and was able to prove it in full generality. It is typical of the increasing sophistication and abstraction of modern mathematics that in the theorem powers and reciprocity are no longer visible (indeed, it requires a fair amount of effort to extract a conventional reciprocity statement from Artin's theorem). Instead, Artin constructed two groups and a function from the first to the second; his theorem asserts that this function is an isomorphism (that is, it is one-to-one, onto, and preserves the product laws of the groups).

$$(26)\qquad \cdots + a_n p^n + \cdots + a_2 p^2 + a_1 p + a_0 + a_{-1} p^{-1} + + \cdots + a_{-m} p^{-m}$$

$$(27)\qquad \mathfrak{F} = \mathfrak{F}_0 \subset \mathfrak{F}_1 \subset \mathfrak{F}_2 \cdots$$

The class field tower. If $\mathfrak{F}$ be an algebraic number field and $\mathfrak{L}$ its class field, as described above, it is not necessarily the case that $\mathfrak{L}$ has class number 1; for, although every ideal in $\mathfrak{F}$ has become principal, some new ideals in $\mathfrak{L}$ may have arisen that are not principal. The process of passing to the class field can be iterated, resulting in the class field tower starting at $\mathfrak{F}$ and successively including other fields (see 27). It was an outstanding open question for many years whether, for any $\mathfrak{F}$, the class field tower had to end in a finite number of steps with a field having class number 1. Then, in 1964, the Russian mathematicians E.S. Golod and Igor Rostislavovich Shafarevich gave a counterexample. An explicit choice of a field $\mathfrak{F}$ having an infinite class field tower is $\mathfrak{Q}(\sqrt{-30030})$.

Abelian fields and the Jugendtraum. If u is a primitive nth root of 1, the algebraic number field $\mathfrak{F} = \mathfrak{Q}(u)$ is formed by adjoining u to the rationals; $\mathfrak{F}$ is called a cyclotomic field. It is known (by Galois theory: see the article ALGEBRAIC STRUCTURES) that $\mathfrak{F}$ is normal over $\mathfrak{Q}$ with a Galois group that is Abelian and has order $\varphi(n)$, in which φ is the Euler φ-function. If $\mathfrak{F}_0$ is any field between $\mathfrak{Q}$ and $\mathfrak{F}$, then $\mathfrak{F}_0$ likewise is Abelian over $\mathfrak{Q}$. In 1877 the German mathematician Leopold Kronecker proved the remarkable converse: any field Abelian over $\mathfrak{Q}$ is a subfield of a suitable cyclotomic field. In a letter to Dedekind dated March 15, 1880, Kronecker said his *liebster Jugendtraum* ("dearest dream of youth") had been to prove an analogous theorem concerning Abelian extensions of imaginary quadratic fields. This was achieved by the German mathematician Heinrich Weber, whose result showed that they are generated by certain values of elliptic functions (see ANALYSIS, COMPLEX). Hilbert's 12th problem called for extensions of this work to arbitrary algebraic number fields. Only scattered results have been obtained. Possibly further extensive development of class field theory is needed to obtain the requisite insight.

The analogy with algebraic functions. In studying algebraic functions in one variable the process begins with a field k, called the constant field, adjoins a variable x to get the field $\mathfrak{F} = k(x)$, and then forms a finite-dimensional extension of $\mathfrak{F}$ to get a field $\mathfrak{L}$. $\mathfrak{F}$ may be thought of as being analogous to the field $\mathfrak{Q}$ of rational numbers, and $\mathfrak{L}$ as being analogous to an algebraic number field. The ring $k[x]$ of polynomials in x is a subset of $\mathfrak{F}$; it is a principal ideal ring like the ring Z of integers. By taking appropriate integers inside $\mathfrak{L}$, a theory remarkably parallel to algebraic number theory is obtained. A great many theorems hold in both cases, and to a considerable extent a unified account covering both cases can be given. In particular, power series in x play a role quite similar to Hensel's p-adic numbers; in fact, they served to inspire him.

When the field k is finite, the analogy becomes closer still. All the major results of class field theory then hold, and there are perfect analogues of the unit theorem and the finiteness of the class number. Indeed, Artin and the U.S. mathematician George W. Whaples in 1945 set forth a simple set of axioms holding simultaneously for algebraic number fields and algebraic function fields over finite fields. The main axiom was the assertion of a neat product formula for valuations, asserting that certain infinite products are equal to 1. Arguing directly from their axioms, Artin and Whaples were able to give new unified proofs of the major theorems.

Analytic methods. In 1840 Dirichlet initiated the use of analysis on a large scale to prove results in number theory. Among other things he proved two remarkable theorems. The first was the existence of an infinite number of primes in every nontrivial arithmetic progression (an arithmetic progression is a sequence of the form a, a

Dirichlet's two analysis theorems

$+ d, a + 2d, \cdots$; it is nontrivial if a and d are relatively prime). The second was a class number formula. Since algebraic number theory had yet to be developed, Dirichlet's formula necessarily referred to binary quadratic forms. Translated into the language of algebraic number theory, his formula gave the class number of $\mathfrak{Q}(\sqrt{-p})$, with p a prime. It is simplest if p has the form $8n + 7$, and then is the sum from $r = 1$ to $r = (p - 1)/2$ of $(r|p)$, in which $(r|p)$ is the Legendre symbol, equal to 1 if r is a quadratic residue of p and -1 otherwise. For instance, if $p = 23$ the sum of $(1|p), \cdots, (11|p)$ is obtained. The numbers 1, 2, 3, 4, 6, 8, 9, are residues and 5, 7, 10, 11 are non-residues. Hence the class number of $\mathfrak{Q}(\sqrt{-23})$ is $7 - 4 = 3$.

The modernization of this work operates in an arbitrary algebraic number field $\mathfrak{F}$. The number, say $Z(t)$, of ideals with norm less than a given number t is counted; the norm of an ideal is an integer formed in analogy to the assignment of the integer $a^2 + b^2$ to the Gaussian integer $a + bi$. As t goes to infinity, $Z(t)/t$ can be proved to have a definite limit given by a formula built out of the class number, the discriminant, and the units of $\mathfrak{F}$. This result is then used to study the Riemann zeta function that can be formed relative to $\mathfrak{F}$. The result is that much information is obtained about the class number and the existence of prime ideals satisfying various restrictions, as called for in Hilbert's 8th problem. (I.K.)

Analytic number theory

THE SCOPE OF ANALYTIC NUMBER THEORY

Analytic number theory is a branch of number theory concerned with the interaction of analysis and number theory. Analysis can be used to prove certain properties of ordinary and algebraic integers and to establish quantitative results. Similarly, arithmetic properties can be used to analyze and shed light on analytic questions.

Among the earliest problems in number theory to which any sort of systematic study was brought to bear is the class of problems known as Diophantine equations, named after the Greek mathematician Diophantus of Alexandria who lived about AD 250. A Diophantine equation is an equation the solutions of which are required to be integers, the simplest example being the Diophantine equation involving first powers of x and y (see 28). The solution of these equations required the development of general properties of divisibility. The pursuit of Diophantine equations of higher degree led Gauss, in about 1820, to a study of a new set of integers, the Gaussian integers.

Diophantine equations

Properties of integers, whether ordinary or algebraic, may be of two types that are here characterized as qualitative, or descriptive, and quantitative. An example of the former is the question of whether, for a given integer n, the Diophantine equation that identifies n with a sum of second powers (see 29) has a solution in integers x_1, x_2, x_3, x_4. An example of the latter is the question of how many solutions this equation has.

In analytic number theory the problems investigated can be divided into three classes. The first class is that in which analysis is used to prove properties of integers, the statements of which can be formulated in terms of elementary concepts of mathematics. These are qualitative properties. One of the most noted examples is the Goldbach conjecture. This conjecture was made by the Prussian-born mathematician Christian Goldbach in 1742, and a related problem was partially solved by the Soviet mathematician Ivan Matveyevich Vinogradov in 1937. Goldbach conjectured that every number greater than or equal to 4 can be expressed as a sum of two primes. For example, the numbers 18 and 30 may be so expressed (see 30). While this conjecture had not been settled by the early 1970s, Vinogradov did prove in 1937 that every sufficiently large odd natural number can be written as the sum of three primes. It is notable that the statements of the conjecture of Goldbach and result of Vinogradov do not involve any analytic notions, yet to date the result of Vinogradov cannot be proved without deep and intricate analytic methods and techniques.

The second class of problem involves the use of analysis to establish quantitative results. Among the most important sequence of integers singled out for special study is the sequence of primes with which a function that indicates the number of primes less than or equal to x is associated (see 31).

Primes and $\pi(x)$ have been studied for many years, and one of the objectives was to find a simple formula for $\pi(x)$. This ambition was only partially realized when, in 1896, the French mathematician Jacques Hadamard and the Belgian mathematician Charles-Jean de la Vallée-Poussin independently proved that $\pi(x)$ is approximately $x/\log x$ in the precise sense that is expressed in terms of a limit (see 32).

The third class of problems makes use of arithmetic properties to analyze and shed light on analytic questions, the two interacting strongly.

Some problems dealt with under these three headings are given below. Qualitative problems include: (1) Various modifications of Goldbach's conjecture. (2) The 18th-century English mathematician Edward Waring's problem; *i.e.*, the solution of the Diophantine equation that identifies a sum of k powers with an integer n (see 33). (3) The existence of infinitely many primes in various sets, such as arithmetic progressions. (4) The existence of infinitely many pairs of primes differing by 2. (5) the existence of primes in various intervals—for example, the existence of a prime in the interval x to $x + x^{1/2}$; (6) the congruence properties of various functions, such as the partition function, coefficients of various modular functions; (7) the existence of solutions of Diophantine equations; (8) the properties of class numbers of algebraic number fields.

Quantitative problems include: (1) The prime factorization of an integer n (see 35). There are many functions associated with n such as the number of divisors of n (see 36). The behaviour of these functions and magnitude of their average values form part of the

(28) $ax + by = c$

(29) $n = x_1^2 + x_2^2 + x_3^2 + x_4^2$

(30) $18 = 13 + 5, \qquad 30 = 23 + 7$

(31) The function $\pi(x)$ associated with the sequence:
$2, 3, 5, 7, 11, 13, 17, 19, 23, \cdots$.
$\pi(x)$ = number of primes $\leqslant x$.
$\pi(10) = 4, \qquad \pi(20) = 8, \qquad \pi(35) = 10, \qquad \cdots$

(32) $$\lim_{x \to \infty} \frac{\pi(x) \log x}{x} = 1$$

(33) $x_1^k + \cdots + x_s^k = n$

(34) $$\sum_{n=0}^{\infty} p(n)x^n = \prod_{n=1}^{\infty} (1 - x^n)^{-1}$$

(35) $n = p_1^{\alpha_1} p_2^{\alpha_2} \cdots p_r^{\alpha_r}$

(36)
$d(n)$ = number of divisors of n
$\tau(n)$ = sum of the divisors of n
$\omega(n) = \alpha_1 + \alpha_2 + \cdots + \alpha_r$
$\Lambda(n) = \begin{cases} \log p \text{ if } r = 1 \\ 0 \text{ otherwise} \end{cases}$, the von Mangoldt function
$\mu(n) = \begin{cases} 0 \text{ if } \alpha_i \geqslant 2 \text{ for some } i \\ (-1)^r \text{ if } \alpha_i = 1 \text{ for all } i \end{cases}$, the Möbius function

(37) $x^m \cdot x^n = x^{m+n}$
$n^s \cdot m^s = (nm)^s$

object of this study. (2) The number of primes in various sequences such as arithmetic progressions, etc. (3) The interval between successive primes. (4) The magnitude of various exponential sums, including character sums. (5) Applications to the determination of the least primitive root mod p. (6) The magnitude of the class number of algebraic number fields. (7) Numbers of solutions of Diophantine equations; *e.g.*, number of solutions of $n = x_1^2 + x_2^2 + x_3^2 + x_4^2$, number of solutions in Waring's problem. (8) The orders of magnitude of coefficients of various power series (see 34). (9) The number of lattice points in various domains; for example, the number of lattice points in a circle. (10) Dirichlet and other densities.

Examples of the third class of problem include the following: (1) Kronecker's limit formulas; (2) Abelian functions; (3) complex multiplication; (4) modular functions over rational and algebraic number fields; (5) the German mathematician Erich Hecke's operators.

METHODOLOGY

History. Historically the use of analysis in number theory started with Euler in 1742 and is based on two simple observations, one concerned with integer powers of x and the second concerned with s powers of integers (see 37). In the first case the variable is x and in the second case the variable is s. Moreover, in the first case the product involves the sums $m + n$ of the integers m and n, and in the second case the product mn. Thus, it is to be expected that the first will be used in additive problems and the second in multiplicative problems. These can be illustrated with examples. For the first the equation that identifies k with squares of integers (see 38) is considered. Then, the series for squared powers of x (see 39) are considered. Multiplying these together leads to a relationship between series (see 40 and 41) in which the coefficient of x^k is the number of ways in which k can be written as a sum of two squares counting order (see 42). Because x^3 does not occur, then 3 cannot be written as a sum of two squares and so forth. If $r(k)$ is the number of solutions of the equation that identifies with k a sum of two squares of integers (see 43), then if $f(x)$ is an infinite sum of squared powers of x, the square of f can be computed in terms of a series with coefficients $r(k)$ (see 44) with the convention that $r(0) = 1$.

To illustrate the second case, the function $d(n) =$ number of divisors of n is considered: $d(n) = \Sigma 1$, the summation extended over all divisions of n. The series expressed in reciprocals of a power of positive integers (see 45) are used. Multiplying these two together leads to a square of such series (see 46).

The term $1/2^s$ occurs twice, as $1 \times 1/2^s$, $1/2^s \times 1$, likewise with $1/3^s$; but $1/4^s$ occurs three times as $1 \times 1/4^s$, $1/4^s \times 1$, $1/2^s \times 1/2^s$.

In general, the question is how many times $1/k^s$ occurs, or, in other words, what the coefficient of $1/k^s$ is. If $k = mn$, then the terms $1/m^s \times 1/n^s = 1/(mn)^s$ contribute 1 to the coefficient, and this happens for each decomposition; there are, however, as many decompositions as there are divisors of n. Hence, the coefficient of $1/k^s$ is $d(k)$ (see 47).

More generally, if any sequence of non-negative integers (see 48) is given, the function (in power series form with coefficients from the previous sequence; see 49) is called the generating function of the sequence. If a sequence of the form $b(k)$ is given (see 50) then the function that is formed from a series of reciprocals of s powers of integers, coefficients being selected from the given sequence (see 51), is called the Dirichlet series associated with the sequence.

The Dirichlet series

There are still other ways that a function can be associated with a given sequence, but attention is restricted for the time being to associations already given (see 49, 51). One association (49) is the more natural for additive problems, whereas another one (51) is more natural for multiplicative problems.

Classification and techniques. *Additive properties.* In the case of additive problems the general problem can be formulated as follows. It is required to write a natural number n as a sum of an element from a set A_1 plus an element from a set A_2 plus, etc. That is, it is required to determine whether an integer n can be written in the form of a sum of n_i (see 52) with $n_i \in A_i$ ($i = 1, 2, \cdots, r$), and the number $\nu(n)$ of such representations also is required. Evidently a representation exists if it can be shown that $\nu(n) \geq 1$.

As above, a sum of powers of x (see 53) is formed quite generally. Then it follows that a product of such sums is possible (see 54). Multiplying leads to another sum of powers of x (see 55). Setting n equal to a

(38) $$k = m^2 + n^2$$

(39) $$\begin{cases} \sum_{m=0}^{\infty} x^{m^2} = 1 + x + x^4 + x^9 + \cdots \\ \sum_{n=0}^{\infty} x^{n^2} = 1 + x + x^4 + x^9 + \cdots \end{cases}$$

(40) $$\sum_{m=0}^{\infty} x^{m^2} \sum_{n=0}^{\infty} x^{n^2} = \sum_{m,n} x^{m^2+n^2}$$

(41) $$(1 + x + x^4 + x^9 + \cdots)(1 + x + x^4 + x^9 + \cdots) = 1 + 2x + x^2 + 2x^4 + 2x^5 + x^8 + 2x^9 + 2x^{10} + \cdots$$

(42) $$\begin{cases} 1 = 1^2 + 0^2 = 0^2 + 1^2 \\ 2 = 1^2 + 1^2 \\ 4 = 4^2 + 0^2 = 0^2 + 4^2 \\ 5 = 1^2 + 4^2 = 4^2 + 1^2 \end{cases}$$

(43) $$k = m^2 + n^2$$

(44) $$f^2(x) = \sum_{m=0}^{\infty} x^{m^2} \sum_{n=0}^{\infty} x^{n^2} = \sum_{k=0}^{\infty} r(k) x^k$$

(45) $$\begin{cases} \zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s} = 1 + \frac{1}{2^s} + \frac{1}{3^s} + \cdots + \frac{1}{n^s} + \cdots \\ \zeta(s) = \sum_{m=1}^{\infty} \frac{1}{m^s} = 1 + \frac{1}{2^s} + \frac{1}{3^s} + \cdots + \frac{1}{m^s} + \cdots \end{cases}$$

(46) $$\begin{cases} \zeta^2(s) = \left(1 + \frac{1}{2^s} + \frac{1}{3^s} + \cdots\right)\left(1 + \frac{1}{2^s} + \frac{1}{3^s} + \cdots\right) \\ \qquad = 1 + \frac{2}{2^s} + \frac{2}{3^s} + \frac{3}{4^s} + \cdots \end{cases}$$

(47) $$\zeta^2(s) = \sum_{k=1}^{\infty} \frac{d(k)}{k^s}$$

(48) $$A = \{a(0), a(1), a(2), \cdots, a(n), \cdots\}$$

(49) $$f(x) = \sum_{n=0}^{\infty} a(n) x^n$$

(50) $$B = \{b(1), b(2), \cdots, b(n), \cdots\}$$

(51) $$g(s) = \sum_{n=1}^{\infty} \frac{b(n)}{n^s}$$

(52) $$n = n_1 + n_2 + \cdots + n_r$$

(53) $$f_i(x) = \sum_{n_i \in A_i} x^{n_i}$$

(54) $$f_1(x) f_2(x) \cdots f_r(x) = \sum_{n_1 \in A_1} x^{n_1} \sum_{n_2 \in A_2} x^{n_2} \cdots \sum_{n_r \in A_r} x^{n_r}$$

sum of integers (see 56), it follows that x^n occurs each time there is a representation in the form given by (52); that is, a sum of integer powers of x each power multiplied by a coefficient $\nu(n)$ (see 57). Naturally, the determination of $\nu(n)$ is by no means resolved without detailed analysis of the functions $f_1(x), \cdots, f_r(x)$. The function $f(x) = f_1(x), \cdots, f_r(x)$ is the generating function for $\nu(n)$.

Generating functions

As another example, the generating function for the number of unrestricted partitions $p(n)$ of a natural number n can be found. A partition of n is a decomposition into an unrestricted sum of natural numbers m_i (see 58). For example, if $n = 5$, then all the cases can be listed (see 59); therefore, $p(5) = 7$.

To obtain the generating function, the partition must be made more systematic; r_1 is the number of 1's, r_2 the number of 2's, r_3 the number of 3's, $\cdots$, r_k the number of k's, occurring in a particular partition; so that n is a sum of products of integers times corresponding r_k (see 60). Thus a partition corresponds to a solution of an equation identifying n with a sum of integers, each integer in the sum belonging to a certain class (see 61). Therefore, the functions composed of sums of powers of x (see 62) are formed and the product is given by a general sum (see 63) with the convention that $p(0) = 1$. Noting that the expression for $f_k(x)$ is a geometric series, it follows that $f_k(x) = (1 - x^k)^{-1}$ and, therefore, that a product expression can be obtained (see 64). This is Euler's example. All questions of convergence have been ignored in this illustration.

Multiplicative properties. Here the problems dealt with are rooted in the multiplicative properties of integers. Let $a(1), a(2), \cdots, a(n), \cdots$ and $b(1), b(2), \cdots, b(m), \cdots$ be any two sequences. Guided again by the observation made earlier, the Dirichlet series is considered for each sequence (see 65). Then a product of sums can be reduced to a single sum (see 66).

Putting $mn = k$, the coefficient of k^{-s} is determined by a sum of terms $a(n)b(m)$, and $a(n)b(m)$ is part of the coefficient whenever $mn = k$. This is written succinctly as a sum over all integers nm whose product equals k (see 67) or equivalently as a sum (see 68), the sum being over all divisors of n.

As a further example, the Dirichlet series for the German mathematician Hans von Mangoldt's function may be found (see 69). If the f is set equal to a sum with typical term $\Lambda(n)$ divided by the s power of n, a moment's reflection shows that the sum of $\Lambda(d)$ over divisions d of n equals $\log n$ (see 70). Therefore $f(s) = -[\zeta'(s)/\zeta(s)]$, in which $\zeta'(s)$ is the derivative of $\zeta(s)$ (see 71).

SPECIFIC TOPICS IN NUMBER THEORY

The distribution of prime numbers. The earliest recorded fact about primes is Euclid's proof that the number of primes is infinite, occurring as proposition 20 in the 9th book of his *Elements*. The sieve of Eratosthenes, introduced about 250 BC, is a technique for exhibiting the primes below a certain number. The subject of primes and their distribution then lay dormant until 1640, when Fermat wrote that he was "almost convinced" that numbers of a form $2^n + 1$ were prime if n was a power of 2. Euler showed that this is false for $n = 2^5$ because $2^{32} + 1$ is divisible by 641.

The next contribution of importance was made by Euler, in a paper, "Variae observationes circa series infinitas," published in the Petersburg Academy, 1742. Euler connected the harmonic series (see 72), being not too much concerned with convergence, with the sum of the reciprocals of the primes (see 73). This ushered a new era in the theory of prime numbers, and a study of the function composed of a sum of s powers of positive integers (see 74) was initiated.

The next contribution was due to the French mathematician Adrien-Marie Legendre. In *Essai sur la théorie des nombres* (1798), he proposed that for large x, $\pi(x)$ had a specific form expressed in terms of the log x (see 75) approximately in which $\pi(x)$, as above, is the number of primes $\leq x$. Legendre was unable to give a proof,

$$(55)\quad f_1(x)f_2(x)\cdots f_r(x)=\sum_{\substack{n_1\cdots n_r\\ n_i\in A_i}} x^{n_1+n_2+\cdots+n_r}$$

$$(56)\quad n=n_1+n_2+\cdots+n_r$$

$$(57)\quad f(x)=f_1(x)f_2(x)\cdots f_r(x)=\sum_{n=0}^{\infty}\nu(n)x^n$$

$$(58)\quad n=m_1+m_2+m_3+\cdots+m_\ell$$

$$(59)\quad \begin{cases} 5=1+1+1+1+1\\ \quad=1+1+1+2\\ \quad=1+1+3\\ \quad=1+2+2\\ \quad=2+3\\ \quad=1+4\\ \quad=5 \end{cases}$$

$$(60)\quad n=1r_1+2r_2+\cdots+kr_k$$

$$(61)\quad \begin{cases} n=n_1+n_2+\cdots+n_k\\ n_1\in A_1=\{0,1,2,\ldots\}\\ n_2\in A_2=\{0,2,4,6,\ldots\}\\ \quad\cdot\\ \quad\cdot\\ \quad\cdot\\ n_k\in A_k=\{0,k,2k,\ldots\} \end{cases}$$

$$(62)\quad \begin{cases} f_1(x)=\sum_{n_1=0}^{\infty}x^{n_1}\\ f_2(x)=\sum_{n_2=0}^{\infty}x^{2n_2}\\ \quad\cdot\\ \quad\cdot\\ \quad\cdot\\ f_k(x)=\sum_{n_k=0}^{\infty}x^{kn_k} \end{cases}$$

$$(63)\quad \begin{cases} F(x)=f_1(x)f_2(x)\cdots f_k(x)\cdots\\ \quad=\sum_{n_1,n_2,\cdots,n_k,\cdots} x^{n_1+2n_2+\cdots+kn_k+\cdots}\\ \quad=\sum_{n=0}^{\infty}p(n)x^n \end{cases}$$

$$(64)\quad \sum_{n=0}^{\infty}p(n)x^n=\prod_{k=1}^{\infty}(1-x^k)^{-1}=F(x)$$

$$(65)\quad \begin{cases} f(s)=\sum_{n=1}^{\infty}\frac{a(n)}{n^s}\\ g(s)=\sum_{m=1}^{\infty}\frac{b(m)}{m^s} \end{cases}$$

$$(66)\quad f(s)g(s)=\sum_{n=1}^{\infty}\sum_{m=1}^{\infty}\frac{a(n)b(m)}{(nm)^s}=\sum_{k=1}^{\infty}\frac{c(k)}{k^s}$$

$$(67)\quad c(k)=\sum_{nm=k}a(n)b(m)$$

$$(68)\quad c(k)=\sum_{d|k}a(d)b\left(\frac{k}{d}\right)=\sum_{d|k}a\left(\frac{k}{d}\right)b(d)$$

and, as a matter of fact, later work shows that if for large x, $\pi(x)$ could be expressed in terms of A (see 76), then the best value of A is 1.

It was noted above that the primes appear to diminish in frequency, the number of primes in an interval of a given length getting steadily smaller as the beginning of the given interval is larger. In a letter to the German astronomer Johann Franz Encke, Gauss in 1792 suggested an explicit rate at which the frequency diminishes and proposed that the number of primes per unit interval beginning at x is $1/\log x$. Thus, he proposed a formula involving an integral of the reciprocal of a logarithmic function (see 77) approximately, the expression $\mathrm{li}(x)$ being an abbreviation for the integral.

The Russian mathematician Pafnuty Lvovich Chebyshev, in 1851, set out to prove that a certain limiting relation holds that involves the number of primes less than or equal to x (see 78). Although he did not succeed, he did at least establish the plausibility of this relation and, therefore, of those of Legendre and Gauss. He proved in particular that if the limit exists, then it must be 1.

Riemann's contribution

In 1859, the German mathematician Bernhard Riemann inaugurated a new era in the theory of distribution of primes. Returning to the function introduced by Euler, Riemann considered the function written as a sum of reciprocals of s powers the positive integers (see 79) with s a complex variable $s = \sigma + it$. This seemingly minor modification had a profound consequence. Using complex function theory, Riemann first derived a functional equation for $\zeta(s)$, expressed $\pi(x)$ in terms of $\zeta(s)$, wrote $\zeta(s)$ in terms of its zeros, and inferred the plausibility of the relation that the number of primes less than or equal to x is asymptotically the same as $\mathrm{li}(x)$ (see 80) in which the tilde sign is used and, in fact, gives a more precise statement. The $\sim$ sign is an abbreviation for the fact that the ratio tends to 1. The completion of this proof was carried out independently and simultaneously by Hadamard and de la Vallée-Poussin in 1896.

In the 20th century much of the work centring on the distribution of primes has been concerned with the finer properties of their distribution. Having established that $\pi(x)$ is approximately $\mathrm{li}(x)$, it is natural to determine how accurately $\mathrm{li}(x)$ in fact represents $\pi(x)$. This problem is intimately connected with the Riemann zeta function and its zeros. If the series form of the function is given with complex argument (see 81), then the series converges for $\sigma > 1$, but there is an analytic continuation into the whole complex plane, and $\zeta(s)$ is meromorphic with a simple pole at $s = 1$ with residue 1. Instead of working with $\pi(x)$, it is more natural analytically to work with a function defined in terms of the logarithm and written ψ (see 82). The connection with $\pi(x)$ is: the statement that $\pi(x)$ is asymptotically equal to x divided by the logarithm of x (see 83) is equivalent to the statement that $\psi(x) \sim x$.

The advantage of working with $\Lambda(n)$ lies in the Dirichlet series associated with $\Lambda(n)$ (see 84) as contrasted with the more complicated series expressed as a sum of reciprocals of s powers of p (see 85). The starting point for studying $\psi(x)$, and hence $\pi(x)$, is the relation that expresses the function ψ as a line integral that involves the zeta function (see 86).

Cauchy's theorem is then used to move the line of integration past the pole of the integrand, but here is encountered a great difficulty because the poles of the integrand involve the zeros of $\zeta(s)$, the function $\zeta(s)$ occurring in the denominator.

The Riemann hypothesis

In a now famous memoir of 1859, Riemann proposed the conjecture that all of the complex zeros $\beta + i\gamma$ of $\zeta(s)$ had $\beta = \frac{1}{2}$. The complex zeros are known to satisfy $0 < \beta < 1$. This is the so-called Riemann hypothesis, which remains unproved. What can be proved is that if the Riemann hypothesis is true, then there exists a constant A such that if $\Delta(x) = \psi(x) - x$, then the absolute value of Δ has a bound that depends on A and the logarithm of x (see 87) and a corresponding result for $\pi(x)$: If $\pi(x) - \mathrm{li}\, x = D(x)$, then the absolute value of $D(x)$ is bounded by a constant B times a function of x

(69) $$\Lambda(n) = \begin{cases} \log p & \text{if } n = p^k \\ 0 & \text{otherwise} \end{cases}$$

(70) $$\begin{cases} f(s) = \sum_{n=1}^{\infty} \dfrac{\Lambda(n)}{n^s} \\ \sum_{d \mid n} \Lambda(d) = \log n \end{cases}$$

(71) $$f(s) \cdot \zeta(s) = \sum_{n=1}^{\infty} \frac{\log n}{n^s} = -\zeta'(s)$$

(72) $$\sum_{n=1}^{\infty} \frac{1}{n}$$

(73) $$\sum_{p} \frac{1}{p}$$

(74) $$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}$$

(75) $$\pi(x) = \frac{x}{\log x - 1.08366}$$

(76) $$\pi(x) = \frac{x}{\log x - A}$$

(77) $$\pi(x) = \int_2^x \frac{dt}{\log t} = \mathrm{li}(x)$$

(78) $$\lim_{x \to \infty} \frac{\pi(x) \log x}{x} = 1$$

(79) $$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}$$

(80) $$\pi(x) \sim \mathrm{li}(x)$$

(81) $$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s} \quad \text{with } s = \sigma + it$$

(82) $$\begin{cases} \psi(x) = \sum_{n \leq x} \Lambda(n) \\ \Lambda(n) = \begin{cases} \log p & \text{if } n = p^k \\ 0 & \text{otherwise} \end{cases} \end{cases}$$

(83) $$\pi(x) \sim \frac{x}{\log x}$$

(84) $$\sum_{n=1}^{\infty} \frac{\Lambda(n)}{n^s} = -\frac{\zeta'(s)}{\zeta(s)}$$

(85) $$\sum_{p} \frac{1}{p^s} = \sum_{n=1}^{\infty} \frac{\mu(n)}{n} \log \zeta(ns)$$

(86) $$\psi(x) = \frac{1}{2\pi i} \int_{a-i\infty}^{a+i\infty} \left(-\frac{\zeta'(s)}{\zeta(s)} \right) \frac{x^s}{s}\, ds \qquad a > 1$$

(87) $$|\Delta(x)| \leq A x^{\frac{1}{2}} \log^2 x$$

(88) $$|\pi(x) - \mathrm{li}\, x| \leq B x^{\frac{1}{2}} \log x$$

(see 88). By contrast the best result known to date is that there are constants c, A such that a bound for the absolute value of Δ as a function of x depends upon c, A, and a complicated function of x (see 89).

This result is due to A. Walfisz and is based on the work of Hermann Weyl, Godfrey Harold Hardy, John Edensor Littlewood, Ivan Matveyevich Vinogradov, and Nikolay Mikhaylovich Korobov.

In the opposite direction, Littlewood has proved that the error $\Delta(x)$ cannot be much different from that predicted by the Riemann hypothesis. More precisely, he has proved that for infinitely many values of x, there is for $c > 0$ a lower bound that depends on c as well as upon the logarithm of the logarithm of the logarithm of x (see 90) and for infinitely many values of x there is an upper bound for Δ of similar structure (see 91). Concerning the finer properties of the primes, there is the result of asymptotic nature concerning π as a function of x (see 92). Thus, if x is sufficiently large, there is a prime between x and $x + x^{5/8}$. Furthermore, it can be deduced that there is a constant A such that for every n an inequality holds for the absolute difference between adjacent primes (see 93). H.L. Montgomery, using sieving methods, has shown that $|p_{n+1} - p_n| \leq Ap_n^{3/5+\varepsilon}$, and M.N. Huxley has made a further refinement of the index to $7/12 + \varepsilon$. This is to be contrasted with the inference to be drawn if the Riemann hypothesis is true (see 94). It is an unsolved problem whether for x sufficiently large a difference expression involving π as a function of x is positive (see 95). Much effort has been devoted to the Riemann hypothesis, but by the 1970s the best known about a region in the strip $0 \leq \sigma \leq 1$ in which the function has no zeros is that σ is greater than or equal to 1 minus a function that involves A and the logarithm of t (see 96), a result due to Korobov and Vinogradov and used to prove the above quoted result on $\Delta(x)$.

(89) $|\Delta(x)| \leq Axe^{-c(\log x)^{3/5}(\log\log x)^{1/5}}$

(90) $\Delta(x) > cx^{\frac{1}{2}} \log\log\log x$

(91) $\Delta(x) < -cx^{\frac{1}{2}} \log\log\log x$

(92) $\pi(x+x^{\frac{5}{8}}) - \pi(x) \sim \dfrac{x^{\frac{5}{8}}}{\log x}$

(93) $|p_{n+1} - p_n| \leq Ap_n^{\frac{5}{8}+\varepsilon}$ for any $\varepsilon > 0$

(94) $|p_{n+1} - p_n| \leq Ap_n^{\frac{1}{2}} \log p_n$

(95) $\pi(x+x^{\frac{1}{2}}) - \pi(x) > 0$

(96) $\begin{cases} \zeta(s) \neq 0 \quad \text{for} \\ \sigma \geq 1 - \dfrac{A}{(\log t)^{\alpha}} \quad \text{with } t \geq 3, \qquad \alpha \geq 2/3 \end{cases}$

(97) $\begin{cases} \displaystyle\sum_{n=1}^{\infty} \frac{\mu(n)}{n^s} = \frac{1}{\zeta(s)} \\ \displaystyle\sum_{n=1}^{\infty} \frac{\varphi(n)}{n^s} = \frac{\zeta(s-1)}{\zeta(s)} \end{cases}$

(98) $\Phi(x) = \displaystyle\sum_{n \leq x} \varphi(n) = \frac{3}{\pi^2} x^2 + \Delta(x)$

(99) $|M(x)| \leq Axe^{-c\sqrt{\log x}}$

(100) $a, a+k, a+2k, \cdots$

(101) $\displaystyle\lim_{x \to \infty} \frac{\pi(a_1, k, x)}{\pi(a_2, k, x)} = 1$

(102) $\begin{cases} 1, 5, 9, 13, 17, 21, \cdots \\ 3, 7, 11, 15, 19, 23, \cdots \end{cases}$

(103) $\log \zeta(s) = \displaystyle\sum_p \frac{1}{p^s} + R(s)$

(104) $\displaystyle\sum_p \frac{1}{p}$

(105) $\varepsilon(n) = \begin{cases} 0 & \text{if } n \not\equiv a \pmod{k} \\ 1 & \text{if } n \equiv a \pmod{k} \end{cases}$

(106) $\displaystyle\sum_p \frac{\varepsilon(p)}{p^s} = \sum_{p \equiv a \pmod{k}} \frac{1}{p^s}$

(107) $\begin{cases} \chi(n) = \chi(m) \quad \text{if} \quad n \equiv m \pmod{k} \\ \chi(mn) = \chi(m)\chi(n) \\ \chi(n) = 0 \qquad \text{if } (n, k) > 1 \\ \chi(n) \text{ is not identically } 0 \end{cases}$

Other arithmetic functions. The analysis of other arithmetic functions such as those referred to above takes place by way of the Dirichlet series determined by them. For example, two summations are given, one of which involves the function μ and relates it to the ζ function, the other of which involves the function φ and relates it to the ζ function (see 97).

Typical results are Φ as a function of x expressed as a sum of φ as a function of n (see 98), in which $|\Delta(x)| \leq Ax \log x$. If $M(x) = \Sigma\mu(n)$, the summation for $n \leq x$, then the absolute value of M is bounded by a function expressed in terms of A and the exponential of a square root of the logarithm of x (see 99).

Primes in arithmetic progressions. If k and a be two relatively prime integers with $k \geq 2$ and the arithmetic progression, a sequence of integers beginning with a (see 100), is considered, then the questions raised by Legendre in 1803 were these:

Legendre's questions

(i) Are there infinitely many primes in this progression; *i.e.*, are there infinitely many $p \equiv a \pmod{k}$?

(ii) If so, and $\pi(a, k, x)$ be the number of such primes $\leq x$, then if $(a_1, k) = (a_2, k) = 1$, is it true that a limiting expression for a ratio of functions π equals 1 (see 101)? That is, are the numbers of primes in the different residue classes modulo k equidistributed?

The example gives the progressions $1 + 4n$, and $3 + 4n$—*i.e.*, two sequences, one beginning with 1 and one beginning with 3 (see 102). Are there as many primes in the first sequence as there are in the second in the sense of the limit of the ratio already given (see 101)? Dirichlet gave an affirmative answer to the first question in 1837 and laid the foundations for an affirmative answer to the second. In doing so, Dirichlet was guided by Euler's proof that $\pi(x) \to \infty$ and was led to the concept of a character. Euler had proved that the logarithm of the ζ-function can be expressed as a sum of reciprocals of s powers of primes plus a remainder (see 103) in which the first sum is over all primes and in which the term $R(s)$ remains bounded as $s \to 1$. It then followed that the sum of the reciprocals of the primes (see 104) diverged in view of the fact that $\zeta(s) \to \infty$ as $s \to 1$.

To duplicate the argument requires a function ε as a function of n being defined to take on values 1 or 0 on conditions that depend on a mod k (see 105) and then requires that the sum over all primes of the ratio of $\varepsilon(p)$ to p^s (see 106) be expressed in terms of functions the properties of which lend themselves readily to investigation. To produce such a function, Dirichlet postulates the existence of a function χ for fixed $k \geq 2$ with specific properties (see 107). The following facts are then established: (a) Such a function does indeed exist, and there are $\varphi(k)$ distinct such characters in which $\varphi(k) =$

the number of integers less than k and having no factors in common with k, called the Euler φ-function. (b) The values of $\chi(n)$ that are different from 0 are $\varphi(k)$-th roots of unity; *i.e.*, satisfy the equation $x^{\varphi(k)} = 1$. (c) There is a character χ_1 the values of which are as follows: $\chi_1(a) = 1$ if $(a, k) = 1$, $\chi_1(a) = 0$ if $(a, k) > 1$; χ_1 is called the principal character. Two further conditions may be expressed symbolically (see 108). The Dirichlet L-series is now defined by a sum over positive integers of ratios of the function χ to s powers of the integers for s a complex number (see 109).

These functions have many properties, some of which are displayed (see 110). The last relation is one of the fundamental and important properties of $L(s, \chi)$. Much attention has been devoted to a proof, but no simple proof is known.

With the help of the various properties enumerated, it is now possible to show that if a^* is chosen such that $aa^* \equiv 1 \pmod{k}$, then an equality exists between sums that relates the function χ, the function L, the function φ, and certain primes (see 111) in which $R(s)$ remains bounded as $s \to 1$. It follows that the limit as s approaches 1 of a restricted sum of reciprocals of s powers of primes is infinity (see 112). Thus the sum with $s = 1$ diverges, and, hence, there are infinitely many $p \equiv a \pmod{k}$. In fact, the above argument shows that the limit as s approaches 1 of a ratio of sums involving reciprocals of s powers of primes is equal to the reciprocal of φ at k (see 113). Thus the proportion of primes $p \equiv a \pmod{k}$ does not depend upon a and is $1/\varphi(k)$ in the sense of the limit of a ratio (see 113). In general, A is any set of natural numbers and B any subset. Then, the following limit (if it exists): the limit as s approaches 1 of a ratio of sums of reciprocals of s powers (see 114) is called the Dirichlet density of the set B with respect to the set A.

Dirichlet density

On the other hand, if $A(x)$ is defined as the number of elements of A that are less than or equal to x and $B(x)$ is similarly defined, then the limit (if it exists) of the ratio of B as a function of x to A as a function of x as x approaches infinity (see 115) is called the natural density of the set B with respect to the set A.

It is known that if the natural density exists, then the Dirichlet density exists. It is a fundamental problem to decide when the converse is true.

Distributions of other arithmetic functions in arithmetic progressions are handled in analogy with the distributions among the entire set of natural numbers, the L-functions usually replacing the zeta function.

Much attention has been devoted to the question of the uniformity of the distribution of primes in arithmetic progressions. De la Vallée-Poussin provided an expression for π in terms of a function φ and a function of x (see 116). The problem of a uniform error $\Delta(x)$, uniform in the sense that it does not depend on k or a, has played an important role in various questions. Some results are formulated in terms of the function ψ equal to a restricted sum of Λ as a function m (see 117).

As a consequence of Siegel's theorem on the class number, Walfisz proved that if $k \leq (\log x)^N$, there exists a constant c depending only on N such that the absolute value of Δ is less than or equal to a function involving constants A, c, and the logarithm of x (see 118) uniformly in k. Vinogradov used this result in his proof of the 3-prime version of the Goldbach conjecture.

Deeper results have been obtained by the mathematician E. Bombieri, which require sieving methods and estimates for the number of zeros of the L-functions. One result takes the following form. Let $\mathfrak{F}$ equal the maximum over a of Δ (see 119) and $\mathfrak{F}^*$ equal a certain maximum of $\mathfrak{F}$, the range considered being y less than or equal to x (see 120) and $\mathfrak{F}$ equal to a sum of $\mathfrak{F}^*$, the range of summation being k less than or equal to x (see 121). Then for any constant c_1 there exists a constant c_2 such that if $X = x^{1/2}(\log x)^{-c_2}$, the absolute value of $\mathfrak{F}$ is less than or equal to a function of x that includes constants A and c_1 also a functional expression X (see 122). The complexity of the result is in the nature of the subject because the primes are so irregularly distributed.

(108)
$$\begin{cases} (d)\ \displaystyle\sum_{a=1}^{k-1} \chi(a) = \begin{cases} \varphi(k) & \text{if } \chi = \chi_1 \\ 0 & \text{otherwise} \end{cases} \\ (e)\ \displaystyle\sum_{\chi} \chi(a) = \begin{cases} \varphi(k) & \text{if } a \equiv 1 \pmod{k} \\ 0 & \text{otherwise} \end{cases} \end{cases}$$

$$L(s, \chi) = \sum_{n=1}^{\infty} \frac{\chi(n)}{n^s} \qquad s = \sigma + it$$

(110)
$$\begin{cases} \text{(i) If } \chi = \chi_1 \text{ the principal character, then } L(s, \chi) \text{ differs from } \zeta(s) \text{ by a simple factor.} \\ \text{(ii) If } \chi \neq \chi_1, \text{ then } L(s, \chi) \text{ converges for } \sigma > 0. \\ \text{(iii) } L(s, \chi) = \displaystyle\prod_p \left(1 - \frac{\chi(p)}{p^s}\right)^{-1} \text{ its "Euler product."} \\ \text{(iv) If } \chi \neq \chi_1, \text{ then } L(1, \chi) \neq 0. \end{cases}$$

(111)
$$\sum_{\chi} \chi(a^*) \log L(s, \chi) = \frac{1}{\varphi(k)} \sum_{\substack{p \equiv a \\ \bmod k}} \frac{1}{p^s} + R(s)$$

(112)
$$\lim_{s \to 1} \sum_{p \equiv a \pmod{k}} \frac{1}{p^s} \to \infty$$

(113)
$$\lim_{s \to 1} \frac{\displaystyle\sum_{p \equiv a \pmod{k}} \frac{1}{p^s}}{\displaystyle\sum_p \frac{1}{p^s}} = \frac{1}{\varphi(k)}$$

(114)
$$\lim_{s \to 1} \frac{\displaystyle\sum_{n \in B} \frac{1}{b^s}}{\displaystyle\sum_{a \in A} \frac{1}{a^s}}$$

(115)
$$\lim_{x \to \infty} \frac{B(x)}{A(x)}$$

(116)
$$\begin{cases} \pi(a, k, x) = \dfrac{1}{\varphi(k)} \dfrac{x}{\log x} + \Delta(x) \\ \text{in which} \\ |\Delta(x)| \leq Axe^{-c\sqrt{\log x}} \end{cases}$$

(117)
$$\psi(a, k, x) = \sum_{\substack{n \leq x \\ n \equiv a \pmod{k}}} \Lambda(n)$$

(118)
$$|\Delta(x)| \leq Axe^{-c\sqrt{\log x}}$$

(119)
$$\mathfrak{F}(x, k) = \max_a \Delta(x) \qquad (a, k) = 1$$

(120)
$$\mathfrak{F}^*(x, k) = \max_{y \leq x} \mathfrak{F}(y, k)$$

(121)
$$\mathfrak{F}(x) = \sum_{k \leq x} \mathfrak{F}^*(x, k)$$

(122)
$$|\mathfrak{F}(X)| \leq Ax(\log x)^{-c_1}, \qquad X = x^{\frac{1}{2}} (\log x)^{-c_2}$$

Other applications of L-functions. There is a close connection between class numbers (see above *Algebraic number theory*) and the L-functions of Dirichlet. In fact, let $\mathfrak{J} = \mathfrak{H}(\sqrt{d})$ be a quadratic extension of the rational field $\mathfrak{H}$, with class number h. Consider the case when $d < 0$ and $d \equiv 1 \pmod 4$ [similar results hold when $d \equiv 2, 3 \pmod 4$]. Then Dirichlet proved that the product πh divided by the square root of d is equal to L (see

123) in which $\chi(n) = (d/n)$ is the Kronecker symbol (an extension of the Legendre symbol) and is a character mod $|d|$. The series for $L(1, \chi)$ may be expressed as a finite sum. In the more general case, there is a constant, symbolized by the Greek letter alpha, α, depending on the field K, such that αh equals the residue of ζ at s equals 1 (see 124), the function $\zeta_K(s)$ being the Riemann zeta function defined by ζ_k at s equals a summation over the class $\mathfrak{A}$ of reciprocals expressed in terms of N (see 125) summed over all integral ideals $\mathfrak{A}$. In certain cases $\zeta_K(s)$ can be written as a product of Dirichlet L-functions and its residue computed in terms of L-functions. Siegel proved that for a quadratic field of discriminant d a ratio of logarithms involving α and h converges to 0 (see 126) as $|d| \to \infty$. This was generalized by the German-born U.S. mathematician Richard Brauer in 1947.

The Circle method. The case of the partition function $p(n)$ was previously considered and its generating function determined. It was found that a power series with coefficients $p(n)$ equals a product over positive integers of the function of x, which in turn equals F (see 127).

In 1917, Hardy and the Indian mathematician Srinivasa Ramanujan obtained an asymptotic formula for $p(n)$ and laid the foundations for a method that was further developed by Hardy and Littlewood, which method has since been called the Circle method. This method has been modified and refined by Vinogradov and has been widely used to derive results on additive problems in number theory. The method will be described briefly as it applies to $p(n)$. Using Cauchy's theorem p as a function of n equals an integral over C of a function involving F (see 128), C being a simple closed contour inside the unit circle D, containing the origin. The function $F(x)$ is analytic inside D, but on the boundary of D, $F(x)$ has a dense set of poles. Thus it is not possible to integrate past the poles but only to come close to these. A circle of radius $N < 1$ is chosen and cut in a prescribed manner into arcs, the Farey fractions being used to determine the arcs and the number of arcs depending on N and tending to infinity as N tends to 1. Moreover, the circle approaches the unit circle as $N \to 1$.

The function $F(x)$ is now approximated along each of the arcs. The success of the method depends upon the precision with which $F(x)$ may be approximated. In this special case $F(x)$ satisfies a functional equation, and the approximation is so effective that a rapidly convergent series for $p(n)$ can be derived, as was shown by the German-born U.S. mathematician Hans Rademacher in 1937.

Vinogradov's modification

Vinogradov's modification is as follows: If, for example, the Goldbach problem for three primes be considered, then $r(n)$ may be the number of solutions of n equal to a sum of three primes (see 129). By use of an idea previously stated (see above *Methodology*), it is readily seen that a power series with coefficients r equals a third power of a sum extended over primes (see 130) in which the summation on the right is over primes.

Vinogradov replaces the infinite series with a finite sum and, because x is then no longer required to be in absolute value < 1, replaces x by $\exp(2\pi it)$, and integrates along the unit circle, which is then transformed into the unit interval or indeed any interval of length 1. If the function f equals a restricted sum of exponentials involving p and t (see 131), r as a function of n is an integral from zero to one of the third power of f times an exponential (see 132). The interval is now dissected into subintervals by analogy with the decomposition into Farey arcs. The intervals are in two classes, basic intervals and supplementary intervals. The basic intervals contribute the principal term. If the basic intervals are denoted by I and the supplementary intervals by S, r as a function of n is a sum of two integrals, one extended over I and one extended over S, each with integrands of the type: third power of f times an exponential (see 133). After suitable approximation on I and S, respectively, the conclusion is reached that r as a function of n is a sum of two terms C and λ all multiplied by a function involving the third power of the logarithm of n (see 134) when $C(n)$ is positive if n is odd and $\lambda(n) \to 0$ as $n \to \infty$. The first term comes from I and the second from S.

$$\frac{\pi h}{\sqrt{d}} = L(1, \chi) \tag{123}$$

$$\alpha h = \text{residue of } \zeta_K(s) \quad \text{at } s = 1 \tag{124}$$

$$\zeta_k(s) = \sum_{\mathfrak{A}} \frac{1}{N(\mathfrak{A})^s} \tag{125}$$

$$\frac{\log \alpha h}{\log \sqrt{|\alpha|}} \to 0 \tag{126}$$

$$\sum_{n=0}^{\infty} p(n)x^n = \prod_{k=1}^{\infty} (1 - x^k)^{-1} = F(x) \tag{127}$$

$$p(n) = \frac{1}{2\pi i} \int_C F(x) x^{-n-1}\, dx \tag{128}$$

$$n = p_1 + p_2 + p_3 \tag{129}$$

$$\sum_{n=0}^{\infty} r(n)x^n = \left(\sum_p x^p\right)^3 \tag{130}$$

$$f(t) = \sum_{p \leq N} e^{2\pi i p t} \tag{131}$$

$$r(n) = \int_0^1 f^3(t) e^{-\pi i n t}\, dt \tag{132}$$

$$r(n) = \int_I f^3(t) e^{-2\pi i n t}\, dt + \int_S f^3(t) e^{-2\pi i n t}\, dt = I_1 + I_2 \tag{133}$$

$$r(n) = (C(n) + \lambda(n)) \frac{n^2}{\log^3 n} \tag{134}$$

$$n = x_1^k + \cdots + x_s^k \tag{135}$$

$$\begin{cases} \text{If } s \geq [10k^2 \log k], \text{ then} \\ r(n) = C(n)\, \gamma(s, k) + \lambda(n) n^{s/(k-1)} \end{cases} \tag{136}$$

It follows that if n is sufficiently large then $r(n) > 0$. The same method has been used to obtain a variety of results. For example, if $r(n)$ is the number of solutions of an equation giving n as a sum of s terms of the type x_1 raised to the kth power (see 135) if s is greater than or equal to a specific function of k involving a logarithm, then r as a function of n is a sum of two terms, one a product of C times γ, one a product of λ and a certain power of n (see 136), in which $C(n)\gamma(s, k) > 0$ and $\lambda(n) \to 0$ as $n \to \infty$. This was proved by Vinogradov.

In particular, the English mathematician Harold Davenport has proved that if $k = 4$, then $r(n) > 0$ if and only if $s \geq 16$. Yury Vladimirovich Linnik (Soviet) and George Leo Watson (English) have proved that for $k = 3$, $r(n) > 0$ if $s \geq 7$.

Although the Goldbach conjecture for even numbers has not been proved, it can be shown using the circle method that almost all even numbers are sums of two primes. This means that if $E(N)$ is the number of even integers, m, that are not the sum of two primes and $m \leq N$, then the limit, as N approaches infinity, of the ratio $E(N)/N$ is zero.

Exponential sums. It is significant that both in the distribution of primes and in additive problems, as well as in numerous other questions, the basic problems frequently reduce to the problem of estimating the size of the exponential sum E as a function of x. This is a sum over all values of n less than or equal to N of an exponential involving f (see 137), in which $f(y)$ is some function of y. In the case of the Goldbach problem, f as a function of y takes on one of two values 0 or 1, depend-

ing on whether y is not or is a prime (see 138). In the case of the zeta function $\zeta(s)$, $(s = \sigma + it)$, the estimates of $\zeta(s)$ can be reduced to a function $E(x)$ in which f as a function of y is expressed in terms of the logarithm of y (see 139). It is to be noted that because each of the terms in the sum has absolute value 1, then trivially the absolute value of E is less than or equal to N (see 140). The basic problem is to show that under suitable conditions on $f(y)$ and on x, the limit as N approaches infinity of the ratio of the absolute value of E to N is 0 (see 141), and the rate at which this takes place is an important part of the problem. A typical result due to Korobov and Vinogradov is the following: If a number of conditions are satisfied that involve r, w, t, M, M', and θ, then the absolute value of a sum of exponentials of the logarithm of m and w is less than or equal to a certain power of M (see 142). The complexity of the statement of the result is fairly typical and it is noted once again that this intricacy is in the nature of the subject.

Elliptic, theta, and modular functions. In addition to analysis of the partition function, Euler considered a function that makes $\theta(x)$ equal a product over all positive integers of the difference between 1 and integer powers of x (see 143) and proved the so-called pentagonal number theorem—*i.e.*, θ as a function of x can be found by calculation to be 1 plus an infinite sum of positive and negative terms each being powers of x (see 144)—the name stems from the relation of the exponents to the pentagon.

More important, however, is the fact that this function was the first example of a theta function. From this result and other related ones, interesting identities and relations involving partitions are proved. Theta functions appeared in the works of Bernoulli (1713), in Fourier's *Théorie analytique de la chaleur* (1822; *The Analytical Theory of Heat*, 1878), but were only systematically introduced and studied by the German mathematician Karl Gustav Jacob Jacobi in *Fundamenta nova Theoriae Functionum Ellipticarum* (1829; "New Foundations of the Theory of Elliptic Functions"). There are four types of theta functions; one is defined by θ as a function of z and q is equal to 1 plus twice the sum over all positive integers of a product involving a cosine function (see 145) with $q = \exp(\pi i\tau)$, $\operatorname{im} \tau > 0$, which for $z = \pi$ takes the form θ as a function of π and q is equal to 1 plus twice the infinite sum over all positive integers of q raised to the squared power of an integer (see 146), a function useful for studying sums of squares.

Using the theory of θ-functions and their transformations, Jacobi proved several results on the numbers of representations of integers by sums of squares. In particular, he proved that the number $r_4(n)$ of representations of n as a sum of four squares is (i) 8 times the sum of the odd divisors of n when n is odd and (ii) 24 times the sum of the odd divisors of n when n is even.

Jacobi also proved the identity an infinite product extending over all positive integers is equal to an infinite sum extending over both negative and positive integers, the product expressed in three factors that involve x, z, and an integer, the sum involving two factors expressed in terms of z, x, and an integer (see 147) from which a number of results could be derived.

The introduction of modular forms and functions began a new era in the interplay between number theory and analysis.

Modular transformations

If $f(z)$ be a function of a complex variable z that is meromorphic in the upper half plane, then if a, b, c, d are integers with $ad - bc = 1$, the transformation w is a rational function of z with coefficients a, b, c, and d (see 148); this is called a modular transformation. The set of modular transformations forms a group generated by the particular transformations w_1 and w_2; these are each simple functions of z (see 149), and a modular transformation takes the upper half plane into itself. If f, as a function of z, is a factor raised to the $2k$ power times f, as a function of a rational function of z, the rational function involving coefficients a, b, c, and d that satisfy a simple condition (see 150), then $f(z)$ is called a modular form of weight (or dimension) $2k$. Examples of such modular forms are the Eisenstein series, G_k as a function of z, a restricted sum over two integer valued variables m and n of a simple function of two variables (see 151), in which m, n range over all integers except the pair (0, 0). The form Δ, as a function of τ, which is a difference of two terms, one term involving G_2, a second term involving G_3 (see 152), plays an important role in the theory. It is a modular form of weight 12. It turns out that Δ, as a function of τ, is a factor involving π and q multiplied by an infinite product over positive integers of a simple function of q and an integer (see 153), in which $q = \exp(2\pi i\tau)$. On the other hand, the function

(137) $$E(x) = \sum_{n \leq N} e^{2\pi i f(n)x}$$

(138) $$f(y) = \begin{cases} 0 & \text{if } y \text{ is not a prime} \\ 1 & \text{if } y \text{ is a prime} \end{cases}$$

(139) $$f(y) = t \log y$$

(140) $$|E(x)| \leq N$$

(141) $$\lim_{N \to \infty} \frac{|E(x)|}{N} = 0$$

(142) $$\begin{cases} \text{Let } r \geq 46, \quad 0 \leq w \leq 1, \quad t \geq 1 \\ M \leq M' \leq 2M, \quad \theta = (266{,}000r^2)^{-1} \\ t^{1/r} \leq M \leq t^{1/(r-1)} \quad \text{then} \\ \left| \sum_{m=M}^{M'} e^{ti \log(m+w)} \right| \leq M^{1-\theta} \end{cases}$$

(143) $$\theta(x) = \prod_{n=1}^{\infty} (1 - x^n)$$

(144) $$\begin{cases} \theta(x) = 1 + \sum_{n=1}^{\infty} (-1)^n \left(x^{\frac{n(3n-1)}{2}} + x^{\frac{n(3n+1)}{2}} \right) \\ \quad = 1 - x - x^2 + x^5 + x^7 - x^{12} - x^{15} + \cdots \end{cases}$$

(145) $$\theta(z, q) = 1 + 2 \sum_{n=1}^{\infty} q^{n^2} \cos 2nz$$

(146) $$\theta(0, q) = 1 + 2 \sum_{n=1}^{\infty} q^{n^2}$$

(147) $$\prod_{n=1}^{\infty} (1 - x^{2n})(1 + zx^{2n+1})(1 + z^{-1}x^{2n-1}) = \sum_{k=-\infty}^{\infty} z^k x^{k^2}$$

(148) $$w = \frac{az + b}{cz + d}$$

(149) $$\begin{cases} w_1 = z + 1 \\ w_2 = -\dfrac{1}{z} \end{cases}$$

(150) $$f(z) = (cz + d)^{-2k} f\left(\frac{az + b}{cz + d}\right) \qquad (ad - bc = 1)$$

(151) $$G_k(z) = \sum_{m,n}{}' \frac{1}{(mz + n)^{2k}}$$

(152) $$\Delta(\tau) = (60G_2)^3 - 27(140G_3)^2$$

(153) $$\Delta(\tau) = (2\pi)^{12} q \prod_{n=1}^{\infty} (1 - q^n)^{24}$$

η, as a function of τ, that is the $\frac{1}{12}$ power of q times an infinite product extended over all positive integers of a simple function of q and an integer (see 154), appears in Riemann's works, and its properties were elucidated by Dedekind. It plays a fundamental role in the problem of partitions, and its relation with $\Delta(\tau)$ is immediate.

The function j, as a function of τ, that is equal to a ratio of a third power involving g_2 to Δ, as a function of τ (see 155), is a modular form of weight 0; it is invariant under the complete modular group. Moreover, if $f(\tau)$ is any function meromorphic in the upper half plane and is a modular form of weight 0, then $f(\tau)$ is a rational function of $j(\tau)$; *i.e.*, the ratio of two polynomials in $j(\tau)$.

It is most remarkable that Abelian extensions of an imaginary quadratic field can be obtained as subfields obtained by adjoining values of $j(\tau)$ to the quadratic field. This settled the *Jugendtraum* of Kronecker. Abelian extensions of the rational field $\mathfrak{Q}$ are subfields of fields obtained by adjoining to $\mathfrak{Q}$ values of the exponential function e^x. Thus the relation between modular forms and algebraic number fields is very profound. Mention should be made of the connection between the zeta functions of algebraic number fields and elliptic functions, connections that were discovered by Kronecker in 1875. Extensions of these results were made by Erich Hecke (German-born), Carl L. Siegel (U.S.), and others.

These connections were used by the mathematician K. Heegner in 1952 and later by the mathematician Harold M. Stark in 1967 and others to determine all imaginary quadratic fields that have unique factorization. The problem had remained unsolved since 1933 when the mathematicians H. Heilbronn and E. Linfoot showed that there could be at most 10 such fields, nine of which were identified.

Another connection between modular forms and number theory was discovered by Hecke as follows: $f(\tau)$ may be expanded in a Fourier series in q such that f, as a function of q, is a power series with coefficients a_n, q being a complex exponential with variable τ (see 156). If $a_0 = 0$, then $f(\tau)$ is called a cusp form. Hecke proved that if $f(\tau)$ is a cusp form of weight $2k$, then the absolute value of a_n is less than or equal to a constant times the k power of n (see 157).

Ramanujan investigated in great detail the function that is a sum over positive integers of the function τ times q raised to an integer power and that is equal to q times a product of terms involving q and an integer (see 158). He conjectured that if $(m, n) = 1$, then $\tau(m)\tau(n) = \tau(mn)$, a fact proved by the U.S.-born mathematician Louis Joel Mordell. He was led to the conjecture that if p is prime, then the absolute value of τ as a function of p is less than a simple function of p (see 159). This conjecture remains unproved though a proof was reported in the 1970s but not yet confirmed.

(154) $$\eta(\tau) = q^{1/12} \prod_{n=1}^{\infty} (1 - q^n)$$

(155) $$j(\tau) = \frac{(720 G_2(\tau))^3}{\Delta(\tau)}$$

(156) $$f(q) = \sum_{n=0}^{\infty} a_n q^n \qquad q = e^{2\pi i \tau}$$

(157) $$|a_n| \leq A n^k$$

(158) $$\sum_{n=1}^{\infty} \tau(n) q^n = q \prod (1 - q^n)^{24}$$

(159) $$|\tau(p)| < 2p^{\frac{11}{2}}$$

(160) $$f(s) = 1 - \frac{1}{2^s} + \frac{1}{3^s} - \cdots$$

(161) $$\left| \sum_{n \leq x} \mu(n) \right| \leq A x^{1/2 + \varepsilon}$$

(162) $$K(a, b) = \sum_{\substack{n \bmod p \\ n\bar{n} \equiv 1 (p)}} e^{\frac{2\pi i}{p}(an + b\bar{n})}$$

(163) $$|K(a, b)| \leq A\sqrt{p}$$

RESULTS OBTAINABLE FROM ELEMENTARY METHODS

A great deal of attention has been paid to the question of whether the results of analytic number theory can be derived without the use of complex analytic machinery, especially such results as those of the Goldbach and Waring problems, the statements of which do not involve analytic concepts. In fact, a number of results have been proved without complex function theory. Several results that have been proved by elementary methods are enumerated below.

(i) The prime number theorem—proved by the Norwegian-born U.S. mathematician Atle Selberg and the Hungarian mathematician Paul Erdös with later refinements by Bombieri.

(ii) Solution to the Waring problem obtained by the Soviet mathematician Yury Vladimirovich Linnik.

(iii) Dirichlet's theorem on primes in an arithmetic progression, proved by the German-born Canadian mathematician Hans Zassenhaus and Atle Selberg.

(iv) Calculation of the number of lattice points inside contours, performed by Vinogradov.

(v) Siegel's theorem on the class number of quadratic fields, proved by Linnik.

The term elementary is in some respects a misnomer. The methods are elementary primarily in avoiding the use of such results as Cauchy's theorem of complex function theory. In fact, they tend to be rather intricate.

Furthermore, there has also been a trend to avoid the use of analysis even in the statements of some of the theorems that on the face of it are analytic in character. For example, in the prime number theorem the function $\log x$ is replaced by $\ell(n) = \Sigma 1/k$, the summation for $k \leq n$, and then $\pi(n)/n$ is compared with $\ell(n)$: Thus, transcendental concepts are entirely removed.

SOME UNSOLVED PROBLEMS OF ANALYTIC NUMBER THEORY

1. The most famous is perhaps the Riemann hypothesis. An elementary formulation follows: If $s = \sigma + it$ and f as a function of s is equal to 1 plus negative and positive reciprocals of integers raised to the s power (see 160), which converges for $\sigma > 0$, then the Riemann conjecture is that if $f(s) = 0$, $0 < \sigma < 1$, then $\sigma = \frac{1}{2}$. Again, if $\mu(n)$ is the Möbius function described above, then the Riemann hypothesis is equivalent to the statement that there exists a constant A such that the absolute value of the function μ with integer arguments is less than or equal to a constant A times the $\frac{1}{2} + \varepsilon$ power of x (see 161), in which ε is any positive number.

2. The Goldbach conjecture for even integers: Every even integer $n \geq 4$ is the sum of two primes.

3. Hecke's hypothesis: If χ is a real character mod k, then $L(s, \chi) \neq 0$ if $0 < s < 1$.

4. Better estimates for exponential sums. In the case of K as a function of a and b—that is, a sum over integers defined in terms of p, summands being of exponential type (see 162)—the mathematician André Weil proved the Riemann hypothesis for function fields and using it showed that the absolute value of K is less than or equal to A times the square root of p (see 163).

Such sharp estimates in general are much to be desired.

5. The least quadratic non-residue. If p is a prime and $n(p)$ is the least quadratic non-residue, then the Riemann hypothesis implies, as shown by the mathematician N. Ankeny, that $|n(p)| \leq A \log^2 p$. A proof without hypothesis is yet to be found. The mathematician Burgess has shown that $|n(p)| \leq A p^{1/4\sqrt{e}}$.

6. If $d > 0$, and $h(d)$ the class number of the quadratic field $\mathfrak{Q}(\sqrt{d})$, then is $h(d) = 1$ infinitely often as Gauss conjectured?

7. More generally, are there infinitely many algebraic number fields that have unique factorization; *i.e.*, for which the class number is 1?

8. Are there infinitely many primes of the form $n^2 + 1$?

9. Artin's conjecture. Given an integer g, are there infinitely many primes p of which g is a primitive root?

10. Ramanujan conjectured that in $q(\prod_{n=1}^{\infty}(1-q^n))^{24} = \Sigma\tau(k)q^k$, the summation for $k = 1$ to ∞, if p is a prime, then $|\tau(p)| \leq 2p^{11/2}$. The mathematician Lehmer conjectured that for every n, $\tau(n) \neq 0$.

11. More general conjectures on coefficients of modular forms of a given weight.

12. Improvement of the error term in the prime number theorem is being sought.

13. Proofs of congruence properties of partitions; *e.g.*, Ramanujan conjectured if $24k \equiv 1 \pmod{m}$, in which $m = 5^a 7^b 11^c$, the function p, with argument expressed in terms of m, n, and λ, is equivalent to $0 \pmod{m}$ (see 164). Some special cases of this are known. For example, the mathematician A.O.L. Atkin has proved some results for $m = 11^c$. The mathematician Sarvadaman Chowla has pointed out that the conjecture is false for $m = 7^3$. The question remains to determine just what congruence properties are true.

14. If $d(n)$ is the number of divisors of n, and it is known that D, as a function of x, is a sum of two terms plus Δ, as a function of x, the first term involving the product of x and $\log x$, the second term involving γ and x (see 165), in which $\Delta(x)$ is an error term. It may be asked whether there exists a constant A such that the absolute value of Δ is less than or equal to A times the $\frac{1}{4} + \varepsilon$ power of x (see 166). A similar conjecture for the number of lattice points in a circle.

15. Do there exist infinitely many Fermat primes; *i.e.*, primes of the form $2^{2^k} + 1$?

16. Do there exist infinitely many regular primes; *i.e.*, primes p such that if h is the class number of the field $\mathfrak{Q}(\exp 2\pi i/p)$ then p is not a factor of h? This has a close connection with Fermat's last theorem.

17. Waring's problem. If $n = x_1^k + \cdots + x_s^k$, then it is known that if $s \geq 2^k + 1$, there exists n_0, such that if $n > n_0$ the equation has a solution in integers $x_1, x_2, \cdots, x_s$. What is the least value of s for which this statement remains valid; *e.g.*, is $s \geq 4k$ sufficient?

18. Are there infinitely many twin primes; *i.e.*, primes p such that $p + 2$ is also prime? (R.G.A.)

Geometric and probabilistic number theory

GEOMETRIC NUMBER THEORY

Geometric number theory, or, as it is sometimes misleadingly called, the geometry of numbers, is a branch of number theory that can be developed by the use of certain geometric methods. It centres on the arithmetical theory of quadratic and higher forms and the problems of the approximation of real numbers by rational numbers. If integers a, b, c satisfy the inequality $ac > b^2$, the (positive definite) binary quadratic form in x and y with coefficients a, b, and c (see 167) takes the value zero when the variables x, y are both zero, but takes only positive integral values for other integral values of the variables. A question of interest is what can be said about the positive integers that will be represented by the form, and, in particular, what will be the smallest positive value taken by the form for integral values of the variables. Lagrange developed an arithmetical technique for answering such questions in 1773, and, in particular, he proved that it is always possible to choose integers x, y such that a quadratic in x and y satisfies a double inequality, being greater than zero and less than a function of its coefficients (see 168). By 1831, the theory had been developed further, and the mathematician L.A. Seeber published an elaborate account of the corresponding arithmetical theory for ternary quadratic forms. In his review of Seeber's book, Gauss introduced a geometric point of view that greatly simplified the proofs of Seeber's results and led to a proof of an important conjecture of Seeber's. If Q as a function of x, y, and z, a ternary quadratic with six coefficients (see 169), is positive definite—*i.e.*, if it takes no negative values, and only takes the value zero when the variables x, y, z are all zero—then it can be expressed, in many ways, as the sum (see 170) of the squares of the three linear forms that are written ξ_1, ξ_2, ξ_3 (see 171). The coefficients will satisfy a determinental identity involving a third-order determinant that is positive with elements symmetric about the diagonal (see 172). Gauss recognized that as x, y, z vary independently over the integers, the corresponding points (ξ_1, ξ_2, ξ_3) will vary over the points of a regular discrete array of points, the points of a lattice. Indeed, the lattice is simply obtained by applying the linear transformation (see 173) already defined (see 171) to the standard lattice Λ_0 of all points (x, y, z) with integral coordinates. A previous formula (see 170) then expresses the value of the quadratic form when the variables x, y, z are integers, as the square of the Euclidean distance of the corresponding lattice point (ξ_1, ξ_2, ξ_3) from the origin. This very simple idea enabled Gauss to re-interpret much of Seeber's work geometrically and to simplify and extend it.

(164) $$p(mn + \lambda) \equiv 0 \pmod{m}$$

(165) $$D(x) = x \log x + (2\gamma - 1)x + \Delta(x)$$

(166) $$|\Delta(x)| \leq Ax^{1/4+\varepsilon}$$

(167) $$ax^2 + 2bxy + cy^2 \qquad (ac > b^2, \qquad a > 0)$$

(168) $$0 < ax^2 + 2bxy + cy^2 < [\tfrac{4}{3}(ac - b^2)]^{\frac{1}{2}}$$

(169) $$Q(x, y, z) = ax^2 + by^2 + cz^2 + 2fyz + 2gzx + 2hxy$$

(170) $$Q(x, y, z) = \xi_1^2 + \xi_2^2 + \xi_3^2$$

(171) $$\begin{cases} \xi_1 = \alpha_1 x + \beta_1 y + \gamma_1 z \\ \xi_2 = \alpha_2 x + \beta_2 y + \gamma_2 z \\ \xi_3 = \alpha_3 x + \beta_3 y + \gamma_3 z \end{cases}$$

(172) $$\begin{vmatrix} a & h & g \\ h & b & f \\ g & f & c \end{vmatrix} = \begin{vmatrix} \alpha_1 & \beta_1 & \gamma_1 \\ \alpha_2 & \beta_2 & \gamma_2 \\ \alpha_3 & \beta_3 & \gamma_3 \end{vmatrix}^2 > 0$$

(173) $$T{:}(x, y, z) \rightarrow (\xi_1, \xi_2, \xi_3)$$

The lattices introduced here are essentially the same as the lattices used in crystallography but are quite distinct from the abstract mathematical structures that the U.S. mathematician Garrett Birkhoff named lattices later.

Although Dirichlet made some use of these geometrical ideas, the next major development was due to Minkowski, who published his *Geometrie der Zahlen* ("Geometry of Numbers") giving a detailed account of his methods in 1896.

Minkowski's application to a complex body

Minkowski introduced the idea of a convex body. A set K is said to be convex, if whenever A and B are points of K, the line segment AB is also in K. A set K is said to be a convex body if it is closed (*i.e.*, contains all the points of its boundary or surface), bounded (*i.e.*, does not extend to infinity), and contains an inner point (*i.e.*, a point not on its boundary). A set is said to be symmetrical in the origin $O = (0, 0, 0)$ if, with each point A in the set, the reflection A' of A in O is also in the set. In three-dimensional space, Minkowski's first fundamental theorem, in its simplest form, asserts that if a convex body is symmetrical in the origin and has volume 8 or more units, then it contains, in addition to the origin, a symmetrical pair of points (x, y, z), $(-x, -y, -z)$ with integral coordinates, not all zero. On applying the transformation T (see 171, 173) the general form is obtained: If a convex body K is symmetrical in the origin and has volume at least eight times the absolute value of

the determinant Δ—that is, a determinant with columns composed of $\alpha_i\beta_j\gamma_k$ (see 174)—giving the volume of the unit cell of the lattice, then K contains, in addition to the origin, a symmetrical pair of points (ξ_1, ξ_2, ξ_3), $(-\xi_1, -\xi_2, -\xi_3)$ of the lattice defined by the transformation (see 171).

Applying this result to the cube of points (ξ_1, ξ_2, ξ_3), satisfying the condition that the absolute value of a typical variable ξ_i is less than or equal to the one-third power of the absolute value of Δ (see 175), Minkowski obtained Dirichlet's 1842 result on linear forms: given the forms referred to (see 171), there will always be integers x, y, z, not all zero satisfying the stated inequalities (see 175). This result leads quite simply to the result that, if θ, φ are any real irrational numbers, there are infinitely many pairs of rational numbers u/w, v/w, u, v, w being integers that are good simultaneous approximations to θ and φ in that the absolute differences between θ and the ratio u to w and between φ and the ratio v to w are each less than or equal to a simple function of w (see 176).

Minkowski obtained many other important results, in particular, his second fundamental theorem, and his improvements of the French mathematician Charles Hermite's estimate for the arithmetic minima of positive definite quadratic forms. To discuss these results and the subsequent development of the subject the limitations of three-dimensional space must be discarded.

The Cartesian coordinates

The 17th-century French mathematician René Descartes had revolutionized three-dimensional geometry by introducing a rectangular Cartesian coordinate system, so that each point of space is represented by a set of three coordinates, and by showing that the whole of geometry could be reduced to the algebra and analysis of the sets of coordinates. For example, if a and b are points with coordinates (a_1, a_2, a_3) and (b_1, b_2, b_3), the distance between these is the square root of the sum of squares of differences between b_1 and a_1 (see 177), and the points on the line segments joining a to b are those with coordinates forming a vector with three components, each of which is expressed in terms of θ and $\{a_k\}$ and $\{b_k\}$ (see 178) when $0 \leq \theta \leq 1$. Furthermore, $\mathbf{a} = (a_1, a_2, a_3)$, $\mathbf{b} = (b_1, b_2, b_3)$ are regarded as vectors, the distance between the points a and b is the distance between vectors $\mathbf{b}$ and $\mathbf{a}$ and is the square root of the sum of squares of differences of components (see 179) of the vector $\mathbf{b} - \mathbf{a}$, and the points on the line segments joining $\mathbf{a}$ to $\mathbf{b}$ are $(1 - \theta)\,\mathbf{a} + \theta\mathbf{b}$, with $0 \leq \theta \leq 1$.

When vector algebra was developed, partly as a result of the Irish mathematician Sir William Rowan Hamilton's attempts to develop applied mathematics in terms of quaternions, there were immediate advantages in developing an algebra for vectors with any arbitrary fixed number n of components. The basic formula for combination of vectors is that if $\mathbf{a} = (a_1, a_2, \cdots, a_n)$, $\mathbf{b} = (b_1, b_2, \cdots, b_n)$ are vectors, and λ, μ are scalars (in this context, just another name for real numbers), then $\lambda\mathbf{a} + \mu\mathbf{b}$ denotes the vector with n components each of which is expressed in terms of λ, μ and a_k and b_k with length of the vector $\mathbf{a}$ determined in the usual way (see 180). The geometrical term length has already been used to describe a purely algebraic object, the square root of the sum of the squares of the components of a vector, which has no realization in ordinary geometry. Mathematicians soon took this process much further, calling the vectors $\mathbf{x}$ that have n components (see 181) the points of n-dimensional Euclidean space, and using geometrical language to describe the vector algebra. For example, the distance between the points $\mathbf{a}$ and $\mathbf{b}$ is defined to be $\|\mathbf{b} - \mathbf{a}\|$, and the line segment joining the points $\mathbf{a}$ and $\mathbf{b}$ is defined to be the set of points $(1 - \theta)\mathbf{a} + \theta\mathbf{b}$ with $0 \leq \theta \leq 1$. While Descartes regarded the sets of coordinates and their algebra as a means of describing the geometric realities of space, the geometrical language used in the study of n-dimensional Euclidean space E^n is now regarded as describing the realities of the corresponding vector algebra of vectors with n real components.

The set Λ_0 of all points $\mathbf{x} = (x_1, x_2, \cdots, x_n)$ with integral coordinates is taken to be the standard lattice in E^n; the general lattice Λ in E^n is obtained by applying a nonsingular linear transformation to Λ_0, and so is the set of points possessing n coordinates ξ_i (see 182) with ξ_i a linear combination of x_j (see 183), $x_1, x_2, \cdots, x_n$ taking all integral values, and the determinant $\det(\alpha_{ij})$ of the coefficient matrix being nonzero. The determinant $d(\Lambda)$ of Λ is defined to be the absolute value of the determinant of the coefficients (see 184).

Using the natural generalizations of the ideas of a convex body symmetrical in $O = (0, 0, \cdots, 0)$, Minkowski's first theorem takes the form: If a convex body K in E^n is symmetrical in O and has volume $2^n d(\Lambda)$ or more, then K contains, in addition to the origin, a symmetrical pair of points of Λ.

Minkowski's second fundamental theorem is explained by introducing the successive minima of a convex symmetrical body for a lattice. For any set S of points and any positive number λ, the set of all points of the form $\lambda\mathbf{s}$ with $\mathbf{s}$ a point of S is called the expansion of S by the factor λ and is denoted by λS. The expansion of S will be a genuine expansion or enlargement of S from the origin if λ exceeds unity; but it will be a contraction or reduction of S toward the origin if λ is less than unity. The first minimum λ_1 of a convex body K in E^n, symmetrical in O, for a lattice Λ is defined to be the least positive number λ_1 such that the expanded body $\lambda_1 K$ contains points of Λ other that O. More generally, if $1 \leq r \leq n$, the rth minimum λ_r is defined to be the least positive number λ_r such that the set of points of Λ in $\lambda_r K$ does not lie in any substance of E^n of dimension less than r. It follows immediately from these definitions that λ_1, $\lambda_2, \cdots, \lambda_n$ is a non-decreasing sequence of positive numbers. Using $V(K)$ to denote the volume of the convex body, Minkowski's first theorem reduces to the inequality setting the nth power of λ_1 multiplied by $V(K)$ less than or equal to $d(\Lambda)$ times the nth power of 2 (see 185); his second theorem makes the stronger and more sophisticated assertion that there is a similar inequality involving the product of n of the $\{\lambda_k\}$ (see

$$(174)\quad \Delta = \begin{vmatrix} \alpha_1 & \beta_1 & \gamma_1 \\ \alpha_2 & \beta_2 & \gamma_2 \\ \alpha_3 & \beta_3 & \gamma_3 \end{vmatrix}$$

$$(175)\quad |\xi_i| \leq |\Delta|^{\frac{1}{3}}, \qquad i = 1, 2, 3,$$

$$(176)\quad \left|\theta - \frac{u}{w}\right| \leq \frac{1}{w^{3/2}}, \qquad \left|\varphi - \frac{v}{w}\right| \leq \frac{1}{w^{3/2}}$$

$$(177)\quad [(b_1 - a_1)^2 + (b_2 - a_2)^2 + (b_3 - a_3)^2]^{\frac{1}{2}}$$

$$(178)\quad ((1 - \theta)a_1 + \theta b_1, (1 - \theta)a_2 + \theta b_2, (1 - \theta)a_3 + \theta b_3)$$

$$(179)\quad \|\mathbf{b} - \mathbf{a}\| = [(b_1 - a_1)^2 + (b_2 - a_2)^2 + (b_3 - a_3)^2]^{\frac{1}{2}}$$

$$(180)\quad \begin{cases} (\lambda a_1 + \mu b_1, \lambda a_2 + \mu b_2, \cdots, \lambda a_n + \mu b_n) \\ \text{further, the length of the vector } \mathbf{a} \text{ is} \\ \|\mathbf{a}\| = [a_1^2 + a_2^2 + \cdots + a_n^2]^{\frac{1}{2}} \end{cases}$$

$$(181)\quad \mathbf{x} = (x_1, x_2, \cdots, x_n)$$

$$(182)\quad \boldsymbol{\xi} = (\xi_1, \xi_2, \cdots, \xi_n)$$

$$(183)\quad \xi_i = \sum_{j=1}^{n} \alpha_{ij} x_j$$

$$(184)\quad d(\Lambda) = |\det(\alpha_{ij})|$$

$$(185)\quad \lambda_1^n V(K) \leq 2^n d(\Lambda)$$

186). While the first theorem is easy to prove, there is no very simple proof of the second theorem; the simplest is probably that due to the mathematician Harold Davenport (1939), despite the fact that he leaves one not quite obvious step to the reader.

Minkowski's first fundamental theorem can be restated in yet another form. If K is any convex body symmetrical in O, there may exist a largest real number $\Delta(K)$ with the property that all lattices Λ with determinant $d(\Lambda)$ less than $\Delta(K)$ have a pair of symmetrical points, not O, in K. Minkowski's theorem asserts that there is such a number $\Delta(K)$ for each K, and that $\Delta(K) \geq 2^{-n}V(K)$. The number $\Delta(K)$ is called the critical determinant of K, and any lattice Λ with $d(\Lambda) = \Delta(K)$ and with no point, other than O, in the interior of K is called a critical lattice of K. These definitions of critical determinant and critical lattice extend immediately to the case in which K is replaced by a star-body S. A star-body is defined to be a closed set, not necessarily bounded, symmetrical in O, containing O as an inner point, and with the star property that, whenever a point X lies in S, then the line segment OX lies wholly in S. Although Minkowski's theorem does not apply, the critical determinant $\Delta(S)$ will exist as a positive real number or will have the conventional value plus infinity. In order to obtain refined applications to number theory, much effort has been devoted to determining or estimating the critical determinants of a whole range of convex bodies and of star-bodies. Although many of the most interesting star-bodies are of infinite volume, some, and in particular all the convex bodies, have finite volume. Minkowski stated that he had proved that, for any star-body S of finite volume $V(S)$, the critical determinant satisfies the inequality involving a function of n, the function being a sum over positive integers of reciprocals of nth powers of the integers (see 187). Minkowski never published a proof (except in the very special case of a sphere), and the first published proof was accomplished by the mathematician Hlawka in 1944.

(186) $$\lambda_1\lambda_2 \cdots \lambda_n V(K) \leq 2^n d(\Lambda)$$

(187) $$\begin{cases} \Delta(S) \leq \dfrac{1}{2\zeta(n)} V(S) \\ \text{with} \\ \zeta(n) = \displaystyle\sum_{r=1}^{\infty} \frac{1}{r^n} \end{cases}$$

(188) $$\frac{n+2}{2}\left(\frac{1}{\sqrt{2}}\right)^n$$

(189) $$\tau_n \sim \frac{n}{e\sqrt{e}}, \quad \text{as } n \to \infty$$

(190) $$n \log n + n \log \log n + 5n$$

(191) $$n^{\log_2 \log_e n + c}$$

Lattice packing

Minkowski's proof of his first theorem was based on the idea of a lattice packing. If K is a convex body (not necessarily symmetrical in O), then the system of translates $\{K + \mathbf{x}_i\}$, $i = 1$ to $i = \infty$, of K by a sequence of vectors $\{\mathbf{x}_i\}$, $i = 1$ to $i = \infty$, is said to be a packing of K, if no two of the translates have any point in common. The packing is said to be a lattice packing with lattice Λ if the sequence of vectors $\{\mathbf{x}_i\}$, $i = 1$ to $i = \infty$, is an enumeration of the vectors of the lattice Λ. The density of a packing is defined to correspond to the intuitive notion of that proportion of the whole of space covered by the sets of the packing. Minkowski gave a very simple proof, using only a few lines of vector algebra, that if K is a convex body symmetrical in O, and if Λ is a lattice, then the translates by the vectors of Λ of the contracted body $\frac{1}{2}K$ will form a packing, if, and only if, O is the only point of Λ in K. His first result follows immediately from this observation and the intuitively obvious remark that the density of a packing cannot exceed unity. The densities of packings and lattice packings of convex bodies have been extensively studied. The work of Lagrange, Seeber, and Gauss already implies that the densest lattice packings of circular discs in the plane and of spherical balls in 3-space are given by the hexagonal lattice and by the body centred cubic lattice. The densest lattice packings of spherical balls were determined by the Russian mathematicians Aleksandr Nikolayevich Korkin and Zolotarev in 1872 and 1877 for dimensions 4 and 5 and by the mathematician Blichfeldt in 1925, 1926, and 1934 for dimensions 6, 7, and 8. Although the densest lattice packings of spherical balls are not known in higher dimensions, some quite dense examples are known. In particular, the Canadian mathematician Harold Scott MacDonald Coxeter (1951) gives a dense packing of spherical balls in 12 dimensions and the U.S. mathematician Joseph Leech (1967) one in 24 dimensions. The mathematician Conway's study (1969) of the remarkable symmetry group of Leech's packing lattice led him to the discovery of three new large simple groups. Much less is known about general packings that are not necessarily lattice packings. The mathematician L. Fejes Tôth has developed a beautiful and almost completely satisfactory theory of the packing of convex domains in the plane. Very little is known, however, even in 3-space, in which mathematicians have been unable to show that the density of a non-lattice packing of spherical balls cannot exceed the density $0.7404 \cdots$ of the densest lattice packing, despite convincing physical evidence that this must be true. Blichfeldt in 1914 showed that in n-dimensions the density of a packing of spherical balls cannot exceed the bound composed of the product of one-half the quantity $n + 2$ multiplied by the nth power of the reciprocal of the square root of 2 (see 188), a bound that has only been very slightly improved since by the mathematician Rogers (1958). A very elementary argument shows that spheres, or indeed any symmetrical convex bodies, can be packed with density at least $(\frac{1}{2})^n$, and this lower bound for the density has only been slightly improved by the mathematician Schmidt (1963). The factor of ignorance between the upper and lower bounds for the density of the densest packing, or lattice packing, of spherical balls remains essentially of the order $(\sqrt{2})^n$.

Lattice coverings

There is a parallel theory of coverings and lattice coverings of space with convex bodies. The condition that no two translates have any common point is dropped and replaced by the condition that each point of space is in at least one of the translates. The density of a covering is now the average number of times a point of space is covered by the system of translates. The thinnest, or least dense, lattice covering of n-dimensional space by spherical balls has been determined for $n = 2$ by the mathematician Kerschner (1939), for $n = 3$ by the mathematician Bambah (1954), and for $n = 4$ by the mathematicians Delauney and Rushkov (1963). Tôth has solved the general covering problem for symmetrical convex plane domains; but again there are virtually no precise results for general coverings in three or more dimensions. Coxeter, Few, and Rogers (1959) have shown that coverings of n-dimensional space by spherical balls must have density that is at least a certain bound τ_n; τ_n becomes asymptotically equal to a constant times n, as n approaches infinity, the constant being the reciprocal of the product of e and the square root of e (see 189). Rogers (1957, 1959) has shown that, for any convex body K, in n-dimensional space, there is a covering with K with density not greater than an expression composed of n times the logarithm of n and the logarithm of the logarithm of n (see 190) and that there is a lattice covering with K with density not greater than an expression involving n raised to a power, the log to the base two of the natural logarithm of n (see 191). Rogers' results, however, are nonconstructive, and there is no effective method of finding coverings with densities that are at all reasonably small.

The results about lattice packings of spherical balls can all be translated to yield results about the arithmetical minima of positive definite quadratic forms. The n linear forms are considered, each ξ_i being a linear combination of n variables such as x_j (see 192) with determinant having absolute value written Δ and being composed of coefficients $\alpha_{i,j}$ (see 193). For each n, there will be a least positive number γ_n such that the inequality, the sum of the squares of the $\{\xi_k\}$ being less than or equal to γ_n times a power of Δ (see 194), always has a solution in integers $x_1, x_2, \cdots, x_n$, not all zero. This constant γ_n was discussed by Hermite (1850) and is sometimes known as Hermite's constant. By the results quoted for the closest lattice packings of spherical balls, its precise value is known up to $n = 8$; for large values of n, it lies between the asymptotic bounds $n/(2\pi e)$ and $n/(\pi e)$. Many results of geometric number theory can be stated in terms of such inequalities. An early result of the Russian mathematician Andrey Andreyevich Markov (1878) asserts that integers x_1, x_2, not both zero, can be found to satisfy the absolute value of the product of ξ_1 and ξ_2 being less than or equal to one-third of Δ (see 195), unless the ratios α_{11}/α_{12}, α_{21}/α_{22} belong to a countable sequence of pairs of conjugate quadratic irrationals, and that in these cases only slightly weaker inequalities hold. Similar results, involving only a finite sequence of exceptions, have been obtained by Markov (1903) and by the mathematician Venkov (1945) for the quadratic form $|\xi_1^2 - \xi_2^2 - \xi_3^2|$ and by Davenport (1938, 1943) and Swinnerton-Dyer (1971) for the product of three linear forms (see 196). It is conjectured that for any $\varepsilon > 0$, it is always possible, for each choice of the $+$ and $-$ signs, to find integers x_1, x_2, x_3, x_4, x_5, not all zero, to satisfy the absolute value of certain sums and differences of squares of ξ_k being less than ε times a power of Δ (see 197), but this conjecture seems to be far beyond the reach of known methods. The best result in this direction is due to combined work of the mathematicians Bryan John Birch (English), Harold Davenport, and Ridout (1958) and asserts the corresponding result for indefinite quadratic forms in 21 or more variables.

(192) $$\xi_i = \sum_{j=1}^{n} \alpha_{ij} x_j$$

(193) $$\Delta = |\det(\alpha_{ij})|$$

(194) $$\xi_1^2 + \xi_2^2 + \cdots + \xi_n^2 \leqslant \gamma_n \Delta^{2/n}$$

(195) $$|\xi_1 \xi_2| \leqslant \tfrac{1}{3}\Delta$$

(196) $|\xi_1 \xi_2 \xi_3|$ Davenport (1939) has also discussed the form $|\xi_1|(\xi_2^2 + \xi_3^2)$ and Oppenheim (1929, 1931) the forms $|\xi_1^2 + \xi_2^2 - \xi_3^2 - \xi_4^2|$ and $|\xi_1^2 - \xi_2^2 - \xi_3^2 - \xi_4^2|$.

(197) $$|\xi_1^2 - \xi_2^2 \pm \xi_3^2 \pm \xi_4^2 \pm \xi_5^2| < \varepsilon \Delta^{\frac{2}{5}}$$

(198) $$\Delta(K \cap (2\mathbf{a} - K)) \leqslant d(\Lambda)$$

(199) $$\xi_i = \sum_{j=1}^{n} \alpha_{ij} x_j, \qquad i = 1, 2, \cdots, n$$

(200) $$\Delta = \det(\alpha_{ij})$$

(201) $$|(\xi_1 + c_1)(\xi_2 + c_2) \cdots (\xi_n + c_n)| \leqslant (\tfrac{1}{2})^n |\Delta|$$

(202) $$|(\xi_1 + c_1)(\xi_2 + c_2)| < \tfrac{1}{128} |\Delta|$$

Nonhomogeneous forms

The examples discussed so far all involve homogeneous forms. When lattice covering problems are expressed in terms of the theory of forms, they involve nonhomogeneous forms. There are a number of further results in geometric number theory that are of this nonhomogeneous nature. One of the few general results of the subject is the remarkable result of the mathematician Macbeath (1952) that: if a closed convex set K in n-dimensional space contains no complete straight line but does contain in its interior a point of a lattice Λ, then there is a point $\mathbf{a}$ of Λ that is reasonably close to the boundary of the convex set K, in that, the volume $V(K \cap (2\mathbf{a} - K))$ of the intersection $K \cap (2\mathbf{a} - K)$ of the convex body K with its reflection $2\mathbf{a} - K$ in the point $\mathbf{a}$ does not exceed $2^n d(\Lambda)$; indeed, Macbeath proves the stronger inequality involving Δ, K, the vector $\mathbf{a}$, and $d(\Lambda)$ (see 198). A much more special nonhomogeneous problem stems from the work of Minkowski, who proved, in the case $n = 2$, and who conjectured, in general, that: given linear forms establishing ξ_i as a linear combination (see 199) of integral variables $x_1, x_2, \cdots, x_n$ with Δ being the determinant of the coefficients (see 200) and given real numbers $c_1, c_2, \cdots, c_n$, then there are integral choices for the variables that ensure that the absolute value of the product of n factors, each the sum of ξ_i and c_i, is less than or equal to the nth power of ½ times the absolute value of Δ (see 201). The conjecture has been proved by R. Remak (1923) in the case $n = 3$ and by Freeman J. Dyson (1948) in the case $n = 4$. B.F. Skubenko (1937) has proved it for $n = 5$. The mathematician N. Tschebotareff (1940), in the general case, proved that weaker inequality with $(\tfrac{1}{2})^n|\Delta|$ replaced by $(\tfrac{1}{2})^{n/2}|\Delta|$. The problem of deciding whether or not Minkowski's conjecture is true or false remains one of the most challenging problems of the subject. Davenport (1950), in the case $n = 2$, has proved a partial converse to Minkowski's result. He proves that, if the forms ξ_1, ξ_2 are given, then constants c_1, c_2 can be found, namely, the absolute value of products of two sums, each of a ξ_i with a c_i, is less than the reciprocal of 128 times the absolute value of Δ (see 202), has no solution in integers x_1, x_2. This enabled Chatland and Davenport (1950) to show that Euclid's algorithm holds in no real quadratic field beyond the last known example (that generated by $\sqrt{73}$). A little later Davenport (1950), by a refinement of his method, showed that Euclid's algorithm holds only a finite number of cubic fields with negative discriminant, and only in a finite number of complex quartic fields with complex conjugate fields.

Critical determinants and critical lattices

The German-born mathematician Kurt Mahler has investigated the problems of geometric number theory from a general point of view. The formal definitions of critical determinant and critical lattice are his. By regarding the lattices in n-dimensional space as points of a larger space of n^2 dimensions and establishing the compactness of certain sets of lattices, Mahler (1946) was able to show that every star-body with finite critical determinant has at least one critical lattice. This general result at once enabled many difficult special results to be proved by rather simpler methods. Mahler's work also led to a much clearer understanding of the circumstances under which one can assert that infinitely many points of a lattice lie in a star-body. In the case of a convex body, symmetrical in O, Swinnerton-Dyer (1953) established the useful result that a critical lattice must have at least $n(n + 1)$ points on the boundary of the convex body.

The classical applications of geometric number theory were mainly to the theory of algebraic numbers and included Dirichlet's theory of units and Minkowski's proof that the absolute value of the discriminant of an algebraic number field exceeds unity. Davenport's contribution to the problem of Euclid's algorithm has already been mentioned. Two striking applications are now mentioned. Davenport, partly in collaboration with Birch and Donald J. Lewis (U.S.), has used results of John William Scott Cassels (English) and Minkowski's successive minima results together with an extension of the Hardy–Littlewood–Vinogradov method to obtain striking new results about the values taken by quadratic and cubic forms with sufficiently many variables.

Schmidt (1971) has used results of Mahler on the geometric number theory of compound convex bodies, to-

gether with the method of Roth, to prove that if $\theta_1, \theta_2, \cdots, \theta_n$ are algebraic numbers and $1, \theta_1, \theta_2, \cdots, \theta_n$ are linearly independent over the rationals and ε is positive, then there is a constant k, depending only on n and ε, such that the inequalities composed by setting the absolute difference between θ_i and the ratio p_i to q less than an expression involving k, q, n, and ε (see 203) have only finitely many solutions in integers $h_1, h_2, \cdots, h_n, q$. The case $n = 1$ is, of course, Roth's theorem. **(C.A.Ro.)**

PROBABILISTIC NUMBER THEORY

The theory of probability, conceived originally in connection with gambling, provides an insight into some remarkable multiplicative properties of the integers—properties that in the absence of probability theory would remain undiscovered or at best inexplicable. Probability illuminates aspects of arithmetic because certain divisibility phenomena reflect the probabilistic idea of independence.

The number of prime divisors. According to the fundamental theorem of arithmetic, each positive integer can be factored in just one way into a product of primes. From the multiplicative point of view then, an integer is built up of primes, and it is natural to ask how many of them it contains. Probability is useful here.

The number $r(n)$ is taken to be the number of distinct primes appearing in the factorization of n. For example, $r(12) = 2$ because $12 = 2 \cdot 2 \cdot 3$ contains the two prime divisors 2 and 3 (the divisor 2 is counted only once, even though it appears twice in the factorization). It is simple to list the values of $r(n)$ for, say, the first 35 values of n (see 204). The case $n = 1$ is special because 1 is not counted as a prime, $r(1) = 0$, whereas $r(n)$ is a positive integer in all other cases.

The number $r(n)$ grows very slowly. The smallest integer containing two distinct prime factors is $6 = 2 \cdot 3$, and the smallest containing three of them is $30 = 2 \cdot 3 \cdot 5$; the smallest containing four will be $210 = 2 \cdot 3 \cdot 5 \cdot 7$, which is off the table. On the other hand, the fact that there is an infinite number of primes implies that $r(n)$ takes on arbitrarily large values: $r(n) = k$ if n is the product of k distinct primes, and, however large k may be, there do exist k distinct primes. The same fact implies that $r(n)$ takes on the value 1 infinitely often: $r(n) = 1$ if n is a prime. As n increases through the integers, $r(n)$ thus fluctuates in an irregular way, taking on arbitrarily large values but also dropping back infinitely many times to 1 (and infinitely many times to 2, and so on).

Distribution of prime factors

In view of this irregularity, it is of mathematical interest to see how $r(n)$ behaves on the average and how its values are distributed. It is supposed that n varies from 1 through N, in which N is a large integer, and the average (see 205) of $r(n)$ over this range is considered. If $N = 100$, this average is 1.71: the typical integer under 100 has rather less than two prime divisors. If $N = 100{,}000{,}000$, the average is not much greater, being approximately 2.9: the typical integer under 100,000,000 has just under three prime divisors—remarkably few. Even for $N = 10^{100}$, sometimes called a googol, the average is only about 5.4. Still, the average does go to infinity with N—but very slowly indeed: if N is the 10^{100}-th power of 10, a considerable number called a googolplex, the average is around 23.9. Except for the case $N = 100$, these figures come from an approximation specifying that the arithmetic average of N values of r is asymptotically equal to the logarithm of the logarithm of N (see 206).

A more detailed description of the way in which the number of prime factors varies is provided by the complete distribution of the values of $r(n)$ as n runs from 1 to N. A sorting of all the cases for $N = 100$ gives the distribution (see 207). That is, of the integers up to 100, 35 contain exactly one prime factor, 56 contain two, and 8 contain three, the corresponding proportions thus being .35, .56, and .08 in a table relating integer values from zero to three (inclusive) with frequency and with proportional frequency (see 207).

The high frequencies are near the average, and they taper off on either side of this central value. The problem probability helps solve is that of describing this distribution in more detail—for large values of N, for which an actual counting out of cases would be impossible. The probabilistic analysis that follows reveals the striking fact that this distribution, when converted to the proper scale, approximately follows the normal law of errors; that is, the proportion of integers n—in the range $1 \leq n \leq N$—for which $r(n)$, properly scaled, lies between specified limits will be approximately the area between those limits under the standard normal density—the famous bell-shaped curve that describes the distribution of various quantities (see PROBABILITY, THEORY OF).

(203) $$\left|\theta_i - \frac{h_i}{q}\right| < \frac{k}{q^{1+(1/n)+\varepsilon}}, \qquad i = 1, 2, \cdots, n$$

(205) $$\frac{r(1) + r(2) + \cdots + r(N)}{N}$$

(206) $$\frac{r(1) + r(2) + \cdots + r(N)}{N} \approx \log \log N$$

(207)

Value	Frequency	Proportional Frequency
0	1	.01
1	35	.35
2	56	.56
3	8	.08

(208) $$\frac{r(n) - \log \log N}{\sqrt{\log \log N}}$$

The appropriate scale is a ratio composed of $r(n)$ and the negative value of and the square root of the logarithm of the logarithm of N (see 208); the centre log log N of the scale comes from the approximation (see 206) for the average value of $r(n)$, and the division by $\sqrt{\log \log N}$ properly counteracts the ever-increasing dispersion about this central value. The proportion of integers up to N for which this ratio (see 208) lies between x and y is for large N approximately the area of the shaded region in Figure 1. For example, if $x = -.2$ and $y = +1.2$, this area is about .46. If N is a googol, so that log log $N \approx 5.4$, then the stated ratio lies between these two limits if $r(n)$ itself lies between 5 and 8. If N is a googolplex, so that log log $N \approx 23.9$, the ratio is in this range if $r(n)$ is between 23 and 29. Thus something like half the integers under a googol have 5 to 8 prime divisors, and something like half the integers under a googolplex have 23 to 29 prime divisors.

Independence. The right-hand column of the table constructed with the values 0, 1, 2, 3 and corresponding frequencies 1, 35, 56, 8 (see 207) can be viewed as a set of probabilities. If an integer is drawn at random from among the integers $1, 2, 3, \cdots, 99, 100$, each having probability $\frac{1}{100}$ of being drawn, then there is probability .56 that it has exactly two prime divisors. Probability theory applies, leading to the distribution law just described, not merely because proportional frequencies can be viewed as probabilities, but because it is possible to bring to bear one of the basic ideas of probability, that of independence.

If Peter throws a pair of balanced dice, there is probability $\frac{6}{36} = \frac{1}{6}$ that the total number of dots showing is seven. If Paul throws a pair, there is probability $\frac{4}{36} = \frac{1}{9}$ that his total is five. The probability that Peter throws a seven *and* that Paul throws a five is the product $\frac{1}{6} \cdot \frac{1}{9} = \frac{1}{54}$, and this is because the two events in question are independent. Mathematically, two events are independent if their probabilities satisfy this product rule, and the definition reflects a phenomenon common in nature: the occurrence of the one event has no influence on the occurrence of the other.

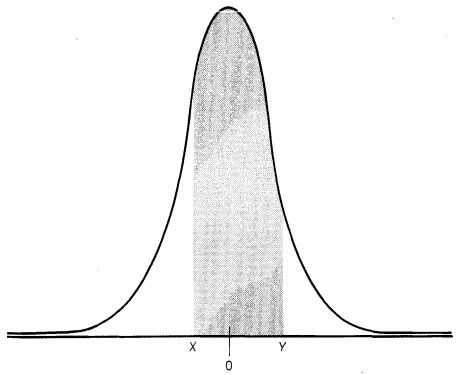

Figure 1: The normal distribution curve, showing two real values x and y and the corresponding shaded area beneath the curve that gives a proportion or a probability (see text).

To see how independence ties in with the behaviour of $r(n)$, the set of multiples of k is considered for each integer k. If this set is denoted A_k, A_2 consists of even integers, A_3 consists of those divisible by 3, and so on. Of these sets (see 209), in which the subscript ranges over the primes, some contain a given integer n and some do not, and $r(n)$ is precisely the number of sets in the list (209) that do contain n. To ask after the statistical behaviour of $r(n)$ is to ask for the probability that $r(n)$ takes on a specified value, say 4, and this is to ask for the probability that n lies in exactly 4 of the sets in the list (209). This probability can in principle be computed and can in fact be understood via the probabilities that n lies in A_2, in A_3, in A_2, and A_3 simultaneously, in A_2 and A_5 and A_{11} simultaneously, and so on for all combinations.

If n is drawn at random from among 1, 2, 3, $\cdots$, 99, 100, the probability that it lies in A_2 is $P(A_2) = \frac{50}{100} = \frac{1}{2}$, because there are 50 even integers up to 100. The probability that n lies in A_3 is $P(A_3) = \frac{33}{100}$, because there are 33 multiples of 3 up to 100. That $P(A_3)$ is approximately $\frac{1}{3}$ reflects the fact that every third integer is a multiple of 3; that $P(A_3)$ is not exactly $\frac{1}{3}$ is due to the fact that 3 does not divide evenly into 100.

Now n lies in the set $A_2 \cap A_3$ (the intersection of A_2 and A_3); that is to say, n lies both in A_2 and in A_3, when it is divisible both by 2 and by 3. And n is divisible both by 2 and by 3 exactly when it is divisible by their product 6; this is so because 2 and 3 have no common factor, and it represents a fundamental arithmetic fact (if n is divisible both by 2 and by 4, say, it does not follow that it is divisible by their product 8, $n = 12$ providing a contrary instance). In brief, the intersection of A_2 and A_3 is A_6 (see 210). The probability that n is divisible by 2 and by 3 is therefore $P(A_2 \cap A_3) = P(A_6) = \frac{16}{100}$, because there are 16 multiples of 6 in the range 1 to 100 (dividing 6 into 100 gives a quotient of 16—and an irrelevant remainder of 4); $P(A_6)$ is approximately $\frac{1}{6} = 0.1666\ldots$ because every sixth integer lies in A_6.

What is essential is the approximation stating that the probability of the intersection of A_2 and A_3 is approximated by the product of the corresponding probabilities (see 211), and the validity of this approximation rests on the fact that 2 and 3 individually divide n if, and only if, their product 6 does, together with the fact that A_2, A_3, and A_6 have respective probabilities approximately $\frac{1}{2}$, $\frac{1}{3}$, and $\frac{1}{6}$. Now this approximation (see 211) can advantageously be viewed as asserting the approximate independence of two events: An integer is drawn at random between 1 and 100; the event that it is divisible by 2 is approximately independent of the event that it is divisible by 3.

The rest of the events in the list (209)—divisibility by 5, divisibility by 7, and so on—are also approximately independent of one another if n is chosen at random between 1 and a large integer N. This is the key idea of probabilistic number theory. Now $r(n)$, the quantity of interest, is the number among these events that actually occur, and it is just this kind of random quantity (mainly for cases in which the events in question are strictly independent) that has received much attention in the classical literature of probability. Under appropriate conditions, such a number of occurrences will, when measured on the proper scale, approximately follow the normal distribution curve, and this is true of $r(n)$ rescaled as above (see 208). This theorem (it becomes a precise mathematical theorem, a form of the central limit theorem, when stated in terms of limits [see 216]) is plausible on probability grounds and can be given a rigorous proof by means of a proper combination of probability theory and number theory—there are difficulties, owing to the fact that the events in the list (209) are only approximately independent.

Euler's function

The Euler φ-function. A different application of probabilistic reasoning explains some properties of Euler's function, the number $\varphi(n)$ of integers less than or equal to n and relatively prime to n (that is, having no factors in common with n). The integers not exceeding 6 and relatively prime to it are 1 and 5, so that $\varphi(6) = 2$. The concern here is with $\varphi(n)/n$, the proportion of integers up to n that share no factors with it. It has a convenient expression as a product of factors of the form 1 minus the reciprocal of p (see 212).

The right side of this equation stands for the product of the factors $(1 - 1/p)$ for all primes p that divide n; if $n = 6$, for example, it is $(1 - \frac{1}{2})(1 - \frac{1}{3})$, which checks with $\varphi(6)/6 = 2/6$.

As before, n is chosen at random between 1 and N. If 3 divides n, it contributes to the product (see 212) the factor $(1 - \frac{1}{3})$; as indicated before, the probability of this is about $\frac{1}{3}$ for large N. If 3 does not divide n, then $(1 - \frac{1}{3})$ does not appear in the product (see 212), and in this case 3 may conveniently be regarded as contributing to the product the factor 1; the probability of this is about $\frac{2}{3}$. So the expected value of the factor contributed by 3, the amount 3 contributes on the average, is about 1 minus the reciprocal of 3 squared (see 213). The product of this and the analogous expected values for the other primes is an infinite product of factors of the type 1 minus the reciprocal of a prime squared (see 214), an infinite product known to have value $6/\pi^2$.

Now the expected value of a product of independent random factors is the product of their individual expected values; the random factors here are approximately independent (see 211). This is indeed true in the limit: the arithmetic average of N terms of the type $\varphi(k)$ divided by k converges to 6 over the square of π (see 215).

If m is chosen at random between 1 and n, the chance that it is relatively prime to n is $\varphi(n)/n$. And if n is chosen at random between 1 and N, and then m is chosen at random between 1 and n, the chance that m and n are relatively prime is the average referred to above (see 215). Because m and n play symmetric roles in this argument, it follows that, if m and n are chosen independently and randomly between 1 and N, the probability that they are relatively prime is near $6/\pi^2$ for large N.

In addition to its expected value, it is possible to describe the distribution of $\varphi(n)/n$. Figure 2 gives this distribution for $N = 100$. The height of the curve over a given point x on the horizontal scale gives the proportion of n, $1 \leq n \leq 100$, for which $\varphi(n)/n \leq x$. (The distribution actually gives discrete points, linked in the diagram by line segments.) The curve is seen to be irregular, rising slowly over most of its range but very sharp-

ly in some places. A probabilistic analysis shows that the corresponding curve for general N tends, as N increases to infinity, toward a limiting curve that is very irregular indeed. The limiting curve has horizontal tangent at almost all (in the technical sense of measure theory) of its points, so that its rate of increase is 0 almost everywhere, but it nonetheless contrives to climb continuously from 0 to 1 over its course (it represents what is called a singular function).

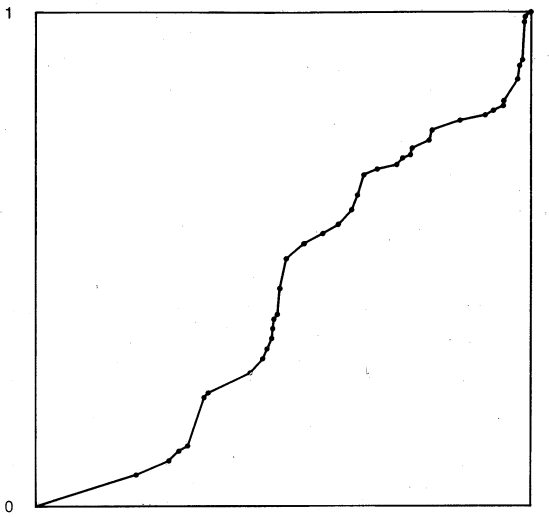

Figure 2: Probability distribution, such that the height of the curve over a given point x on the horizontal axis gives the proportion of n for which $\phi(n)/n \leq x$.

The theorems. The exact theorem governing the behaviour is of the above ratio (208) that identifies the limit of $P_N(A)$ as N approaches infinity as the integral of the normal density and in which $P_N(A)$ for a set A of integers is $1/N$ times the number of integers n that satisfy $1 \leq n \leq N$ and at the same time lie in A [P_{100} was denoted P above; in (216) $\{n: \cdots\}$ denotes the set of integers satisfying the condition following the colon].

It should be noted that the number of multiples of k up to N is $[N/k]$, the integer part of N/k, so that $P_N(A_k)$ is approximately the reciprocal of k (see 217), the approximation valid for large N because the two quantities in question differ by less than $1/N$. It is a consequence of the fundamental theorem of arithmetic that distinct primes p and q each divide n if and only if their product does. Therefore, $A_p \cap A_q = A_{pq}$ and P_N of the intersection of A_p and A_q is approximately a product of two factors, one involving A_p and one involving A_q (see 218). If $\delta_p(n)$ is 1 if the prime p divides n, and 0 otherwise, then r as a function of n is the sum over primes of $\delta_p(n)$ (see 219). The approximation (218) shows that the summands here are approximately independent random variables if n is random, $n \leq N$. The expected value of $r(n)$ is a sum of values of P_N that has two approximations (see 220), in which the first approximation comes from above reasoning and the second is a basic fact of number theory (the combined error is bounded, so the percentage error goes to 0). The variance of $r(n)$ is essentially what it would be if the summands were truly independent, and this turns out to be asymptotically log log N as well. The normalizing constants (see 216) are thus the asymptotic mean and standard deviation of the sum (see 219) and the summands behave sufficiently like independent random variables that the central limit theorem (see 216) does hold. This was first proved by sieve methods; simpler proofs based on the method of moments have since been found.

Error estimates for the central limit theorem (216) have been found; these coincide with the estimates for independent random variables.

It is a consequence of the central limit theorem that, if x_N goes to infinity faster than $\sqrt{\log \log n}$, then the limit, as N approaches infinity, of P_N is 1 when applied to the set of integers n for which the absolute difference between $r(n)$ and the log log N is less than x_N (see 221). This stands to the previous result as the law of large numbers stands to the central limit theorem. From this limit (221) it follows that, for most values of n under N, $r(n)$ is near log log N; the central limit theorem (216) gives very detailed information about how $r(n)$ is distributed around this central value.

(219) $$r(n) = \sum_p \delta_p(n)$$

(220) $$\sum_p P_N(A_p) = \sum_{p \leq N} \frac{1}{N}\left[\frac{N}{p}\right] \approx \sum_{p \leq N} \frac{1}{p} \approx \log \log N$$

(221) $$\lim_{N \to \infty} P_N\{n{:}|r(n) - \log \log N| < x_N\} = 1$$

(222) $$f(n) = \sum_p f(p)\, \delta_p(n)$$

Additive functions

A function $f(n)$ of integers is called additive if $f(mn) = f(m) + f(n)$ whenever m and n are relatively prime, and it is called completely additive if, in addition, $f(p^\alpha) = f(p)$ for prime powers p^α. If f is completely additive, then it can be written as a sum over primes of products $f(p)\delta_p(n)$ (see 222), a special case of which was previously given (see 219)—$r(n)$ is completely additive with $r(p) = 1$. The summands (see 222) being approximately independent, as in the case of $r(n)$, it is possible to establish for completely additive functions a general central limit theorem, similar to the one that was already stated (see 216), under conditions that parallel those of the classical Lindeberg theorem. It is even possible to treat the case in which the limiting normal distribution is replaced by a more general infinitely divisible distribution.

Similar results hold if $f(n)$ is additive but not completely additive. An example of such a function is the number of prime divisors of n with multiplicity counted, so that

$f(12) = 3$ because 2 appears twice in the factorization $12 = 2 \cdot 2 \cdot 3$ and 3 appears once. The central limit theorem (216) is unaltered if $r(n)$ is replaced by this function.

The central limit theorem and the law of large numbers are represented in probabilistic number theory by the above limits (216) and (221) and their generalizations. There are also representatives of certain probability theorems that concern the convergence of random series, and the limit theorem for $\varphi(n)/n$ is one of these.

The logarithm of the ratio of $\varphi(n)$ to n is a sum over primes of products involving $\delta_p(n)$ and a logarithmic function (see 223), and this is a completely additive function. The $\delta_p(n)$ behave very much as do independent random variables that assume the values 1 and 0 with probabilities p^{-1} and $1 - p^{-1}$. If the $\delta_p(n)$ were exactly like such variables, it would follow from probability theory that, since $\Sigma_p p^{-1} \log (1 - p^{-1})$ converges, the series (see 223) converges with probability 1; moreover, the distribution function $F(x)$ of the total sum could be identified as the one having as characteristic function (Fourier transform; see 224) the product of the characterstic functions of the various summands. As N increases, the $\delta_p(n)$ mimic ever more closely the independent variables, and in the limit (223) does have the distribution function $F(x)$ just derived (see 225). Results on random series imply $F(x)$ is a singular function; the curves corresponding to the one in Figure 2 converge to $F(\log x)$, which must also be singular.

$$\log\frac{\varphi(n)}{n} = \sum_p \delta_p(n) \log\left(1 - \frac{1}{p}\right) \tag{223}$$

$$\int_{-\infty}^{\infty} e^{itx}\, dF(x) = \prod_p \left\{1 - \frac{1}{p} + \frac{1}{p}\exp\left[it \log\left(1 - \frac{1}{p}\right)\right]\right\} \tag{224}$$

$$\lim_{N\to\infty} P_N\left\{n: \log\frac{\varphi(n)}{n} \leq x\right\} = F(x) \tag{225}$$

$$\lim_{N\to\infty} P_N\left\{n: \log\frac{\sigma(n)}{n} \leq x\right\} = G(x) \tag{226}$$

$$D\left\{n: \log\frac{\sigma(n)}{n} \leq x\right\} = G(x) \tag{227}$$

A generalization of this result covers a broad class of completely additive functions for which the series $\Sigma_p |f(p)|/p$ and $\Sigma_p |f(p)|^2/p$ converge (if these diverge, as for $r(n)$, central limit theory applies instead). It is possible also to treat functions that are only additive (not completely additive), such as $\log \{\sigma(n)/n\}$, in which $\sigma(n)$ is the sum of all the divisors (prime or not) of n. In this case, as N increases, the distribution function converges to a function $G(x)$ whose characteristic function can be identified (see 226).

All these results can be restated in terms of density. A set A of integers has density d if $\lim_N P_N(A) = d$, which is expressed by $D(A) = d$. The limit relation that was just derived can be restated in terms of D (see 227). The distribution function $G(x)$ is continuous for all x, as follows from an analysis of its characteristic function, which is interesting because it shows that the set of deficient numbers (those satisfying $\sigma(n) < n$) and the set of abundant numbers (those satisfying $\sigma(n) > n$) have densities and that the set of perfect numbers (those satisfying $\sigma(n) = 2n$) has density 0 (it is conjectured that the last set is finite).

Except for one (see 215), all the results here were discovered in the present century. Hardy and Ramanujan proved the law of large numbers (see 221) in 1920 by nonprobabilistic methods, and Paul Turán in 1934 gave it a probablistic proof. The mathematicians Paul Erdös (Hungarian) and Mark Kac (U.S.) proved the central limit theorem in 1939, extensions and refinements of which as well as other results (see 226) are associated with the names Davenport, Delange, H. Halberstam, J. Kubilius, I.J. Schoenberg, and A. Wintner. (P.P.B.)

BIBLIOGRAPHY. The following works are concerned with elementary topics: HAROLD T. DAVIS (comp.), *Tables of the Higher Mathematical Functions*, vol. 2 (1935, reprinted 1963), contains extensive tabular and bibliographical material on Bernoulli numbers. Additional references on Bernoulli numbers include: H.S. VANDIVER, "An Arithmetical Theory of the Bernoulli Numbers," *Am. Math. Soc. Transl.*, 51:502–531 (1942); JAMES V. USPENSKY and MAXWELL A. HEASLET, *Elementary Number Theory*, ch. 9 (1939); ALAN FLETCHER, J.C.P. MILLER, and LOUIS ROSENHEAD, *An Index of Mathematical Tables*, pp. 40–80 (1946); and H.S. VANDIVER, "On Developments in an Arithmetic Theory of the Bernoulli and Allied Numbers," *Scr. Math.*, 25:273–303 (1961). For information on Fermat's last theorem, see LOUIS J. MORDELL, *Three Lectures on Fermat's Last Theorem* (1921); H.S. VANDIVER and G.E. WAHLIN, "Report of the Committee on Algebraic Numbers," *Bull. Natn. Res. Coun., Wash.*, no. 62, ch. 2 (1928); and H.S. VANDIVER, "Fermat's Last Theorem: Its History and the Nature of the Known Results Concerning It," *Am. Math. Mon.*, 53:555–578 (1946). Several treatises on algebra have chapters on the arithmetic theory of continued fractions. HUBERT S. WALL, *Analytic Theory of Continued Fractions* (1948, reprinted 1967), deals with questions of convergence and the function-theoretic aspects of continued fractions. The paper of J.S. MACNERNEY, "Investigation Concerning Positive Definite Continued Fractions," *Duke Math. J.*, 26:663–677 (1959), deals with continued fractions whose partial numerators and denominators are matrixes.

The reader interested in algebraic number theory may wish to consult some of these works: DAVID HILBERT, *Die Theorie der algebräischen Zahlkörper* (*Jahresbericht der deutschen Mathematiker-Vereinigung*, vol. 4, 1897), reprinted in vol. 1 of Hilbert's *Gesammelte Abhandlungen*; this work (the *Zahlbericht*) is not available in English. It contains an extensive bibliography covering the literature up to 1897. The "Report of the Committee on Algebraic Numbers," *Bull. Natn. Res. Coun., Wash.*, no. 28 (1923), and no. 62 (1928), is an updating of the *Zahlbericht*. HARRY POLLARD, *The Theory of Algebraic Numbers* (1950), is a brief, elementary account in classical style. The following take the modern p–adic view: EMIL ARTIN, *Algebraic Numbers and Algebraic Functions* (1967); EDWIN WEISS, *Algebraic Number Theory* (1963); and Z.I. BOREVICH and I.R. SHAFAREVICH, *Number Theory* (1966; orig. pub. in Russian, 1964), also contains a good treatment of analytic number theory. The following also incorporate a treatment of class field theory: EMIL ARTIN and JOHN TATE, *Class Field Theory* (1967); J.W.S. CASSELS and ALBRECHT FROHLICH (eds.), *Algebraic Number Theory* (1967); SERGE LANG, *Algebraic Number Theory* (1970). ANDRE WEIL, *Basic Number Theory* (1967), also includes class field theory as well as some material on analytic number theory.

The following works are especially useful as references on analytic number theory. SARVADAMAN CHOWLA, *The Riemann Hypothesis and Hilbert's Tenth Problem* (1965); HAROLD DAVENPORT, *Multiplicative Number Theory* (1967); HELMUT HASSE, *Vorlesungen über Zahlentheorie*, 2nd rev. ed. (1963); KARL PRACHAR, *Primzahlverteilung* (1957); JEAN-PIERRE SERRE, *Cours d'arithmetique* (1970); CARL L. SIEGEL, *Analytische Zahlentheorie* (1963–64); EDWARD C. TITCHMARSH, *The Theory of the Riemann Zeta-Function* (1951); IVAN M. VINOGRADOV, *The Method of Trigonometrical Sums in the Theory of Numbers* (1954; orig. pub. in Russian, rev. ed., 1953), are recent works, suitable for an introduction to topics in analytic number theory, and are by authors who have contributed significantly to the subject. Other good introductory works include RAYMOND AYOUB, *An Introduction to the Analytic Theory of Numbers* (1963); JOSEPH LEHNER, *A Short Course in Automorphic Functions* (1966); and HANS RADEMACHER, *Lectures on Analytic Number Theory* (1954–55).

Some works concerning geometric number theory and related topics are J.W.S. CASSELS, *An Introduction to Diophantine Approximation* (1957) and *An Introduction to the Geometry of Numbers*, 2nd ed. (1971); L. FEJES TOTH, *Lagerungen in der Ebene auf der Kugel und im Raum* (1953) and *Regular Figures* (1964); CORNELIUS G. LEKKERKERKER, *Geometry of Numbers* (1969); HERMANN MINKOWSKI, *Geometrie der Zahlen* (1896, reprinted 1969), *Diophantische Approximationen* (1907, reprinted 1961), and *Gesammelte Abhandlungen*, 2 vol. (1911, reprinted 1967); and CLAUDE A. ROGERS, *Packing and Covering* (1964).

On probabilistic number theory, see GODFREY H. HARDY and EDWARD M. WRIGHT, *An Introduction to the Theory of Numbers*, 4th ed. (1960), an excellent introduction to the theory of numbers, touching incidentally on probabilistic number theory; MARK KAC, *Statistical Independence in Probability, Analysis and Number Theory* (1959), which contains a very readable introduction to probabilistic number theory and is highly recommended; and JONAS KUBILIUS, *Probabilistic Methods in the Theory of Numbers* (1964; Eng. trans. from the 2nd Russian ed., 1962), a full-scale treatment of the subject with a large bibliography.

Some additional references on various aspects of number theory are as follows: LEONARD E. DICKSON, *History of the Theory of Numbers*, 3 vol. (1919–23), a monumental topical history; and *Modern Elementary Theory of Numbers* (1939); H.J.S. SMITH, *Report on the Theory of Numbers* (1859–65, reprinted 1965); GEORGE B. MATHEWS, *Theory of Numbers* (1892); ROBERT D. CARMICHAEL, *The Theory of Numbers* (1914) and *Diophantine Analysis* (1915), reprinted together as *The Theory of Numbers and Diophantine Analysis* (1959); OYSTEIN ORE, *Number Theory and Its History* (1948); BURTON W. JONES, *The Arithmetic Theory of Quadratic Forms* (1950); TRYGVE NAGELL, *Introduction to Number Theory*, 2nd ed. (1964); WILLIAM J. Numerical Analysis

The term numerical analysis, which has been used since 1947 when the Institute of Numerical Analysis was founded at the University of California, describes the branch of mathematics concerned with methods of finding numerical solutions to problems.

To illustrate the use of numerical analysis, the concept of a function and the procedure known as interpolation will be described. The idea of a function in mathematics involves an association of each object in one set of objects with each object in another set. In particular, if the two sets considered are sets of real numbers, then each number can have an associated number given by some rule (see below). For example, the number 2 may have 4 associated with it, 3 may have 9, 4 may have 16, and, in general, x may have x^2. If $y = x^2$, y is said to be a function of x. It is usual to denote a function of x by $f(x)$. The correspondence does not have to be given by a formula (as $y = x^2$) but could be given by a tabulation.

Now a given $f(x)$ has values that depend on the values of the argument x; *i.e.*, independent variants upon the value of which that of a function depends. These values may be found for particular values of x by using the formula that defines the function. It is straightforward, for instance, to find the values of x^2 corresponding to values of x. In cases in which the formula is cumbersome, however, it is often easier to interpolate; *i.e.*, to calculate several values for the function and use numerical analysis to obtain intermediate values of the function. The procedure is to calculate widely spaced values with more decimal places than are ultimately required and then to interpolate values by an approximate process and round them off to the desired number of figures. An English mathematician named Henry Briggs used a similar procedure in 1624 to construct his celebrated table of logarithms (exponents [raised numbers] indicating the process to which a number is raised to produce a given number; *e.g.*, the logarithm of 100 to the base 10 is 2). The interpolation problem was first taken up by Briggs and was solved by the celebrated 17th-century English mathematician Sir Isaac Newton and James Gregory, a 17th-century Scottish mathematician and astronomer. Newton gave a great amount of attention to the interpolation formulas and investigated their application in detail; his directions for the construction of tables are very practical.

Early work on interpolation

Numerical analysis is also used for obtaining values of the differential coefficients of a function, solving differential equations, performing integrations, and solving systems of linear equations. In spite of the trend of modern mathematics toward greater abstraction and generality, many scientific and technological fields require quantitative results rather than qualitative ones. Thus, space flight would not be possible without the precise numerical solution of the underlying equations of motion. The modern development of numerical analysis has been strongly influenced by the development of the electronic computer.

A constructive method is formulated mathematically as an algorithm; that is, a prescribed sequence of algebraic, arithmetical, or logical operations. Special algorithmic languages, such as Fortran and Algol, have been developed for the description of algorithms. These languages can be read by the computing machine without further translation. Problems in algebra can usually be solved by terminating algorithms with a finite number of steps. An example is the Euclidean algorithm for finding the greatest common divisor of two integers. Problems in analysis usually require nonterminating algorithms that have an infinite number of steps. Only a finite number of steps can, of course, be carried out in any concrete application, but for a convergent algorithm the accuracy of the answer should increase indefinitely with the number of steps performed.

The prototype of a nonterminating algorithm is the principle of iteration, which in the simplest case may be described as follows. If f is a real function of a real variable, x_0 is chosen, and $x_1 = f(x_0)$, $x_2 = f(x_1)$, and generally $x_{n+1} = f(x_n)$ are formed where n runs through the positive integers. Under certain conditions the sequence of numbers $\{x_n\}$ tends to a solution of the equation $x = f(x)$. A trivial example is $f(x) = 1 + 0.1x$, $x_0 = 1$, $x_1 = 1.1$, $x_2 = 1.11$, $x_3 = 1.111$, and it is evident that $x_n \to 1.111111 \cdots = 10/9$, the unique solution of $x = 1 + 0.1x$. The same principle may be used to solve systems of equations and functional equations.

Use of numerical analysis to study numerical errors

In addition to the invention of efficient algorithms for the solution of specific problems, research in numerical analysis is concerned with the study of the numerical errors occurring in the application of these algorithms. Two kinds of errors are distinguished, commonly called truncation error and rounding error. Truncation errors are caused by terminating an essentially infinite algorithm after a finite number of steps. By a careful assessment of this error, it may be possible to estimate in advance the number of steps necessary to attain a predetermined accuracy, to speed up the convergence of the algorithm, and thus to attain the desired accuracy more quickly. The rounding error is caused by the fact that even in an electronic computer the results of most arithmetical operations have to be rounded off. Although the individual rounding errors are small, their cumulative effect can, in view of the large number of arithmetical operations performed, grow very rapidly and under unfavourable conditions invalidate the final result. In order to be sound, an algorithm must remain immune to the accumulation of rounding errors. This immunity is called numerical stability. (Ed.)

FINITE DIFFERENCES

Successive differencing of functions; interpolation. If a function $f(x)$ be given in a table for the values a, $a + 1$, $a + 2$, $\cdots$ of the argument, then the excess of any term $f(a + 1)$ above that which immediately precedes it, or the function $f(a + 1) - f(a)$, is called the first difference of the function $f(a)$ and is written $\Delta f(a)$ in which Δ is the Greek capital delta. Likewise, the first difference of $f(a + 1)$ is $f(a + 2) - f(a + 1)$, which is written $\Delta f(a + 1)$. The differencing procedure may be applied again to the new list of numbers $\Delta f(a)$, $\Delta f(a + 1)$, $\cdots$. The difference of the function $\Delta f(a)$ (see Box, equation 1), which is usually written $\Delta^2 f(a)$, is called the second

(1) $$\Delta(\Delta f(a)) = \Delta f(a+1) - \Delta f(a)$$

difference of $f(a)$. By repeating the process it is possible to form the third, fourth, $\cdots$, nth differences (see 2) by means of the relation that the nth difference is the difference of the $(n-1)$th (see 3). It is possible to list these differences in order to display the algebraic structure (see 4) in which n is a positive integer and the binomial coefficient notation is used. The procedure may be reversed to express a value of $f(a+n)$ in terms of the initial value and the differences. It follows that f at $(a+1)$ can be so expressed (see 5) and f at $(a+2)$ can be so expressed (see 6). In general f at $(a+n)$ is a succession of increasing differences of f at a, each difference being weighted with a binomial coefficient (see 7). Differences are arranged in tabular form, in what is called a difference table (see Table 1). The differences are usually written on a line between the two numbers for which

Table 1: Differences of $f(a)$

	entry	1st	2nd	3rd
$a-2$	$f(a-2)$			
		$\Delta f(a-2)$		
$a-1$	$f(a-1)$		$\Delta^2 f(a-2)$	
		$\Delta f(a-1)$		$\Delta^3 f(a-2)$
a	$f(a)$		$\Delta^2 f(a-1)$	
		$\Delta f(a)$		$\Delta^3 f(a-1)$
$a+1$	$f(a+1)$		$\Delta^2 f(a)$	
		$\Delta f(a+1)$		
$a+2$	$f(a+2)$			

they represent the differences. It will be observed that the even differences fall on the same line as the argument and function, while the odd differences lie between the lines. Thus, for the function $a^3 - a^2$ the table is Table 2. The third differences of this function are constant, and

Table 2: Differences of $f(a) = a^3 - a^2$

a	$f(a)$	Δ	Δ^2	Δ^3	Δ^4
-2	-12				
		10			
-1	-2		-8		
		2		6	
0	0		-2		0
		0		6	
1	0		4		
		4			
2	4				

all the following differences are zero. The difference of x^n is a polynomial of the $(n-1)$th degree (see 8). Therefore the first difference of a polynomial of the nth degree is a polynomial of degree $n-1$. Hence the nth difference of a polynomial of degree n is a constant, and all higher differences will be zero. Products of x and factors composed of x after subtraction by increasing integer values (see 9) are called factorials. It is then possible to take a difference of factorials (see 10). The rule for differencing factorials $x^{(n)}$ with respect to x is analogous to the rule for differentiating x^n with respect to x. In like manner, second differences of factorials are possible (see 11). Moreover, the nth difference of a factorial (see 12) is the product of the integers 1, 2, 3, $\cdots$ n. A polynomial can always be represented by a series of factorials. If $f(x)$ is a polynomial of degree n, then its representation in differences at the point $(a+x)$ (see 13) is the form analogous to Taylor's theorem for a polynomial.

Divided differences. The case in which the values of the argument, for which the function is known, are unequally spaced will now be considered. It is supposed that $f(x)$ is to be tabulated for $x = x_0, x_1, x_2, \cdots x_n$, in which the intervals $x_1 - x_0$, $x_2 - x_1$, $\cdots$ need not be equal. For abbreviation, this may be written in square bracket notation (see 14). The first-order divided differences are then defined by ratios of differences of square brackets to differences in the corresponding x values (see 15). The order inside the brackets is immaterial (see 16). The difference between two first-order differences divided by the interval of the independent variable that they span is called the second-order divided difference (see 17). The divided differences of higher orders are formed in the same way. In general (see 18), it is possible to form the divided difference of the nth order. As an example, the entries in Table 3 are the cubes of the integers. It is easily seen that $[x_0, x_1, \cdots, x_n]$ is a linear function of $f(x_0)$, $f(x_1)$, $\cdots$ $f(x_n)$. From the definition it follows that specific calculations can be made showing this to be true for two points and three points (see 19), and in general it is true for n points (see 20), as can be proved by induc-

(2) $\Delta^3 f(a), \Delta^4 f(a), \cdots, \Delta^n f(a)$

(3) $\Delta^n f(a) = \Delta(\Delta^{n-1} f(a))$

(4)
$$\begin{cases} \Delta f(a) = f(a+1) - f(a) \\ \Delta^2 f(a) = f(a+2) - 2f(a+1) + f(a) \\ \Delta^n f(a) = \sum_{s=0}^{n} (-1)^{n-s} \binom{n}{s} f(a+s) \end{cases}$$

(5) $f(a+1) = f(a) + \Delta f(a)$

(6) $f(a+2) = f(a) + 2\Delta f(a) + \Delta^2 f(a)$

(7) $f(a+n) = \sum_{s=0}^{n} \binom{n}{s} \Delta^s f(a)$

(8) $\Delta x^n = (x+1)^n - x^n = \sum_{s=0}^{n-1} \binom{n}{s} x^s$

(9) $x^{(n)} = x(x-1)(x-2)\cdots(x-n+1)$

(10) $\Delta x^{(n)} = (x+1)^{(n)} - x^{(n)} = n x^{(n-1)}$

(11) $\Delta^2 x^{(n)} = n(n-1) x^{(n-2)}$

(12) $\Delta^n x^{(n)} = n!$

(13) $f(a+x) = \sum_{s=0}^{n} \frac{x^{(s)}}{s!} \Delta^s f(a)$

(14) $[x_s] = f(x_s), \qquad s = 0, 1, 2, \cdots, n$

(15)
$$\begin{cases} [x_0, x_1] = ([x_0] - [x_1])/(x_0 - x_1) \\ [x_1, x_2] = ([x_1] - [x_2])/(x_1 - x_2) \end{cases}$$

(16) $[x_0, x_1] = [x_1, x_0], \qquad [x_1, x_2] = [x_2, x_1]$

(17) $[x_0, x_1, x_2] = ([x_0, x_1] - [x_1, x_2])/(x_0 - x_2)$

(18)
$$[x_0, x_1, \cdots, x_n] = \frac{[x_0, x_1, \cdots, x_{n-1}] - [x_1, x_2, \cdots, x_n]}{x_0 - x_n}$$

(19)
$$\begin{cases} [x_0, x_1] = \dfrac{f(x_0)}{x_0 - x_1} + \dfrac{f(x_1)}{x_1 - x_0} \\ [x_0, x_1, x_2] = \dfrac{f(x_0)}{(x_0 - x_1)(x_0 - x_2)} + \dfrac{f(x_1)}{(x_1 - x_0)(x_1 - x_2)} + \\ \qquad + \dfrac{f(x_2)}{(x_2 - x_0)(x_2 - x_1)} \end{cases}$$

(20)
$$\begin{cases} [x_0, x_1, \cdots, x_n] = \dfrac{f(x_0)}{(x_0 - x_1)(x_0 - x_2)\cdots(x_0 - x_n)} + \\ \qquad + \dfrac{f(x_1)}{(x_1 - x_0)(x_1 - x_2)\cdots(x_1 - x_n)} + \\ \qquad + \dfrac{f(x_n)}{(x_n - x_0)(x_n - x_1)\cdots(x_n - x_{n-1})} \end{cases}$$

Table 3: Divided Differences of $f(x) = x^3$

tion. It follows that the divided difference $[x_0, x_1, \cdots, x_n]$ is a symmetric function of its arguments $x_0, x_1, \cdots, x_n$ so that the order in which these are taken is indifferent. It appears from the definition of the divided differences that if $x_s = s$ $(s = 0, 1, 2, \cdots, n)$, then the nth divided difference is expressed in terms of nth differences (see 21). If $f(x) = 1/x$, the nth divided difference is a simple expression (see 22). As another example, if $f(x) = x^n$, then $[x_1, x_2, \cdots, x_n] = x_1 + x_2 + \cdots x_n$ and $[x_0, x_1, \cdots, x_n] = 1$. The divided differences of order n of a polynomial of the nth degree are constant and all the following differences are zero. If in the definitions of the divided differences x_0 is replaced by x, this system of equations may be written for f at x in terms of divided differences (see 23). From this there is obtained in succession a general expression for f at x including a remainder term (see 24) in which the remainder is expressed in a formula (see 25). This formula, discovered by Newton, is called Newton's interpolation formula with divided differences. It is one of the fundamental propositions of the calculus of finite differences. Other interpolation formulas used by the Scottish mathematician James Gregory, the 18th-century British mathematician James Stirling, the 19th-century German mathematician Carl Friedrich Gauss, and the 19th-century German astronomer Friedrich Wilhelm Bessel all follow as special cases from Newton's formula, and Newton himself investigated these special cases. If $f(x)$ is a polynomial of degree $p < n$, the remainder term R_n vanishes. In more general cases, an approximate value of R_n may be obtained. If $f(x)$ has a continuous derivative of order n in the interval considered, it follows from Rolle's theorem that the remainder equals the nth derivative of the function evaluated at the point ξ (see 26), ξ being situated in the smallest interval containing the numbers $x_1, x_2, \cdots x_n, x$. If all the differences diminish rapidly, so that from and after the mth order they are not worth taking into account in practice, it denotes that a polynomial of degree m will be a sufficient representation of the function in the considered interval. As an example of the use of Newton's formula from Table 3, the 3rd power of x can be expressed (see 27). Here the divided differences have been taken on the descending diagonal line.

Newton's interpolation formula

If in (20) x_0 is replaced by x, after a slight modification Lagrange's interpolation formula results (see 28), in which $\phi(x) = (x - x_1)(x - x_2) \cdots (x - x_n)$, and the remainder term R_n is the same as in Newton's formula (24). It is seen that for $x = x_s$ $(s = 1, 2, \cdots n)$ the right-hand side of (28) takes the value $f(x_s)$. If $f(x)$ is a polynomial of degree $p < n$, the remainder term vanishes. Lagrange's interpolation formula shows how a polynomial can be passed through any number of the tabulated values and the polynomial used for approximating the function between these entries. The Lagrange formula, however, has the defect that if another point of interpolation were added, the new higher degree interpolation polynomial could not be obtained by easily modifying the previous ones. Instead, it is necessary to start the computation of the new polynomial all over again. Newton's formula (24), on the other hand, has the advantage that the next higher degree interpolation polynomial is found simply by adding a new term.

Thus, for example, if it is desired to construct a polynomial of the second degree in x that shall have the values 3, 1, 3, the values of x being −1, 0, 2, respectively, then from (28) a simple calculation shows that the polynomial has coefficients 1, −1, and 1 (see 29).

Reciprocal differences. A method of interpolation will now be described by means of rational functions. It is more general than polynomial interpolation. Reciprocal differences, introduced by Thiele, led to the approximate representation of a function by a continued fraction. The reciprocal difference of $f(x)$ of the first order is defined (see 30) to be the reciprocal of the divided difference. The reciprocal difference of second order is defined in terms of the first-order reciprocal differences (see 31). It is seen that this difference is symmetric in the arguments x_0, x_1 and x_2, that is, its value does not change with interchange of the arguments. Proceeding to reciprocal difference of the third order, (see 32) and generally for the nth order (see 33), it can be proved that reciprocal differences of any order are symmetric functions of their

$$(21)\quad [x_0, x_1, \cdots, x_n] = \frac{\Delta^n f(0)}{n!}$$

$$(22)\quad [x_0, x_1, \cdots, x_n] = \frac{(-1)^n}{x_0 x_1 \cdots x_n}$$

$$(23)\quad \begin{cases} f(x) = f(x_1) + (x - x_1)[x, x_1] \\ [x, x_1] = [x_1, x_2] + (x - x_2)[x, x_1, x_2] \\ \qquad \cdot \\ \qquad \cdot \\ \qquad \cdot \\ [x, x_1, \cdots, x_{n-1}] = [x_1, x_2, \cdots, x_n] + \\ \qquad\qquad + (x - x_n)[x, x_1, x_2, \cdots, x_n] \end{cases}$$

$$(24)\quad \begin{cases} f(x) = f(x_1) + (x - x_1)[x_1, x_2] + \\ \qquad + (x - x_1)(x - x_2)[x_1, x_2, x_3] + \cdots + \\ \qquad + (x - x_1)(x - x_2) \cdots \\ \qquad\quad (x - x_{n-1})[x_1, x_2, \cdots, x_n] + R_n \end{cases}$$

$$(25)\quad R_n = (x - x_1)(x - x_2) \cdots (x - x_n)[x, x_1, x_2, \cdots, x_n]$$

$$(26)\quad R_n = (x - x_1)(x - x_2) \cdots (x - x_n)\frac{f^{(n)}(\xi)}{n!}$$

$$(27)\quad x^3 = -1 + (x + 1) + (x + 1)x + (x + 1)x(x - 2)$$

$$(28)\quad f(x) = \sum_{s=1}^{n} \frac{f(x_s)}{x - x_s}\frac{\phi(x)}{\phi'(x_s)} + R_n$$

$$(29)\quad f(x) = \frac{3x(x-2)}{(-1)(-3)} + \frac{(x+1)(x-2)}{1(-2)} + \frac{3(x+1)x}{3 \cdot 2} = x^2 - x + 1$$

$$(30)\quad \begin{cases} \rho_1(x_0 x_1) = \dfrac{x_0 - x_1}{f(x_0) - f(x_1)} \\ \rho_1(x_1 x_2) = \dfrac{x_1 - x_2}{f(x_1) - f(x_2)} \end{cases}$$

$$(31)\quad \rho_2(x_0 x_1 x_2) = \frac{x_0 - x_2}{\rho_1(x_0 x_1) - \rho_1(x_1 x_2)} + f(x_1)$$

$$(32)\quad \rho_3(x_0 x_1 x_2 x_3) = \frac{x_0 - x_3}{\rho_2(x_0 x_1 x_2) - \rho_2(x_1 x_2 x_3)} + \rho_1(x_1 x_2)$$

$$(33)\quad \begin{cases} \rho_n(x_0 x_1 \cdots x_n) \\ \quad = \dfrac{x_0 - x_n}{\rho_{n-1}(x_0 x_1 \cdots x_{n-1}) - \rho_{n-1}(x_1 x_2 \cdots x_n)} + \\ \quad + \rho_{n-2}(x_1 x_2 \cdots x_{n-1}) \end{cases}$$

arguments. In equations (30–33) x is written for x_0 and $\rho_1(xx_1)$, $\rho_2(xx_1x_2)$, $\cdots$ is eliminated. This leads to a sequence of identities for f at x (see 34). This continued fraction is called Thiele's interpolation formula. If in the continued fraction $x = x_1, x_2, \cdots, x_n$ is stated successively, then $f(x_1), f(x_2), \cdots, f(x_n)$ is obtained. It follows that Thiele's formula gives a method of obtaining a rational function that agrees in value with a given function at any number of prescribed points. Augustin-Louis Cauchy, a French mathematician, has given another approximate representation by a rational function in which the numerator and denominator are formed in a way similar to Lagrange's formula (28).

Interpolation formulas with ordinary differences. The cases in which the points of interpolation are equally spaced will now be considered. If in Newton's formula (24) x_s is set equal to $a + s - 1$ and x is replaced with $a + x$, then a formula (see 35) for a function evaluated at $(a + x)$ in terms of ξ is obtained, in which ξ is some number in the range spanned by 0, $n - 1$, and x. This is the Gregory-Newton formula for forward interpolation. It was discovered by Gregory in 1670. The remainder term was given by Cauchy. It uses the differences on a downward diagonal line, and it is best suited for interpolation near the beginning of a table of differences.

The Gregory-Newton formula

If in (24) x_s is set equal to $a - s + 1$ and x is replaced with $a - x$, then Newton's backward interpolation formula is obtained for a function evaluated at $(a - 2)$ (see 36). This formula is used when it is desired to find values of the function near the end of a table. It uses the differences on an upward diagonal line.

A formula will now be derived that employs values on a horizontal line of the difference table. If in (24) elementary substitutions (see 37) are made and x is replaced with $(a + x)$, then there follows an expression for f at $(a + x)$ in terms of f at a and differences of ascending orders (see 38). This formula, often called the Newton-Gauss formula of interpolation, is convenient for use when the value of the argument, for which the function is required, is near the middle of the table of differences. From Newton's formula (28) others can be derived.

Numerical differentiation. By means of a table of a function, the successive differential coefficients of the function can be approximated, and this process is called numerical differentiation. From the forward difference formula (35), differentiating with respect to x and letting $x \to 0$, it follows that a formula for the first derivative of f is obtained (see 39). From formula (36) it follows in a similar way that a difference expression for the first derivative of a function is obtained (see 40). Another example is furnished by differentiating the Newton-Gauss formula of interpolation (38). The higher derivatives may be obtained in the same manner, but the error in their evaluation increases with their order.

Numerical integration. The approximate value of an integral can be expressed as a linear function of a certain number of values of the function to be integrated, and this process is called numerical integration or mechanical quadrature. Integrating from a to b, the function $f(x)$ given by Lagrange's formula (28) gives an approximation formula for the integral of a function (see 41) in which a remainder term is expressible as an integral (see 42). The coefficients of $f(x_s)$ depend upon the interpolation points $x_0, x_1, \cdots, x_n$ but are independent of the form of $f(x)$. If in this formula equidistant arguments $x_s = a + sh$, in which $s = 0, 1, \cdots n$ are taken and $(b - a)/n$ is equal to h, the 18th-century English mathematician Roger Cotes's formula for an integral results (see 43), in which integration is reduced to the evaluation of coefficients (see 44). The value of the coefficients $c_{n,s}$ were calculated by Cotes for $n = 1, 2, 3, \cdots 10$. There is a large number of other numerical integration formulas.

Summation of series. To evaluate the sum of a function ϕ evaluated at integer points x to $x + (n - 1)$ (see 45) it is sufficient to find a function $f(x)$ so that $\Delta f(x)$ is equal to $\phi(x)$. Then by summation the desired sum is found to be a simple difference between the function at $(x + n)$ and the function at x (see 46). Thus from the difference formula for factorials (see 47) it follows that the

$$
(34)\quad \begin{cases}
f(x) = f(x_1) + \dfrac{x - x_1}{\rho_1(x, x_1)} \\
f(x) = f(x_1) + \dfrac{x - x_1}{\rho_1(x_1, x_2) + \dfrac{x - x_2}{\rho_2(x, x_1, x_2) - f(x_1)}} \\
f(x) = f(x_1) + \dfrac{x - x_1}{\rho_1(x_1, x_2) + \dfrac{x - x_2}{\rho_2(x_1, x_2, x_3) - f(x_1) + R_1}} \\
R_1 = \dfrac{x - x_3}{\rho_3(x, x_1, x_2, x_3) - \rho_1(x_1, x_2)} \\
\cdot \\ \cdot \\ \cdot
\end{cases}
$$

$$
(35)\quad f(a + x) = \sum_{s=0}^{n-1} \binom{x}{s} \Delta^s f(a) + \binom{x}{n} f^{(n)}(a + \xi)
$$

$$
(36)\quad f(a - x) = \sum_{s=0}^{n-1} (-1)^s \binom{x}{s} \Delta^s f(a - s) + \\
+ (-1)^n \binom{x}{n} f^{(n)}(a - \xi)
$$

$$
(37)\quad x_{2s} = a - s, \qquad x_{2s+1} = a + s
$$

$$
(38)\quad \begin{cases}
f(a + x) = f(a) + \dfrac{x}{1} \Delta f(a - 1) + \dfrac{x(x + 1)}{2!} \Delta^2 f(a - 1) + \\
\quad + \dfrac{x(x^2 - 1)}{3!} \Delta^3 f(a - 2) + \\
\quad + \dfrac{x(x^2 - 1)(x + 2)}{4!} \Delta^4 f(a - 2) + \cdots
\end{cases}
$$

$$
(39)\quad f'(a) = \sum_{s=1}^{n-1} (-1)^{s-1} \frac{\Delta^s f(a)}{s} + \frac{(-1)^{n-1}}{n} f^{(n)}(a + \xi)
$$

$$
(40)\quad f'(a) = \sum_{s=1}^{n-1} \frac{\Delta^s f(a - s)}{s} + \frac{1}{n} f^{(n)}(a - \xi)
$$

$$
(41)\quad \int_a^b f(x)\, dx = \sum_{s=0}^{n} \frac{f(x_s)}{\phi'(x_s)} \int_a^b \frac{\phi(x)}{x - x_s}\, dx + R
$$

$$
(42)\quad \begin{cases}
R = \displaystyle\int_a^b \phi(x)\, [x, x_0, x_1, \cdots, x_n]\, dx \\
\phi(x) = (x - x_0)(x - x_1) \cdots (x - x_n)
\end{cases}
$$

$$
(43)\quad \int_a^b f(x)\, dx = (b - a) \sum_{s=0}^{n} c_{n,s} f(a + sh)
$$

$$
(44)\quad c_{n,s} = \frac{1}{n} \int_0^n \binom{t}{s} \binom{n - t}{n - s}\, dt
$$

$$
(45)\quad \sum_{s=0}^{n-1} \phi(x + s)
$$

$$
(46)\quad \sum_{s=0}^{n-1} \phi(x + s) = f(x + n) - f(x)
$$

$$
(47)\quad \Delta x^{(m+1)} = (m + 1) x^{(m)}
$$

sum of a factorial can be calculated (see 48). If $m = 2$, this gives a known arithmetic expression (see 49). For a factorial expression of the form with negative index (see 50) ϕ can be easily calculated (see 51). Thus, by (46), if $n \to \infty$, the summation of a new series is achieved (see 52). Special cases follow (see 53).

Functional equations. A relation that is characteristic of a function and more or less determines its form is called a functional equation. Differential and difference equations are examples of functional equations. The functional equation in which a function f is restricted so that the sum of two of its values equals its value at the sum of the arguments (see 54) has the solution $f(x) = cx$, in which c is an arbitrary constant (see 55). Cauchy has proved that if a solution is continuous it will always be of the above form. Another 19th-century French mathematician, Gaston Darboux, showed that if a solution is only bounded in an interval it will still be of the same form, but a 20th-century German mathematician, Georg Karl Wilhelm Hamel, and a 19th–20th-century French mathematician, Henri-Léon Lebesgue, proved the existence of discontinuous solutions of a complicated form.

Similarly, it is seen that the equation in which a function f is restricted so that the product of two of its values equals its value at the sum (see 56) has the solution $f(x) = c^x$, in which again c is an arbitrary constant, for if the logarithm of both sides is taken, this equation is referred to the preceding one.

The functional equation involving a specific linear combination of functional values (see 57) has a solution expressed in logarithms and c_1 and c_2 (see 58), in which c_1 and c_2 are functions of x unaffected by the change of x into $2x$ and $1/c_3$ is the constant 8 $(\log 2)^2$. This can easily be verified by substitution in the equation.

Difference equations. First a linear equation of order n with constant coefficients will be considered (see 59). Using a previous expression (see 4), it can always be written in the form of a linear combination of functional values of a function u, with coefficients q_i, the linear combination set equal to 0 (see 60), in which $q_0, q_1, \cdots q_n$ are constants, and it is supposed that q_0 and q_n do not equal zero. Setting $u(x)$ equal to ρ^x gives a linear combination in terms of ρ (see 61). The polynomial whose product with the x power of ρ is restricted by the equation to vanish (see 62) is called the characteristic function of the given equation. If ρ_s is a zero of this function, ρ_s^x will be a solution of the difference equation. If the characteristic function has n unequal zeros $\rho_1, \rho_2, \cdots \rho_n$, there are n particular solutions $\rho_1^x, \rho_2^x, \cdots \rho_n^x$, and the general solution of the difference equation (60) is a linear combination of these (see 63) in which coefficients $\pi_1(x) \cdots \pi_n(x)$ are periodic functions of period one. For example, a particular difference equation involving three terms (see 64) has the solutions 2^x and 3^x, and the general solution is a weighted average of these (see 65).

If the characteristic function has one or more multiple zeros, the function u is written in two factors (see 66). It follows that the value of u at the general point $x + n$ can be computed (see 67). Substitution in a previous formula (60) yields a sum (see 68).

Letting ρ_1 be a zero of multiplicity m, then it will solve a basic equation (see 69). If $s < m$ and ρ equals ρ_1 in a previous equation (68) an expansion is obtained (see 70). The right-hand side vanishes if $v(x)$ is a polynomial of degree $r < m$. The difference equation (60) thus has the solution $\rho_1^x p_1(x)$, in which $p_1(x)$ is a polynomial of degree $m - 1$, and consequently the m solutions $\rho_1^x x^s$ $(s = 0, 1, 2, \cdots m - 1)$ so that a zero of multiplicity m gives a set of m particular solutions. Thus, if the characteristic function $f(\rho)$ has the distinct zeros $\rho_1, \rho_2, \cdots \rho_r$, there is the general solution (see 71) in which the coefficients of the polynomials $p_s(x)$ are periodic functions of unit period. An exemplary equation (see 72) has the solutions 2^x, 2_2^x, and 3^x and the general solution is a linear combination of these (see 73).

Next the important difference equation identifying u at $(x + 1)$ with the product of x and $u(x)$ (see 74) is

(48) $$\sum_{s=0}^{n-1} (x+s)^{(m)} = \frac{(x+n)^{(m+1)} - x^{(m+1)}}{m+1}$$

(49) $$1 \cdot 2 + 2 \cdot 3 + 3 \cdot 4 + \cdots + n(n+1) = \frac{n(n+1)(n+2)}{3}$$

(50) $$f(x) = x^{(-m)} = \frac{1}{(x+1)(x+2)\cdots(x+m)}$$

(51) $$\phi(x) = \Delta f(x) = -mx^{(-m-1)}$$

(52) $$\sum_{s=0}^{\infty} (x+s)^{(-m-1)} = \frac{x^{(-m)}}{m}$$

(53) $$\sum_{s=0}^{\infty} \frac{1}{(x+s)(x+s+1)(x+s+2)} = \frac{1}{2x(x+1)}$$

(54) $$f(x) + f(y) = f(x+y)$$

(55) $$cx + cy = c(x+y)$$

(56) $$f(x)f(y) = f(x+y)$$

(57) $$f(4x) - 4f(2x) + 4f(x) = x$$

(58) $$c_1 x + c_2 x \log x + c_3 x (\log x)^2$$

(59) $$\sum_{i=0}^{n} p_i \Delta^i u(x) = 0$$

(60) $$Q(u(x)) = \sum_{i=0}^{n} q_i u(x+i) = 0$$

(61) $$Q(\rho^x) = \rho^x \sum_{i=0}^{n} q_i \rho^i$$

(62) $$f(\rho) = \sum_{i=0}^{n} q_i \rho^i$$

(63) $$\sum_{s=1}^{n} \pi_s(x)\, \rho_s^x$$

(64) $$u(x+2) - 5u(x+1) + 6u(x) = 0$$

(65) $$\pi_1(x) 2^x + \pi_2(x) 3^x$$

(66) $$u(x) = \rho^x v(x)$$

(67)
$$\begin{cases} u(x+1) = \rho^{x+1}(v(x) + \Delta v(x)) \\ u(x+2) = \rho^{x+2}(v(x) + 2\Delta v(x) + \Delta^2 v(x)) \\ u(x+n) = \rho^{x+n} \sum_{s=0}^{n} \binom{n}{s} \Delta^s v(x) \end{cases}$$

(68) $$Q(\rho^x v(x)) = \rho^x \sum_{s=0}^{n} \frac{\rho^s}{s!} f^{(s)}(\rho)\, \Delta^s v(x)$$

(69) $$f^{(s)}(\rho_1) = 0$$

(70) $$Q(\rho_1^x v(x)) = \sum_{s=m}^{n} \frac{\rho_1^{x+s}}{s!} f^{(s)}(\rho_1) \Delta^s v(x)$$

(71) $$u(x) = \sum_{s=1}^{r} \rho_s^x\, p_s(x)$$

considered. It is satisfied by the Eulerian integral (see 75) for, if x is greater than zero, integration by parts shows that this is the case (see 76). This solution of (74) is called the gamma (Γ) function, and it is denoted by $\Gamma(x)$. Putting $x = 1$ in (75) gives $\Gamma(1) = 1$. If n be a positive integer, it then follows from (74) that $\Gamma(n+1) = n!$ The first attempts to define the gamma function originated in the problem of finding, by a certain interpolation, a function of a real variable x that is continuous when x is positive and reduces to $x!$ when x is a positive integer. When x is large, $\Gamma(x)$ is given approximately by Stirling's formula (see 77). By repeated application of (74) it follows that a recursion relation for Γ is obtained (see 78). The relation can be written in a slightly different form (see 79). It follows from Stirling's formula that the second fraction on the right-hand side tends to 1 as n tends to infinity. Therefore, a limiting expression for Γ is obtained (see 80). This formula is also due to Euler. From this a product formula follows (see 81). A comparison of this with the infinite product for $\sin x$ (see 82) at once gives the functional equation that relates the product of two gamma functions with the sine function (see 83). Inserting $x = \frac{1}{2}$, the result $\Gamma(\frac{1}{2}) = \sqrt{\pi}$ is obtained.

The use of E, Δ, and D

Operational methods in the solution of difference and differential-difference equations. The symbol E is used to denote the operation of giving to x in a subject function the increment 1, and D is used to denote the operation of differentiation (see 84). With this notation, the first difference is expressed in terms of E (see 85). It is convenient to abbreviate by writing $\Delta = E - 1$, and similarly $E = 1 + \Delta$ and $E = e^D$. The meaning of these relations is that the operation indicated by the symbol on the left is equivalent to the series of operations on the right. The operators E, Δ, and D each combine with constant quantities and with each other by the rules of algebra, and they may be treated as if they were mere symbols of quantity. The difference equation (60) may be written symbolically with f and E (see 86) in which $f(x)$ is the characteristic function. It can be solved by the operational method of the 19th-century English logician and mathematician George Boole as follows. By letting $f(x)$ have the zeros $\rho_1, \rho_2, \cdots, \rho_n$, then f can be written as a specific product of factors (see 87). The difference equation (86) can be written as a product of successive operations operating upon u with the result set equal to 0 (see 88), in which the order of the successive operations is indifferent. If the equation constructed from the first such operation (see 89) is solved, a particular solution of the difference equation results because the operator that remains (see 90) when performed on zero must produce zero. If the zeros are all different, n particular solutions ρ_r^x ($r = 1, 2, \cdots, n$) are attained by solving n separate equations (see 91). If the zero ρ_r is repeated m times, however, it is necessary to solve the equation that includes the corresponding operator term raised to the mth power (see 92). An observation is necessary (see 93). A consequence follows (see 94) making possible a simple equation (see 95). The difference equation (86) then has m solutions (see 96). A zero of multiplicity m gives a set of m particular solutions. In all cases the general solution of (86) can be obtained. A more general equation will now be considered (see 97), in which $\phi(x)$ is a given polynomial of degree m. Writing $1 + \Delta$ for E, the symbolic solution of equation (97) is available (see 98).

It is supposed that $f(\rho)$ does not admit the root 1 and $1/f(1+\Delta)$ is expanded in powers of Δ (see 99), stopping at the term in Δ^m, for $\phi(x)$ is nullified by higher powers of Δ. Hence this operator expansion operating upon ϕ (see 100) satisfies the equation (97). To the solution thus obtained the general solution of the associated homogeneous equation (86) is added. The general solution of (97) is then the sum of the solution already obtained plus products of the $\{\pi_r\}$ and the $\{\rho_r^x\}$ (see 101), in which $\pi_1 \cdots \pi_n$ are arbitrary periodic functions of period one. For example, the equation in which values of u at four points are weighted with coefficients and set equal to x (see 102) has a characteristic function that is

(72) $u(x+3) - 7u(x+2) + 16u(x+1) - 12u(x) = 0$

(73) $\pi_1 2^x + \pi_2 2^x x + \pi_3 3^x$

(74) $u(x+1) = xu(x)$

(75) $u(x) = \int_0^\infty e^{-t} t^{x-1}\, dt$

(76) $\int_0^\infty e^{-t} t^x\, dt = x \int_0^\infty e^{-t} t^{x-1}\, dt$

(77) $\Gamma(x) \sim x^x e^{-x} \sqrt{\frac{2\pi}{x}}$

(78) $\Gamma(x) = \frac{\Gamma(x+n)}{x(x+1)\cdots(x+n-1)}$

(79) $\Gamma(x) = \frac{n^x(n-1)!}{x(x+1)\cdots(x+n-1)} \frac{\Gamma(x+n)}{n^x \Gamma(n)}$

(80) $\Gamma(x) = \lim_{n\to\infty} \frac{n^x(n-1)!}{x(x+1)\cdots(x+n-1)}$

(81) $\Gamma(x)\Gamma(1-x) = \frac{1}{x} \prod_{n=1}^{\infty} 1 \Big/ \left(1 - \frac{x^2}{n^2}\right)$

(82) $\sin x = x \prod_{n=1}^{\infty} \left(1 - \frac{x^2}{n^2\pi^2}\right)$

(83) $\Gamma(x)\Gamma(1-x) = \frac{\pi}{\sin \pi x}$

(84) $Eu(x) = u(x+1), \qquad Du(x) = \frac{du(x)}{dx}$

(85) $\Delta u(x) = Eu(x) - u(x) = (E-1)u(x)$

(86) $f(E)u(x) = 0$

(87) $f(E) = (E-\rho_1)(E-\rho_2)\cdots(E-\rho_n)$

(88) $(E-\rho_1)(E-\rho_2)\cdots(E-\rho_n)u(x) = 0$

(89) $(E-\rho_n)u(x) = 0$

(90) $(E-\rho_1)(E-\rho_2)\cdots(E-\rho_{n-1})$

(91) $(E-\rho_r)u(x) = 0$

(92) $(E-\rho_r)^m u(x) = 0$

(93) $f(E)\rho^x u(x) = \rho^x f(\rho E)u(x)$

(94) $\begin{cases} (E-\rho_r)^m u(x) = \rho_r^x (\rho_r E - \rho_r)^m \rho_r^{-x} u(x) \\ \quad = \rho_r^{x+m} \Delta^m \rho_r^{-x} u(x) = 0 \end{cases}$

(95) $\Delta^m \rho_r^{-x} u(x) = 0$

(96) $\rho_r^x x^s, \qquad s = 0, 1, 2, \cdots, m-1$

(97) $f(E)u(x) = \phi(x)$

(98) $\frac{1}{f(1+\Delta)} \phi(x)$

easily determined (see 103) and can be evaluated formally at $1 + \Delta$ (see 104). It follows that a linear expression in x (see 105) is a particular solution, and the general solution is obtained from this by adding three products of the general type described (see 106).

Differential-difference equations, it has been noted, are functional equations involving derivatives and differences. There is a very close similarity between the theory of differential-difference equations and the theory of difference equations. It has been shown that every solution of a linear homogeneous difference equation can be written as a linear combination of a finite number of particular solutions. Solutions of linear homogeneous differential-difference equations with constant coefficients can likewise be written as sums of independent particular solutions, but there are infinitely many such solutions that must be found by transcendental methods, and the entire theory is accordingly more complicated. As an example, an equation that is first order and inhomogeneous (see 107) may be considered in which q_0 and q_1 are given constants, and $q_0 + q_1 \neq 0$, $q_1 \neq 0$. The operator $f(D)$ is defined (see 108). The equation is expressible in operator form (see 109). A symbolic solution is obtained by performing the inverse operation (see 110). Expanding in powers of D gives the reciprocal of the operator $f(D)$ (see 111). If $p(x)$ is a polynomial of degree n, $D^s p(x) = 0$, if $s > n$, and thus (see 112) in terms of powers of D operating upon p a particular solution is obtained. Now the differentiation properties of the exponential (see 113) are relevant. Then $\exp(\rho_s^x)$ is a solution of the homogeneous equation (see 114) if and only if ρ_s is a zero of the characteristic function (see 115). There are, in general, infinitely many zeros $\rho_1, \rho_2, \rho_3, \cdots$. The homogeneous equation thus has solutions of the form of a linear combination of exponentials (see 116) in which $c_1, c_2, c_3, \cdots$ are arbitrary constants decreasing sufficiently to ensure convergence, and the equation to be solved (107) therefore has a general solution (see 117) composed of the sum of u and the stated combination of exponentials. (N.E.N.)

(99) $$\frac{1}{f(1+\Delta)} = a_0 + a_1\Delta + a_2\Delta^2 + \cdots + a_m\Delta^m$$

(100) $$(a_0 + a_1\Delta + \cdots + a_m\Delta^m)\phi(x)$$

(101) $$(a_0 + a_1\Delta + \cdots + a_m\Delta^m)\phi(x) + \sum_{r=1}^{n} \pi_r \rho_r^x$$

(102) $$u(x+3) - 4u(x+2) + u(x+1) + 6u(x) = x$$

(103) $$f(E) = E^3 - 4E^2 + E + 6 = (E+1)(E-2)(E-3)$$

(104) $$f(1+\Delta) = 4 - 4\Delta - \Delta^2 + \Delta^3$$

(105) $$\frac{1+\Delta}{4}x = \frac{x+1}{4}$$

(106) $$\frac{x+1}{4} + \pi_1(-1)^x + \pi_2 2^x + \pi_3 3^x$$

(120) $$D^k f(x_i) = D^k P_3(x_i) \qquad k = 0, 1;\ i = 0, 1, 2, \cdots, n$$

(121) $$D^k f(x_i) = D^k P_{2m-1}(x_i), \qquad \begin{cases} 0 \leq k \leq m-1 \\ 0 \leq i \leq n \end{cases}$$

APPLICATIONS OF NUMERICAL ANALYSIS

Approximation. Approximation of a function $f(x)$ by a simpler function $A(x)$ is one of the most widely used ideas in numerical analysis. The difference $f(x) - A(x)$ is the error of the approximation, and this must be kept reasonably small over the range of x considered. The interpolating functions mentioned previously are examples of approximating functions in which the error is zero at selected points along the x-axis. An interpolating function, however, may not give a good fit between these selected points (nodes), and the first derivatives of the interpolating function may bear little resemblance to the first derivatives of the original function $f(x)$. Accordingly, it is often advantageous to break up the range of x, over which an approximation is required, into a number of non-overlapping subintervals and to fit each subinterval with a polynomial of low degree. For example, if there are n subintervals (see 118) the piecewise linear approximating function, denoted by $P_1(x)$, satisfies $n + 1$ restrictions (see 119). This approximating function may well give a good fit between the nodes, but of course contributes nothing toward obtaining some agreement between the first derivatives of the function and its approximation. Consequently, the possibility of constructing a piecewise approximating function that has the same values of function and first derivative as $f(x)$ at the nodes, x_i $(i = 0, 1, 2, \cdots, n)$ is considered. Such a function is a piecewise cubic polynomial, denoted by $P_3(x)$, in which its function values and first derivatives are matched to those of f at $n + 1$ points (see 120). In general, the piecewise polynomial $P_{2m-1}(x)$ in which functional values and $m - 1$ derivatives are matched at $n + 1$ points (see 121) interpolates the function and its first $(m - 1)$ derivatives at the nodes x_i $(i = 0, 1, 2, \cdots, n)$. Such approximating functions are known as piecewise Hermite interpolates, named for a 19th-century French mathematician, Charles Hermite.

Hermite interpolates

In problems in which the approximate has to match $f(x)$ but not $Df(x)$, $D^2f(x)$, etc., it is undesirable to introduce derivatives of $f(x)$ as additional parameters (arbitrary constants). Consequently, a desirable property in piecewise functions might be continuity of the derivatives at the nodes without specifying the values of the derivatives there. Piecewise approximates of this type are known as splines, the most popular form of which is the cubic spline. Given the values of f_i $(i = 0, 1, 2, \cdots, n)$ a cubic polynomial is fitted between successive pairs of nodes and continuity of both first and second derivatives is required at all internal nodes.

The natural form of the cubic spline for equally spaced nodes distance h apart in the range $[0, b]$ is a cubic in

(x/h) (see 122) in which a specialized notation is used (see 123). Applying the condition that the spline should equal the function at each of $n + 1$ points (see 124), there are $(n + 1)$ linear equations for the $(n + 3)$ coefficients, and so there are two free parameters, which can be fixed arbitrarily.

Approximation of functions of two space variables over rectangular regions can be carried out by splitting the region up using a rectangular grid, and using piecewise bivariate Hermite functions or splines. These are tensor products of the univariate Hermite functions or splines described in this section. When the region is not rectangular, approximation is very difficult even with piecewise approximating functions.

So far the approximates have agreed with $f(x)$ at $(n + 1)$ points in the range. This of course is not necessary, and two frequently used measures of the error function $e(x)$ are the integral of the square of the error function, integrated on $\mathfrak{R}$, and the maximum over $\mathfrak{R}$ of the absolute value of the error function (see 125, 126) in which $\mathfrak{R}$ is the range of x considered. The approximating function $A(x)$ is chosen to make one or other of these expressions as small as possible. The former is called the least squares measure and the latter the maximum measure of the error. With regard to the latter measure a very important result exists. It is that among all polynomials of degree n or less, a unique polynomial exists that minimizes, for $x \in \mathfrak{R}$, max $|f(x) - P_n(x)|$. This minimum value of size E is taken with alternating sign at $(n + 2)$ arguments in $\mathfrak{R}$.

Finally, rational functions are mentioned as a possible class of approximating functions. These functions are ratios of polynomials. They are particularly suitable when $f(x)$ has one or more singularities (or poles) within R. The denominator of the rational function is chosen to have zeros coinciding with the poles of the original function $f(x)$.

Differentiation and integration. Numerical differentiation involves finding the derivatives of functions that are either given as a table of values or are given analytically in such a complicated manner that the exact derivatives are exceedingly tedious to evaluate. The standard procedure is to obtain a polynomial approximation $p(x)$ to the function $f(x)$ and to accept derivatives of the approximation (see 127) as approximations to the derivatives of the function (see 128). In the case of the function given as a table of values, the polynomial $p(x)$ is an interpolating polynomial, and examples of these for equally and unequally spaced data were given earlier. Alternatively, the function with a complicated form $f(x)$ may be replaced, for example, by a cubic spline, its having the same values of function and first two derivatives as $f(x)$ at selected points in the range. It should be pointed out that numerical differentiation is unquestionably inaccurate in many cases because two functions, say $f(x)$ and $p(x)$, can be very close together over a range of x and nevertheless have very different slopes in this range. The accuracy also diminishes with increasing order of the derivatives.

Numerical integration is one of the most successful operations in numerical analysis. In most integration formulas the integrand $f(x)$ is replaced by an approximating polynomial, and it is integrated exactly over the required range. The approximating polynomial is usually a high degree interpolating polynomial over the complete range or a piecewise polynomial in which the range has been divided into several equal parts with a simple polynomial over each part. Very popular examples of the latter are the trapezoidal rule (piecewise linear; see 129) and the rule of the 18th-century English mathematician Thomas Simpson (piecewise quadratic; see 130), each involving h, in which h is the length of a part.

So far the numerical integration formulas considered have been of the form of a sum of products of coefficients and functional values evaluated at arguments (see 131), in which the arguments x_i have been equally spaced distance h apart. The possibility of choosing the arguments x_i and the coefficients A_i so that the numerical integration formula is exact for $f(x)$ being any polynomial of degree $\leq 2n + 1$ is worth consideration. This in fact can be done and leads to the development of Gaussian quadrature formulas. These formulas, as might be expected, are more accurate than formulas with equally spaced arguments, but they require extra work because the location of the arguments must be found in advance.

(122) $$\begin{cases} S_{0,b}\left(\frac{x}{h}\right) = \alpha_0 + \alpha_1\left(\frac{x}{h}\right) + \alpha_2\left(\frac{x}{h}\right)^2 + \alpha_3\left(\frac{x}{h}\right)^3 + \\ \qquad + \sum_{s=1}^{n-1} \beta_s \left(\frac{x}{h} - s\right)_+^3 \end{cases}$$

(123) $$\left(\frac{x}{h} - s\right)_+ = \begin{cases} 0 & \frac{x}{h} \leq s \\ \left(\frac{x}{h} - s\right) & \frac{x}{h} > s \end{cases}$$

(124) $$S_{0,b}\left(\frac{x_i}{h}\right) = f_i, \qquad i = 0, 1, 2, \cdots, n$$

(125) $$\int_{x \in R} [e(x)]^2 \, dx$$

(126) $$\max_{x \in R} |e(x)|$$

(127) $$p'(x), \; p^{(2)}(x), \; p^{(3)}(x), \; \ldots$$

(128) $$f'(x), \; f^{(2)}(x), \; f^{(3)}(x), \; \ldots$$

(129) $$\int_{x_0}^{x_n} f(x)\,dx \doteq \tfrac{1}{2}h[f_0 + 2f_1 + \cdots + 2f_{n-1} + f_n]$$

(130) $$\int_{x_0}^{x_n} f(x)\,dx \doteq \tfrac{1}{3}h[f_0 + 4f_1 + 2f_2 + 4f_3 + \cdots + 2f_{n-2} + 4f_{n-1} + f_n]$$

(131) $$\sum_{i=0}^{n} A_i f_i$$

Computational methods in linear algebra. The solution of many linear problems in science and engineering reduces to the mathematical problem of solving a set of linear equations. In matrix form, the set of equations can be represented by $A\mathbf{x} = \mathbf{b}$, in which A is a square matrix of order n with real elements, and $\mathbf{x}$, $\mathbf{b}$ are column matrices (that is, matrices composed of one column), each with n real elements. The matrix A is assumed to be nonsingular; that is $|A| \neq 0$, in which $|A|$ is the determinant of A. The problem is to find the elements of the vector $\mathbf{x}$, given the elements of A and $\mathbf{b}$. This simple looking problem can be deceptively difficult.

There are two principal types of method for solving linear systems, direct and iterative. The direct method reaches the solution after a finite number of different operations. The iterative method begins with a guess at the solution and by repeated use of the same operation guides the original guessed value toward the required solution. Iterative methods are usually employed when the matrix A has a particular structure incorporating large blocks of zero elements.

Direct method of solution

The most popular direct method of solution is Gaussian elimination, which is now described. Rows and columns of A are interchanged until the maximum modulus element is in the top left-hand position. This is the first pivot and is called a_{11}. The first equation is divided by the first pivot. Now the first equation is multiplied by a_{21}, the leading element in the second row, and subtracted from the second equation; then the first equation is multiplied by a_{31}, the leading element in the third row, and subtracted from the third equation; and so on. This annihilates the

first column except for unity in the first equation. The first equation is thus obtained after being divided by a_{11} together with a system of $(n-1)$ equations. The maximum modulus element is then moved up to the top left-hand corner of the $(n-1)$ block by interchanging rows and columns, and the process repeated. If $(n-1)$ such eliminations are performed, the resulting linear system, which is triangular, is equivalent to the original linear system (*i.e.*, it has the same solution). The triangular system is easily solved by back substitution and so the solution of the original system is obtained. If A is symmetric and positive definite, the method described can be considerably simplified. The modified method is known as Choleski's method.

Iterative methods

The iterative methods used originally for solving linear systems are those of the 19th-century German mathematician Karl Gustav Jacob Jacobi and Gauss-Seidel (the 19th-century German astronomer P.L. Seidel). In recent years, however, the method of successive overrelaxation (S.O.R.) has been universally accepted as the best iterative method. In this method, the matrix A is written as $(I\text{-}L\text{-}U)$, in which I is the unit matrix and L, U are lower and upper triangular matrices, respectively, with zero entries on the main diagonals. The S.O.R. method is given by a relation between successive values of the vector that involves $\mathbf{x}_0$ and w (see 132) in which $\mathbf{x}_0$ is the guessed value of the solution, and w is a parameter to be determined, which probably lies in the range $1 \leq w \leq 2$. The value of w that gives the fastest convergence of the iterative method in a particular problem is usually obtained empirically.

Finding eigenvalues and eigenvectors

Another computational problem in linear algebra, which is just as important as solving a set of linear equations, is finding the eigenvalues and associated eigenvectors of a matrix A with real elements. In mathematical terms this reduces to finding the numbers λ (written as Greek letters lambda) for which the linear system $(A - \lambda I)\,\mathbf{x} = 0$ has a solution other than $\mathbf{x} = \mathbf{0}$. Each such number λ, which can be real or complex, is called an eigenvalue of A, and the corresponding solution vector $\mathbf{x}$ ($\neq \mathbf{0}$) is called the associated eigenvector. In general, a matrix A of order n has n eigenvalues and n associated eigenvectors. If only a few eigenvalues are required, iterative methods are usually employed, but if all the eigenvalues are required, direct methods involving similarity transformations are often used. These transformations reduce the matrix A to simpler form without altering the eigenvalues. The direct methods in common use for symmetric matrices are those of the U.S. mathematicians Wallace Givens and Alston S. Householder, both of which reduce A to tridiagonal form. This is a form with zero elements everywhere except on the principal diagonal and the two subdiagonals adjacent and on opposite sides of the main diagonal. Standard procedures exist for finding the complete eigenvalue system for a tridiagonal matrix.

Nonlinear equations. In solving a set of linear equations $A\mathbf{x} = \mathbf{b}$ in which A is a square matrix, it was accepted that a unique solution existed provided $|A| \neq 0$; that is, n linearly independent linear equations are required to find n unknowns. This simple guideline no longer applies with nonlinear equations, for it is seen immediately that one nonlinear equation may have any number of solutions. For example, $x^2 - 2 = 0$ has two solutions, $x = \pm\sqrt{2}$, and $\sin x = 0$ has an infinity of solutions $x = r\pi$, in which r is any integer. It is a nontrivial matter to solve one nonlinear equation in one unknown, and this case is examined first, writing the single equation in the form $f(x) = 0$. Although x is used for the unknown quantity, in fact x can lie anywhere in the complex plane. The equation is now rewritten as $x = g(x)$, which is not a unique form in any particular example. The second degree polynomial equation (see 133), for example, can be rewritten as any one of three or more forms (see 134). Any of the forms motivate the iterative method in which successive values of x, designated by symbols with superscripts, are related through some function g (see 135) with the appropriate form of g, in which x_0 is an initial guess at a root of the equation. The method is successful if the iteration converges to the required root. In the above example, which has $x = 2$ as a solution, the iterative process (see 136) diverges for any starting value other than 2, whereas another possible process (see 137) converges to the required solution for a wide range of possible starting values. The general convergence condition for the first order (or linear) iterative method described is given in the following theorem. Letting $x = X$ be a root of $f(x) = 0$, and I be an interval containing the point $x = X$ and also the initial approximation x_0, and if the absolute value of the derivative is bounded by a number less than 1 (see 138) for all points in I, then the iteration expressed in terms of a general function g (see 139) converges to the root X.

The absolute value of the derivative (see 140) determines the rate of convergence of the process, and it is advantageous to make it as small as possible, say zero. Such an iterative procedure is second order (or quadratic), and the most popular method of this class owes its origin to Newton in which a specific form of g (see 141) leads to the iterative method in which the $(k+1)$th point is obtained from the kth by subtracting the ratio of the function to its derivative (see 142) measured at the kth point.

The practical solution of systems of nonlinear equations is significantly more difficult than the solution of a single equation, although most of the methods for a single equation extend in an obvious manner to systems. The importance of finding a good method for solving nonlinear systems cannot be stressed enough, since many nonlinear problems in science and engineering reduce to the mathematical problem of solving a set of nonlinear equations.

The extension of Newton's iterative method to a system is indicated because this extension forms the starting point for many practical methods of solving nonlinear systems. The system of equations is written as $f_i(x_1, x_2, \cdots x_n) = 0$ $(i = 1, 2, \cdots n)$, and the square matrix, the Jakobian J, is introduced (see 143). Newton's

(132) $$\begin{cases}\mathbf{x}_{i+1} = (I - wL)^{-1}[wU + (1-w)I]\mathbf{x}_i + w(I - wL)^{-1}\mathbf{b} \\ i = 0, 1, 2, \cdots\end{cases}$$

(133) $$f(x) \equiv x^2 - x - 2 = 0$$

(134) $$x = x^2 - 2, \qquad x = 1 + \frac{2}{x}, \qquad x = (2+x)^{1/2}$$

(135) $$x^{k+1} = g(x^k), \qquad k = 0, 1, 2, \cdots$$

(136) $$x^{k+1} = (x^k)^2 - 2, \qquad k = 0, 1, 2, \cdots$$

(137) $$x^{k+1} = (2 + x^k)^{1/2}$$

(138) $$\left|\frac{dg(x)}{dx}\right| \leq K < 1$$

(139) $$x^{k+1} = g(x^k), \qquad k = 0, 1, 2, \cdots$$

(140) $$\left|\frac{dg(x)}{dx}\right|$$

(141) $$g(x) = x - \frac{f(x)}{\dfrac{df(x)}{dx}}$$

(142) $$x^{k+1} = x^k - \left(\frac{f(x)}{\dfrac{df(x)}{dx}}\right)^k, \qquad k = 0, 1, 2, \cdots$$

$$(143)\quad \begin{cases} J(x_1, x_2, \cdots, x_n) = \left[\dfrac{\partial f_i(x_1, x_2, \cdots, x_n)}{\partial x_j}\right] \\ i, j = 1, 2, \cdots, n \end{cases}$$

$$(144)\quad \mathbf{x}^{k+1} = \mathbf{x}^k - J^{-1}(\mathbf{x}^k) f(\mathbf{x}^k), \qquad \begin{cases} k = 0, 1, 2, \cdots \\ |J(\mathbf{x})| \neq 0 \end{cases}$$

$$(145)\quad f_i(\mathbf{x}^k) + \sum_{j=1}^{n} f_{ij}(\mathbf{x}^k)(x_j^{k+1} - x_j^k) = 0, \qquad \begin{cases} i = 1, 2, \cdots, n \\ k = 0, 1, 2, \cdots \end{cases}$$

$$(146)\quad x_1^{k+1}, x_2^{k+1}, \cdots, x_n^{k+1}$$

$$(147)\quad \begin{cases} x_i^{k+1} = x_i^k - w\dfrac{f_i(x_1^{k+1}, \cdots, x_{i-1}^{k+1}, x_i^k, \cdots, x_n^k)}{f_{ii}(x_1^{k+1}, \cdots, x_{i-1}^{k+1}, x_i^k, \cdots, x_n^k)} \\ i = 1, 2, \cdots, n \qquad k = 0, 1, 2, \cdots \end{cases}$$

$$(148)\quad y^n = f(x, y, y', \cdots, y^{(n-1)})$$

$$(149)\quad y(x_0) = A_0, \qquad \cdots, \qquad y^{(n-1)}(x_0) = A_{n-1}$$

$$(150)\quad y' = p, \qquad p' = f(x, y, p)$$

$$(151)\quad \mathbf{Y}' = \mathbf{F}(x, \mathbf{Y}), \qquad \mathbf{Y} = [y, p]^T$$

$$(152)\quad \mathbf{F} = [F_1, F_2]^T$$

$$(153)\quad \mathbf{Y}(x_0) = [A_0, A_1]^T$$

$$(154)\quad y^{(2)} = f(x, y, y')$$

$$(155)\quad y(a) = y_a, \qquad y(b) = y_b$$

$$(156)\quad \begin{cases} k_1 = hf(x, y) \\ k_2 = hf(x + \frac{1}{2}h, y + \frac{1}{2}k_1) \\ k_3 = hf(x + \frac{1}{2}h, y + \frac{1}{2}k_2) \\ k_4 = hf(x + h, y + k_3) \\ y(x + h) = y(x) + \frac{1}{6}(k_1 + 2k_2 + 2k_3 + k_4) \end{cases}$$

$$(157)\quad \begin{cases} y_{k+1} = y_{k-3} + \dfrac{4h}{3}(2y'_{k-2} - y'_{k-1} + 2y'_k) \\ y_{k+1} = y_{k-1} + \dfrac{h}{3}(y'_{k+1} + 4y'_k + y'_{k-1}) \end{cases}$$

$$(158)\quad \tfrac{14}{45} h^5 y^{(5)} \quad -\tfrac{1}{90} h^5 y^{(5)}$$

$$(159)\quad \sum_{i=1}^{n} c_i e^{\lambda_i x}$$

method for the system then can be expressed in vector form (see 144). If the equation expressing Newton's method is multiplied through by J, this becomes (see 145) a linear system of equations of order n to be solved for the successive values of the vector exponents (see 146) at each iteration. A practical variant of this is the generalized Newton's method involving parameter w (see 147) in which w is to be determined empirically in order to speed up the convergence.

Ordinary differential equations. The numerical solution of ordinary differential equations is one of the most important branches of numerical analysis because many physical problems lead to ordinary differential equations that cannot be solved analytically. The two main types of problem are initial value and boundary value. The former requires a function $y(x)$ to be found for $x \geq x_0$ which satisfies an nth-order equation (148) and takes initial values (149) consisting of the function and its first $n - 1$ derivatives at $x = x_0$. When $n \geq 2$, the single differential equation can be replaced by a system of first order equations. For example, if $n = 2$, the second order equation becomes a first order system (see 150) with the initial conditions $y(x_0) = A_0$, $p(x_0) = A_1$. This can be written in vector form (see 151, 152) in which vector components are $F_1 = p$ and $F_2 = f(x, y, p)$. The initial condition is also expressible in vector form (see 153). A typical boundary value problem is given by a second order differential equation (see 154) together with the two boundary values at points a and b (see 155). The solution is required for $a \leq x \leq b$.

In the vast majority of numerical methods for ordinary equations the differential equation is replaced by a difference equation. A discrete set of equally placed arguments x_k distance h apart is chosen, and a sequence of corresponding values $y(x_k)$ is calculated from the difference formula.

The Runge-Kutta and Milne methods

The initial value problem for a single first order equation may be considered first. The most popular classes of methods here are Runge-Kutta (named for the 19th–20th-century German mathematician Carl David Tolmé Runge and the 20th-century German aerodynamicist M. Wilhelm Kutta) and predictor-corrector multistep methods. An example of the former is easily constructed (see 156) and an example of the latter (see 157) is Milne's method (named for the 20th-century U.S. mathematician and astrophysicist William Edmund Milne) in which the predictor is an explicit formula, and the corrector is a more accurate implicit formula. The accuracy of these methods is measured by the local truncation obtained after Taylor expansions (named for the 18th-century English mathematician Brook Taylor) have been carried out for the various terms in the difference formula. These are positive and negative constants times fifth order terms (see 158) for the predictor and corrector formulas of Milne's method, respectively.

There is little point in a method being locally accurate, however, if it is not convergent and stable. A method is convergent if as the grid size h tends to zero, the approximate solutions converge to the exact solution of the problem. Convergence is concerned with truncation error only. A method is stable if a round-off error, committed anywhere in the calculation, propagates in such a way that it does not significantly influence the true solution. Necessary and sufficient conditions for the stability of a multistep method can be given in terms of the roots of the characteristic polynomial. For example, in the corrector formula of Milne's method, if $h = 0$, and $y_k = C\lambda^k$, in which C is a constant, then the characteristic polynomial is $\lambda^2 - 1$ with roots ± 1. This method is stable in the sense that the roots are distinct and lie on the unit circle.

In any calculation, however, the grid size h is not zero, and if the true solution is decreasing, one of the characteristic roots is greater than unity, and so Milne's method is relatively unstable. An exact stability analysis of a multistep method for finite h is a difficult and tedious task. On the other hand, Runge-Kutta methods are always stable for sufficiently small grid size, and so convergence theorems are much more straightforward than for multistep methods.

Many of the numerical methods for solving a single equation carry over to a system. A complication in the calculation of the solution arises, however, if the system is "stiff." To illustrate stiffness in a system, the linear system $\mathbf{y}' = A\mathbf{y}$, of order n, in which the eigenvalues of A are distinct, is considered. The general solution of this system is given by a linear sum of exponentials (see 159) in which $\{\lambda_i\}$ appearing in the exponent are the eigenvalues of A and $\{c_i\}$ are constants. If the real parts of some of the eigenvalues of A are negative and very much larger than the real parts of others, the terms corresponding to the large eigenvalues die away quickly and the system is said to be stiff. When difference methods are applied to the linear system, stability restrictions on the grid size take the form $\{|h\lambda i| < d\}$, in which d is a fixed quantity. If some of the $|\lambda_i|$ are large, the permissible step forward is small even when the corresponding contribution to the true solution is negligible. A simple method that is very satisfactory with stiff equa-

tions is the trapezoidal rule. For the linear system this takes a form (see 160) that is easily expressed. For a nonlinear system $y^1 = f(x, y)$, the stiffness analysis above applies except that the eigenvalues are now those of the Jacobian matrix (see 161).

Finally, boundary value problems are often solved numerically by shooting methods. In these, additional starting values are assumed to enable initial value methods to be used. Once the right-hand boundary is reached, the calculated value is compared with the boundary condition there, and the additional initial conditions modified until agreement is reached at the right-hand boundary. If, for example, the problem $y^2 = f(x, y, y')$ with $y(a) = y_a$ and $y(b) = y_b$ is solved as an initial value problem using a two-step difference method, the additional condition $y'(a) = c$, in which c is a parameter, must be assumed. The parameter c is modified until the solution at $x = b$ agrees with the value y_b.

Partial differential equations. The rapid growth of high speed computers has led to intense development in the numerical solution of partial differential equations. A method universally applicable to linear and nonlinear problems that give rise to elliptic, parabolic, and hyperbolic partial differential equations is the method of finite differences, and most of what follows will be devoted to this method, followed by the finite element method as a means of obtaining numerical solutions of elliptic problems.

The method of finite differences

The independent variables in a partial differential equation are either all space variables (elliptic case), or the time variable together with one or more space variables (parabolic and hyperbolic cases). The region over which the solution is required is usually closed in an elliptic problem, and open otherwise. The elliptic or steady problem has boundary conditions over the perimeter or surface enclosing the region, whereas the parabolic and hyperbolic or unsteady problems have initial condition(s) at $t = 0$ and boundary conditions on the sides of the open region. In the finite difference method, the region over which the solution is required is covered by a rectangular grid with grid lines parallel to the coordinate axes. The grid spacing in the direction of the space variables is h, whereas the grid spacing in the direction of the time axis (parabolic and hyperbolic cases) is k. If the original region is rectangular in shape, then the rectangular grid can be made to fit the region exactly. If the original region is not rectangular, then complications arise with a rectangular grid in the vicinity of the boundary of the original region.

Initially the elliptic problem is considered, and at each grid point inside the region, each partial differential in the equation is replaced by an equivalent difference replacement. Thus, for each internal grid point there is formed, depending on the equation, a linear or nonlinear expression connecting a finite number of unknown function values. At grid points on the boundary of the region, either the function values (Dirichlet conditions, named for the 19th-century German mathematician Peter Gustav Lejeune Dirichlet) or the normal derivatives are known (Neumann conditions, named for the 19th-century German Karl Neumann), which on discretization produce linear expressions at each boundary grid point. The totality of equations at the internal and boundary grid points leads to the matrix equation $A\mathbf{U} = \mathbf{b}$ in the case of a linear equation and to the nonlinear system of equations $f_i(U_1, U_2, \cdots, U_n) = 0$ $(i = 1, 2, \cdots, n)$ in the case of a nonlinear equation, in which n is the number of grid points at which the solution is required. The iterative method of successive overrelaxation (S.O.R.) has already been described for solving the linear system and the generalized Newton's method for solving the nonlinear system. As the grid spacing h is reduced in an elliptic problem, the number of grid points, and hence the number of equations (linear or nonlinear), to be solved increases. In the limit as $h \to 0$, the theoretical solution of the system of equations should tend to the real solution of the problem. This is the problem of convergence, which is usually not a serious problem with elliptic equations.

(160) $$\mathbf{y}_{r+1} - \mathbf{y}_r = \tfrac{1}{2}h[(A\mathbf{y})_{r+1} + (A\mathbf{y})_r], \qquad r = 0, 1, 2, \cdots$$

(161) $$\frac{\partial(f_1, f_2, \cdots, f_n)}{\partial(y_1, y_2, \cdots, y_n)}$$

(162) $$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2}$$

(163) $$U_m^{n+1} = (1 + r\delta_x^2)U_m^n$$

(164) $$(1 - \tfrac{1}{2}r\delta_x^2)U_m^{n+1} = (1 + \tfrac{1}{2}r\delta_x^2)U_m^n$$

(165) $$(1 - \tfrac{1}{2}r\delta_x^2)(1 - \tfrac{1}{2}r\delta_y^2)U_m^{n+1} = (1 + \tfrac{1}{2}r\delta_x^2)(1 + \tfrac{1}{2}r\delta_y^2)U_m^n$$

(166) $$\begin{cases} (1 - \tfrac{1}{2}r\delta_x^2)U_m^{n+\frac{1}{2}} = (1 + \tfrac{1}{2}r\delta_y^2)U_m^n \\ (1 - \tfrac{1}{2}r\delta_y^2)U_m^{n+1} = (1 + \tfrac{1}{2}r\delta_x^2)U_m^{n+\frac{1}{2}} \end{cases}$$

(167) $$\frac{\partial^2 u}{\partial t^2} = \frac{\partial^2 u}{\partial x^2}$$

(168) $$U_m^{n+1} = 2(1 - p^2)U_m^n + p^2(U_{m+1}^n + U_{m-1}^n) - U_m^{n-1}$$

Use in time-dependent problems

In time-dependent problems that lead to parabolic and hyperbolic equations, the finite difference approximation is set up as in the elliptic case. The method of solution of the set of difference equations (linear or nonlinear), however, is entirely different. The calculation starts with the initial condition(s) at $t = 0$ and proceeds in a step-by-step manner in the direction of increasing time. For example, in the parabolic heat conduction equation in one space variable (see 162), two possible difference replacements are an explicit formula (see 163) and the implicit Crank–Nicolson formula (see 164) involving r, δ_x, and U_m^n, in which $r = k/h^2$, δ_x is the standard central difference operator, and U_m^n is the exact difference solution at the grid point $x = mh$, $t = nk$. These formulas advance the calculation from $t = 0$ to $t = k$ $(n = 0)$ then from $t = 1$ to $t = 2k$ $(n = 1)$, and so on. The solution by the explicit formula is straightforward, whereas the implicit formula requires the solution of a set of linear equations at each time step. The principal computational hazard with a calculation advancing in time is that a round-off error will grow as the calculation advances and swamp the true solution. This is the problem of instability. With the two difference methods described above the stability conditions are $0 < r \leq \frac{1}{2}$ for the explicit method and $r > 0$ for the Crank–Nicolson method. With the heat conduction equation in two space dimensions, the unconditionally stable counterpart of the Crank–Nicolson method can be written down (see 165). For ease of calculation, this can be split into two formulas (see 166). Advancing the calculation from $t = nk$ to $t = (n + \frac{1}{2})k$ requires the solution of sets of equations along lines parallel to the x-axis, followed by an advancement from $t = (n + \frac{1}{2})k$ to $t = (n + 1)k$, which requires the solution of sets of equations along lines parallel to the y-axis. This method was first introduced by Peaceman and Rachford and is known as an alternating direction implicit (A.D.I.) method.

In calculations involving hyperbolic equations, extra care must be taken to ensure that the rate of advancement of a calculation, as given by the difference formula, is not in excess of the rate governed by the characteristic curves. For example, in the case of the wave equation in one space dimension (see 167) the standard explicit difference replacement includes the parameter p (see 168) in which $p = k/h$. The characteristic curves of the wave equation consist of two families of straight lines inclined at angles $\pm \pi/4$ respectively to the t-axis. The lines of advancement or wave fronts of the finite difference calculation must make angles of less than $\pi/4$ with the

$$\alpha(x)y(x) = F(x) + \lambda \int_a^b K(x, \xi; y(\xi))\, d\xi \tag{169}$$

$$\alpha(x)y(x) = F(x) + \lambda \int_a^x K(x, \xi; y(\xi))\, d\xi \tag{170}$$

$$y(a),\ y(a+h),\ y(a+2h),\ \cdots,\ y(b) \tag{171}$$

positive and negative directions of the t-axis, and this leads to the condition $0 < p \leq 1$ on the grid ratio. This is the Courant-Friedrichs-Lewy condition, which is all important in an explicit difference calculation of a hyperbolic equation.

There are, of course, methods other than the finite difference method for obtaining numerical solutions of partial differential equations. Such a method, used extensively, particularly in elliptic problems, is the finite element method. Here the region under consideration is divided up into a number of parts or elements. In each element a function of the space variables is chosen in such a way that continuity of the overall function is maintained along the interelement curves or surfaces. For example, in a region in two dimensions covered by a triangular grid, linear functions in the triangles can give continuity along the internal sides. Thus in this case the overall approximating function is a piecewise linear function, involving parameters that are the function values at the vertices of the triangular grid. In many elliptic problems, the solution minimizes a certain integral involving derivatives of the unknown function. The piecewise approximating function obtained above is substituted into this integral formulation, and the values of the parameters found that minimize the integral. This is the approximate solution of the original elliptic problem. This technique, known as the Ritz method, makes use of a variational principle and involves the finite element method.

Integral equations. An integral equation is one in which the function to be determined appears under an integral sign, an abbreviation for the limit of a sum. Not unnaturally, the usual procedure for finding a numerical solution of an integral equation is to replace the integral by a suitable quadrature formula and to solve the discretized problem by an appropriate standardized procedure. There are two main types of integral equation: (A) the Fredholm equation (named for the 19th–20th-century Swedish mathematician Ivar Fredholm) that relates α, y, and F through an integral from a to b of λK (see 169) in which α, F, K are given functions, and λ, a, b are given constants; and (B) the Volterra equation, similar in structure to the Fredholm equation but with an indefinite integral (see 170). In these equations $y(x)$ is the function to be determined, and K is known as the kernel. If K can be written as $k(x, \xi)y(\xi)$, the integral equation is linear. Also when $\alpha = 0$ the integral equation is of the first kind and when $\alpha = 1$ the integral equation is of the second kind. From a numerical point of view, the distribution between Volterra and Fredholm equations corresponds to the distinction between initial and boundary value problems in ordinary differential equations.

The two types of integral equation

The usual numerical procedures for solving integral equations may be described as follows: in the Fredholm equation, the range $a \leq x \leq b$ is divided up equally into n parts: $b - a = nh$. A quadrature formula like the trapezoidal rule or Simpson's rule (see above *Numerical integration*) then replaces the integral leading to a set of simultaneous algebraic equations for $(n - 1)$ unknown quantities (see 171). These are solved by the methods described in the section on nonlinear equations, unless the system is linear when the methods described in the section on linear algebra are used. With equations of Volterra type, the upper limit of the integral is taken successively as $a + b$, $a + 2b$, $\cdots$, leading to a series of sets of equations, which is solved by a step-by-step procedure. The quantities $y(a + h)$, $y(a + 2h)$, $\cdots$, are calculated in turn. (A.R.Mi.)

Nurhachi

Nurhachi was the hereditary chieftain of a Juchen tribe in Manchuria who, in the 17th century, became the founder of the Manchu, or Ch'ing, dynasty in China (1644–1911). The Juchen (Jurchen) were a Tungus people who belonged to those border groups at the periphery of the Chinese Empire that normally were under the influence of the Chinese Imperial Court. Juchen leaders had earlier established the Chin dynasty (1122–1234) and controlled North China until they were conquered by the Mongols. In his own buildup of power among the Juchen, Nurhachi followed an Imperial tradition.

Nurhachi's tribe was the so-called Chien-chou Juchen, one of five Juchen tribes of Manchuria. The Chien-chou Juchen lived to the east of the Chinese border in the Long White Mountains north of the Yalu River. Four other Juchen tribes, the Hata, the Hoifa, the Ula, and the Yehe, were located farther north of the central forest and steppe region of Manchuria. These tribes were rivals for power in a frontier relationship of alternate fighting and cooperation, which included intermarriage. In this setting, Nurhachi established his career from very small beginnings. Born in 1559, he was called to leadership in his early 20s, after his father and grandfather had been killed in battle with rivals, supported in this case by China's Ming dynasty, which fostered rivalries among tribes on its borders as a way to make them less dangerous. At first, therefore, Nurhachi had to fight for survival in a situation of decline and disintegration of his own tribe. In 1586 he defeated Nikan Wailan, a rival in his own tribe, who was supported by the Chinese. From this basic success, Nurhachi moved on to destroy, one by one, the challenges of the other Juchen states. To isolate his Juchen opponents from the Chinese, Nurhachi invaded the Chinese-controlled part of Manchuria and moved, thus, on to a more ambitious military and political venture, the attack against the Chinese Empire.

Struggle for leadership of the Juchen

In preparation and while defeating Juchen rivals, Nurhachi established a Manchu state, which at first remained undefined in its political relationship of his Manchurian opponents as well as to the Chinese Empire. But its potential became clearer as the organization advanced. In 1599, under Nurhachi's direction, a Manchu nobleman

and scholar, Erdeni, knowledgeable in both Mongol and Chinese, created a Manchu system of writing that laid the foundation for a Manchu national literature. This was the year also in which the state of Hata, the first of the Juchen rivals, was defeated and incorporated into the Nurhachi state. In 1601 Nurhachi established what was to become the military organization of the Manchus, the banner system. Although basically military, the banners were also units of administration and taxation for the Manchu people and their families. Their commanders and administrators were appointed by Nurhachi, thus injecting an administrative structure into the Juchen tribal system. He assigned the four banners to three of his sons and one nephew, thereby preserving a part of the clan tradition without endangering his own authority. There were originally four banners; four more, established in 1615, were also given to reliable relatives.

This ingenious transformation of a tribal group into a military bureaucracy, which may have been inspired by the model of the military–political structure of Chinese frontier settlements in Manchuria and elsewhere, prepared the way for the Manchu conquest of China.

To provide an economic base for expansion, Nurhachi shrewdly used his position in Manchuria to amass a great fortune from his monopoly of mining in the area and the trade in pearls, fur, and ginseng (a medicinal root) from the area and from Korea. He even developed a new, profitable method of curing ginseng. He also accumulated silver reserves from his tribute missions to Peking, which combined tribute with the trading ventures.

The beginning of the conquest of China

Nurhachi launched his first attack against China in 1618. By that time, he already had defeated two more of the Juchen rivals, the Hoifa and the Ula, and incorporated them in his union, and the final showdown with the most dangerous opponent, the Yehe, and their Chinese supporters was at hand. The Chinese border city of Fu-shun was captured when its commander, Li Yung-fang, defected to the Manchu side. This defection was possible only because the Chinese official saw in the Manchu system the opportunity of serving a Manchu ruler without abandoning his Chinese cultural and political experience. He was only the first of a number of Chinese who surrendered or were captured and entered Manchu service in an administration that adapted many Chinese methods.

Nurhachi's relationship to the Ming emperor at Peking was at first ambiguous. He himself went several times at the head of tribute missions to Peking. In 1601, when the four banners were established, Nurhachi issued a vague claim of having founded a great "Yeh," a family realm or state. In 1616, before the attack against Fu-shun, Nurhachi proclaimed himself as khan ("emperor"), using the Chinese phrase T'ien Ming (Heavenly Mandated). He called his dynasty Chin or sometimes Hou Chin (Later Chin) to indicate a continuation of the Juchen dynasty of the 12th century. Even then, this assertion of Imperial authority did not necessarily imply a challenge to the supreme authority of the Ming, since the Chin dynasty of the 12th century had never ruled the whole of China. The attack against Imperial Chinese forces that followed in 1618 was justified by seven alleged grievances, accusations against the Chinese for their support of his enemies, their responsibility for the killing of Nurhachi's father and grandfather, and other complaints, all within the loyalty relationship between the Ming and his own state.

Nurhachi's ambition, however, clearly went further. He moved his capital into Chinese Manchuria, first to Liao-yang and finally to Shen-yang (Mukden), in 1625, and from there attempted to defeat the Chinese forces guarding the entrance to China proper. In February 1626 he was defeated for the first time by the Chinese at Ning-yuän and died September 30 of wounds.

Nurhachi thus never saw final success of his great political–military venture. On the foundation he established, however, his successors carried out his plans. As a tribal ruler who rose to khanship, Nurhachi had a harem of three wives and many concubines, mostly taken from the families of Juchen chieftains. He had 16 known sons, of whom one, Abahai (died 1643), succeeded him as khan, and another, Prince Dorgon, perhaps one of the most brilliant of the early Manchu leaders, as regent directed the final conquest of China and established the Manchu dynasty in Peking in 1644.

BIBLIOGRAPHY. ARTHUR W. HUMMEL (ed.), *Eminent Chinese of the Ch'ing Period, 1644–1912*, vol. 1, pp. 594–599 (1944), is the most useful biography of Nurhachi, written by FANG CHAO-YING, a well-known specialist in the field of history of the Manchus. It contains a detailed listing of Chinese, English, and Japanese sources on Nurhachi and his period. FRANZ MICHAEL, *The Origin of Manchu Rule in China* (1942, reprinted 1965), analyzes in detail the role of Nurhachi in creating the Manchu state and contains a bibliography of works on Manchu history.

(F.H.M.)

Nürnberg

A city of great importance in the historical development of Europe, as well as a modern industrial and commercial centre, Nürnberg (English Nuremberg) is situated in the forested uplands of the southern part of the Federal Republic of Germany. It is the foremost city in Franconia, the northern section of the *Land* (state) of Bavaria, and is exceeded in regional importance only by Munich (for related information see BAYERN).

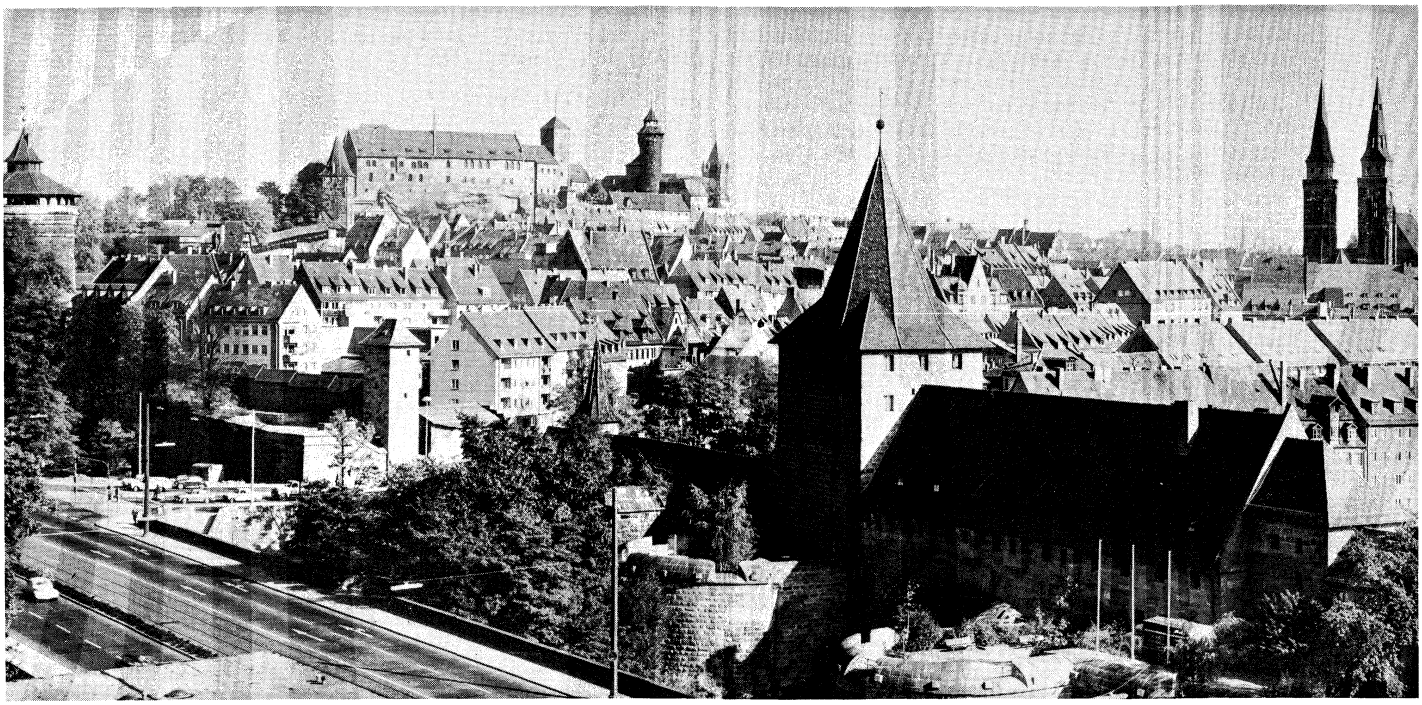
History. First mentioned in official records as Noremberg, in 1050, the city had its origin in a castle built about ten years earlier by the German emperor Henry III, duke of Bavaria. From a sandstone rock, rising 165 feet (50 metres) above the surrounding plain, the castle looked down on the Pegnitz River, commanding its strategic exit from the Jura Uplands, and thus dominating one of the ancient trade routes of Europe. At the foot of the rock, on the north bank of the Pegnitz, the vassals of the castle, together with artisans and merchants, soon established an embryonic settlement. Meanwhile, on the steeply rising southern bank of the river, another royal seat became the nucleus of a second settlement during the course of the 12th century, and, in 1219, the city was granted its first charter. The privileges this bestowed on the city were a direct result of the dearth of natural resources in the area: the soil was infertile, there were no vineyards, and the river was not navigable. In 1225 construction started on the city's first church, the St. Sebald, subsequently renowned as a pilgrims' shrine. A city council, consisting predominantly of members of wealthy patrician families, is first mentioned in 1256. The city soon gained full independence, becoming a free imperial city, with extensive land holdings and joining the Rheinische Städtebund (League of Rhineland Cities). A city wall was erected, and Nürnberg adopted its own seal.

The castle

A second church, the St. Lorenz, was built on the south side of the river in 1260, amid the growing community of Lorenzer *Stadt*. Nürnberg's character was now changing; no longer solely a fortified settlement, it was developing into a city of craftsmen and patricians, and manufacture and commerce became the foremost sources of income. In 1332 the city was granted the right to buy and sell free of tax in 72 different localities, and in the course of the 14th century Nürnberg concluded trade agreements with almost all the important cities and most of the larger territories of central Europe. From 1356 onward, the head of the Holy Roman Empire held his first imperial diet at Nürnberg, a significant indication of the city's growing influence; in 1424 the imperial crown jewels were transferred to the city, remaining in the Hospital Church of the Holy Ghost for over 350 years.

Early commercial expansion

In 1471 the painter Albrecht Dürer was born in Nürnberg. Thanks to Dürer and his famous contemporaries—the painter Michael Wohlgemuth (his teacher), the wood sculptor Veit Stoss, the brass founder Peter Vischer, the stonecutter and sculptor Adam Kraft, as well as the cobbler-poet Hans Sachs—the arts flourished in Nürnberg as never before or since. In 1525 the tenets of the Reformation were adopted by the city, and in 1526 the scholar and Protestant leader Philipp Melanchthon founded one of Germany's first *Gymnasiums*, an institution that continues to bear his name. Together with the humanist Willibald Pirkheimer, the astronomer Regiomontanus, and the cosmographer Martin Behaim, the designer of



Nürnberg, with a portion of the medieval wall surrounding the old city in the foreground and the imperial castle in upper left. St. Sebalduskirche is in the upper right.
By courtesy of the German Information Center

the first globe, Melanchthon laid the foundation for Nürnberg's reputation as a centre of learning in the developing Western world.

When the architect Jakob Wolff the Younger rebuilt the city hall in the style of a Renaissance palace in 1616, Nürnberg was at the pinnacle of its economic and cultural development; yet by 1806 it had lost its status as a free imperial city and, much indebted, became part of the kingdom of Bavaria. The shift of world trade routes from the land to the sea, following the discovery of America and of the seaway to India, and the devastations of the Thirty Years' War were the initial causes of this decline. Not until the dawn of the industrial age, when the first German railway (linking Nürnberg and Fürth) was opened, on December 7, 1835, did the city begin to flourish again, as a modern industrial centre.

The contemporary city. *The site.* Located at a height of between 948 and 1,230 feet (289 and 375 metres) above sea level, and lying to the west of the Jura Uplands, modern Nürnberg is situated on both banks of the Pegnitz River, at the point where it flows into a broad, level basin. The Pegnitz Valley is filled with geologically recent sand deposits, but there are occasional outcrops of older rock, the most noteworthy of which is the gray and reddish-brown sandstone eminence on which the Nürnberg castle is built.

The city owes its economic development to its location at the intersection of two natural trade routes running across Europe from north to south and from east to west. Sheltered by the hills of the Steigerwald to the west, Nürnberg has a relatively meagre rainfall, and its climate is almost continental.

Topography. The inner city, divided into two parts by the Pegnitz, is to this day encircled by the three-mile-long wall completed in 1452, and 60 of the original 128 towers are still intact. Even the older, inner, line of fortifications, dating from 1140 and 1320, can still be traced. Unfortunately, only a few historic buildings survived the massive bomb damage wrought toward the end of World War II, although some have been restored. The most important are the Gothic churches of St. Sebald and St. Lorenz, and, adjoining the market place, the Frauenkirche (Church of Our Lady). The Heilig Geist Spital (Hospital Church of the Holy Ghost), rising above the Pegnitz, is now an old people's home. In addition, there are the Mauthalle (customs house) on the Königstrasse, the Weinstadel (wine storage house), the Renaissance city hall, the Schöne Brunnen (a fountain), the Fembohaus (today a museum of the old city), and, finally, towering above them all, the imperial castle and its stables and granary, the latter now converted into a youth hostel.

Circling the city walls is the Ringstrasse, affording access to the main railroad station, the general post office, the Opera House, and the main commercial buildings. Extensions of the city, built in the 19th and early 20th centuries, lie beyond. These consist of blocks of workers' flats and large industrial plants, merging into modern garden suburbs and dormitory towns. Among the latter, the Langwasser community, to the south, has been planned for the needs of a population of 60,000. The uninterrupted expanse of woods framing Nürnberg to the north, east, and south, including the modern pine plantations of the Sebaldus and Lorenz Woods, serve as a reminder that the city was once a settlement in a clearing in the midst of the former imperial forest. The city covers a total area of about 52 square miles, of which only about 40 percent is built, with over 50 percent cultivated or forested.

Outlying regions

In the west, Nürnberg borders on the city of Fürth, which had 94,000 inhabitants by the early 1970s. The two communities have, in effect, become one twin city, with an uninterrupted built-up area linked by the axis of the Fürther Strasse, which runs along the former Nürnberg–Fürth railroad.

In the north, the so-called garlic land, an area under intensive vegetable cultivation, separates Nürnberg from the city of Erlangen, which had 86,000 inhabitants by the early 1970s. Close ties are also maintained between these two cities, Erlangen being important as a university town and a centre of the electrical industry. To the east and south, Nürnberg spreads into the industrial regions of the Pegnitz and Rednitz valleys.

Population. Numbering 40,000 in 1600, the city's population had shrunk to 25,000 by the beginning of the 19th century, reflecting Nürnberg's historic decline. The industrial age led to a rapid increase, and, by 1890, 143,000 people were living in the city. By 1914 the population had risen to 280,000, reaching 423,000 by 1939, but falling again to 195,000 by 1945, primarily as a result of war damage. Of 125,000 dwellings, about 60,000 were destroyed completely and about 51,000 were severely damaged. Eventually the city was extensively reconstructed, and by 1970 the population had climbed to 473,600. Al-

War damage

though 50 percent of the inhabitants are employed in industry, this is quite insufficient to meet the demand for labour, and consequently 80,000 people commute daily from the surrounding areas.

Economic life. For centuries, the metalworking crafts have been Nürnberg's chief industry. First there were the armorers, cannon founders, gunsmiths and sword smiths, and the pioneer compass and clock makers of the Middle Ages. They were followed by makers of gold foil, the manufacturers of wire, needles, and pins, the makers of metal toys, and, in the contemporary city, the electrical industry and the machine-building industries, together with bicycle and office-machine factories. About 45 percent of Nürnberg's labour force is employed in manufacturing, with about 40 percent of these making fine mechanical and optical goods and electrical apparatus (the latter of particular importance, as 10 percent of West Germany's total capacity is located there). Other major manufacturing employers include the motor vehicle, printing, chemical, wood and paper, and textile industries. The most important nonmanufacturing sectors are wholesale and retail trade, with 16 percent of the labour force; services, 12.5 percent; and transportation, 7 percent. When the International Toy Fair was established after World War II, Nürnberg became the world centre for this industry. To accommodate this and other exhibitions, a large area south of Nürnberg was converted into a centre for exhibits, sports, and recreation.

International exhibitions

Transportation. Nürnberg owes much of its development to its excellent situation near the important European trade routes. In the Middle Ages no fewer than 12 highways met in the city, making it a traffic centre for the whole of Europe. Today, it is a focal point not only for the old European highways, which now lead from The Netherlands via Vienna to the Balkans, from Italy to Scandinavia, from France to Bohemia, and from Switzerland to Poland, but also for modern Federal German and European highways; it is also connected to the Munich–Berlin and Frankfurt–Cologne autobahns. Already situated on the old Ludwigs-Danube-Main Canal, Nürnberg has built a modern harbour linked in the early 1970s with the new Europa-Kanal, which joins the Rhine, Main, and Danube rivers. Nürnberg's airport, on the north of the city, provides connections, particularly to the international airport in Frankfurt am Main.

Administration and services. Nürnberg is the regional headquarters for the postal service and for the Federal railroad and is the seat of a municipal court, a circuit court, and an appellate court. Although it lacks regional importance in the overall field of local government, it is the seat of the Federal Employment Institution.

There are a number of institutions of higher learning in and around the city, including the Faculty of Economic and Social Sciences of the University of Erlangen-Nürnberg, and the Ohm Polytechnic Institute for Applied Technology (founded in 1823 and named after the famous physicist Georg Simon Ohm, discoverer of Ohm's law, who taught from 1833–49). The Academy of Arts, founded in 1662, is the oldest in Germany. Other institutions, also the earliest of their kind in the nation, are the Pegnesische Blumenorden, a literary society founded in 1644, and the city's public library, which is over 600 years old. In addition to the museum of the old city located in the so-called Fembohaus—the only surviving patrician house, with a splendid Renaissance gable—the city is the home of the unique Germanisches Nationalmuseum, located in a former Carthusian monastery, which was chartered in 1852 to exhibit the history of German culture from its earliest time to the present. Its magnificent collections include a complete collection of Dürer's printed graphic works.

Cultural heritage

Ample provision has been made for cultural life in Nürnberg: there are an opera house and two theatres, as well as the modern Meistersingerhalle, which is available for the many congresses as well as for the concerts that take place in the city. Performances of annual organ concerts are usually held in the medieval churches. The design of the zoological gardens at the Schmausenbruck is of exceptional beauty.

Frank. Georg. Ges.*, Bd. 19 (1972).

(E.Wt.)

Nursing

The functions served by nursing are summarized in a statement from the Code of Ethics of the International Council of Nurses:

> Nurses minister to the sick, assume responsibility for creating a physical, social and spiritual environment which will be conducive to recovery, and stress the prevention of illness and promotion of health by teaching and example. They render health service to the individual, the family, and the community, and coordinate their services with members of other health professions. Service to mankind is the primary function of nurses and the reason for the existence of the nursing profession. Need for nursing service is universal. Professional nursing service is therefore unrestricted by considerations of nationality, race, color, political or social status.

Men and women engaged in nursing throughout the world comprise the largest single group of health workers, and the availability of effective nursing care in a country is a principal measure of its potential advancement in health. Modern nursing is essential not only to hasten the recovery of sick people but also to provide people with knowledge that will improve their health and productivity. Since health possesses humanitarian and economic values, nursing is an instrument of social progress. An analysis of nursing includes its history, the number and kinds of nursing personnel, the education that prepares nurses for their contribution to health, organizations among nursing personnel, and the relations of nursing with other professions.

HISTORY

Sensitivity to the suffering of others and desire to comfort have been found among human beings from earliest times. Attitudes toward childbearing, toward the aged, and toward death and ideas about the causes of sickness have influenced nursing and healing practices throughout time. Evil spirits were to be cast out; offended gods, placated. Ceremonials, fetishes, concoctions of extraordinary ingredients were used.

Early developments. Reports of early civilizations—Egyptian, Indian, Chinese, Aztec, Greek—refer to bleeding, cautery, applications of poultices and bandages, bonesetting, and trephining, or the removal of sections of bone from the skull. Hospices and hospitals were established to provide refuge for the weak and hospitality for sick strangers. The beginnings of medicine, surgery, psychiatry, midwifery, sanitation, and nursing can be traced in these records. Codes of ethics for those who give health care were formulated. The Oath of Hippocrates persists to this day (its text may be found in the article MEDICINE, HISTORY OF).

When Christianity came, with its teachings of love and brotherhood, healing and caring for the sick gained new impetus. Among the early converts to Christianity were highborn Roman matrons. Phoebe, a friend of St. Paul, "succored many"; Marcella made her palace into a monastery for women; Fabiola turned her home into a hospital. These women and others like them exemplified new intellectual freedom for women and their participation in religious and social action at a high level.

Contribution of Christianity

For several centuries thereafter the spread of health work moved slowly. Monastic orders grew, and from them some health services radiated; but large areas of the

world were untouched, and the monastic surge to undertake health work seemed to diminish. Later, military and chivalric orders were founded, supporting the Crusades and combining the making of war with charitable and hospital work. Some established companion orders for women. The Knights Hospitallers of St. John established two hospitals in Jerusalem and branches of the order in other countries, one in England around 1100. This order included among its functions the care of the insane; its influence on services during disasters and emergencies extends to modern times.

The monastic and chivalric orders established in various forms among health workers the beginnings of hierarchical organization, amateur participation that provided the roots of volunteerism, and a sense of calling or vocation.

Nursing can be seen to rise from two wellsprings, one scientific, the other religious and social.

Acceleration of scientific advancement in health began with the 16th century. A French surgeon, Ambroise Paré, a Flemish anatomist and physician, Andreas Vesalius, a Spanish theologian and physician, Michael Servetus, and an English physician, William Harvey, were leading contributors to progress. Servetus was burned at the stake, and Vesalius barely escaped a similar fate. The 19th century brought the "germ theory" of disease and ways of treating and preventing infectious diseases, then the largest cause of death. Anesthesia was discovered. Wars were times of advance.

It is often said that research produced more medical and health knowledge in the decades after World War II than in all previous centuries combined. Atomic and space sciences played a part. In the United States, governmental financial support of medical research grew to large proportions. Federal support of nursing research and research training in the United States from 1964 to 1971 approximated $20,000,000. The constantly growing mass of new knowledge to be applied in health services by health workers challenges the educational system for physicians, nurses, and others and strains the system of distribution of services to an awakened public.

Paralleling these scientific advances were advances made through the years in social and religious action. The work of St. Vincent de Paul and, later, of John Howard typify this kind of action. After making thorough studies of conditions, they recommended marked changes in hospitals and prisons. A new dimension, planning based on facts, thus was added. St. Vincent, with Saint Louise de Marillac, founded the Daughters of Charity (1633). He believed that the sisters should have general education, as well as training for their work. In the following century Howard revealed deplorable conditions in nursing—filth, stealing, and ill treatment of patients. Both men influenced reforms and emphasized citizens' responsibility for health and welfare of people everywhere.

The work of Florence Nightingale

19th-century reform. In the 19th century the movement for reform in nursing was led by Florence Nightingale, a woman of intellectual and moral power. Family contacts with humanitarian leaders and an education that included training in science, mathematics, and political economy were her preparation. She analyzed nursing as it was practiced in several countries, formulated her ideas, and wrote extensively.

In 1854 Florence Nightingale was asked by the British secretary of war to go to the Crimea, where absence of sewers and of laundering facilities, lack of supplies, poor food, disorganized medical service, and absence of nursing led to a death rate of more than 50 percent among wounded soldiers. Her work and that of the nurses whom she recruited brought sufficient improvement to lower the death rate to 2.2 percent. Thus, British military medicine was reorganized and the role of good nursing established. A gift of £44,000 was raised by popular subscription, and Florence Nightingale used it to establish a school of nursing at St. Thomas's Hospital.

Florence Nightingale believed nursing to be suitable as an independent career for capable, trained women, that nursing services should be administered by nurses with special preparation, and that relationships between physicians and nurses should be professional. She maintained that schools of nursing should be independent of hospitals and should be administered by nurses with physicians as paid teachers as needed, with proximity to hospitals for student experience. She believed that there was a substantial body of knowledge and skills to be learned in nursing. Nurses were to be prepared for hospital nursing and care of the sick at home, and they were to teach good health practices to patients and families.

Within 25 years after the Nightingale school was established, the old system of nursing in England by low-paid, untaught women or pauper inmates had almost disappeared, and patients began to receive effective nursing care to accompany the constantly improving medical care. This kind of revolution has taken place in most developed countries. In newer countries, efforts are made to bypass some of these steps in evolution and to bring nursing along with other health professions to the point of meeting modern challenges more quickly.

20th-century developments. In the 20th century the number of nurses of all kinds has increased rapidly, as has the number of kinds of nursing personnel. Recently, some nurses have specialized in clinical areas.

The development of physicians' assistants sometimes overlaps with the development of nurse specialists, though efforts are made to differentiate the two categories. Pediatric-nurse practitioners, for example, undertake functions previously performed only by physicians—taking histories, performing physical examinations on children, and running clinics for mothers and babies. Experimentation with shifts in functions from medicine to nursing is growing rapidly.

Planning aimed at bringing nursing resources into balance with needs for nursing personnel to implement health programs is a recent movement. Almost every state in the United States is involved in continuous planning for this purpose. Several other countries are similarly involved. The World Health Organization (WHO) has developed a guide for such planning published in English, French, Russian, and Spanish; this guide helps countries to set goals and avoid disadvantages of haphazard growth. Coordinated planning among the several health professions and occupations is a desirable new trend.

Historians may characterize the 1970s as a time of planning, research, expansion of functions of nursing, improvements in delivery of health and nursing services, development of specialities, changes in utilization of existing types of nurses and development of new types, and reorganization of nursing education.

NURSING PRACTICE, EDUCATION, AND ORGANIZATION

Methods of classifying nurses

Kinds of nursing. Nursing personnel and the kinds of nursing in which they engage may be classified in several ways: by legal designation—registered nurses, licensed practical nurses, and, in addition, unlicensed nurses' aides; by the kind of educational preparation—vocational, technical, and professional, including graduate education—that they have received; by the kind of work they do—institutional, community, educational, research, or journalistic; by the level of responsibility that they assume—that of staff nurse, teacher, supervisor, administrator, or consultant; and by the place of employment—hospital, physician's office, public health agency, school (school health nurses), industry, a school of nursing, including undergraduate and graduate programs. Nurses may also be classified as generalists or specialists. Most descriptions of nursing, including the following, mix these classifications.

Hospital nursing. Hospital nursing occupies approximately two-thirds of the total nursing force in most countries. Nurses giving direct care to patients in hospitals of the United States include registered nurses, some of whom may be specialists; licensed practical nurses; and nurses' aides. Aides and sometimes practical nurses, if there are any, are called auxiliaries in many other countries. In large, highly organized hospitals, administrators of nursing services need special preparation and occupy demanding executive positions.

Certain areas of hospitals are highly specialized—surgical suites (operating rooms), recovery and intensive-care

units, and coronary-care units. In these, nurses giving direct patient care and their supervisors must have the additional preparation afforded by graduate study or by continuing education or staff-development (in-service-education) programs.

Almost all hospitals except the smallest have established staff-development programs; teaching and directing such programs for nursing personnel are relatively new roles for nurses, and the number of such nurses grows rapidly. These programs are usually responsible for the teaching of nurses' aides, who are often hired with no pre-employment preparation, as well as for general and special staff development in nursing throughout the hospital.

The rapid development of hospitals in response to advances in science and new community responsibilities requires new kinds of nursing. Some hospitals are using nurse-midwives in maternity departments. This practice is new in the United States. Nurse specialists are utilized in many other areas as well—medical, surgical, obstetric, pediatric, psychiatric, and rehabilitative; these nurses often cross over to other fields as consultants. For example, public-health nurses are employed to ease patients' adjustment to returning home and to assure planned continuity of health care. A few nurses occupy ombudsman, or patient-advocate, positions. Some perform studies and researches aimed at solving problems and at devising improved ways of caring for patients.

New health problems bring new responsibilities to nurses in hospitals. Drug abuse, alcoholism, and family planning, for example, are areas that call for new knowledge on the part of nurses, as well as for decisions about the organization of the new services in hospitals.

Outpatient and home care

Outpatient and home care are sometimes organized by hospitals to reduce costly hospitalization for patients. Some clinics in outpatient departments can be operated almost exclusively by nurses—clinics for hypertension (high blood pressure), chronic heart disease, and for poststroke and maternity patients are examples. Satellite clinics bring services close to patients' homes. All this means expanded learning of assessment methods by nurses—simple physical examination and history taking, for example, and new understanding of community problems and organization of nursing services.

Nursing homes provide services for a large number of patients throughout the United States. In such establishments nurses play a central role. A high proportion of the staff is composed of nurses' aides, who need to be taught and supervised by registered nurses in such a way that rehabilitative care rather than mere custodial care is given to patients. In the 1970s there were many excellent U.S. nursing homes, but many were in need of reform, a process in which nurses are expected to participate.

Mental hospitals accommodate almost half the hospitalized patients in the United States. Efforts to return many of these patients to their communities are meeting with some success. In some of these hospitals, as well as in the new community mental-health centres, nurses with graduate degrees share in the treatment of patients and conduct group therapy, another role that has recently developed.

Public-health nursing. Public-health nursing, more recently called community-health nursing, is given by two kinds of agencies in the United States, governmental and private. School nurses are included in reports of this field in the United States. Approximately 50,000 registered nurses were employed in the 1970s by almost 10,000 agencies, 6,000 local school boards, 600 visiting-nurse services, and more than 3,000 state and local health departments. These agencies also employed about 4,000 licensed practical nurses. Of the registered nurses employed by these agencies, 41 percent possessed a bachelor's or a higher degree.

Visiting-nurse services care for the sick at home and carry on individual, family, and community programs of prevention and health teaching. These services are usually supported by civic and other forms of private philanthropy and by fees from patients who can afford to pay. Some of the visiting-nurse services have contracts with local government health and welfare agencies and with industrial health units to provide services. Many have deep, traditional roots in their communities, which provide volunteer board members.

In most countries public-health nursing is carried on primarily by government agencies. The numbers reached by government services are highest in such countries as Great Britain, Canada, Australia, New Zealand, the Scandinavian countries, Finland, Yugoslavia, and the United States. In new countries, community nursing is important for the development of health programs. In rural and isolated communities, a public-health nurse may be the only person available for any kind of health service.

Nurses as educators. Nursing education is a field that combines nursing with the teaching of students of nursing and, for some nurses, with the administration of educational programs. A higher proportion of the teachers in each of the kinds of nursing-education programs teach in clinical situations, in which students learn to care for patients and families in hospitals, at home, and in other situations. Teachers must have knowledge of how learning takes place, be expert in their own field, and know how that field relates to the total scheme of health promotion. The full-time teachers of nursing in the United States are distributed among the various kinds of educational programs approximately as follows:

Teaching programs

Programs leading to bachelor's and higher degrees	4,500
Associate-degree programs	1,800
Diploma programs (hospital schools)	9,000
Licensed-practical-nurse programs	3,700
Total	19,000

In addition, there are about 2,500 part-time teachers with approximately the same distribution.

Teaching in staff-development programs of hospitals and other health agencies and in continuing-education programs offered usually by universities or associations is a growing field of employment.

Private, office, and industrial nursing. Private, office, and industrial (recently called occupational-health) nursing as fields of employment account for about 15 percent of the registered nurses in the United States. Licensed practical nurses are also employed in these fields.

Military nursing. Military nursing provides an essential part of the health care given to men and women of the armed services in most countries. Trained nurses were part of military forces of countries involved in World War I. In the United States many of these nurses were drawn from a reserve maintained by the Red Cross. By the close of World War II much progress had been made in assigning the nurses rank and responsibilities commensurate with their training and abilities.

Male nurses were not commissioned as officers in the nurse corps until after World War II. In the 1960s the flag grade (that of general) was accorded to leading nurses in the military nurse corps. Medical corpsmen save lives on battlefields and hospitals and are highly skilled. Several plans have been made to hold them in health work after they leave military service. The number of registered nurses in the early 1970s commissioned and on active duty in the United States Army, Navy, and Air Force Nurse corps was approximately 12,000.

Government nursing. This field includes military nursing and public-health nursing as carried on by federal, state, and local health departments, functions already touched upon.

The Veterans Administration operates the largest single hospital system in the United States, employing approximately 17,000 nurses and a large number of nursing assistants. And the Department of Health, Education, and Welfare provides health care, including both hospital and public-health nursing services, to approximately 400,000 American Indians on reservations and to Alaska natives.

Federal programs to further nursing

Various branches of the department, primarily the division of nursing, administer programs aimed to increase and improve nursing services and education throughout the United States. The programs take the following main forms: consultation service; conduct of studies and research and publication; collection of data on nurse supply and health needs as a basis for planning; mobilization of numerous advisory committees on plans and evaluations;

granting of federal funds for scholarships, operation of schools, construction of facilities, and for research and demonstrations. The sum of the funds granted to institutions and students and for projects (excluding research) in the period 1964–72 was $325,944,000.

The office of the Department of Health, Education, and Welfare carried out a similar program for practical-nurse education and can be given credit for a large part of the rapid expansion of schools and increase in students. The number of nurses employed in the operation of these programs of federal assistance to schools and students is extremely small, but the impact on the development of nursing is great.

Education. Modern education of nurses began with the Nightingale era. It has a dual purpose: (1) to provide personnel to meet the needs of people for nursing services of all kinds and (2) to supply training that will enable young men and women to follow one of the varied careers in this health service and to progress from one type of career to another.

The basic educational program for nurses is scientific and humanistic in content. Many programs lead to the bachelor's degree. Nursing specialists, teachers, and other leaders in the field may need advanced training at the master's or doctoral level. All educational programs include experience with patients in hospitals, homes, or other settings. Table 1 shows the diversity and relative capacities of programs in the United States. In addition, 850,000 nurses' aides of various kinds employed in the 1970s were prepared through training programs operated usually by the employing institution.

Table 1: Nursing Programs in the United States

	locale	number of programs	approximate number students graduating
Practical nurse	vocational high schools, community colleges, and hospitals	1,350	37,000
Diploma	hospitals	641	23,000
Associate degree	community colleges	450	27,000
Bachelor's degree	colleges and universities	270	20,000
Master's degree (for nurses with bachelor's degree)	universities	73	2,000
Doctoral degree in nursing*	universities	8	30

*A number of nurses study in related doctoral programs.

For comparison, in 1925 in the United States, there were approximately 2,500 diploma programs, no associate-degree programs, only a handful of master's degree programs, and a very small number of bachelor's degree and practical-nurse programs.

In almost all other countries in which nursing education exists there are at least two kinds of programs—those leading to diplomas and those that train auxiliaries, though a large portion of auxiliaries in some countries are untrained. A growing number of countries have one or more bachelor's degree programs; some have several.

Countries with bachelor's degree programs

Among the latter are Canada, Colombia, Ecuador, Panama, Peru, Great Britain, Lebanon, Egypt, India, the Philippines, Taiwan, and Thailand. Bachelor's degree programs are evolving in other countries, and master's degree programs have been established in Canada, Colombia, India, and elsewhere.

Postbasic programs for nurses with diplomas have been established in many countries. But not all of these are within universities. Some programs offer courses in general education, as well as nursing courses, and some, in universities, may become programs leading to a bachelor's degree. The purposes of the postbasic programs vary and include the preparation of teachers, supervisors, or administrators and of nurse specialists in various fields including midwifery, public health, and teaching of auxiliaries. Some augment the education received in other programs. Enrollment is generally small in relation to the need for their graduates.

A number of centres were established for the presentation of centralized postbasic programs for nurses from several countries. Among these are centres for African nurses in Senegal, at the University of Ghana and at the University of Ibadan, in Nigeria. In combination these provide opportunity for both French- and English-speaking nurses. Nurses from many countries study in postbasic programs in Wellington, New Zealand. The University of Alexandria serves in this role, as well as in other roles.

The effort to establish new bachelor's degree programs and postbasic programs in many countries and to improve existing diploma and midwifery courses and courses for auxiliaries was stimulated greatly by the World Health Organization and its six regional offices.

The progress of nursing education in any country is affected by the developments in general education. In the United States and some other countries, high school graduation or its equivalent has for many years been a requirement for admission to schools preparing registered nurses. In the United States this is also a requirement for admission to practical-nurse programs. Of the 136 schools preparing registered nurses in Latin America, 58 percent call for nine to ten years of previous schooling, the remainder having requirements roughly equivalent to those prevailing in the United States. In some other countries some schools may require only six years of previous education. This situation is expected to improve along with the programs for general education.

The rapid development of community colleges in the United States brought with it an increase in the number of associate-degree (two-year) programs in nursing, and the placement of professional education in colleges and universities helped nursing education. The first (*i.e.*, lowest) professional degree in nursing in the United States in the early 1970s was the bachelor's; in nursing the master's degree program was usually considered the education for specialization, whereas in many other professions the first degree is the master's.

The movement in general education to attract and retain youth with disadvantaged educational backgrounds is paralleled in nursing education.

Qualifications of teachers affect the quality of education. In the United States about 45 percent of teachers in all schools of nursing possessed the master's degree. The percentage of teachers in bachelor's and higher-degree programs with the master's was above 80, while about 10 percent of the administrators of bachelor's or higher-degree programs in nursing possessed doctoral degrees.

Texts and reference books in nursing were not available in the language of many countries in the early 1970s. A few texts in English were translated into Spanish and Japanese, but translations from other languages are not always appropriate to the culture and health problems of a particular country. Hence, international organizations, including the World Health Organization, were working on these problems and on the needed expansion of all libraries. The literature of nursing was growing rapidly, but in the early 1970s the nursing literature of the United States still represented a large portion of the total.

Licensing and registration. After the number of nurses has become substantial and the essential nature of nursing has become established in a country, the need to regulate the practice of nursing under law becomes evident. These laws are aimed at the protection of the public.

Laws define nursing and establish titles under which nurses practice. Most laws establish boards empowered to give examinations and maintain registers of qualified nurses. Boards also are usually empowered to maintain lists of schools the graduates of which are eligible to take examinations. Further, the laws that regulate nursing usually provide ways to recognize licenses acquired by nurses from other states and countries.

The first state to pass a nurse practice act in the United States was North Carolina, which did so in 1903, and within the next two decades all states had adopted laws regulating nursing. The title established by these laws and their revisions is that of registered nurse; graduates of three kinds of educational programs—bachelor's degree

and associate-degree programs and diploma programs—are eligible to seek this title. All states also have laws giving another title—licensed practical nurse, or, in two states, licensed vocational nurse. Educational programs for this title are typically one year in length.

Establishment of nurses' register in England and Wales

The Nurses Act of 1919 established the General Nursing Council for England and Wales to maintain a register of nurses; similar acts were passed in 1919 for Scotland and in 1922 for Northern Ireland. The advent of the National Health Service (1946) called for enlargement of the council and its functions, and in 1949 an act was passed that consolidated all previous acts and established regional committees to work with schools of nursing for their improvement and for ways to meet new challenges. The title used in England for the grade called registered nurse in the United States is that of state-registered nurse, with a few variations, and the required education is three years or more. Legislation in 1960 changed the title of a less qualified grade from state-enrolled assistant nurse to state-enrolled nurse. Educational preparation for this title is 12 to 18 months. These steps illustrate the progress of licensure and registration in a country and its responsiveness to change.

National and state nursing associations are prime movers in urging legislation for licensure and registration and in securing amendments. The American Nurses' Association gives leadership to state associations and state boards regarding changes in definitions, the desirable provisions of the law, and the legislative process.

The International Council of Nurses exerts leadership among national nursing associations in their efforts to pass and amend laws, and a guide was published recently. The staff of the World Health Organization also has assisted new countries in this important process.

Organizations. Near the beginning of the 20th century, nurses began to organize national associations. The purposes of such organizations usually include: promotion of nursing care of high quality, promotion of desirable legislation in nursing and health, formulation of nursing and educational standards, professional development and welfare of nurses, and representation of nursing with other professional associations and government agencies. Many nursing associations publish professional journals. In large countries the national associations have state or provincial and district constituent associations.

An example of a thriving and vigorous national organization is the American Nurses' Association, founded in 1896, which continues to operate aggressive programs in line with the purposes mentioned above. It affects legislation related to health and nursing in the Congress through its educational and lobbying activities and exerts leadership in revision of state laws governing registration and the practice of nursing. A strong program for economic security has elevated nurses' salaries and the conditions of patient care, partly through collective bargaining. The official statements of the association set the course of action. Its official publication is the *American Journal of Nursing*.

The International Council of Nurses

In 1899 the International Council of Nurses was founded as a federation of autonomous national nursing associations. By 1970 there were member associations from 74 countries, and the council was working in another 50 countries, many of them new countries, to assist in the development of national associations and ultimate membership in the council and to encourage national legislation on registration and nursing practice. An international congress is held every four years. The council's journal, *International Nursing Review*, makes a substantial contribution to worldwide literature of nursing. The Florence Nightingale International Foundation, which is related to the council, has conducted an international conference on research in nursing, as well as an international exchange of nurse scholars.

Several national colleges of nurse-midwifery and an international college work for improvement of maternal and infant health. Nurses participate in international and national associations for public health, mental health, industrial health, and school health and in such areas as heart-disease, cancer, and respiratory-disease control. The Nursing Section of the American Public Health Association is its second largest section. Practical nurses and auxiliaries are usually organized, if at all, in separate organizations. There are two such organizations in the United States, the National Association for Practical Nurse Education and Service and the National Federation of Licensed Practical Nurses. Various groups from special organizations in several countries—deans of schools of nursing and operation-room nurses are examples. Nursing councils are parts of regional commissions on higher education in the United States.

A unique organization—the National League for Nursing—combines nurses, related professionals, and other public-spirited citizens in the United States for meeting the nursing needs of people throughout the country. This organization also carries on a program of national accreditation of all the various kinds of educational programs. Its journal is *Nursing Outlook*. With the American Nurses' Association it sponsors *Nursing Research*.

The diversity of participation of nurses demonstrates the interrelationships with nurses needed for achievement in health, social, and educational missions.

Studies and surveys of nursing. Studies of nursing have been made in many countries. In the words of the Expert Committee on Nursing (1966) of the World Health Organization,

> Minor modifications of existing nursing systems will be inadequate to meet new situations and demands in a rapidly changing society. . . . Nursing must break with some of its traditions as well as alter existing stereotypes.

Studies often collect the facts and recommend and push needed changes.

In the United States in 1923, *Nursing and Nursing Education in the United States*, a classic, drew attention to the inadequacies of the hospital-nursing-school system to prepare nurses for community-health and new-hospital demands. The Grading Committee Reports (1928 and later) were comprehensive and showed the magnitude of the needed reform. Fiscal studies (1945 and following) related cost of education to quality and stimulated decisions on who should pay costs. *Nursing Schools at the Mid-Century* served as a basis for a new, unified system of accreditation. A group of studies by Esther Lucile Brown resulted in a series of publications (1948–71) dealing with professionalism, humanization of nursing, and new roles for nurses. The surgeon general's consultant group on nursing (1963) studied and recommended changes in federal aid to nursing education. The National Commission for the Study of Nursing and Nursing Education (United States, 1971) produced *An Abstract for Action*—a blueprint for new developments in nursing.

In almost every country where nursing is well established, similar studies have been produced. Early studies in each country express the beginnings of awareness of need for modernization of nursing. Studies are also done when marked changes in health programs indicate that changes are needed in nursing—for example, at the time of inception of the National Health Service in England. Efforts of nurses and others to start nursing-education programs in colleges and universities usually involve studies of health needs and nursing personnel.

WHO publications

A recent trend of great value has been the collaboration of several disciplines and interests, so that resultant actions in health are unified. The inclusion of *Planning and Programming for Nursing Services*, published in 1971 in the World Health Organization series of public-health papers in English, French, Spanish, and Russian, can serve as an example. The inclusion of nurses among the official groups that study health needs in many countries is another effective and unifying influence.

The current nursing situation: the worldwide nurse shortage. The world has more nurses than ever before, yet all but a few countries claim marked shortages of nursing personnel.

In countries with highly developed health services, rapid advances in the medical sciences have increased what can be done to aid a patient. But to implement the new knowledge requires a marked increase in nursing personnel.

Table 2: Ratio of Nurses to Population in the Americas

	nurses per 10,000 population	auxiliaries per 10,000 population
North America	34.8	53.0
Central America	3.7	8.4
South America	2.3	9.2

Further, an increase in the educational status of large populations in mass communication increases demands for services, and the acceptance of health as a human right leads to the acknowledgement of the need to provide services to all persons in society. Still, it is doubtful that these demands will be met in the near future.

In the United States in the early 1970s there were approximately 750,000 registered nurses employed—a ratio of about 360 per 100,000 people. The need for registered nurses was estimated at 1,000,000 for 1975; and for 1980, 1,100,000. The goal for licensed practical nurses for 1975 was 550,000, some 150,000 more than at the beginning of the decade. Aides, orderlies, and attendants in the early 1970s were estimated at 850,000.

Canada reported a need for at least 120,000 registered nurses, 20,000 more than at the beginning of the 1970s.

In new countries that only recently initiated education systems for health personnel, shortages were severe. Older countries that were still economically underdeveloped also exhibited acute shortages. The ratio of nurses to population in the Americas in the late 1960s is shown in Table 2.

Worldwide variation in availability of nursing personnel is shown in Table 3, which perforce uses many rough estimates of both nurses and population.

Distribution of nurses

The Americas and Europe (including the U.S.S.R.) have almost three-fourths of the world's nurses, leaving about one-fourth for all of Asia, Africa, and Oceania.

Shortages are claimed even in countries with the highest ratios of nurses to population. It is asked whether these shortages could be alleviated, partially, at least, by better distribution of the supply and by making better use of the nurses available. Shortages are most damaging in the quality and quantity of teachers, since teachers are critical in any effort to increase and improve nursing.

Table 3: World Ratio of Nurses to Population

area	ratio of nurses to population	
	in country with highest ratio	in country with lowest ratio
Europe	1 to 330	1 to 1,200
Americas	1 to 230	1 to 6,000
Asia	1 to 430	1 to 8,200
Africa	1 to 800	1 to 12,500

ROLES OF THE INTERNATIONAL RED CROSS AND THE WHO

The International Red Cross. The International Red Cross plays two major roles in nursing: it affords educational opportunities for nurses, and it affords nurses opportunity to serve in programs embodying the Red Cross principles of humanity, impartiality, and neutrality. Through participation in Red Cross activities, public-spirited citizens acquire valuable knowledge of health needs of people and how nursing helps to meet these needs. Also, nurses broaden their concepts of community and worldwide service.

Twenty-five national Red Cross societies operate 240 schools of nursing; six operate postbasic education programs; and 60 operate training programs for auxiliaries. In addition, many societies carry on programs preparing nurses to teach health in the home; this instruction reaches many thousands of people, who thus learn individual responsibility for health and the care of mothers and children and of patients suffering from simple illnesses. Many societies also train nurses to care for people in disasters and emergencies and deploy nurses to sites of emergencies when needed; some nurses volunteer to serve in emergencies that occur in other countries.

Red Cross societies have established community nursing services. In the United States these services were forerunners of some local health-department nursing programs, and they serve similarly in other countries in the 1970s.

National Red Cross societies are placing new emphasis on community development and youth programs. Societies are urged to be constantly alert to social changes, such as those resulting from urbanization, migration, or drug abuse, and to coordinate their efforts with other voluntary and official agencies. Nurses with knowledge of community conditions can and do contribute to planning and action through board and community memberships, as well as in their participation in the carrying out of Red Cross programs.

The World Health Organization. The World Health Organization has included nursing in its activities from its beginning in 1948. Nurses are included on teams, such as those concerned with maternal and child health, malaria, and tuberculosis. The development of nursing itself was recognized as a health force, and member nations request assistance in developing educational programs for nurses, auxiliaries, and midwives and to organize public-health programs and hospitals.

Nursing activities of WHO

More than 130 nations are members of the World Health Organization; in 1971 alone, more than 100 of these were helped in their nursing needs by WHO. The many activities of nursing programs of the World Health Organization headquarters and the six regional offices may be illustrated by the following few examples.

Nurses were recruited from many countries and provided for health teams and nursing projects requested by member nations. In 1971, 370 nurses and nurse-midwives from various countries served on 200 projects, of which 33 concerned more than one country.

Help was given countries to establish nursing in the organization of their national health departments to assure the planning and implementing of the nursing portions of programs. A travelling seminar held in four cities of the U.S.S.R. was attended by nurses from 17 countries who studied the use of information about people's health needs in planning programs.

Governments were aided in the establishment of nursing and nursing-education systems, including those in midwifery. Other programs in which assistance was given included upgrading diploma schools; development of basic and postbasic programs in universities; revision of entry requirements; coordination of classroom teaching with clinical practice of students; adaptation of hospitals and health agencies for students' experience; preparation of public-health nurses, administrators, midwives, and teachers, including teachers of auxiliaries and of indigenous midwives. (In many countries more than half of all the births are attended by untrained midwives.)

Fellowships were granted to nurses for overseas study. Nearly 400 fellowships were granted in 1970, most of which were used to help students prepare for teaching, administration, public-health nursing, midwifery, maternal and child health, and for learning to plan health services. When consultants from the World Health Organization work in countries, they strive to leave national counterpart personnel to continue the work, and study outside the country may be needed to develop such personnel.

BIBLIOGRAPHY. AMERICAN NURSES' ASSOCIATION, *Facts About Nursing* (compiled and published every one or two years), a comprehensive compilation of statistical information about all fields of nursing and nursing education; JEROME P. LYSAUGHT, *An Abstract for Action* (1970), a condensed report of the National Commission for the Study of Nursing and Nursing Education on the characteristics and concepts of nursing practice in the United States; J.C. GOLDMARK, *Nursing and Nursing Education in the United States* (1923), a classic report on the status of nursing in the United States with recommendations for actions that are still pertinent; FRED DAVIS (ed.), *The Nursing Profession: Five Sociological Essays* (1966), a review in depth of these areas covered: nursing leadership (cross national); structure and organization of nursing practice; problems in collegiate education in nursing; and nurse-patient relationships; INTERNATIONAL COUNCIL OF NURSES, *Principles of Legislation for Nursing*

Education and Practices (1969), a guide (available in English, French, and Spanish) to nursing associations that desire to initiate or revise nurse practice acts; WORLD HEALTH ORGANIZATION (WHO), *The Work of WHO* (annual), report of the Director General, a comprehensive report of WHO program activities including nursing; PAN AMERICAN HEALTH ORGANIZATION AND REGIONAL OFFICE OF WHO (annual), report of the Director, a comprehensive report of program activities including nursing; UNITED STATES DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE, PUBLIC HEALTH SERVICE, *Toward Quality in Nursing, Needs and Goals: Report of the Surgeon General's Consultant Group on Nursing* (1963), survey of nursing in the United States with recommendations for federal and other actions to expand and improve nurse-power; Y.L. and B. BULLOUGH, *The Emergence of Modern Nursing*, 2nd ed. (1969), a survey of prospects for nursing; UNITED STATES DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE, DIVISION OF NURSING, *Health Manpower Service Book*, sect. 2, "Nursing Personnel" (1969), a compilation of statistical information about nursing—most of this and more is found in *Facts About Nursing* (above); ESTHER LUCILE BROWN, *Nursing Reconsidered*, 2 vol. (1970–71), report and interpretation of new functions performed by nurses and a review of developments in the last decade; I.M. STEWART and A.L. AUSTEN, *A History of Nursing*, 5th ed. (1962), a concise and well-documented history of nursing from earliest time to present.

(L.P.Le.)

Nutrition

Nutrition may be defined as the study of all of the processes by which micro-organisms, plants, and animals absorb and utilize food substances. Nutrition involves the identification of individual nutrients essential for growth and for the maintenance of individual organisms; it includes the determination of interrelationships among nutrients within individual organisms, as well as the evaluation of the quantitative requirements of organisms for specific nutrients under various environmental conditions. Treated in this article are the identity of nutrients, the ways in which they vary from one organism to another, and the ways in which requirements for certain of them arose. Nutrition in man is dealt with in a separate article, NUTRITION AND DIET, HUMAN.

GENERAL FEATURES

Functions of food. Food serves three functions in most living organisms. It provides materials that are metabolized either by oxidative or by fermentative processes to supply the energy required for the absorption and translocation of nutrients, for the synthesis of cell materials, for motility and locomotion, for excretion of waste products, and for all other activities of the organism. Second, food must supply the electron donors (reducing agents) required for the formation of the reduced coenzymes (enzyme components) normally necessary for the synthetic processes that occur within the cell. The functions of food as energy sources and electron donors are shown diagrammatically in the bottom half of Figure 1 labelled catabolism. In the third instance, food provides the materials from which all of the structural and catalytic components of the living cell can be assembled by processes sometimes called anabolism (Figure 1). But the three roles of food are not mutually exclusive; energy-yielding substances in many organisms may function in all three ways, and essential nutrients, if present in excess, may frequently be metabolized to supply energy.

By courtesy of World Health Organization

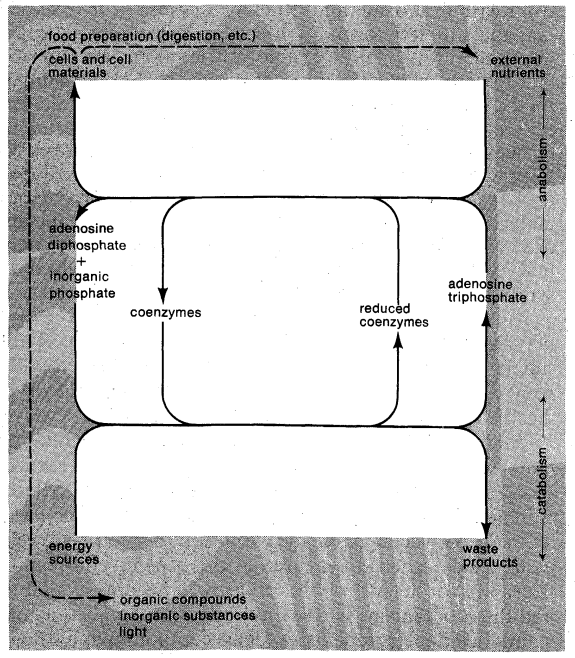

Figure 1: Relation between the functions of food (as energy source, ultimate electron donor, and source of essential nutrients for synthesis of cell materials) and the catabolic or anabolic phases of metabolism (see text).

The essential precursors (*i.e.*, the substances from which other substances are formed) of cell materials can be divided into two groups—nonessential nutrients, which can be synthesized by the cell from other materials, and essential nutrients, which, because they cannot be synthesized by the cell, must be supplied in foods. All of the inorganic materials required for growth, together with an assortment of organic compounds whose number may vary from one to 30 or more, depending on the organism, fall in the latter category. Although organisms are able to synthesize nonessential nutrients, such nutrients are nevertheless frequently utilized directly if present in food, thereby saving the organism the need to expend the energy required to synthesize them.

One method of classifying living organisms on a nutritional basis is based on the way in which the functions of food are carried out. Thus, organisms such as green plants and some bacteria that need only inorganic compounds for growth are called autotrophic organisms; and organisms, including all animals, fungi, and most bacteria, that require both inorganic and organic compounds for growth are called heterotrophic. Although these general terms are widely employed, as knowledge of nutritional behaviour of widely varied groups of organisms has increased, the classification has been extended to describe various nutritional patterns that have been observed. In one scheme, organisms are classified according to the energy source they utilize. Phototrophic, or photosynthetic, organisms trap light energy and convert it to chemical energy in the form of an energy-rich compound, adenosine triphosphate (ATP; see Figure 1); chemotrophic, or chemosynthetic, organisms utilize inorganic or organic compounds to supply their ATP requirements. An additional method of differentiation is based on the type of electron-donor material utilized to form the reduced coenzymes required for synthesis of cell constituents. If the electron-donor material consists of inorganic compounds, the organism is said to be lithotrophic; if organic, the organism is organotrophic. Combinations of these patterns may also be used to describe organisms; higher plants, for example, are photolithotrophic; *i.e.*, they utilize light energy, with the inorganic compound water serving as the ultimate electron donor. Certain photosynthetic bacteria, which cannot utilize water as the electron donor and require organic compounds for this purpose, are called photoorganotrophs. Animals, by this classification, are chemoorganotrophs, *i.e.*, they utilize chemical compounds to supply ATP and organic compounds as electron donors.

Nutritional patterns

Table 1 is a listing of several different types of organisms grouped according to these classifications. Such classification schemes are based on arbitrary criteria and, thus, provide a convenient description of the predominant life-style of an organism rather than an inflexible categorization of it. To illustrate, higher plants grown in sunlight are classic examples of autotrophic (or, more exactly, of photolithotrophic) organisms; during germination and growth of seedlings in the dark, however, higher plants have a heterotrophic (more specifically, a chemoorganotrophic) pattern of nutrition, utilizing the

Table 1: Some Representative Organisms of Various Nutritional Types

organism	energy source or substrate oxidized	oxidant	electron donor	waste product
Photolithotrophs				
Higher plants	light	—	water	oxygen
Green algae	light	—	water	oxygen
Photosynthetic bacteria				
Chlorobium species	light	—	hydrogen sulfide	sulfur
Chromatium species*	light		hydrogen sulfide or sulfur	sulfur or sulfate ion
Photoorganotrophic bacteria				
Athiorhodaceae†	light		organic compounds (*e.g.*, isopropanol)	oxidized compounds (*e.g.*, acetone)
Chemolithotrophic bacteria				
Nitrobacter species	nitrite ion	oxygen	same as substrate	nitrate ion
Nitrosomonas species	ammonia	oxygen	same as substrate	nitrite ion
Thiobacillus thiooxidans	sulfur	oxygen	same as substrate	sulfate ion
Hydrogenomonas species	hydrogen	oxygen	same as substrate	water
Carboxydomonas species	carbon monoxide	oxygen	same as substrate	carbon dioxide
Gallionella species	ferrous ion	oxygen	same as substrate	ferric ion
Chemoorganotrophs				
Animals	carbohydrates, fatty acids, amino acids, etc.	oxygen	same as substrate	carbon dioxide, water, ammonia or urea, etc.
Most bacteria	carbohydrates, fatty acids, amino acids, etc.	oxygen‡	same as substrate	‡
Most yeasts	carbohydrates	oxygen‡	same as substrate	carbon dioxide, water‡

*Some species also grow as photoorganotrophs. †Some species also grow as photolithotrophs. ‡Some species of bacteria and yeasts also grow without oxygen (*i.e.*, anaerobically); others grow only in the absence of oxygen (*i.e.*, they are obligate anaerobes). In such cases oxygen is not used; the substrate undergoes oxidoreduction reactions to yield ATP, together with a mixture of partially oxidized and reduced compounds as waste products.

organic compounds stored within the seed for growth. In contrast, certain chemolithotrophs—*e.g.*, *Thiobacillus thiooxidans*, a bacterium that obtains energy by oxidizing sulfur or hydrogen sulfide gas to sulfate and utilizes carbon dioxide as a sole source of carbon—cannot become organotrophic or heterotrophic under any conditions yet tested. These nutritional designations are useful, even though some predominantly chemolithotrophic organisms may have lost the ability to synthesize one or more organic compounds and, thus, require them for growth.

Despite wide variations in the nature of the external energy source utilized by various organisms, all organisms form from it the immediate intracellular source of energy, ATP, which is common to all cells. Through its conversion during metabolism to a less energy rich compound, adenosine diphosphate (ADP), ATP provides the energy for the chemical and mechanical work required if an organism is to maintain itself. This similarity in metabolic organization of even the most diverse organisms is shown diagrammatically in Figure 1, which emphasizes food as energy sources and as cell-precursor materials. The energy requirements of the organism can be measured in units called calories; the need for cell-precursor materials cannot be. In a related article, METABOLISM, bioenergetics and intermediary metabolism are considered.

All animals, fungi, and most bacteria are chemoorganotrophs (*i.e.*, organic compounds supply both ATP and serve as electron donors). In these organisms the multiple roles played by foodstuffs are partially obscured because the carbon-containing compounds that serve as energy sources also serve as electron donors and provide intermediate compounds from which many cell materials are synthesized. Similarly, essential organic nutrients, when present in excess, may be utilized in part to provide the energy needs of the organisms.

Nutritional evolution of organisms. Little factual knowledge concerning the nutritional evolution of living organisms is available. Nucleic acids, proteins, carbohydrates, and fats, which are present in all living cells, are formed by specific reaction sequences from a limited number of smaller compounds, most of which are common to all living organisms and, according to current theories, were available on earth before life arose. Since less complex metabolic organization and less energy are required, for example, to synthesize cellular proteins from the preformed amino acids that comprise them than from carbon dioxide and other precursors, it is assumed that the simplest forms of life were heterotrophic organisms requiring many organic nutrients for growth and that they selected such nutrients from their surroundings.

Evolution of autotrophy

As the supply of these preformed substances was exhausted (*e.g.*, through uptake by heterotrophic organisms or through fermentative and oxidative processes in organotrophic organisms), the organisms presumably developed the capacity to synthesize them from simpler (precursor) materials present in the environment; in some organisms, this synthesizing capacity eventually evolved to the extent that carbon from carbon dioxide could be utilized to synthesize organic compounds. At this point, autotrophy as it now is known became possible; autotrophy, in fact, may have evolved as a result of the exhaustion of the supply of preformed organic materials in the environment and the consequent necessity of organisms to synthesize the requirements themselves in order to survive. Implicit in this theory is the demonstrable assumption that autotrophic cells contain the most complex biosynthetic organization found in living things and that heterotrophic cells are simpler in that certain biosynthetic pathways do not occur. After the evolution of photosynthesis, a constantly renewable source of the organic compounds necessary for heterotrophic cell growth became available, and those organisms whose environments supplied a constantly available supply of a given compound could lose, through changes in their genetic material (mutations), the ability to synthesize that compound and still survive. Entire biosynthetic pathways may have been lost in this

way; as long as such mutant organisms remained in an environment that supplied the necessary compound, the simplification in cellular organization and the energy saved by using preformed cell components would have given them a competitive advantage over the more complex parents from which they were derived and permitted stabilization of the mutation within the cell type. A theory that the requirements of present-day organisms for essential organic nutrients arose through the loss of synthetic abilities present in more complex parent organisms was expressed as early as 1913, elaborated in classical papers published between 1936 and 1940, and confirmed by the discovery during the period from 1940 to 1950 that artificially produced mutant offspring of micro-organisms can be readily obtained and may require the presence of one or more preformed organic compounds, which the parent micro-organisms could synthesize (see also LIFE).

Methods of ingestion or penetration of nutrients. Foodstuffs of chemoorganotrophs are composed chiefly of large molecules, such as nucleic acids, proteins, lipids, and carbohydrates, which are derived from other organisms. When these materials are eaten as food, they usually must be broken down into the low-molecular-weight substances from which they were formed (*e.g.*, purine and pyrimidine bases from nucleic acids, amino acids from proteins, fatty acids from fats, and simple sugars from carbohydrates) before they can be absorbed and utilized. The breakdown process is generally accomplished outside the cells (extracellularly) of both single-celled and multicellular organisms through hydrolysis (break-down involving water), catalyzed by specific enzymes secreted for this purpose. (See DIGESTION AND DIGESTIVE SYSTEMS.) Some single-celled organisms (*e.g.*, the protozoan genus *Amoeba*), however, engulf particulate matter and hydrolyze it intracellularly.

The organic products of digestion produced extracellularly, together with essential inorganic nutrients, must cross one or more cell membranes before they can be utilized for growth. The absorption process is not yet understood and may vary according to the nature and the concentration of the nutrient involved. When nutrient concentrations are high, some materials (*e.g.*, water) may diffuse through the cell membrane to enter the cell. Efficient absorption of some materials, however, can occur from solutions containing very small quantities of nutrients, frequently against a concentration gradient; *i.e.*, from an extracellular solution containing very small quantities of the nutrients to an intracellular solution containing larger quantities. Such transfer processes, referred to as active transport, are energy dependent and are catalyzed within the cell membrane by a variety of systems, each of which is specific for the compound or class of compounds being transported. The nature of such catalysts has not yet been established with certainty; those best characterized involve either specific proteins with high affinity for the nutrient substance being transferred, enzymes that chemically modify the nutrient during its passage through the membrane or both.

In multicellular animals, absorbed nutrients are transferred into the circulating blood and lymph, from which they are reabsorbed by individual cells. In higher plants, translocation of nutrients occurs through transport elements found in the plant tissues (phloem and xylem). (See also MEMBRANE, BIOLOGICAL; PLANT INTERNAL TRANSPORT.)

The determination of essential nutrient requirements. It has been estimated that the approximate quantities of chemical elements in the human body (in percent of wet weight) are oxygen, 65; carbon, 18; hydrogen, 10; nitrogen, 3; calcium, 2; phosphorus, 1.1; potassium, 0.35; sulfur, 0.25; sodium, 0.15; chlorine, 0.15; magnesium, 0.05; iron, 0.004; manganese, 0.00013; copper, 0.00015; and iodine, 0.00004. Also present are traces of about 20 other elements—*e.g.*, zinc, cobalt, aluminum, arsenic, barium, boron, bromine, cadmium, chromium. Analytical figures such as those for man given above serve to distinguish between chemical elements that occur in relatively large amounts—oxygen, carbon, nitrogen, sulfur, and phosphorus—and the so-called trace elements, an obsolescent term applied to elements that are present in small amounts and that at one time could be detected in tissues but not analyzed accurately.

Trace elements

Although of interest, analyses such as the above are not instructive from the nutritional standpoint since only a few of the elements (*e.g.*, oxygen) are utilized in uncombined form in metabolic processes, and the mere presence in tissues of a trace element (the term is used loosely from this point to include all combined forms of the element that occur naturally; see Table 2) does not reveal whether its presence results from incidental contamination or whether it plays an essential metabolic role and therefore qualifies as an essential inorganic nutrient. In succeeding sections, inorganic and organic compounds that serve as essential nutrients (*i.e.*, cannot be synthesized by a cell and must be supplied in food) for one or another of the organisms studied thus far are dealt with.

The methods used to determine the individual pure substances necessary for growth are similar in principle for all organisms. Occasionally, crude diets lacking only one or a few nutrients result in some naturally occurring deficiency disease; the substance that cures such a condition can be determined directly by adding the nutrients to the diet. Certain vitamins were recognized in this way. In the absence of a deficiency condition, a crude nutrient medium (or diet) adequate for growth is selected for the organism to be studied, and attempts are then made to replace the various ingredients of the medium with purified materials and, finally, with substances of known composition. If replacement with substances of known composition permits growth, the added materials necessary for growth can be determined with relative ease; if the pure substances do not allow growth, attempts are next made to isolate and identify by chemical procedures the substances present in crude materials that permit growth.

Table 2: Essential Inorganic Nutrients for Living Organisms*

element	utilizable ionic form	representative organisms exhibiting the requirement
Boron	$B_4O_7^{2-}$	certain vascular plants and algae; no evidence of an animal requirement
Calcium	Ca^{2+}	plants, animals, most micro-organisms
Chlorine	Cl^-	higher animals; no evidence for requirement in plants
Chromium	Cr^{3+}	probably essential in higher animals
Cobalt	Co^{2+}	essential in ruminants; probably functions chiefly through microbial incorporation into vitamin B_{12}
Copper	Cu^{2+}	plants, animals, most micro-organisms
Fluorine	F^-	highly beneficial to bone and tooth formation in animals, including man
Iodine	I^-	higher animals; no evidence for requirement in plants or micro-organisms
Iron	Fe^{2+}	animals, higher plants, most micro-organisms
Magnesium	Mg^{2+}	animals, plants, micro-organisms
Manganese	Mn^{2+}	animals, plants, micro-organisms
Molybdenum	MoO_4^{2-}	animals, plants, nitrogen-fixing bacteria
Nitrogen	NO_3^-, NH_4^+	plants, micro-organisms (animals derive nitrogen mostly from organic sources, and utilize limited amounts of NH_4^+, but not NO_3^-)
Phosphorus	PO_4^{3-}	animals, plants, micro-organisms
Potassium	K^+	animals, plants, micro-organisms
Selenium	SeO_4^{2-}	higher animals
Silicon	SiO_4^{4-}	certain Protozoa and Porifera
Sodium	Na^+	animals, some plants, some marine bacteria
Sulfur	SO_4^{2-}	plants, many bacteria (animals derive sulfur mostly from organic sources)
Vanadium	VO_4^{2-}	various tunicates and holothurian echinoderms; some algae
Zinc	Zn^{2+}	all animals, plants, most micro-organisms

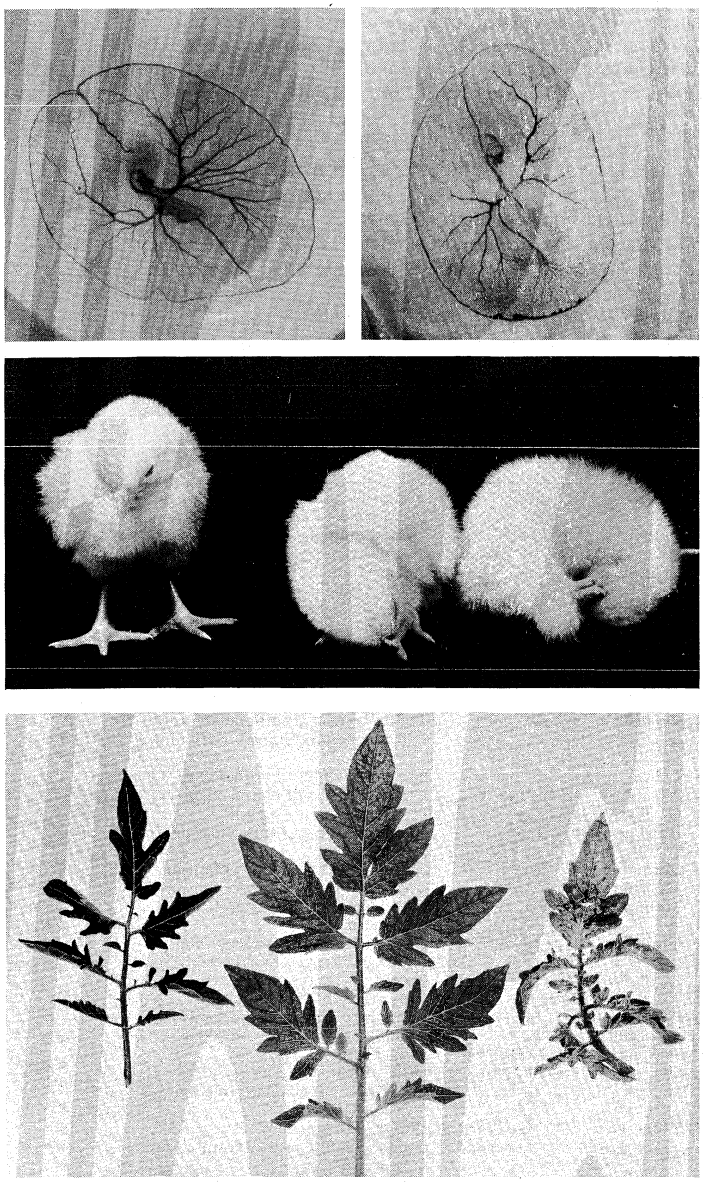
*Carbon dioxide (CO_2) and water (H_2O), although not formally tabulated, are important nutrients for all organisms; external sources of carbon dioxide, however, are required for only a few heterotrophic organisms since it is a prominent waste product of energy metabolism in these organisms.

The process was initially slow, because little was known of the detailed composition of tissues, and very few pure nutrients were available. With the identification of each new nutrient, however, the job of identifying additional ones became easier. Now that detailed nutritional requirements of many organisms are known, and essentially all of the organic nutrients are available as pure compounds, determination of the nutrient requirements of a previously unstudied organism is a comparatively easy task. Elucidation of trace-element requirements remains troublesome, however, because these substances occur commonly as contaminants in other materials.

ESSENTIAL INORGANIC NUTRIENTS

Table 2 is a list of inorganic elements (minerals) that are essential for the growth of living things, together with one or more examples of organisms that exhibit a requirement for them. The list excludes inorganic substances that serve only as energy sources for certain lithotrophic organisms. The effects of certain mineral deficiencies on the development of higher plants and animals are illustrated by several photographs. Naturally occurring deficiencies of several different trace elements occur throughout the world in special types of soils and are therefore of tremendous economic and agricultural importance. Several excellent accounts of these deficiencies have been published (see below *Bibliography* under Underwood, Hoagland, Altman).

By courtesy of (bottom) D. Arnon; from (top left, top right, centre) J.E. Savage, *Federation Proceedings*, vol. 27, p. 927 (1968)



Effects of mineral deficiencies on the development of higher plants and animals.
(Top left) Normal 72-hour embryo from hen fed ten parts per million of supplementary copper. (Top right) Anemic 72-hour embryo from hen receiving copper-deficient diet. (Centre) A normal chick, left, from hen receiving an adequate amount of zinc in its diet and two chicks from hens given zinc-deficient diets. (Bottom) Tomato leaves from plants grown in (left to right) copper-deficient soil, complete nutrient solution, and zinc-deficient soil.

Several examples of specialized mineral requirements are present in Table 2. Boron, for example, has been demonstrated to be required for the growth of many—perhaps all—higher plants but has not been implicated as an essential element in the nutrition of either micro-organisms or animals. Trace amounts of fluorine (as fluoride) are certainly beneficial and perhaps essential, for proper tooth formation in higher animals, but no essential role for fluorine in other organisms has been found. Similarly, iodine (as iodide) is required in animals for formation of thyroxine, the active component of an important regulatory hormone; it plays no known role in other organisms. Silicon (as silicate) is a prominent component of the outer skeletons of diatomaceous protozoans and similar organisms and is required in them for normal growth. Although silicon is present in higher animals, no essential role for it has been found thus far, and no nutritional requirement has been demonstrated. A less obvious example of a specialized mineral requirement is provided by calcium, which is required by higher animals in comparatively large amounts because it plays a role in the formation of bone and eggshells (in birds); for other organisms, calcium is an essential nutrient but only as a trace element. Several additional examples of specialized requirements are evident from Table 2.

Specialized mineral requirements

Mineral elements in wide variety are present in trace amounts in almost all foodstuffs. For this reason, diets adequate for growth but completely free of a given mineral element are extremely difficult to prepare. As a consequence it is not yet certain that all of the essential mineral nutrients are known. Furthermore, it cannot be assumed that, because a given mineral element is nonessential, it plays no useful role in metabolism. For example, the potassium requirement of certain bacterial species, called lactic-acid bacteria, which produce lactic acid as a byproduct of metabolism, can be completely replaced by rubidium. But, in other species, small amounts of potassium will still be required, even though rubidium is present. Thus, rubidium, although it is not an essential nutrient, can apparently fulfill in certain species many or all of the essential functions normally performed by potassium; in a specialized environment low in potassium, rubidium could partially replace the essential nutrient. (See below *Bibliography* under MacLeod and Snell.) Strontium has a somewhat similar relationship to calcium in these and other organisms.

Important antagonistic relationships between mineral nutrients also are known. A large excess of rubidium, for example, interferes with potassium utilization in some lactic-acid bacteria; zinc can also interfere with manganese utilization in the same organism. In animal nutrition, excessive molybdenum or zinc (both essential minerals) interferes with the utilization of copper, another essential mineral, and, in higher plants, excessive zinc can lead to a disorder known as iron chlorosis. Proper nutrient growth media for micro-organisms and plants or diets for animals, therefore, require not only that the essential mineral elements be provided in sufficient amounts but also that they be used in the proper ratios to each other.

Antagonistic relationships between mineral nutrients

ESSENTIAL ORGANIC NUTRIENTS

The principal energy sources of chemoorganotrophic organisms (carbohydrates, proteins, and fats) and the products of their breakdown are derived from other living organisms. In addition, bacteria from soil can be grown using as energy sources either hydrocarbons (organic compounds containing carbon and hydrogen) or any of a large variety of synthetic organic compounds that do not occur naturally and are not considered here.

Considered in this section is the nature of the essential organic nutrients that certain organisms can no longer synthesize and that, since they are essential building blocks of various cell components, must be supplied to them preformed. These essential compounds include certain amino acids, which are the precursors of protein; purine and pyrimidine bases or their derivatives, which are the precursors of nucleic acids; fatty acids, which are precursors of fats and phospholipids; and, occasionally (in mutant organisms), simple sugars (*e.g.*, glucose). Other essential organic nutrients include the vitamins, which are required in very small amounts (relative to, for example, the amino acids), because of either the catalytic role or the regulatory role they play in metabolism.

Amino-acid requirements. Proteins usually contain about 20 different amino acids (see Table 3) or their derivatives, and there are organisms known that require none, several, or most of them for growth. Many yeasts and bacteria (*e.g.*, *Escherichia coli*) are able to synthesize all of their amino acids from other compounds (glucose and ammonium salts). Animals may require up to nine or ten different amino acids in their diets (Table 3). Species of lactic-acid bacteria have been identified as requiring none (*Streptococcus bovis*), a few (*Lactobacillus plantarum*), or as many as 17 amino acids; *Streptococcus equinus* requires all of the amino acids listed in Table 3 except alanine.

Table 3: Amino Acids Required for Growth of Various Organisms

amino acid*	essential nutrient for
L-Alanine	*Pediococcus cerevisiae*
L-Arginine	chicks, rats, *Lactobacillus casei*
L-Aspartic acid	*Streptococcus equinus*
L-Cysteine	*S. equinus*
L-Glutamic acid	*Lactobacillus plantarum*
Glycine	*S. equinus*
L-Histidine	rats, chicks, man, *Streptococcus faecalis*
L-Isoleucine	rats, chicks, man, *S. faecalis*
L-Leucine	rats, chicks, man, *S. faecalis*
L-Lysine	rats, chicks, man, *S. equinus*
L-Methionine	rats, chicks, man, *S. faecalis*
L-Phenylalanine	rats, chicks, man, *S. equinus*
L-Proline	*S. equinus*
L-Serine	*Lactobacillus delbrueckii*
L-Threonine	rats, chicks, man *L. plantarum*
L-Tryptophan	rats, chicks, man, *L. plantarum*
L-Tyrosine	*L. delbrueckii*
L-Valine	*L. plantarum*, rats, chicks, man

*For structures of the amino acids, see PROTEIN.

Randomness of amino-acid requirements

The apparently random distribution of amino-acid requirements is compatible with the theory that the loss of synthesizing abilities occurred as the result of a random mutation process followed by stabilization of the mutations in different species (see above *Nutritional evolution of living organisms*). Indeed, mutant forms of the bacterium *Escherichia coli* that require any of the amino acids of Table 3 are readily obtained by appropriate procedures; the parent type *E. coli*, however, does not require any amino acids as essential nutrients. It is curious, therefore, that the nutritionally demanding lactic-acid bacteria and the much less demanding *E. coli* exist side by side and are the most prominent inhabitants of the intestinal tract of animals. Two amino-acid derivatives not listed in Table 3, glutamine and asparagine, are products of enzymatic digestion of proteins and are required for growth of some micro-organisms. An apparent requirement of some organisms for peptides, which are compounds containing two or more amino acids, is considered below.

Purine and pyrimidine bases and related compounds. A large number of species of micro-organisms require one or more of these substances as precursors for the synthesis of nucleic acids. Examples are given in Table 4; all higher animals examined have retained the capacity to synthesize purine and pyrimidine bases. Certain compounds (putrescine, spermidine, spermine) that are closely associated with nucleic acids in living cells, although synthesized by most organisms, are required preformed by certain bacteria; *e.g.*, *Haemophilus parainfluenzae, Neisseria perflava.*

Table 4: Purines, Pyrimidines and Their Derivatives Required as Essential Nutrients by Certain Micro-organisms*

compound	example of dependent micro-organism
Pyrimidine bases	
Uracil	*Staphylococcus aureus*
Orotic acid	*Lactobacillus bulgaricus* 09
Purine bases	
Adenine	*Shigella boydii* 9329
Guanine	*Streptococcus equinus*
Hypoxanthine	*Neisseria gonorrhoeae*
Xanthine	*Streptococcus equinus*
Pyrimidine deoxyribonucleosides	
Thymidine	*Lactobacillus delbrueckii* 730
Purine ribonucleotides	
Adenosine	*Gaffkya homari*
Guanosine	*Gaffkya homari*
Cytidine	*Tetrahymena geleii*

*Adapted from Guirard and Snell (1962) from which references may be obtained.

Lipids and related compounds. Phospholipids are essential components of all cell membranes, and it is not surprising, therefore, that some organisms, having lost the ability to synthesize certain lipids (since they are supplied in their diets), require them as essential nutrients. Essential fatty acids for rats (and most vertebrates) include linoleic and arachidonic acids and, perhaps, linolenic acid, as well. For many bacteria (*e.g.*, *Erysipelothrix rhusiopathiae*, several species of lactic-acid bacteria), oleic acid is essential for growth, although it can be replaced in most cases by linoleic acid and by an unusual fatty acid called lactobacillic acid. (See also LIPID.)

Choline, inositol, and cholesterol

Choline, a nitrogen-containing compound found in the phospholipid lecithin, is usually listed among the nutrients required by rats, although it can be synthesized by them if sufficient vitamin B_{12} is present. Choline is also required for growth of certain pneumococcal bacteria. Inositol, another structural component of certain lipids, is an essential nutrient for many yeasts but appears to be synthesized by most animals. Finally, the steroid cholesterol is an essential nutrient for a wide variety of protozoans and for the bacteria-like organisms known as mycoplasmas. Higher animals are able to synthesize this important cell constituent; it is not present in most bacteria.

Vitamins. One of the most dramatic continuing chapters in the history of the study of nutrition has been the discovery, isolation, and characterization of the many trace organic components required both in the diets of animals and in the growth media of micro-organisms. Vitamins may be defined as nutritionally essential organic substances that play a catalytic role within the cell, usually as components of coenzymes or other groups associated with enzymes. It is not generally realized that over half of the water-soluble vitamins required by man were discovered when they were found to be growth factors for micro-organisms. In Table 5 are listed the vitamins found thus far to be required by animals, by micro-organisms or by both; photographs are included to show typical effects of vitamin deficiency in animals. Vitamin deficiencies in young animals usually result in growth failure, various symptoms whose nature depends on the vitamin, and eventual death. Certain vitamins (retinol, calciferol, tocopherol and ascorbic acid) appear to play no essential role in single-celled organisms. Para-aminoben-

zoic acid is a vitamin for several bacteria only because it is an essential precursor of the vitamin folic acid, which, since it is unable to cross the bacterial cell membrane, must be synthesized from para-aminobenzoic acid. Heme and lipoic acid are typical vitamins for organisms that cannot synthesize them, but they have a catalytic role in all organisms; they are synthesized by higher animals. A few bacteria have lost the ability to convert certain vitamins to their functional forms, the coenzymes; the preformed coenzymes (or intermediates in their synthesis) thus are vitamins for such organisms. *Haemophilus parainfluenzae*, for example, requires nicotinamide adenine dinucleotide (a coenzyme derived from nicotinic acid), certain strains of *Neisseria gonorrhoeae* required thiamine pyrophosphate (a coenzyme derived from thiamine), and certain lactic-acid bacteria require either pyridoxamine phosphate (a coenzyme derived from vitamin B_6) or pantetheine (a coenzyme derived from pantothenic acid) for growth. Further details of this important group of nutrients are dealt with in the article VITAMIN, and in detailed accounts of bacterial or animal nutrition (see below *Bibliography*).

Table 5: Vitamins Required by Various Organisms

vitamin*	examples of dependent organisms
Fat-soluble vitamins	
Retinol (Vitamin A)	all vertebrates; many invertebrates
Calciferol (Vitamin D)	most vertebrates
Tocopherol (Vitamin E)	many vertebrates
Vitamin K	many vertebrates; *Mycobacterium paratuberculosis*
Water-soluble vitamins	
Ascorbic acid (Vitamin C)	man, primate apes, guinea pigs
Biotin	all vertebrates studied; many microorganisms
Folic acid (Pteroylglutamic acid)	all vertebrates studied; many bacteria (*e.g., Lactobacillus casei, Streptococcus faecalis*)
Nicotinic acid	all vertebrates investigated; many yeasts and bacteria
Pantothenic acid	all vertebrates; many yeasts, bacteria, and protozoans
Riboflavin (Vitamin B_2 or G)	all vertebrates; many bacteria, protozoans
Thiamine (Vitamin B_1)	all vertebrates; many fungi, yeasts, bacteria, and protozoans
Vitamin B_6 (Pyridoxine, pyridoxal, pyridoxamine)	all vertebrates; many yeasts, bacteria, and protozoans
Vitamin B_{12} (Cobalamine)	all vertebrates studied; some bacteria
Para-aminobenzoic acid	*Acetobacter suboxydans, Clostridium acetobutylicum*
Heme	*Haemophilus influenzae*
Lipoic acid	*Streptococcus lactis, Tetrahymena geleii*

*For chemical formulas and references, see related article VITAMIN and bibliographic citations.

Interdependency of nutritional requirements. The effects of one mineral nutrient in reducing or increasing the requirement for another have been mentioned previously (see above *Essential inorganic nutrients*). Similar relationships occur among organic nutrients and originate for several reasons, the most common of which are discussed briefly below.

Competition for sites of absorption by the cell. Since absorption of nutrients frequently occurs by way of active transport processes within cell membranes, an excess of one nutrient (A) may inhibit absorption of a second nutrient (B), if they share the same absorption pathway. In such cases, the apparent requirement for nutrient B increases; B, however, can sometimes be supplied in an alternate form that is able to enter the cell by a different route. Many examples of amino-acid antagonism, in which inhibition of growth by one amino acid is counteracted by another amino acid, are best explained by this mechanism. Under some conditions, for example, *Lactobacillus casei* requires both D- and L-alanine, which differ from each other only in the position of the amino, or NH_2, group in the molecule, and the two forms of this amino acid share the same absorption pathway. Excess D-alanine inhibits growth of this species, but the inhibition can be alleviated either by supplying additional L-alanine or, more effectively, by supplying peptides of L-alanine. The peptides enter the cell by a pathway different from that of the two forms of alanine and, after they are in the cell, can be broken down to form L-alanine. Relationships of this type provide one explanation for the fact that peptides are frequently more effective than amino acids in promoting growth of bacteria (see below *Bibliography* under Leach and Snell).

Amino-acid antagonism

Competition for sites of utilization within the cell. This phenomenon is similar to that regarding competition for absorption sites, but it occurs inside the cell and only between structurally similar nutrients (*e.g.*, leucine and valine; serine and threonine).

Precursor–product relationships. The requirement of rats for the essential amino acids phenylalanine and methionine is substantially reduced if tyrosine, which is formed from phenylalanine, or cysteine, which is formed from methionine, is added to the diet. These relationships are explained by the fact that tyrosine and cysteine are synthesized in animals from phenylalanine and methionine, respectively. When the former amino acids are supplied preformed, the latter are required in smaller amounts. Several instances of the sparing of one nutrient by another because they have similar precursor–product relationships have been identified in other organisms.

Changes in metabolic pathways within the cell. It has been well established that rats fed diets containing large amounts of fat require substantially less thiamine (vitamin B_1) than do those fed diets high in carbohydrate. The utilization of carbohydrate as an energy source (*i.e.*, for ATP formation) is known to involve an important thiamine-dependent step, which is bypassed when fat is used as an energy source, and it is assumed that the lessened requirement for thiamine results from the change in metabolic pathways. *Streptococcus faecalis* provides additional examples, in that either the vitamin folic acid or purine bases plus a pyrimidine base (thymine) and either the vitamin biotin or the fatty acid oleic acid are required for growth of this organism on an otherwise-adequate nutrient medium. These relationships occur because the synthesis of purine and pyrimidine bases requires a folic-acid-dependent enzyme, and synthesis of oleic acid requires a biotin-dependent enzyme. The products, thymine and oleic acid, must therefore be available to the cell if growth is to occur in the absence of folic acid or biotin; growth occurs, on the other hand, if either the products or the vitamins that permit their synthesis are supplied to the cells in the nutrient medium. Many known similar examples emphasize the fact that the nutritional requirements of a given organism can vary within certain limits, depending upon the composition of the nutrient medium.

COMPARATIVE MAGNITUDES OF THE REQUIREMENTS FOR DIFFERENT TYPES OF NUTRIENTS

Trace elements and vitamins are distinguished from other nutrients on the basis of the relatively smaller amounts required. An idea of the magnitude of these differences is provided in Figure 2. Potassium, a mineral element present in comparatively large amounts in all organisms, is required by *Lactobacillus casei* in amounts over 200 times greater than the requirement for manganese (Figure 2). The magnitude of the requirement for potassium is similar to that for the amino acid leucine (Figure 2); that for manganese is similar to that for the vitamin pantothenic acid but substantially larger than that for another vitamin, folic acid. Nutrients such as manganese and the vitamins, which are required in small amounts, are sometimes referred to as micronutrients because of these quantitative relationships. Potassium and leucine are macronutrients. For *Lactobacillus*, glucose is the energy source, and, to permit the amount of growth described, approximately 1,000 times more glucose is required than is needed of the macronutrients potassium and leucine. These ratios are fairly representative of organoheterotrophs in general. Lactic-acid bacteria, however, form lactic acid from glucose; other organisms, which oxidize this substance to carbon dioxide and water, require only about 5 percent of the amount of glucose required by lactic-acid bacteria for equivalent ATP production and, hence, for equivalent growth.

From E.E. Snell, *Wallerstein Laboratory Communications* (1948)

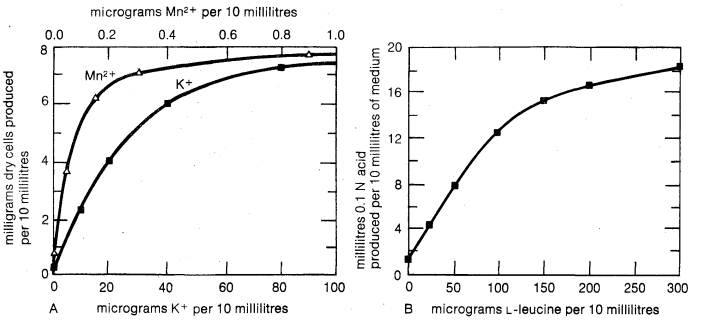

Figure 2: *Amounts of nutrients needed for growth of lactic acid bacteria.*
(A) Potassium (K^+) and manganese (Mn^{2+}) required for *Lactobacillus casei*. (B) Leucine required for *L. plantarum*.

Distinction between micronutrients and macronutrients

Graphic plots of data, called dose–response curves (Figure 2), if obtained in nutrient media that contain an excess of nutrients other than the one being examined, provide the basis for a convenient method (called microbiological assay) whereby all of the nutrients required by a specific organism may be determined. It is necessary only to compare the growth response elicited in a nutrient medium containing an unknown quantity of a nutrient to that produced in nutrient media containing various known quantities of the pure nutrient in order to determine the amount of the nutrient present in the unknown. Microbiological procedures employing lactic-acid bacteria have been widely used to determine quantities of the soluble vitamins in foods since they were first used, in 1939, for the determination of riboflavin. Similar methods, employing organisms that grow on soil, frequently have been used to determine deficiencies of inorganic nutrients in soil samples. The methodology is much more convenient and more accurate than are animal assays; the principle of all such assays, however, is identical, and any organisms with known specific nutritional requirements for a given substance can be used for its determination in this way.

SYNTROPHISM

Since the nutritional requirements and metabolic activities of organisms differ, it is clear that two or more organisms growing together may produce quite different overall changes in the environment than would the same organisms growing separately. A rough example is provided by a balanced aquarium, in which aquatic plants utilize light and the waste products of animals—*e.g.*, carbon dioxide, water, ammonia—to synthesize cell materials and generate oxygen, which in turn provide the materials necessary for animal growth. Such relationships are common among micro-organisms; *i.e.*, intermediate or end products of metabolism of one organism may provide essential nutrients for another. The mixed populations that result in nature provide examples of this phenomenon, which is called syntrophism; in some instances, the relationship may be so close as to constitute nutritional symbiosis, or mutualism. Several examples of this phenomenon have been found among thiamine-requiring yeasts and fungi, certain of which (group A) synthesized the thiazole component of thiamine molecule but require the pyrimidine portion preformed; for a second group (group B), the relationship is reversed. When group A and group B are grown together in a thiamine-free medium, both types of organisms survive, since each organism synthesizes the growth factor required by its partner; neither organism grows alone under these same conditions. Thus, two or more types of micro-organisms frequently grow in situations in which only one species would not. Such nutritional interrelationships may explain the previously noted fact that the nutritionally demanding lactic-acid bacteria happily coexist with the nutritionally nondemanding coliform bacteria in the intestinal tracts of animals. It is known that the bacterial flora of the intestinal tract synthesize sufficient amounts of certain vitamins (*e.g.*, vitamin K, folic acid) so that detection of deficiency symptoms in rats requires special measures, and the role of rumen bacteria in ruminant animals (*e.g.*, cows , sheep) in rendering otherwise-indigestible cellulose and other materials available to the host animal is well known. These few examples indicate that syntrophic interrelationships are widespread in nature and may contribute substantially to the nutrition of a wide variety of species. Parasitism, in which the host organism supplies all of the requirements for growth of the associated parasite without deriving any apparent advantage in return, represents a less desirable type of nutritional dependency.

Influence of populations on each other

BIBLIOGRAPHY. A very large and widely scattered literature exists on nutrition of micro-organisms, plants, and animals. Only a sampling is given below. Reasonably current lists of nutrients—both organic and inorganic—required by plants and animals, with a brief description of deficiency symptoms, may be found in the handbook by P.L. ALTMAN and D.S. DITTMER (eds.), *Metabolism* (1968). Similar compilations for bacteria and yeasts are presented by B.M. GUIRARD and E.E. SNELL, "Nutritional Requirements of Microorganisms," in I.C. GUNSALUS and R.Y. STANIER (eds.), *The Bacteria*, vol. 4, pp. 33–93 (1962); and by S.A. KOSER, *Vitamin Requirements of Bacteria and Yeasts* (1968). The latter two references also give an account of the discovery and inter-relationships of the organic nutrients for micro-organisms. Extended accounts of the vitamin requirements of animals, including their discovery and assay, are presented by W.H. SEBRELL and R.S. HARRIS (eds.), *The Vitamins*, 2nd ed., 7 vol. (1967–). N. JOLLIFFE describes the major vitamin deficiencies in man in *Clinical Nutrition*, 2nd ed. (1962). Amino-acid nutrition of man has been discussed fully in A. ALBANESE (ed.), *Protein and Amino Acid Nutrition* (1959). More specific accounts of the chemistry of the vitamins and the reactions by which they are degraded in living organisms are presented in M. FLORKIN and E.H. STOTZ (eds.), *Comprehensive Biochemistry*, vol. 11, *Water-Soluble Vitamins, Hormones, Antibiotics*, and vol. 21, *Metabolism of Vitamins and Trace Elements* (1963, 1970). Classical and still very useful accounts of the inorganic nutrition of plants and animals (including man) are, respectively, the books by D.S. HOAGLAND, *Inorganic Elements in Plant Nutrition* (1945), and by E.J. UNDERWOOD, *Trace Elements in Human and Animal Nutrition*, 3rd ed. (1971). R.A. MACLEOD and E.E. SNELL discuss cases of ion antagonism in bacteria and their significance in the article, "Ion Antagonism in Bacteria as Related to Antimetabolites," *Ann. N.Y. Acad. Sci.*, 52: 1249–1259 (1950). A useful account of the photosynthetic bacteria is given by S.R. ELSDEN, "Photosynthesis and Lithotrophic Carbon Dioxide Fixation," *The Bacteria*, vol. 3 (1962); periodic reviews of progress in our understanding of autotropic bacteria appear in the serial publication, *Annual Review of Microbiology*.

(E.E.Sn.)

Nutritional Diseases and Disorders

Nutritional diseases and disorders include (1) the effects of either an inadequate or an excessive consumption of food or of some particular type of food and (2) the inability to assimilate food or some particular type of food because of a disease process, a structural defect, or a chemical disorder. Good nutrition cannot be achieved without a satisfactory diet; the condition that develops in its absence is called dietary malnutrition. Malnutrition may also develop in a patient offered and consuming a satisfactory diet if he has certain diseases or disorders that interfere with the proper usage of his food. This type of malnutrition is referred to as malnutrition conditioned by a particular disease or disorder; *e.g.*, malnutrition conditioned by a gastrointestinal disorder or by a metabolic disorder. Most foods have to be digested, broken down to their component parts, before they can pass from the gastrointestinal tract into the substance of the body where they are used. Some of these components are used for the production of energy. Others are used for tissue growth and repair. The components of starches and fats—*i.e.*, sugars, glycerol, and fatty acids—are the chief energy sources. The principal components of proteins are amino acids, on which the first call is for tissue building or repair. If energy-yielding nutrients are in short supply, amino acids are diverted from their primary purpose and are used as energy sources, but the process is an economically wasteful one, since high-protein foods are expensive. Other products of the digestion of foods, not significant as energy sources, are required for metabolism; this group includes vitamins, minerals, and trace elements. (Trace elements are also minerals, but derive their name from the fact that only slight amounts of them are needed in the diet. They include iron, copper, manganese, and zinc.) All of these products of the digestion of foods may be referred to as nutrients. Nutrients are described as nonessential or essential according to whether the body is able or unable to synthesize them from other nutrients. Essential nutrients include many amino acids, some fatty acids, many vitamins, and some minerals and trace elements. Of some of these essential nutrients, the body carries large stores, which are exhausted only after a considerable length of time; *e.g.*, calcium from the skeleton and vitamin A from the liver. Water, obtained from both foods and drink, is one of the most essential nutrients, as is oxygen from the atmosphere. The latter, because it comes through the respiratory tract, is not usually called a nutrient (see NUTRITION).

Types of food and of nutrients

Nutrients are used by the body (1) to produce energy to maintain bodily temperature and effect internal and external work and (2) to build and maintain the bodily tissues. Ordinarily, energy is derived mainly from carbohydrates and fats. Proteins are ordinarily used mainly for tissue building and repair. Protective nutrients—*e.g.*, vitamins—are contained in most varieties of energy and protein sources. If energy-yielding foods are devoid of protective nutrients—*e.g.*, refined sugar—they are referred to as empty calories. Allowances of foods and nutrients have been recommended by various authorities for different ages, degrees of activity, and climates. These recommended allowances usually carry a substantial margin over minimum requirements to provide a safety factor for stresses of various types, including disease. In a fortunate environment, individuals may live in apparently good health on as much as a third less than the recommended allowances of many nutrients. Below that level health and efficiency must certainly be impaired, even if the effects are not immediately apparent. Customary dietary patterns in apparently healthy people in different parts of the world are vastly different; this indicates the great adaptability of the body, which possesses a number of alternate metabolic pathways.

Undernutrition, usually characterized by thinness, is due to an imbalance between calories available and those expended as energy. Overnutrition, characterized by fatness, is due to overconsumption of calories in relation to energy expenditure. Much malnutrition, as in scurvy and pellagra, is neither undernutrition nor overnutrition but, rather, a deficiency of one or more essential noncalorie nutrients. This type of malnutrition is sometimes called qualitative malnutrition, to distinguish it from quantitative malnutrition represented by undernutrition and overnutrition. Increasingly the term malnutrition is used to cover all the results of unsatisfactory provision or utilization of food, including overnutrition and obesity.

Undernutrition and qualitative malnutrition are responsible over the world as a whole for a vast amount of disease and disordered health. The problem, in the 20th century, is being enlarged by rapid increases in population. In tropical countries it is easier to produce relatively empty calories than good protective foods, and malnutrition complicates the problems of tropical parasitism, tropical disease, and the many other adverse environmental factors that may undermine growth and development during infancy, childhood, and adolescence, leading to heavy infant and child mortality and shortened life expectancy. Malnutrition represents one of the major problems of the 20th century. In theory, food production can be greatly increased, but it is questionable whether man has yet achieved the necessary international social organization either to match food production to the rate of population increase or to control the rate of that increase.

Throughout history there have been privileged groups whose resources have permitted the development of obesity. In the 20th century, western affluence has extended to the greater part of certain populations, bringing with it certain advantages (faster growth, increase in stature from generation to generation, and greater life expectancy), on the one hand and disadvantages on the other. Habitual indulgence in some foods is beginning to threaten the rising curve of life expectancy, especially through obesity or through degenerative disease of the arteries and the resultant coronary heart disease. Almost all diseases have multiple causes, some of which, especially the dietary causes, may operate over the greater part of a lifetime before manifesting their effects in middle or old age.

DEFICIENCY DISEASES

Deficiency diseases may best be considered under five main headings, according to the principal deficiency: (1) water, (2) calories, (3) vitamins, (4) proteins, and (5) minerals. There is considerable overlap between these groups.

Water. Some 65% of a normal body consists of water distributed between three compartments: (1) within the cells, (2) between the cells, and (3) within the circulatory system. A great variety of diseases disturb the water balance, but in healthy people only dehydration and overhydration result from wrong intake of water. The prominent symptom of dehydration is thirst, which develops quickly when water is unavailable. Dehydration becomes rapidly worse, and death may ensue within a day or two. Water is lost to the body by evaporation from the lungs and skin, through the urine, and through the stools, which loss can attain to serious amounts in states of diarrhea. Lung and skin losses are increased by work that causes sweating, particularly in a hot, dry climate. The kidneys usually excrete between one and two litres of urine per day (roughly one to two quarts), but when dehydration threatens they can conserve water through concentration of the urine; the specific gravity of the urine then increases and its colour darkens through concentration of pigments.

Overhydration from overdrinking is uncommon in healthy people, because the combined effects of excretion by the kidney and satiation, the opposite of thirst, are usually adequate even for the most enthusiastic drinker.

The distribution of water between the three compartments is largely determined by the electrolytes sodium and potassium. The important positively charged ion, or cation, in the interstitial fluid is sodium. Mammals, which have acquired an energy-dependent mechanism for removing sodium from the individual cells, the sodium pump, have potassium as their principal cation within the cells. (The cell membrane is permeable to sodium ions, and the sodium concentration outside the cells is stronger than within, so that one would expect sodium to pass

from the tissue fluids into the cells; its movement in the opposite direction requires energy. The process, whatever it may be, that involves this expenditure of energy is called the sodium pump.) Electrolyte and fluid balance are both maintained by the regulatory power of the sodium pump and of the kidney tubules. Upon this bare factual skeleton is built a complicated structure for medical regulation of fluid and electrolyte balance in disease; upset of the delicate electrolyte and fluid balance may be aggravated by deficient or excess intake of water.

In addition to sodium and potassium, sea water (the original source of animal life) contains the elements calcium, magnesium, sulfur, nitrogen, carbon, iodine, iron, and phosphorus. All of these can be detected in the human body, and many play important parts in metabolism (see below). There are also a number of elements present in the surface of the earth that are found in the human body in minimal quantities. Some of these have important known functions; others may be inert contaminants derived from the food consumed.

Calories. Energy, ultimately dependent upon solar energy, is taken into the body through food. It is expended in mechanical work, in the work of the internal organs, in maintaining body temperature, and in promoting growth. In adults, excess energy intake over energy expenditure leads to overnutrition and eventually to obesity, and the reverse leads to undernutrition with loss of weight. In children, moderate undernutrition, instead of leading to weight loss, may simply impair the rate of growth. Energy intake is measured in terms of kilocalories (abbreviated kcal) or simply as calories. In the near future, by international convention, the term calorie will be replaced by the term joule with an agreed conversion factor. The principal food sources of energy are starches and fats.

If the quantity of a properly balanced diet is insufficient, the result is simple undernutrition. In practice this balanced quantitative deficiency seldom occurs, except (1) during infancy, either with inadequate breast feeding or with insufficient although properly balanced bottle formulas; and (2) with voluntary limitation of intake among adolescents and adults in well-nourished communities. In adolescents and in adults who are voluntarily restricting their intake of a well-balanced diet, often for the cure or prevention of obesity, loss of weight occurs and energy and vitality may be impaired. In some cases neurotic behaviour develops, and in anorexia nervosa (see below), obsessions or delusions may be present.

Apart from these exceptions, undernutrition is almost invariably associated with an unbalanced diet. According to the particular pattern of imbalance, a variety of manifestations of qualitative malnutrition will be associated with evident undernutrition. Extreme examples may be seen in prolonged famines, during serious civil disorder, and in concentration camps. Of more common occurrence, except in situations of extreme crisis, is chronic malnutrition due to deficiency of one or more body-building or protective nutrients in persons who are not obviously undernourished. This type of malnutrition is discussed in the following sections.

Vitamins, antivitamins, and provitamins

Vitamins. For normal nutrition and metabolism the body requires certain organic substances, called vitamins, that it cannot make for itself, at least in sufficient quantity. Because they are required in such small quantity, the vitamins do not contribute significantly to the energy needs of the body. In their absence, the carbohydrates, fats, and proteins required for energy production, tissue building, and tissue repair cannot be properly metabolized.

The relation between the quantity of a vitamin obtained in the diet and its utilization and requirement by the body is not direct. Some vitamins, such as nicotinic acid, may occur partly in nonavailable form and may not be absorbed. Substances called antivitamins, present in some natural foods, may block the vitamins at their site of action. Some substances, called provitamins, are not themselves effective but may be converted into vitamins in the body; *e.g.*, beta-carotene is converted to vitamin A, and the amino acid tryptophan can be converted to niacin. Some vitamins, such as vitamin K, are synthesized in limited amount by bacteria present in the intestines.

Each of the vitamin-deficiency diseases is commonly attributed to a deficiency of a single vitamin, and many have been produced in animals and in human volunteers by diets apparently complete apart from the vitamin under trial. In human experience, these supposed single-vitamin diseases usually arise from unhealthy and unbalanced diets that are also deficient in other vitamins or in nonvitamin nutrients. In these complex nutrient-deficiency states, the nutrient whose deficiency plays the largest part in the causation of symptoms is often referred to as the most limiting nutrient; *e.g.*, niacin is the most limiting nutrient in pellagra, but there are often deficiencies of other B vitamins, and protein deficiency is commonly present.

Scurvy

A good example of a single-nutrient disease is scurvy, the scourge of mariners in the days of long ocean voyages. Its devastating effects have been immortalized in Samuel Coleridge's "The Rime of the Ancient Mariner." In 1497, the Portuguese navigator Vasco da Gama lost 100 of his 160 men in rounding the Cape of Good Hope. Early explorers suspected that the juice of the leaves of various plants had antiscorbutic properties. In 1753, a Scottish naval surgeon, James Lind, established the concept of deficiency diseases by showing that scurvy can be both cured and prevented by the use of orange and lemon juice. Captain James Cook used this knowledge in his exploration of Australia and New Zealand. Scurvy is an eminently preventable disease, and it is now seen mainly at the extremes of life and in institutions where there is willful disregard of the principles of nutrition. Infants reared on reconstituted dried milks suffer from scurvy unless ascorbic acid is added to the milk powder or orange juice is administered daily. Elderly widows and widowers not infrequently develop scurvy from negligent attempts to simplify their own catering and cooking. At an early stage scurvy results in swelling and bleeding of the gums and bleeding into the skin. Bleeding into the muscles and under the periosteum, the membrane that covers the bones, in small children, may also occur. Each of these manifestations is fairly easily recognized by those who are nutritionally aware. Anemia develops and resistance to infection is gravely lowered. It is probable that, in the classical epidemics among mariners and in prisons, the diet was unsatisfactory in many ways and that other deficiency states contributed to the more serious complications and to death; but experiments on human volunteers fed diets lacking in ascorbic acid but otherwise satisfactory have shown that scurvy can be and often is a single-nutrient-deficiency disease. Apart from scurvy and iron-deficiency anemia, described below, few single-nutrient-deficiency states are encountered naturally.

Fat-soluble vitamins

Vitamins A, D, E, and K are grouped together as the fat-soluble vitamins, although their chemical structure and their actions are quite distinct. They have certain features in common: (1) animal products in Western diets furnish a substantial part of the ordinary human requirement; (2) because of their fat solubility, they are not easily excreted and can accumulate to a dangerous degree if supplied too richly in the diet. Moreover, these vitamins tend to be stored in the liver of fish and marine mammals; thus vitamin A intoxication has occurred from the consumption by human beings of the liver of polar bears, and cod-liver oil is used in the treatment of rickets, a disease due to vitamin D deficiency.

The earliest and most widely prevalent manifestation of vitamin A deficiency is night blindness, because the retinal pigment rhodopsin (visual purple) requires retinol (vitamin A) for its functioning. Retinol deficiency manifests itself as inability of the eyes to adapt in dim light. Moreover, epithelial cells throughout the body—the various cells covering or lining the body and its organs—degenerate in vitamin A deficiency. In the eyes, the conjunctiva and cornea undergo changes that lead eventually to breakdown and complete blindness. Other epithelial cells including the skin and the mucous lining of the respiratory and urinary tracts degenerate, with characteristic results such as hardening and drying of the skin,

respiratory infections, and kidney stones. (All of these changes can be simulated to more or less degree by diseases that have nothing to do with vitamin A deficiency.) Vitamin A deficiency is an important cause of blindness, particularly in the first five years of life.

The vitamin in the diet is obtained from milk, butter, cheese, egg yolk, liver, and some of the fatty fish. The body can also make vitamin A from beta-carotene and some other plant pigments furnished by yellow and red fruits and vegetables and many green leaves. Absorption and conversion of carotene to retinol is variable but is averaged at one-sixth for dietetic calculations. It is sparsely supplied in starchy diets, which, after weaning, lead to widespread protein-calorie malnutrition. There is not much loss of retinol or carotene in ordinary cooking, but exposure of curative fish oils (*e.g.*, cod-liver oil) to bright sunlight and of vegetables and fruits to drying in the sunlight leads to considerable losses.

Vitamin D deficiencies

Rickets and osteomalacia, the adult form of rickets, are the important manifestations of vitamin D deficiency. Their differences are due largely to the fact that the skeleton reacts in one way to vitamin D deficiency in the growing phase and in another way in adult life.

Vitamin D, like vitamin A, is fat soluble; it is obtained in the diet principally from dairy products and from fatty fish and their oils and livers. Fish obtain the vitamin from plankton that has been exposed to sunlight at the surface of the sea. The human body is not entirely dependent upon its consumption of vitamin D because certain substances in the skin can be converted to vitamin D by exposure to sunlight. The dietary requirement for vitamin D is therefore dependent in part upon exposure to sunlight. Much of the pioneer work on rickets was done in Scotland, where the smog of the industrial revolution clouded the limited sunlight in tenement districts. The condition was largely abolished by routine administration of cod-liver oil to children. In tropical and subtropical climates, sunlight plays an important role in the availability of vitamin D, although exposure to sunlight in these areas may be limited by social customs such as swaddling of infants and the purdah system of veiling and covering women of childbearing age.

Vitamin D is concerned with the absorption of calcium and, secondarily, of phosphorus from the gastrointestinal tract. This process is also affected by the ratio of calcium to phorphorus and the amount of phytate in the diet. (Phytate, present in cereals, interferes with the availability of calcium.) Internally, vitamin D in part controls the metabolism of calcium and phosphorus in relation to growth, development, and maintenance of the bony skeleton. Relationships particularly with the parathyroid hormone are complex, and many aspects are still obscure. The most evident effect of vitamin D deficiency is interference with bone growth and bone maintenance. In children who have learned to walk, the growing ends of bones are enlarged and misshapen, with many characteristic skeletal deformities, including knock-knee, bossing of the frontal bone of the skull, and a line of beadlike nodules (the "rachitic rosary") at the junctures of the ribs and the breastbone. Softening of the skull bones (craniotabes), which may result from a number of causes, is commonly attributable to vitamin D deficiency when it occurs in the first year of life; the frequency is still controversial. The bony deformities are always slow to resolve, and some of them may remain permanent. A common permanent adult deformity in the past was contracted pelvis leading to difficulties in childbirth.

Rickets has been largely abolished in certain countries by routine prophylactic administration of vitamin D to infants and young children. During World War II there was compulsory fortification of infant formulas, margarine, and certain other foods with vitamin D. Subsequently, food manufacturers began to add vitamin D to other foods for infants and children, and suspicions about widespread overdosage were aroused. This aspect of food fortification has to be carefully supervised. In developing countries, particularly within the tropics, prevention of vitamin D deficiency depends upon health education, which discourages swaddling of children and purdah in women. If there is heavy cloud overcast, the prophylactic administration of vitamin D may be required in some form suitable to local conditions.

Vitamin E

Vitamin E covers a mixture of vitamins, called tocopherols, of which the important alpha variety was isolated from wheat-germ oil and has been synthesized. Early experiments on vitamin-E-deficient rats led to abortion in the female and sterility in the male. The anti-oxidant activity of the vitamin is related in some way to the health of muscles, skin, and perhaps all tissues. The tocopherols have been found in virtually every foodstuff used by man. The richest sources are eggs and oils expressed from some cereals, beans, and peas. Western diets are estimated to contain some 20 milligrams of vitamin E, which is thought to be an abundance.

Vitamin K

Vitamin K is necessary for the normal formation of prothrombin, one of the coagulation factors, by the liver. Vitamin K deficiency has never been clearly demonstrated in adults, but since the anticoagulants used in treatment of coronary thrombosis, and in other disorders involving blood clotting, act by inhibiting the production of prothrombin by the liver, vitamin K is used to counteract overdosage. A fat-soluble vitamin, it is often used prophylactically if there is disordered absorption of fats, as in obstruction of the bile ducts. It is thought that the adult freedom from vitamin K deficiency is achieved by synthesis of vitamin K by the bacteria of the large bowel.

The newborn infant, who has a sterile intestinal tract and consumes mostly milk, a poor source of the vitamin, suffers easily from prothrombin deficiency and may show a tendency to bleed in the first week of life. This deficiency is treated with vitamin K, but it is almost certainly complicated by other deficiencies that interfere with the early production of prothrombin by the liver of the newborn babe.

Vitamin B complex; vitamin B_{12}, folic acid, and anemia

Vitamins B_1 and B_{12} are well-identified members of a group of water-soluble vitamins that tend to have the same food sources. Some of the members have been eliminated with advancing knowledge (*e.g.*, vitamins B_3 and B_4 are probably the same as B_1). Vitamin B_1 is now identified as thiamine; nicotinic acid (niacin) was previously known as vitamin B_2 or the pellagra-preventing factor; riboflavin was separated from the same complex; vitamin B_6 is now identified as pantothenic acid and biotin; vitamin B_{12}, identified as cyanocobalamin, has important relationships with folic acid.

Deficiencies of the vitamin B complex lead to many disorders of function and structure. Deficiency of one member is likely to be complicated by deficiency of other members of the complex. These complex deficiencies tend, in general, to occur when diets are excessively dependent upon starches as staple sources of calories for energy production. This dependence is often magnified by the consumption of refined cereals (*e.g.*, white flour, white rice), in which the vitamin-carrying germ and husk are eliminated, and by growing consumption of refined sugar.

The discovery that the previously fatal disease Addisonian pernicious anemia could be cured by the consumption of large amounts of semicooked liver led ultimately to the identification of the effective factor in liver as cyanocobalamin (vitamin B_{12}). Pernicious anemia is due to deficiency of cyanocobalamin, the failure resulting not from a deficiency in the diet but from a familial or acquired deficiency of the small intestine's ability to absorb the vitamin. Dietary deficiency of cyanocobalamin is rare except in those who consume no animal flesh or products at all, but a similar type of anemia is widely encountered as a manifestation of dietary deficiency of folate coenzymes (substances that enhance or make possible the action of enzymes), usually referred to as folic acid, folacin, or folates. Both cyanocobalamin and folacin are needed for formation of healthy red blood cells, but their actions are in other respects different.

In some parts of the developing world, folate-deficiency anemia is a serious public health problem. Even in the Western world, there is evidence that many pregnant women suffer from undetected folate deficiency. Programs for routine administration of folic acid as well as

of iron are under consideration for improving the health of women during the childbearing period. During pregnancy the fetus has to be supplied with these and other nutrients; stores are often drawn from a woman already marginally depleted. The whole subject of dietary requirement and sources in respect of cyanocobalamin and folic acid, and the contribution of the intestinal bacterial flora to folate uptake, is still somewhat obscure.

Beriberi

Beriberi and pellagra are well-known diseases, usually regarded as single-nutrient-deficiency diseases, that result from too great reliance on certain cereals as sources of energy. Pellagra occurs widely in populations depending mainly on maize, while beriberi is endemic among populations that depend upon excessively milled rice. Both diseases can be prevented by addition of small quantities of protein-rich foods that contain the missing principles. Pellagra is due to deficiency of the vitamin niacin in available form and of the amino acid tryptophan, from which the body can make niacin. Maize is deficient in both nutrients. Natural rice is a good source of energy, but when it is highly milled, the vitamin thiamine (B_1) is removed with the husk and the germ of the grain. The milling of rice improves its keeping qualities, and thiamine can be restored in synthetic form or can be provided in sauces or gravy. The keeping quality of rice can be improved by parboiling, without removal of the husk and germ.

In the 1870s, after beriberi had become a devastating disease of sailors in the Japanese navy, the Japanese naval diet was revised; part of the polished rice was replaced by barley, and evaporated milk and meat were introduced. The success of these changes in eradicating the disease was attributed to the beneficial effect of a more liberal protein allowance, and the important part played by polished rice in the unrevised diet was missed.

In the absence of the vitamin thiamine, carbohydrates are incompletely metabolized, and poisonous lactic and pyruvic acids accumulate in the tissues. This deficiency state affects the nerves, heart, and circulation. According to the effect on these different systems, beriberi may be "dry" or "wet." The former is due to degeneration of the long nerves to the extremities, and the latter to edema, the presence of abnormal amounts of fluid in the tissues, resulting from failure of the heart and circulation. Mixed types are found. Experimentally, a pigeon paralyzed from a diet of polished rice can be restored to activity in a few minutes by an injection of thiamine. In moderate cases of human beriberi, thiamine, taken orally or injected, causes rapid improvement in a few days. In longstanding cases, possibly because of associated deficiencies, cure is much slower; indeed, in severe cases, part of the degeneration may be irreversible. Beriberi has been described in infants suckling from mothers suffering from thiamine deficiency. In Western countries, thiamine deficiency is now encountered almost solely in chronic alcoholics.

Pellagra

Pellagra, from a word meaning "rough" or "sour" skin, was first described in Spain in the 18th century, after the introduction of maize from the Americas. Preventable, it still occurs widely in the maize belts of the world, except that of the southern United States, which has been freed of pellagra by the economic advancement that occurred during World War II. Investigation of the relationship between pellagra and maize provides a fascinating story in the history of human nutrition research, but there is still an element of uncertainty. The three classical theories of a toxin in maize, of deficiency of protein, and of vitamin deficiency have been partly resolved by the knowledge that the amino acid tryptophan, relatively lacking in the protein of maize, is the precursor of the vitamin niacin and that the niacin that does exist in maize and in some other cereals is held in a bound or unavailable form. A more recent theory, that an excess of the amino acid leucine leads to amino acid imbalance, has still to be finally evaluated. The dermatitis of pellagra results from sensitization of the skin to sunlight and hence has a characteristic distribution. In some of the maize belts of the world today, "rough skin" with light-sensitive distribution is the only sign of widespread pellagra. At a more severe stage, smooth sore tongue, gastrointestinal upset, and diarrhea occur in epidemics. In severe cases mental disturbance and psychosis appear. The more severe features of the disease are easily curable with the administration of niacin. Complete restoration to health almost certainly requires liberalization of the diet with more varied sources of protein. This enhanced diet is apparently what has abolished the condition in the southern United States. As in the case of beriberi, pellagra in developed regions is seen particularly in chronic alcoholics. Hartnup disease, a rare disease resembling pellagra, is due to an inborn error of metabolism.

The foregoing discussions of beriberi and pellagra concern deficiencies in two important staple cereals upon which a large part of the world is dependent for its energy production. Equivalent deficiencies exist, or can be induced by modern processing, in other important staple cereals such as wheat, barley, and sorghum. Undue dependence upon these processed cereals or upon root staples such as potatoes, yams, and cassava may produce not only vitamin deficiences but also deficiencies of minerals and of amino acids, the building blocks of proteins.

Protein deficiencies; kwashiorkor

Proteins. Proteins are required in children for tissue building and in adults for tissue repair. One of the principal reasons for the widespread occurrence of protein deficiency in the world is excessive dependence upon starchy foodstuffs derived from cereals and root staples. If, on the other hand, calories from carbohydrates and fats are in short supply, protein is wastefully used to supply energy. Protein requirement and recommended allowances are therefore dependent in large degree upon the adequacy of supply of energy from carbohydrates and fats (see PROTEIN).

All proteins consist of a mixture of amino acids. There are more than twenty such acids, slightly under half of which cannot be synthesized by man and are known as essential amino acids. Every protein is unique in pattern, and its quality is almost more important than its quantity. Most good sources of protein are also carriers of important vitamins and minerals.

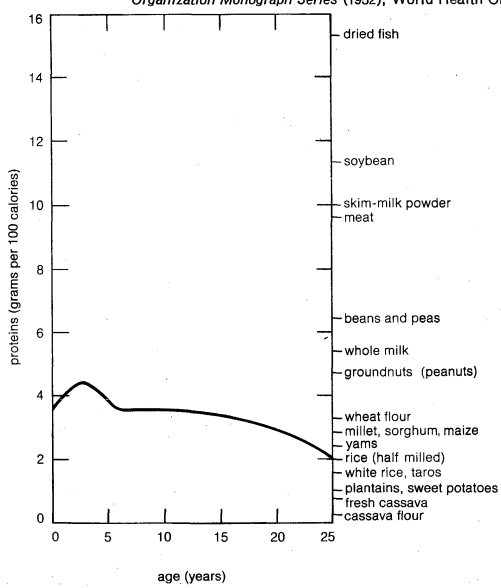
Up to the 1940s the attention of nutritional scientists had largely been applied to vitamin-deficiency diseases. It was not generally recognized that protein deficiency might be severe and widespread without gross undernutrition. An English physician, Cecily Delphine Williams, in 1932 described, in what is now Ghana, a disease in young children that she suspected to be due to deficiency of some amino acids and that she called kwashiorkor from a local tribal word. To some extent before and to a considerable extent after her description workers in underprivileged countries had described similar types of disease under a variety of names. As a result of inquiries instituted by the World Health Organization (WHO), it was soon evident that all of these diseases were due, in children recently weaned from the breast, to reliance on starchy foods that were relatively low in proteins, often also defective in their amino acid composition. The name kwashiorkor became internationally accepted. In the typical case, the child may appear not to be much undernourished, but the false appearance is contributed to by edema. It was later realized that every gradation exists between classical (edematous) kwashiorkor and the more severe undernutrition called marasmus, with a corresponding decrease in weight for age. The term protein-calorie malnutrition was coined to cover the full spectrum. The variable common characteristics of this spectrum are growth failure, peevish apathy, edema, fatty liver, changes in hair and skin, diarrhea, and death. Protein-calorie malnutrition is always due to failure to include adequate quantity or quality of amino acids, in the form of good protein, in the diet of children recently weaned from the breast or still in the preschool period, at which age the protein requirement is relatively high. It has been observed that cure of kwashiorkor can be initiated by the use of synthetic formulas containing essential amino acids, glucose for calories, an appropriate salt mixture, and water. Such initiation of cure can be brought about even in the absence of all vitamins from the formula. Since the protein deficiency of protein-cal-

orie malnutrition is always complicated by varying patterns of calorie, vitamin, and mineral deficiency, a full diet is naturally required for consolidation of cure and for return to full health. As the supply of calories, usually from cereal or root carbohydrates, including plantains, becomes less and less satisfactory for the needs of energy and growth, the spectrum of protein-calorie malnutrition passes from classical kwashiorkor through marasmic kwashiorkor to infantile marasmus. The same gradation occurs as breast feeding becomes less satisfactory in quantity and duration; when classical kwashiorkor appears, it is at an interval of three to six months after the late weaning of a well-developed baby. Marasmus is often seen at three months in the baby of a mother who has gone back early to work and left her child in the care of another.

Equivalent syndromes may be present at all ages; it is now recognized that severe undernutrition almost always includes some protein deficiency. When starved of calories, the body wastefully uses the amino acids of proteins for energy production instead of for tissue building or repair. The need for protein is aggravated in tropical countries by parasitic infestation. In all regions gastrointestinal infection, which promotes severe diarrhea in an intestine already wasted by protein-calorie deficiency, often leads ultimately to death.

The role of protein quantity is well illustrated in the Figure, which shows the amounts of protein provided by the common foodstuffs in quantities yielding 100 kilocalories of energy. Protein quality is more complex and depends in part on the pattern of constituent amino acids

From J. Brock and M. Autret, "Kwashiorkor in Africa," *World Health Organization Monograph Series* (1952); World Health Organization



Daily protein requirement per 100 calories, according to age, and yields of protein provided by common foods, in quantities yielding 100 calories.

and on the vitamins also present in the protein-containing foodstuff. Throughout the developing and underprivileged areas of the world, protein-calorie malnutrition is by far the most severe and widespread human dietary deficiency. In many of these regions almost every child, unless he happens to come from a privileged home, passes through a phase of retarded growth and development during the second and third years of life; *i.e.*, after weaning. When dietary protein, better in quality or in quantity, is consumed as the child competes with the rest of the members around the family cooking pot, growth and general improvement in health occur. The lost ground is at least partially made up by this growth spurt. In recent years, there has been conjecture about the possibility that the body is permanently damaged during the period of retardation of growth and development. It has been thought, for example, that this early deprivation might be partially responsible for widespread adult cirrhosis of the liver in areas where kwashiorkor is endemic. Recent protein-deprivation studies in a variety of animals strongly suggest that there is a vulnerable period between birth and weaning when protein deprivation may permanently impair brain development. Such a possibility could be of vast economic and social importance. It appears that this vulnerable time, if it occurs in human beings, is between birth and weaning—*i.e.*, during the first six months of life —rather than after weaning. On this premise, permanent mental retardation would be more likely to occur in infantile marasmus than in classical kwashiorkor. Since both clinical conditions are part of the spectrum of protein-calorie malnutrition, and since man is a long-lived animal, it is difficult to draw hard and fast conclusions.

Possible permanent after-effects of protein-calorie malnutrition

Fats and carbohydrates. Most human diets contain between 10 and 15 percent of protein. The balance is carbohydrates and fats. In general, carbohydrates may vary from as high as 90 percent among poor persons to as low as 40 percent among the wealthy; the balance is made up from fats, which may amount to 45 percent among the wealthy. Emphasis has been placed upon the great importance of protein quality because of the selective need for essential amino acids in growth and tissue repair. The quality of carbohydrates and fats as sources of energy is less important, and the body is adaptable to a relatively high or low ratio of carbohydrates to fat as sources of energy and to great differences in the types of carbohydrate and fatty foods.

In the discussion of protein-calorie malnutrition above, it was pointed out that adequate supplies of energy allow economy of protein for tissue building or repair and prevent the wasteful use of protein as a source of energy. This process of economy has a limit, set by the quality of the protein. If energy sources are largely provided by carbohydrates from root vegetables and cereals, protein-calorie malnutrition easily occurs if the quality of protein is limited by relative deficiency of one or more essential amino acids; *e.g.*, lysine and tryptophan in maize. Another important factor with respect to carbohydrate foods is the tendency in the last few decades toward milling and refining, which eliminate important vitamins and produce so-called empty calories, which yield energy but contain little of the protective nutrients present in unrefined food. White bread, white rice, and white table sugar are examples of refined foods. Modern agricultural techniques using selective breeding are able to produce cereals and other carbohydrate foods with high quantities of protein and better amino acid patterns.

Fats also vary greatly in their composition, and some of them contain more than others of certain unsaturated essential fatty acids such as linoleic, which the body cannot synthesize. (Fats are called saturated if they cannot absorb more hydrogen.) Fats of animal origin and oils that have been "hardened," as in the pastry fats, are saturated—they contain less of the unsaturated essential fatty acids. In some way (see below), the relative consumption of unsaturated and of saturated fats has a bearing on the problem of the human disease atheroma and particularly of its special presentation as coronary heart disease.

Fats are also important sources of the fat-soluble vitamins. The view of nutritionists that proteins should make up 10–15 percent of the diet, and carbohydrates 55–65 percent, does not take adequate cognizance of the importance of quality in all three of these main components of the diet's energy sources. Moreover, it does not give sufficient credit to the remarkable adaptability of the human body to varying diets (see CARBOHYDRATE).

Minerals. A normal adult has 1.2 kilograms (about 2.6 pounds) of calcium in his body; of this, all but a fraction is in the bony skeleton, where, mostly in combination with phosphate, it provides the hard structure to a protein cellular matrix. In childhood and adolescence, adequate dietary intake of calcium is essential for healthy growth; in adult life the skeleton acts as a reserve store of calcium. That the skeleton is not inert but is potentially in active exchange, even in the adult, is shown by the fact that lead accumulating slowly in the skeleton of lead workers can be mobilized rapidly by induced metabolic changes and subsequently removed. That this exchange is

Calcium

incomplete is shown by the damaging effect of radioactive strontium from atmospheric fallout; this becomes relatively fixed with ultimate damaging effect on bone. Disturbances of the absorption, metabolism, and excretion of calcium may result from a variety of endocrine disturbances and other diseases.

Extra quantities of calcium are needed throughout the period of growth and during pregnancy and lactation, when the mother has to supply the calcium needs of her fetus or infant. An important source of calcium for growing children is milk, whole or skimmed or as cheese. The rest of the calcium is derived from a great variety of foods. The calcium in a half-pint of milk is enough to meet the needs of all ages, except at puberty and during pregnancy and lactation, when one pint is an adequate supplement to a good diet. There has been considerable dispute about recommended allowances of calcium, and undoubtedly the tendency has been to set these too high. Allowance has not been made by nutritionists for the versatility of the body's processes of adaptation. Excessive recommendations of calcium lead inevitably to overconsumption of cows' milk, which may contribute to excessive intakes of saturated fats.

Magnesium; iron

Magnesium, like calcium, is stored in the skeleton; it appears to have some overlap with calcium in metabolism. It is also, next to potassium, the predominant metallic cation in living cells. It is an essential part of many enzyme systems. It is also an essential component of chlorophyll, the respiratory pigment of plants. Because of its reserve in the skeleton and its widespread presence in diets containing vegetables, there is probably never a dietary deficiency of magnesium.

Human disease resulting from dietary deficiency of phosphorus, sulfur, nitrogen, or carbon is unknown, presumably because these substances are found in a wide range of foods. Phosphorus deficiency has been reported in cattle on certain pastures deficient in phosphate.

Iron is a nutrient of great interest and importance. It is an essential component of hemoglobin and myoglobin, the oxygen-transporting proteins of the blood and of the muscles, respectively; deficiency might be expected to have serious effects. Its quantity in most daily diets is rather small (10–20 milligrams). The intestinal tract absorbs iron from the diet by an active process that is controlled in such a way that when iron stores are satisfied, most of the dietary iron is excreted in the feces, unless the dietary iron intake is so excessive that the control mechanism is inadequate. The normal daily wear-and-tear destruction of circulating red cells releases hemoglobin to the extent of 20 milligrams of iron per day. This is recycled, and most of it is incorporated in new hemoglobin; otherwise the body would rapidly run short. By the same token, the body's iron reserves are seriously taxed by increased demands on the blood supply in pregnancy and by loss of blood as by menstruation or from bleeding ulcers. If acute and severe, blood losses are usually corrected by blood transfusion. The long-continued loss of blood often leads to chronic iron deficiency, of which anemia of the type called hypochromic is the commonest manifestation. Iron deficiency, although easily corrected by iron preparations administered orally, is still probably the commonest single-nutrient disease in Western culture. It is probably responsible for considerable minor ill health among women who bear many children.

Trace element deficiencies

Early work in the mid-19th century on plant and animal requirements of macromineral elements—the elements such as sodium, potassium, and calcium that are needed in substantial amounts—was handicapped by the absence of chemically pure preparations. What are now called the micromineral or trace mineral elements often contaminated experimental preparations of the macromineral elements with which they are frequently associated in the soil. Since they have been chemically separated and identified, a number of these trace mineral elements have proved to be essential constituents of vitamins and hormones. The term trace element is now applied to elements that occur as not more than 1 part in 20,000 in the body. For centuries it has been known that goitre (enlargement of the thyroid gland) is endemic throughout the world in regions such as Switzerland that are heavily mountainous. Burnt sponge had been used as a cure for goitre since the 13th century, and it was suggested in Switzerland in 1820 that the then recently discovered element iodine might be the curative agent contained in burnt sponge. In 1896 it was demonstrated that the thyroid gland is rich in iodine. Thyroxine, an iodine-containing amino acid, was isolated in 1915 and synthesized in 1927 as the hormone of the thyroid gland. In the goitre belts of the world, deficiency of iodine prevents the formation of thyroxine, and the thyroid gland becomes enlarged and nodular in its abortive attempts to produce its hormone. The geographical distribution of endemic goitre is probably explained by leaching of the very soluble iodine out of the soil of mountainous areas into the sea where, *inter alia*, it is incorporated in sponges. Endemic goitre can now be prevented by the addition of iodine, as iodide or iodate, to table salt.

Fluorine

The nutritional significance of fluorine is a more recent discovery. Nineteenth-century chemists noted its invariable presence in bones and teeth. In the last quarter of the 19th century, fluorine was recommended for administration to pregnant women in the interest of sound teeth, and in 1892 it was suggested that the high incidence of caries (tooth decay) in England was due to deficiency of fluoride in the diet. In the present century, abundant evidence has established that in geographical regions where the water supply contains less than 0.5 part per million of fluorine, the addition of small quantities to the water or the local application of fluorine to the teeth of growing children greatly reduces the incidence of caries. In other parts of the world where the level of fluorine in the natural water is extremely high, teeth become affected by a mottling, and parts of the skeleton become dense and are affected by rheumatic and degenerative changes.

Scientific enquiry suggests most strongly that the easiest way of preventing fluorine deficiency tooth decay is to add fluorine to the drinking water to bring its fluorine content up to 0.5–1.0 part per million, at which level there is no risk to the body. Exposure to levels above ten parts per million for several years is required before mottling of the teeth appears; fluorosis of the skeleton is seen only after decades of exposure. In the absence of fluoridation of public water supplies, physicians and dentists can successfully prevent early caries by administering appropriate quantities of fluorine to small children or by ensuring application of fluorine to the teeth at regular intervals.

Copper and other metallic elements

Copper appears to be necessary to aid the incorporation of iron into hemoglobin, the oxygen-carrying protein of the red blood cells. Cobalt is a component of vitamin B_{12} (cyanocobalomin), essential for the formation of healthy red blood cells. Zinc deficiency is suspected of contributing to a syndrome (encountered in Iran) of retarded growth and sexual development. Zinc deficiency in animals may produce dermatitis and gastrointestinal upset. Manganese deficiency has not been recognized in man; in cattle grazing on manganese-deficient peat pastures, poor growth and reproduction and sometimes anemia, bone changes, and disturbances of the central nervous system may be observed. Manganese poisoning, affecting the central nervous system, occurs in workers in manganese mines. Selenium deficiency produces disease in animals but has not yet been described in man. The possible relations of deficiency of molybdenum, nickel, aluminum, and silicon are being investigated.

OVERCONSUMPTION

Obesity. By far the commonest effect of continued overconsumption of calories is obesity, a state of excess accumulation of fat in and on the body. It is often wrongly defined as a state in which weight is in excess of a 10 percent margin allowed over standard weight tables for age, height, sex, and race. Fat on the body is easily seen and measured. It is assumed that if there is excess fat in the subcutaneous tissue, there is probably also excess fat inside the body. More accurately, the amount of fat in the body can be calculated from the specific gravity of the total body, which in turn is measurable by comparison of weight underwater with weight in air. The more fat there

is, the lower is the body specific gravity. To describe weight in excess of 10 percent above standard weight as obesity is misleading, because some persons who have inherited a large frame and bulky muscles may be 20 percent or more in excess of standard weight without being obese. Nevertheless, weight is a valuable screening measure for obesity. After middle age, the specific gravity of the body may fall with little or no change in weight or skin-fold thickness. This results from disuse atrophy of the muscles and from replacement of muscle with fat and does not amount to obesity. This age change can be delayed by exercise but is not necessarily unhealthy.

Theories concerning causes of obesity

Obesity is becoming more and more of a problem in developed countries and among privileged communities. In simplest terms it is caused by consistent consumption of more calories than are required to meet the energy expenditure of that particular person, but this simple explanation conceals a great deal of difficult theory about causation. It is an impression, and probably a fact, that some persons put on fat more readily than others. This may have a simple double explanation: namely, that these people are more interested in food or that they expend less energy—the guzzling and lazy theory. This latter theory probably accounts for obesity in only a small minority. Overeating may be a habit culturally imposed by family custom, may be an occupational hazard (*i.e.*, of the pastry cook), may be induced by institutional dietetics (as in schools and tuberculosis sanatoriums), or may be an expression of boredom or emotional frustration. Underexpenditure of energy may be determined by cultural family environment, city office life, or temperament. It has been shown that obese adolescents at summer holiday camps expend less energy than their leaner friends even when engaged in active games such as tennis and swimming. Some persons may consume too many calories through ignorance of the high calorie content of alcoholic liquors. There is evidence that nibbling may contribute to obesity, even when the total calories consumed in the day are the same as when eating is confined to regular meals.

In summary, many aspects of the causation of obesity can be explained in terms of disproportion between calorie consumption and energy expenditure. Other factors may also play a role: it is frequently suggested that obese subjects may have a metabolic trend toward easy storage of fat, and a large number of differences have been demonstrated between obese and nonobese subjects in respect of hormone secretion and metabolism. The reasons for most of the metabolic and hormonal differences are obscure, since the basal metabolic rate is not lower than the normal range, and obesity due to identifiable endocrine diseases (*e.g.*, diseases of the thyroid and pituitary) constitutes a small minority of cases. Endocrine changes at puberty, during pregnancy, and at the menopause may contribute to obesity at these stages of life, but their effects can be obviated by appropriate adjustment of calorie consumption to energy expenditure. One theory for obesity, that some defect in nervous control may lead to abnormal deposition of fat in certain fat depots, called "greedy fat depots," originated from observation of certain rare diseases (lipodystrophies) in which fat is laid down in one part and disappears from another part of the body. This suggests control of fat deposition and fat mobilization by segmental nerves. There is abundant evidence that depot fat is in a continuous state of flux, or turnover, and is not an inert store.

Effects of obesity

If, as is evident from the discussion thus far, a complete and certain explanation of the causes of obesity cannot be given in the majority of instances, the effects of obesity can be stated with some certainty. Obese persons have a reduced life expectancy, and their life insurance premiums are greatly increased. They suffer disproportionately from a number of diseases and disabilities. The tendency toward obesity and susceptibility to these diseases may both be inherited, or either may cause the other. Diabetes of the middle-aged is strongly associated with obesity, and there is association of obesity in females with gallbladder disease. Contrary to general impression, coronary heart disease and obesity are not causally related, but obesity should be firmly treated to reduce the load on damaged hearts. Obesity is a mechanical load on the lower spine and the major weight-bearing joints, the hips, the knees, and the ankles. Reduction of the weight of obese persons may mitigate the middle-aged tendency to degenerative diseases of the joints and muscular rheumatism. Obesity of the trunk may interfere seriously with breathing and may contribute to pulmonary heart disease. Obesity is associated with proneness to accident. Finally, there is considerable association, both as cause and effect, between obesity and psycho-emotional disturbance. Many obese persons are jovial, but some suffer a considerable sense of inferiority. This is particularly evident among girls and young women in Western culture, where slimness is the vogue. Misdirected attempts at weight reduction may lead to deficiency disease and debility or, in a few persons, may go on to self-imposed starvation (anorexia nervosa). All in all, improved expectation of life, health, and happiness can result from the prevention of obesity or from effective and maintained weight reduction in obesity.

For obese people, the solution is simple but difficult: a reduction in calorie intake and an increase in expenditure of energy. To achieve reduction of calorie intake and increased energy expenditure is comparatively easy over a month or two; to maintain this altered balance over many years is extremely difficult. For many obese persons the craving to eat more is sometimes as strong as that for alcohol in the alcoholic and for a cigarette in the chain smoker. Vigorous games such as squash may lead to reduction of weight by several pounds, but this reduction is due simply to sweat, and weight is quickly restored when any liquid, even water, is consumed. Effective attempts to increase energy expenditure require many hours of muscular work or exercise on the feet.

In almost no field are there more fads and theories than in the dietary management of obesity. The many programs advocated for correction of obesity include complete starvation for a variable period, avoidance of either carbohydrates or protein at any one meal, avoidance of liquids at mealtimes, avoidance of nibbling and between-meal snacks, avoidance of refined sugar, high-fat diets, citrus diets, and grape diets. Few of these principles have any scientific basis except in so far as they achieve reduction of total calorie intake. Reduction of calorie intake is the only sound principle, provided that it is associated with the regular consumption of enough of those foods that provide essential nutrients: good proteins, vitamins, and minerals.

Surfeits of sugars and fats; overconsumption of vitamins and of other individual nutrients

Short-term overconsumption. Apart from the long-term effects of overconsumption of calories, short-term effects may occur from surfeit. The most obvious effect is acute alcoholic intoxication, if alcohol, in reasonable quantities, be regarded as a legitimate source of calories. Acute excess both of fats and of sugars may cause nausea and vomiting, perhaps through overloading of some metabolic functions of the liver. The same effect may come from surfeit of meat and other protein-rich foodstuffs. Gastrointestinal distension is largely mechanical and is related to the bulk of food consumed. Acute intoxication with either vitamin A or vitamin D has been reported after eating the liver of polar bears, which is extraordinarily rich in these two vitamins.

Long-term overconsumption of individual nutrients. Long-term overconsumption of individual nutrients is uncommon except in the case of fat-soluble vitamins, which are not easily excreted. Chronic intoxication both with vitamin A and with vitamin D is well known. Excess of the more common water-soluble nutrients is usually cleared by the body's excretory mechanisms. Nutritional siderosis (iron-overload) from overconsumption of iron is common throughout the African continent. This results principally from the use of iron containers for the brewing of alcohol and the processing of foods by fermentation. The daily intake of iron may be increased to ten times the normal average by such procedures. Siderosis is almost certainly harmful to the body, although the mechanisms by which it causes damage are not fully understood.

DISEASE AS A CAUSE OF MALNUTRITION

In the previous sections diseases and disorders resulting from wrong eating or malnutrition have been considered. In reverse, many diseases of themselves cause malnutrition even when a perfect diet is available. The principal mechanisms include (1) inborn errors of metabolism (see METABOLISM, DISEASES OF); (2) diseases of the gastrointestinal tract that impair digestion and absorption (see DIGESTIVE SYSTEM DISEASES); (3) kidney disease that causes retention of toxic substances that should have been removed and causes loss of nutrients such as proteins (see EXCRETORY SYSTEM DISEASES); (4) acquired disorders of metabolism that prevent absorbed nutrients from being properly handled inside the body; this group includes liver disease, disturbances of the endocrine glands, a great variety of infections, and the effects of cancer; (5) mental disease; (6) chains of abnormalities—vicious circles.

Inborn errors of metabolism. In the early 1900s a group of diseases was identified that were due to inherited defects, called inborn errors of metabolism. At present between 500 and 600 inborn errors of metabolism have been described, and the number is likely to grow. The inherited defect in these diseases is incurable, but the body does have some limited powers of adaptation by switching to metabolic pathways that are dependent upon other enzymes. The general principle of treatment is to eliminate from the diet those foods or nutrients that require for their digestion, absorption, or metabolism an enzyme that the body lacks. Alternative pathways can be encouraged, provided that essential nutrients are not involved. In the latter case little can be done. Some classical disorders of this type, all named from abnormal substances in the urine, are alkaptonuria, pentosuria, phenylketonuria, porphyria, and cystinuria. Many similar diseases are now known to be due to inborn enzyme defects in tubular reabsorption in the kidney.

Abnormal reactions to certain foods—food idiosyncrasies—often have a familial pattern. Some produce allergic disturbances, especially urticaria (hives). Unusual foods such as shellfish and exotic fruits are often offenders. Many of the reactions that remain unexplained are expected to be explained eventually in terms of minor enzyme deficiencies that are inborn errors of metabolism. These include the taste of sulfur after consuming eggs and "acidity" and "hives" after consuming certain fruits, such as tomatoes and oranges. Other reactions may be of mental origin; these often form the basis of fad diets.

Forms of sprue

Gastrointestinal tract. There are several varieties of sprue, all of which involve failure of absorption of dietary fat. The absorption of many other nutrients is primarily or secondarily impaired. The general term malabsorption syndrome is commonly used. Tropical sprue affects Europeans living and working for extended periods in the tropics. Another variety, occurring outside of tropical areas, is due to reaction against a protein called gluten that occurs in wheat and in other cereals. Another group of diseases impairs primarily the digestion, assimilation, and excretion of protein (protein-losing enteropathy).

Kidney diseases. In one group of kidney diseases (nephrotic syndromes), protein leaks out of the kidney into the urine in quantities sufficient to contribute to states of protein deficiency. In other groups, amino acids, the building blocks of protein, or glucose and other sugars may be lost. Many cases in this group are due to inborn errors of metabolism. In some acquired kidney diseases, nutrients are lost in the urine or their metabolism in the body is impaired by the presence of toxic substances—*e.g.*, urea, which upsets metabolic cycles.

Secondary metabolic diseases. Most disturbances of the endocrine glands upset metabolism to some extent and in variable ways. Diabetes mellitus causes nutritional wasting in one form, while another form of diabetes is associated with and may in part be caused by obesity. Many metabolic processes are regulated by the liver, and therefore all disorders or disturbances of the liver may affect metabolism. All infections and intoxications may do likewise, as does cancer. The mechanisms are complex and only partially understood.

Mental disease or disorder. In mental diseases, bizarre disturbances of appetite, taste, and food preference may result. A well-known example is the condition known as anorexia nervosa. Obsessive reactions against one's own appearance may develop, particularly in girls, at the time of puberty. Pubertal puppy fat may lead to fear of obesity and may link with fantasies of a sylphlike figure. In late adolescence or early adult life, the same symptoms may develop after bereavement or after disappointment in love. These persons cut down their food intake to an inadequate level. They become extraordinarily cunning in concealing their self-imposed starvation. Food is surreptitiously disposed of in the toilet or is vomited after a meal. The physical results in women include cessation of menstruation, and a peculiar growth of downy hair develops on various parts of the body, especially over the upper cheeks.

Vicious circles. Particularly in the gastrointestinal tract, deficiencies of some vitamins or protein seriously impair the functional capacity of the mucous membranes and glands that produce enzymes required for digestion and absorption. These nutritional deficiencies impair the capacity of the gastrointestinal tract to digest and absorb the nutrients contained in the defective diet. In this way a chain of effects is set up whereby nutrient deficiency causes failure of digestion and absorption, and this in turn further aggravates the developing deficiency. A worldwide manifestation of such chains of effects is seen in protein-calorie malnutrition in infants and young children, which may manifest itself as diarrhea. This diarrhea in turn aggravates the malnutrition and finally causes collapse from deficiency of water and electrolytes. Of particular interest in this context is the fact that many of the dietary deficiency diseases described earlier may be closely mimicked by diseases of metabolism. Thus rickets and pellagra may develop in persons who live on a diet that has been recommended because of inborn errors of metabolism.

HABITUAL DIETARY PATTERN AND DISEASE

Interplay of heredity and environment

The interplay of heredity and environment is clearly to be seen in diseases arising from inborn errors of metabolism. Phenylketonuria, arising from inability to digest the amino acid phenylalanine, leads, if unchecked, to mental deficiency and ultimately to death. If a diet lacking phenylalanine is instituted early enough in infancy and maintained, normal intelligence can be safeguarded. Similarly, in the disorder arising from gluten intolerance, lifelong ill health can be warded off by a diet lacking gluten. In other words, the environment (in the form of a proper diet) even in inborn errors of metabolism may be more important than heredity in shaping the ultimate constitution of the sufferer.

The two diseases just mentioned have been selected because in them the important environmental determinants are dietary. It has become increasingly apparent that there are a large number of diseases in which the ultimate breakdown is the result of the interplay over years or decades between heredity and many aspects of the environment. In some of these there is considerable evidence to suggest that the habitual dietary pattern is one of several important causative agents in the environment. Two good examples are coronary heart disease, resulting from fatty deposits in the coronary arteries (atherosclerosis), and diabetes mellitus.

Coronary heart disease, or ischemic heart disease, is the modern great scourge of privileged people over the age of 40. There is abundant evidence that it is on the increase and the increase is related to the privileged living that results from social and economic success in Western civilization. The environmental causative factors may include tension and strain, cigarette smoking, lack of exercise, and wrong eating. None of these environmental factors can be considered alone when attempting to explain causation; inherited differences between families must be considered along with the environment. In regard to diet there are many differences between what is consumed by privileged Western communities and what is consumed by underprivileged developing rural and

urban people. These differences tend to disappear with privilege and socioeconomic "development," and the incidence and prevalence of coronary heart disease goes upward with the change. This has been exemplified in the case of Japanese migrating to Hawaii and California, of the Irish migrating to the United States, of Yemenites migrating to Israel, and of the rural Bantu in southern Africa migrating to cities. Among the most unfavourable dietary trends are the total quantity and degree of saturation of fats in the diet. Saturated fats of animal origin and vegetable oils artificially saturated by manufacturing processes increase at the expense of unsaturated oils of natural vegetable origin. Cane sugar (sucrose) increases at the expense of natural starchy carbohydrates. Both these dietary changes have demonstrably unfavourable effects on fats (lipids) in the blood, which are known to be linked with the tendency to atherosclerosis in coronary arteries. In brief, Western privileged diet may be one of several factors jointly producing a most devastating disease of modern civilization. There is evidence that atherosclerosis in the coronary arteries may start in adolescence and may have been operating continuously over three or more decades before the disease manifests itself.

Diabetes mellitus is another disease of multiple causation that undoubtedly has inherited roots and that must be precipitated by a variety of environmental factors operating over long periods. One of these environmental factors may be diet. Its prevalence varies widely from place to place in the world and varies significantly among different populations in the same geographical area. Much complicated research is summarized in the statement that latent or potential diabetes is a worldwide disorder that is precipitated into damaging diabetes by environmental factors that include diet. The dietary causes certainly include overconsumption of calories, with resultant obesity, and perhaps undue dependence upon sugar (sucrose) as a source of calories.

SOPHISTICATED DIETS

Refined foods; harmful additives

Since man graduated from being a food gatherer to being a food producer, there has been an increasing tendency to cater, in food production, storage, and processing, to taste at the expense of physiological need. The extraction of white flour from the more healthy whole wheat meal was one of the trend setters. In the 20th century this process has followed a steeply rising curve. The results include certain widely prevalent deficiency diseases such as beriberi, increasing dental caries, and orthodontic problems.

Another manifestation of 20th-century food technology is the increasing presence of potentially toxic additives and contaminants in foods processed for delivery and consumption in large urban communities. Foods produced and consumed on one's own farm have many psychological and gustatory advantages, but it is not possible to make such foods available to inhabitants of large cities. Good bottled, canned, or frozen foods purchased in a supermarket may be more healthful than their so-called fresh counterparts that have been exposed and soiled in city retail markets. There is nothing inherently unhealthy in properly preserved foods. The same must be said about foods that have been produced with the aid of artificial fertilizers, such as phosphates and nitrates. Natural humus and manure are used by producers if they yield better and healthier growth of plants; these plants in turn will be more acceptable both to dairy herds and to human consumer-purchasers.

Of more potential danger is the modern tendency to stimulate the growth of meat-yielding animals with antibiotics and hormones that remain in meat, milk, or eggs intended for human consumption. The same is true of a great variety of modern pesticides that are used because they produce better crop yields, also of the colouring matters that are included in sweets and some canned foods to catch the consumers' eye. These and other additives and contaminants have considerable potentiality for harm to their human consumers. Some of them, ordinarily in doses relatively much larger than are consumed by the public, may produce cancer in experimental animals. This whole subject is under intensive scrutiny by the World Health Organization (WHO) and the Food and Agriculture Organization (FAO) and will need more and more careful scrutiny by national health authorities. Decisions concerning these potential hazards cannot be made without taking the growing population pressure into consideration; this is becoming so heavy that alternatives to the use of artificial agricultural and veterinary aids that become potentially dangerous additives and contaminants may be world starvation or malnutrition.

Many authorities now believe that the increasing pace of food sophistication in the present technological age has led to a considerable body of back-to-nature food faddism, characterized by dogmatic statements based on little or no scientific evidence. It is unreasonable to consider the real and alleged deleterious effects of food sophistication without recognizing that some degree of sophistication is inevitable as a result of the displacement of peasant subsistence by urban industrialized living. The latter is necessary to modern technology, and in spite of its dangers technology has brought with it many advantages, including a great increase in life expectation, increased productivity, and leisure for culture. Technological sophistication has brought improved quantity and quality of foodstuffs to the ordinary man and held at bay the effects of population pressure. It undoubtedly entails some potentially dangerous trends that will need to be carefully watched.

HEALTHFUL DIETS

In the face of 20th-century population pressure, one of the greatest challenges to mankind is to produce and make available to every person in the world sufficient calories to meet his energy demands, and a sufficient pattern and balance of protective nutrients to ensure healthy growth and maintenance. In developed nations, for all but the submerged minority, availability is ensured, and only health education is needed to bring about discriminating selection, healthy preparation, and disciplined consumption of food. For the submerged sections, lack of education and of earning power must be temporarily met by subsidized distribution. For a very large part of the developing world, however, neither education, earning power, nor adequate food production are assured. In general, hunger is periodic or seasonal and the drive of hunger keeps calorie deficiency vocal. Far more dangerous is the silent apathy of the millions whose hunger is satisfied by starchy calories and whose deficiencies of protein, vitamins, and minerals impair development and health. This is particularly dangerous for the under-five age group. Visible undernutrition and malnutrition represent only the peak of the iceberg; the real cause of poor growth and failure to thrive in young children, and of apathy at all ages, is represented in that part of the iceberg which is below the level of ordinary recognition.

It is usually admitted that recommended allowances have too wide a margin over the genuine minimum requirement and that this makes them unrealistic in the developing world. Nevertheless, they are probably right as an objective to be aimed at, and the width of the margin protects well-nourished communities from unusual stresses and does no harm except where excessive calories replace undernutrition with obesity.

The mere production, distribution, and marketing of food in appropriate quantity and quality is not enough. Health education in the broadest sense is necessary to ensure that recommended allowances are translated into familiar foodstuffs in appropriate quantity and combination. It should also ensure intelligent marketing, hygienic storage, cooking, and serving of food, and relaxed, unhurried eating in the home.

THERAPEUTIC DIETS

Certain diets that were previously believed to be important in the cure of disease are now recognized to be more appropriately directed towards the relief of symptoms. For example, it is now believed that, apart from the need to fulfill recommended allowances, diets for the treatment of duodenal ulcer should be directed towards the

relief of symptoms rather than regarded as fundamental for the cure of the ulcer. Diets for the management of diabetes mellitus in obese middle-aged adults are now directed particularly toward the reduction of weight, rather than to the disturbed metabolism itself. In some fields the importance of therapeutic diets has been greatly increased. The introduction of long-term dialysis (the use of semipermeable membranes, as in the "artificial kidney," to remove waste products from the blood) in chronic kidney disease has led to the inevitable removal of some part of the patient's store of nutrients. The restoration, through diet, of these nutrients and the maintenance of the best nutrient and calorie balance has become a complex and expert dietetic science. The therapeutic dietician has great responsibility for ensuring that a person being treated is able to translate recommended allowances into foods that are available and acceptable to him and is informed on the proper preparation, cooking, and serving of these diets.

(J.F.B.)

Nutrition and Diet, Human

Nutrition is the process of assimilating food. The study of nutrition is the study of foods and their use in diet and therapy. Nutrients are the chemical components of foods utilized by the body, either as a source of energy or for building and maintaining tissues. Nutrients are conveniently divided into proteins, carbohydrates, fats, minerals, and vitamins.

The scope of nutrition

The scope of human nutrition and diet has now extended far beyond the purely chemical and physiological interpretation of the processes involved. Modern nutritionists are professional people whose training may have been in medicine, biochemistry, physiology, agriculture, or other science, but who have become increasingly involved in a wide range of problems in the general area of public health nutrition (see also FOOD SUPPLY OF THE WORLD). Infants and young children have physiological needs for growth above those of the normal adult. Old people, because of physical or mental infirmity, may fail to ingest adequate amounts of the right kinds of foods. These are vulnerable groups among whom ill health may occur because of undernutrition. The effects of undernutrition on health are seen most clearly on a worldwide basis, among the poverty-stricken, regardless of their location. The prevention of undernutrition, though it requires social action and financial assistance, is dependent as well on professional nutritional advice. It is not only the poor who suffer from malnutrition. In wealthy communities the prevalence of obesity, diabetes, atherosclerosis, and other dietary disorders is increasing and, although the precise causes of these are not always known, faulty food intake appears to be an important factor. There are nutritional problems among the affluent as well as among the poor.

Dietetics is concerned with menu planning and the provision of detailed advice about food and special diets for both individuals and institutions. Dietitians have a professional training with emphasis on the dietary treatment of the sick. Many of them work in hospitals, but others are employed in teaching or advisory capacities.

FUNCTIONS OF FOOD

The human body is a heat engine that releases the energy present in the foods and utilizes it partly for the mechanical work performed by muscles and in secretory processes and partly for the work necessary to maintain its structure and functions. The performance of this work is associated with the production of heat; heat loss is controlled so as to keep body temperature within a narrow range (see also METABOLISM).

Unlike other engines, the human body is continually breaking down (catabolism) and building up (anabolism) its component parts. Certain foods supply nutrients essential to the manufacture of the new material and provide energy needed for the chemical reactions involved.

The supply of energy. The energy taken in food and that utilized in daily life can both be measured. The measuring unit has been the kilocalorie (kcal) which is 1,000 gram calories; a gram calorie is the amount of heat required to raise one gram of water from 14.5° to 15.5° Celsius at one atmosphere of pressure. Nutritionists are now coming into line with other branches of science and using joules as the unit of energy; one kilocalorie is approximately equivalent to 4.2 kilojoules.

The energy present in food can be determined directly by measuring the output of heat when the food is oxidized in a calorimeter. Heats of combustion of individual proteins, fats, and starches are about 5.4, 9.3, and 4.1 kilocalories per gram, respectively.

Not all of this energy is available to the body because some ingested material is not absorbed from the gut and is lost in the feces; further, the nitrogenous compounds are not completely combusted, and some of the energy in proteins is lost in the urine, mostly as urea. Corrections for these losses give physiological values for dietary protein, fat, and carbohydrate of approximately four, nine, and four kilocalories per gram, respectively. These are called the Atwater factors, after an American physiologist, who, between 1895 and 1905, calculated the quantitative aspects of energy exchanges. Tables of energy value and nutrient content of common foods provide background data for general dietetic advice (see Table 1).

Sources of energy

Proteins, fats, and carbohydrates can, within wide limits, be interchanged as sources of energy. Among the members of prosperous communities most diets provide 12 percent of the energy as protein, about 40 percent as fat, and 48 percent as carbohydrate. In many poor agricultural societies, for whom cereals provide most of the energy, the figures for the individuals' diets are 10 percent for protein, 10 percent for fat, and 80 percent for carbohydrate. Throughout most of the world, protein provides between 8 and 14 percent of the energy ingested. High fat diets are associated with a high incidence of atherosclerosis (deposits of lipid material in the larger arteries), and high carbohydrate diets are likely to lead to obesity. Both diets are likely to be deficient in minerals and vitamins. Wide variations in the proportions of fat and carbohydrate in the diet may, nevertheless, be compatible with good health. Ethyl alcohol is another source of energy to the body. Only a small part of the intake, usually less than 5 percent, is excreted in the urine and expired air; most is oxidized in the liver, where it serves as a source of energy with a value of seven kilocalories per gram (almost that of pure fat). Muscle cannot utilize alcohol, and alcohol intake reduces the use of fat and carbohydrate by the liver. In this way alcoholic drinks increase the energy value of a diet and often contribute to obesity and fat deposits in the liver.

Building and maintenance. The body of a young adult human male weighing 65 kilograms (143 pounds) consists of some 11 kilograms of protein, nine of fat, one of carbohydrate, four of minerals, and 40 of water. During the first 20 years of life, an average of about 1.5 grams of protein and 150 milligrams of calcium must be retained from the diet every day in order to build soft tissues and skeleton. Tissues, however, are not static, and their components are being continually catabolized and replaced at varying rates. The inner epithelial lining of the gut is replaced every three or four days and red blood cells have a lifespan of only 120 days. On the other hand, collagen, a protein constituent of tendons, is probably turned over at intervals of ten years or longer. Much of the material derived from the breakdown of tissues is re-utilized, but

new material is also required from food. Probably some 400 grams of tissue protein is replenished daily, but the minimal dietary requirement of protein is only about 40 grams per day.

Essential nutrients. Experiments with animals on artificial diets have enabled nutritionists to establish a long list of dietary substances essential for normal growth and the maintenance of good health. Most of these are present in sufficient quantities in all human diets; deficiency of any of them, however, may lead to serious symptoms of ill health in man. They include protein, minerals, and vitamins.

Protein. Growing children need more protein per kilogram of body weight than do adults. Protein requirement at all ages is increased by infections not only because there is an increased utilization of protein but also because illness usually impairs the appetite and thus reduces dietary intake of all substances, including protein. In many countries of the world children are weaned on a diet of cereal paps with little or no supplement of milk or other protein-containing foods. Such a diet at the least retards growth and development, and if a child on such a diet suffers from an acute infection, notably measles or gastroenteritis, a severe illness, which may take several forms—known variously as protein-calorie malnutrition, kwashiorkor, or nutritional marasmus—may ensue. The death rate from protein malnutrition in many poverty-stricken communities is enormous. There are areas in which more than 50 percent of the children die before their fifth birthday because of protein and energy deficiencies and repeated infections. The availability of suitable protein-rich foods for all children under five is the most important nutritional problem in the world today. In some instances, even where such foods are available or could be made easily available, they are not used because of ignorance of methods of child feeding.

Protein deficiency

Primary protein deficiency is not common among adults, for whom cereals in general satisfy the protein requirement. It does occur, however, in Africa and in certain other parts of the world where the staple food is cassava, a root with a low protein content.

Secondary protein deficiency, in which there is ample protein in the diet, arises from: (1) gastrointestinal disorders which interfere with the intake or digestion of protein or the absorption of amino acids, (2) chronic infections and injury, which increase the need for and utilization of protein, and (3) large losses of protein from the body, *e.g.*, in the urine, in some forms of kidney disease, and from the skin surface in the serous exudate from extensive burn areas.

Minerals. Iron is required for the synthesis of hemoglobin, the pigment in red blood cells. Normally the iron liberated from old cells is retained and can be re-utilized. When, however, there is chronic bleeding from wounds or during severe and prolonged menstruation, the normal amount of dietary iron may be insufficient to replenish the body's supply. Losses of iron in the menses, the needs of a fetus, and the inevitable loss at labour and in the milk of a lactating woman increase the iron requirements of women during their reproductive life. Most dietary iron is in a form which cannot be absorbed from the gut. Many diets contain about 12 milligrams of iron, of which less than ten percent need be absorbed by a normal adult male. At best only about 25 percent (3 milligrams) can be absorbed and this is only marginally adequate to meet the needs of menstruating women. If menstrual losses are large, iron-deficiency anemia inevitably follows unless the diet is supplemented with absorbable iron compounds. In most countries, because the dietary iron is insufficient to replenish menstrual losses, some 20 percent of the women are anemic, fortunately, as a rule, only to a minor degree. Iron-deficiency anemia may follow bleeding from any part of the gastrointestinal tract and, in such cases, may be severe. This is likely to happen, for example, when there is a heavy infection with hookworms, as occurs in many areas of the tropics, or in cases of bleeding ulcers.

Iron, calcium, sodium, potassium, magnesium, iodine, and trace elements

Calcium is needed for the development, growth, and maintenance of bone tissue, including teeth. It is probable that all human diets contain an amount sufficient for this purpose. Calcium deficiency may, however, arise from a failure to absorb the mineral, from a lack of vitamin D—causing a failure of bone development in children (rickets) and softening of bone in adults (osteomalacia)—or from disturbances of the secretions of the parathyroid hormone and of estrogen. Osteomalacia may follow any long-standing disease of the small intestine interfering with absorption. Osteoporosis, despite adequate calcium intake, may arise after the menopause (see BONE DISEASES AND INJURIES).

Sodium is present only in small quantities in most natural foods, but salt is added, often in large amounts, by food processers and by cooks. Dietary sodium deficiency occurs only in poor tropical communities in which low intakes of salt are unable to meet large losses in the sweat. Sodium is the predominant ion in extracellular fluid; an excess can cause edema, an accumulation of such fluid, especially in conditions such as congestive heart failure. A low sodium intake leads to a lowering of the blood pressure and brings about diuresis, ridding the body of the excess extracellular fluid. There is now much evidence that excess dietary salt may contribute to high blood pressure in some individuals, but many other factors are also responsible.

Potassium, present in all natural foods, is the predominant intracellular ion. Deficiency of it does not occur as a result of a primary dietary lack, but it may arise when there is acute water loss following diuresis or chronic diarrhea and may result from persistent misuse of purgatives or diuretics. All wasting diseases are associated with loss of potassium from the tissues. Potassium deficiency disturbs the excitability of tissues and leads to paralysis of muscle, including cardiac muscle. Sodium and potassium

*Recommended intakes calculated as providing 10 percent of energy requirements. †The figures are calculated from energy requirements and the recommended intake of thiamine of 0.4 mg/1000 kcal. ‡1 nicotinic acid equivalent = 1 mg available nicotinic acid or 60 mg tryptophan. §1 retinol equivalent = 1 μg retinol or 6 μg β-carotene or 12 μg other biologically active carotenoids. ‖No dietary source may be necessary for those adequately exposed to sunlight, but the requirement for the housebound may be greater than that recommended. ¶These figures apply to infants who are not breast-fed. Infants who are entirely breast-fed receive smaller quantities; these are adequate since absorption from breast milk is higher.

are two of the most important ions in maintaining the homeostatic equilibrium of the body fluids.

Like potassium, magnesium is present in most foods. Deficiency, however, may follow chronic diarrhea and be a cause of weakness, depression, and disturbances in muscle contraction.

Iodine is necessary for the synthesis of the hormones of the thyroid gland. In the absence of adequate intake, the gland enlarges into what is known as a goitre. Goitres can become so large as to interfere with speaking and breathing, but can be prevented by administering medicinal iodine or adding iodides to dietary salt. Iodine deficiency is most marked in isolated villages in the Himalayas, the Andes, and other mountainous districts, where it probably affects more than 1,000,000 people and is difficult to prevent. Iodized salt was not used before the 1930s, and the Midwestern part of the United States was known as the "goitre belt" because of the low iodide content of its drinking water.

Trace elements include copper, cobalt, zinc, manganese, selenium, and molybdenum, which are all present in the body and probably essential nutrients serving as catalysts or components of organic molecules. Diseases attributable to lack of these elements in animals are known to veterinarians; if similar diseases occur in man, they are rare, although undoubted cases of zinc deficiency have been reported in children in villages in the Middle East. Cobalt is a component of vitamin B_{12}, a deficiency of which may lead to pernicious anemia.

Vitamins. These are organic compounds that the body is unable to synthesize and which, therefore, must be supplied in the diet or manufactured in the gut by the intestinal flora. Many of them function as components of enzyme systems. Vitamins were originally identified by letters as each new one was discovered, but this method of nomenclature is being replaced as the vitamins become known by their chemical names. Five major diseases are associated with dietary lack of vitamins: (1) beriberi and thiamine (vitamin B_1), (2) pellagra and nicotinamide (niacinamide), (3) scurvy and ascorbic acid (vitamin C), (4) xerophthalmia, a type of dry conjunctivitis leading to keratomalacia, or softening of the cornea (carotene or vitamin A), (5) rickets or osteomalacia in adults (calciferol or vitamin D).

Vitamin deficiency diseases

These were major diseases in the 19th century and were all "man-made" in that they arose as a result of changes in food habits or the way of life. During the last 70 years most of them have ceased to be of major importance, although small outbreaks and isolated cases still occur.

Keratomalacia, however, caused by severe deficiency of vitamin A, leads to permanent blindness in children, and appears to be on the increase. It has been estimated that it causes blindness in 20,000 children every year. A source of vitamin A is milk, which the child receives first from the breast (or "formula") and then from dairy animals. The vitamin also occurs in fish-liver oils, butter, egg yolks, cheese, and certain vegetables. In poor tropical countries where the supplies of dairy milk and other sources of carotene are inadequate, children usually continue to receive a little breast milk for two to three years. This may not provide sufficient vitamin A to prevent xerophthalmia and the associated night blindness caused by lack of the vitamin's action in the retina of the eye, but it usually prevents irreversible keratomalacia. The latter may occur after an infant has been weaned early onto a diet totally devoid of vitamin A. This is occurring more frequently in the growing cities in the tropics where there are many pressures on migrant women from the countryside to adopt Western ways of life, including early weaning of infants. These tragic cases of blindness arise from lack of knowledge of mothercraft and the unavailability of suitable infant foods.

Vitamin B_{12} and folic acid are two vitamins necessary for the normal development of the red blood cells and deficiency of either or both of these vitamins leads to anemia. A primary dietary vitamin B_{12} deficiency is rare, but a secondary deficiency caused by the failure of the stomach to secrete a factor necessary for its absorption is responsible for the disease known as pernicious or Addison's anemia. Folic acid deficiency leads to a similar anemia and may be secondary to chronic gastrointestinal disorder. It occurs commonly as a primary dietary deficiency in many poor tropical countries. Pregnancy increases the requirements of folic acid.

Table 3: Recommended Daily Dietary Allowances, 1968 Revisions*

*The allowance levels are intended to cover individual variations among most normal persons as they live in the United States under usual environmental stresses. The recommended allowances can be attained with a variety of common foods, providing other nutrients for which human requirements have been less well defined. †Entries on lines for age range 22–35 years represent the reference man and woman at age 22. All other entries represent allowances for the midpoint of the specified age range. ‡Assumes protein equivalent to human milk. For proteins not 100% utilized factors should be increased proportionately.

Riboflavin is a vitamin frequently lacking in the diet of people on inadequate cereal diets, and deficiency is associated with degenerative conditions of the skin and mucous membranes.

Fat-soluble vitamins

Vitamin K is essential for the production in the liver of prothrombin, a substance necessary in the process of blood coagulation. Deficiency probably never arises as a primary dietary defect, but, because the vitamin is fat soluble, it occurs when there is a failure to absorb fats from the small intestine, *e.g.*, in obstructive jaundice or with frequent ingestion of mineral oil. Vitamin K deficiency may lead to frequent and massive hemorrhage.

Vitamin E (tocopherol) is required by man, but there are few records of dietary deficiency. The vitamin has been recommended as a panacea for many ailments, but claims have seldom been supported by reliable evidence.

The dietary intake of each vitamin required to prevent the appearance of a deficiency disease can be measured with some precision. These are minimum requirements and much less than the amounts present in a "good diet"; they do not allow a reserve to be built up in the tissues. It is possible by various blood and urine tests to assess these reserves; when they are found to be low, a state of subclinical vitamin deficiency is said to exist. It is also claimed that high levels of vitamin intake are associated with high levels of health and in particular with freedom from infectious diseases. The evidence that vitamins promote health in any way apart from preventing deficiency diseases has not been universally accepted. The recommended intakes or allowances of vitamins (Tables 2 and 3) carry a safety margin which allows for a wide range of individual needs. Intakes may be less than recommended without any obvious effect on health; high intakes are of no benefit and may be dangerous in the case of the fat-soluble vitamins A and D (see VITAMIN).

CLASSES OF FOODS

Foods can be divided into nine classes: (1) cereals and cereal products, (2) starchy roots, (3) pulses and legumes, (4) vegetables and fruits, (5) sugars, preserves, and syrups, (6) meat, fish, and eggs, (7) milk and milk products, (8) fats and oils, and (9) beverages. Each of these contributes some of the nutrients essential for the makeup of a good diet.

Cereals. Rice, wheat, maize, and various millets are the main foods of man. In many poor communities over 75 percent of the dietary energy (calories) comes from cereals; this proportion falls with increasing prosperity, though even among the affluent it is seldom below 25 percent. The main source of this energy is starch, but from 9 to 14 percent comes from protein. Cereals are thus a good source of protein. The mixture of amino acids in different cereal proteins, however, is not the same, and any diet in which the protein is derived mainly from a single cereal is likely to be deficient in one or more essential amino acids and thus unsatisfactory, especially for growing children. One protein, however, can supplement another, and thus a suitable mixture of cereals may provide a sufficient amount of all essential amino acids. Cereals contain little fat and hence diets with a high proportion of cereals are likely to be deficient in the fat-soluble vitamins A and D. Cereals likewise contain no vitamin C, but the outer layers of the grain and the germ are rich sources of the water-soluble B vitamins: thiamine, niacin, and riboflavin. Unfortunately, these are largely removed in modern milling processes. White rice and white wheat flour are nutritionally inadequate; essential B vitamins must be provided by other foods or as supplements to the cereal product (*i.e.*, "fortified" cereals). Cereals contain calcium and iron, but not always in forms readily absorbed from the gut.

Cereal protein

Starchy roots. Potatoes, cassava, and yams are easily cultivated and are valuable as cheap sources of energy. Their nutritive value, in general, resembles that of cereals, but their protein content is lower. Protein deficiency may be common in tropical communities in which the staple food is cassava or yams. The potato, however, provides some protein—less than cereal does—but also contains some vitamin C and the pigment beta-carotene, convertible in the body into vitamin A. In 1910 a Danish investigator lived for a whole year on a diet comprised solely of potatoes and kept fit and well. Were it not for the remarkable nutritive value of the potato, the poor natives of the Andes and of Ireland might not have survived during certain periods of their history.

Pulses and legumes. Peas and beans, the seeds of *Fabaceae*, resemble the cereals in nutritive value but have a slightly higher protein content and, since they are not subject to milling, are a good source of B vitamins. They are thus a valuable supplement to a cereal diet, especially in tropical or subtropical countries; moreover, they, particularly the soybean, are also valued for their taste.

Vegetables and fruits. Vegetables and fruits all have similar nutritive properties. Because 70 percent or more of their weight is water, they provide comparatively little energy or protein, but many contain vitamin C and carotene, two nutrients which cereals lack. Fresh fruits, particularly the citrus variety, and their juices, are usually rich in vitamin C, but vegetables are an uncertain source, especially as this vitamin is easily destroyed in cooking. Vegetables and fruits contain indigestible cellulose, which adds bulk to the intestinal content and is useful in preventing constipation. Vegetables also provide calcium and iron but often in a form which is poorly absorbed.

Sugars, preserves, and syrups. The average consumption of sugar in the United States, United Kingdom, and other affluent nations is more than two pounds per person per week, and provides more than 20 percent of the energy intake of most individuals in these countries. Sugar, however, contains no protein, no minerals, and no vitamins, and thus has been called a source of "empty calories." Diets containing a large proportion of sugar may be low in essential nutrients. High sugar intake is associated with dental caries, diabetes mellitus, and atherosclerosis. The evidence for the causal relationship is strong in the case of dental caries, much disputed with respect to diabetes and atherosclerosis.

Advantages and disadvantages of dietary sugar

Sugar is, of course, an excellent preservative, and jams contain from 30 to 60 percent. Honey and natural syrups (*e.g.*, maple) are composed of more than 75 percent sugar and only extremely small amounts of other nutrients. Toffees, candies, and boiled sweets may be 50 to 90 percent sugar.

Meat, fish, and eggs. Meats generally consist of about 20 percent protein, 20 percent fat, and 60 percent water; the amount of fat present in a particular portion of meat varies greatly, not only with the kind of meat—pork, beef, lamb, etc.—but also with its quality; the "energy value" varies in direct proportion with the fat content. Meat is valuable for its protein, which is of high biological value. Meat also is a good source of iron and contains nicotinic acid and riboflavin, but, except for liver, little vitamin C or vitamin A. Most meats have similar nutritive value. Although many peoples are particular about the meats they eat, and many have religious customs prohibiting their eating certain meats or may be revolted by the idea of eating offal, snails, guinea pigs, frogs, locusts, lizards, snakes, dogs, and monkeys, the fact is that all of these are nutritious.

Beef teas and beef extractives, on the other hand, may be to some pleasant drinks that stimulate appetite, but they provide few nutrients.

Fish and other seafoods are excellent sources of protein and many species contain oils rich in vitamins A and D. Small fish (*e.g.*, sardines), if ingested whole, are also a source of calcium.

Eggs have a deservedly high reputation as a food. The white is protein and the yolk is rich both in protein and vitamin A. Eggs also provide calcium and iron; egg yolk, however, has a high cholesterol content.

Milk and milk products. Milk serves as a complete food for the human infant during its early months. Table 4 compares the composition of human and cows' milk, and indicates how rich both are in nutrients, especially calcium. Milk, however, is a poor source of iron and infants kept solely on milk for many months may develop iron deficiency anemia.

The vitamin C present in milk is destroyed by heating (pasteurization), which in many countries is required to prevent the milk from spreading bacterial and other infections. Infants fed solely on boiled milk are likely to develop scurvy unless given fruit juice or other sources of ascorbic acid. Ergosterol in milk may be converted to vitamin D by irradiation of the milk.

There are a large number of preparations of cows' milk suitable for feeding infants. Those made by firms of repute are excellent; others, sold to the rapidly growing urban population in the tropics cannot always be recommended; if made from skimmed milk they contain no fat-soluble vitamins. If these are his sole diet, an infant may go blind from keratomalacia unless vitamin supplements are also given. Skimmed milk as a supplement for children on mixed diets is a valuable additional source of protein (casein) and calcium.

Table 4: The Composition of Human and Cows' Milk
(all values per 100 g)

	human	cows'
Calories	70	66
Carbohydrate (g)	7	5
Protein (g)	2	3.5
Fat (g)	4.0	3.5
Calcium (mg)	25	120
Phosphorus (mg)	16	95
Iron (mg)	0.1	0.1
Vitamin A (i.u.)	170	150
Vitamin D (i.u.)	1.0	1.5
Thiamine (μg)	17	40
Riboflavin (μg)	30	150
Nicotinic acid (μg)	170	80
Ascorbic acid (mg)	3.5	2.0

Cows' milk is not suitable for extremely young infants because its protein concentration is too high. It can be "humanized" by dilution and the addition of sugar. Preparations are also available in which the butterfat has been replaced by a preparation of vegetable oils that closely resembles the fat present in breast milk. Babies thrive on such milks, or "formulas," but there is no scientific evidence that the normal infant gains extra benefit from the fat substitution that inevitably makes the preparations more expensive.

Infant "formulas"

It would be difficult, but not impossible, to rear a healthy child without milk, after weaning. Experimental nutritional data shows how milk benefits toddlers and school children. For healthy adults milk may be a pleasant but not necessarily an essential food. If large quantities are ingested, the intake of fats containing unsaturated fatty acids becomes high and this could possibly predispose to arteriosclerosis.

Cheese making is an ancient art, formerly used by farmers' wives to dispose of surplus milk. There are many local varieties, all nutritious and especially rich in protein and calcium.

Sour milks are prepared by fermentation, using as a starter a preparation containing *Lactobacillus acidophilus*, which converts lactose to lactic acid and prevents the growth of pathogenic organisms. Sour milks are not only hygienic but also nutritious.

Fats and oils. The fats most used by man are butter, suet from beef, and lard from pork. Important vegetable oils include olive oil, groundnut oil, coconut oil, cottonseed oil, sesame or gingelly oil, mustard oil, red palm oil, and corn (maize) oil. All these are high in calories. Only butter (other than the previously mentioned fish-liver oils) contains any of the vitamins A and D, but red palm oil does contain carotene which is converted to vitamin A in the body. All natural fats and oils serve as sources of "empty calories" and a large intake may depress the appetite for more nutritious foods. Some fatty acids, however, are essential to the human body's metabolic reactions, and some intake of absorbable fat is necessary for the absorption of the fat-soluble vitamins.

Margarines, vanaspatis, and other artificial fats are prepared by hardening mixtures of vegetable oils and also whale oil. Fat-soluble vitamins are usually added and some margarines are nutritionally equivalent to butter.

Beverages. Although most adults drink one to two litres (about one to two quarts) of water a day, much of this is in the form of coffee, tea, fruit juices, "soft drinks," beer, wines or spirits, or other liquids. In general, these are appreciated more for their taste and the substances they contain, or for their effects, than for their nutritive value. Fruit juices are, of course, useful for their vitamin C content and, being rich in potassium and low in sodium, are valuable in such therapeutic diets. Coffee and tea by themselves are of no nutritive value, but may be a vehicle for large intakes of sugar, milk, or lemon. The alcohol in beer, wines, and spirits can serve as a source of energy. Beer contains two to six percent alcohol, natural

Ethyl alcohol and "empty calories"

wines ten percent, and most spirits just over 30 percent. Since ethyl alcohol has an energy value of seven kilocalories per gram, very significant amounts of energy can be obtained from alcoholic drinks. With one or two exceptions, they contain no nutrients and are only a source of "empty calories." One exception, so-called country beer, may be an important source of the B vitamin group for some South American and African communities. The only vitamin present in significant amounts in beer from a brewery is riboflavin. Wines are devoid of vitamins, but sometimes contain large amounts of iron, probably acquired from iron vessels used in preparation, especially of cheap wine. It is possible for excess iron to be absorbed and stored in the liver where it may contribute to toxic manifestations.

RECOMMENDED INTAKES OF NUTRIENTS

Public Health nutrition involves standards of physiological and metabolic requirements that can be used to plan, within variable limits, nutritional policies, to assess the significance of surveys of dietary intakes, and to draw up ration scales; *e.g.*, for the armed services and those who live in such institutions as boarding schools, hospitals, prisons, extended care facilities, and the like.

The Food and Nutrition Board of the United States National Academy of Sciences–National Research Council, the United Kingdom Department of Health and Social Security, the United Nations Food and Agricultural Organization, and other national bodies have drawn up tables of daily nutrient allowances. Tables 3 and 4 set out the British and U.S. standards. Other authorities differ, mainly in detail, and some of these differences are considered below following a statement of four general points:

1. The figures are for recommended intakes and are not necessarily requirements.
2. Individuals vary significantly in their need for nutrients, notably for vitamins. The figures in Tables 2 and 3 are intended for application to large groups in which individual differences are averaged out.

Allowances versus requirements

3. The recommendations in Tables 2 and 3 are higher than the minimal requirements for the prevention for deficiency diseases and provide safety margins intended to cover most individual variations and also to prevent ill health associated with subclinical deficiency states. Even if an individual had an intake 25 percent or more below the recommended figure for any nutrient, it need not necessarily follow that he would suffer from malnutrition. In the present state of knowledge the correct size for the safety margins can be little more than a guess and there are legitimate differences of opinion. Both environments—internal and external—exert a great effect on individual nutrient requirements.
4. The requirement for energy is in a category different from that of most other nutrients, since the body has no means of disposing of an excess other than by converting it into fat and storing it in depots. Excess protein can be converted into carbohydrate and keto-acids and utilized as fuel or converted to fat and stored as such. An excess of minerals is rejected by control mechanisms regulating absorption in the small intestine and passed out in the feces. Excess intake of any of the water-soluble vitamins is rapidly excreted in the urine. There is no way by which the body can dispose of excesses of the fat-soluble vitamins A and D, which are stored in the liver and can give rise to dangerous toxic effects. Long ago Eskimos learned that polar bear liver was poisonous to man, and it is now known that this is because of its high vitamin A content. Poisoning with vitamins A or D is extremely rare with most natural foods, but it can occur among children overdosed with concentrates.

Energy requirements. The body needs dietary energy in amounts equal to the energy expended in the external work of daily physical activities, in the internal work of tissue maintenance, for repair in the case of disease or injury, and, in the case of children, for growth.

The French chemist, Antoine-Laurent Lavoisier, initiated the quantitative study of energy exchange in animals. He constructed a small calorimeter in which he was able to place a guinea pig and calculate the animal's heat output from measurements of the rate at which ice in the calorimeter melted. Lavoisier also measured man's rate of oxygen consumption and showed that it rose with exercise. During the 19th century numerous calorimeters for small animals were constructed, as were respiration chambers for humans, which allowed the rates of oxygen utilization and carbon dioxide release to be measured. It was not until the end of the century, however, that a calorimeter chamber was constructed in which a man could live for three or four days. During this 72–96-hour period all the energy expenditure could be measured as heat and equated with the net energy intake (energy in food minus energy in feces and urine). In this way the law of conservation of energy in man was demonstrated. There is, of course, no doubt that the human body operates within the limits imposed by the law of conservation of energy. Energy output is related to the rate of oxygen utilization, with one litre of oxygen equivalent to approximately 4.8 kilocalories of energy.

Quantitative studies in energy exchange

Measurements of the heat output of man, direct calorimetry, are difficult. By contrast, measurements of oxygen consumption by indirect calorimetry are relatively easy and can be made on humans in their normal day-to-day environment, at home, and at work in offices, factories, fields, and mines, and during recreations, including most sports.

Basal metabolism

The energy expended for maintenance at rest, known as the basal metabolism, amounts to about 1.25 kilocalories per minute for a man weighing 65 kilograms (one pound = 2.2 kilograms) and 0.90 kilocalorie per minute for a woman weighing 55 kilograms. The basal metabolism, if expressed per unit of body weight or per unit of surface area, as has been the tradition for a long time, appears higher in men than in women. This is so because women have a large store of body fat that is metabolically inert. The basal metabolism per unit of lean body mass is the same in the two sexes.

The metabolic rate is raised by as much as 30 percent after a meal, if the meal is rich in protein. This is known as the specific dynamic action of protein and is due in part to the work of secretion of the digestive juices and in part to chemical processes, mainly in the liver, involved in the metabolism of amino acids and other absorbed products of digestion.

The metabolism of a seated person usually is not raised by more than 50 percent above the basal level. The arms are light, and little physical work is involved in writing or sewing. Although the metabolism of the brain is high and accounts for 20 percent of the resting energy expenditure, it is not raised significantly by mental activity.

Energy expenditure is increased fourfold, up to about five kilocalories per minute, by a brisk walk and is usually between two and four times the resting rate during the accomplishment of such light work as most assembly-line labour in industry, domestic activities, painting and carpentry, and in participation in recreations such as golf or bowling.

An increase of up to sixfold or 7.5 kilocalories per minute constitutes moderate work and is characteristic of most pick-and-shovel jobs, gardening, tennis, and bicycling. Work involving energy expenditures above this is graded as heavy. Although many jobs in coal mining, lumbering, and the steel industry involve periods of strenuous work, relatively few persons in a modern industrial society do significant amounts of continuous heavy work. Cross-country skiing is the recreation with one of the greatest demands for energy and involves rates of 15 kilocalories per minute, or even more, for long periods.

Most individuals in urban societies have their days divided into three eight-hour portions. Normally, one is spent in bed and asleep, one at work, and one in recreation or in other nonoccupational activities. The period in bed at approximately basal rates involves about 500 kilocalories of energy. A rough guide for occupational work is as follows: sedentary (about 900 kilocalories per eight-hour period), including office workers, drivers, pilots, teachers, journalists, clergy, doctors, lawyers, architects, and shop workers; and moderately active (about 1,200 kilo-

calories per eight-hour period), including virtually all engaged in light industry and assembly plants, railway workers, postmen, joiners, most farm labourers, and builders' labourers.

A man's energy expenditure, however, is determined in an urban society more by how he uses his spare time than by the nature of his job. Nonoccupational activities may range from 800–1,800 kilocalories per eight-hour period. Energy requirements from food may vary from 2,200 kilocalories per day for sedentary activities to more than 4,000 for the very active. These figures are generalities and cannot be applied to peasant farming, still the way of life for the majority of the world's male population. Here there may be marked seasonal variations with men "very active" at seed and harvest time, and "sedentary" during some periods in between. Surveys in Africa and Asia indicate that a yearly average shows most peasants to be moderately active.

Corresponding figures for women show a total of about 2,200 kilocalories per day. The range of expenditure is not as wide as for men, and the great majority of women need food providing from 1,800 to 2,400 kilocalories per 24-hour period.

Much of the work done by humans consists in contracting muscles to move the body or its parts. Energy expenditure during walking, for example, is directly related to body weight, and the basal metabolism to body size. So, in theory, big people should require more food than small people. The theory does not always hold true, and some large men and women are less physically active than smaller ones and thus have somewhat lower energy requirements. On the other hand, athletes, large and small, have required food (energy) intakes far in excess of their size counterparts in less active occupations. It should be borne in mind, however, that exercise alone is not, by far, the most important factor in weight loss. The few glasses of beer consumed at the end of a golf game more than replace the calories used in playing the game.

As age advances, physical activity is curtailed and the need for dietary energy is reduced. Tables 2 and 3 indicate what may be considered normal requirements at different ages, including childhood, and also the additional needs for pregnancy and lactation, but, again, there is great individual variation.

Protein requirements. As long ago as 1909 it was shown that adult men on year-long experimental diets providing only 40 grams of protein daily remained in good health. The minimal protein requirement, as estimated by the amount of dietary protein required to maintain nitrogen balance (*i.e.*, replacement of body protein constantly broken down) is of the same order. Most Western diets provide at least twice this amount, and there is no doubt that such diets contain a great surplus of protein. The recommended intakes of protein given in Table 2 provide 10 percent of the energy input. Several authorities show lower figures, which are physiologically sound but appear to be impractical since it is difficult to prescribe low-protein diets that are nutritionally acceptable and provide as well as the necessary amounts of other nutrients.

Comparative requirements for calcium, iron, phosphorus, magnesium, and iodine

Mineral requirements. The United Kingdom recommended intake of calcium is 500 milligrams daily, which is in line with the United Nations recommendation, but lower than the United States figure of 800 milligrams. Good Western diets, on the average, provide 1,000 milligrams, over half of which usually comes from milk. Many Eastern diets provide less than 500 milligrams but are not associated with any signs of calcium deficiency, and all the evidence points to the fact that about 500 milligrams is ample.

The recommended iron intake for a woman is 15 milligrams daily in Table 2, whereas the United States statement of requirement is 18 milligrams and the United Nations ranges from 14 to 28 milligrams, depending on the protein content of the diet. The higher figures are physiologically sound in that these intakes are necessary to meet the large menstrual losses occurring in some 5 to 10 percent of women. It is neither easy nor inexpensive to provide diets containing 15 milligrams of iron, and higher figures may be unrealistic, unless foods are artificially enriched with iron—a technical problem not yet satisfactorily solved. It has been recommended that the best way to prevent iron-deficiency anemia in women with large menstrual losses is with medicinal iron.

In addition the United States daily recommendation covers phosphorus, 0.8 milligram; iodine, 140 micrograms; and magnesium, 350 milligrams. Few, if any, natural diets do not meet the requirements for phosphorus and magnesium. It has been pointed out that endemic goitre caused by iodine deficiency is widespread in some areas. Prevention is possible by adding iodides or iodates to table salt or by mass medication with a single injection of iodized oil.

Vitamin requirements. The recommended intakes in Table 2 for all of the vitamins, except vitamin C, are almost identical with those of the United States and United Nations. All provide a good margin of safety above the minimal requirements and are compatible with practical dietetics. In addition, United States authorities recommend vitamin E, 30 units; folic acid, 400 milligrams; pyridoxine (vitamin B_6), two milligrams; and cyanocobalamin (vitamin B_{12}), five micrograms.

There is little doubt that 10 milligrams daily of vitamin C is more than ample to prevent scurvy. Most British diets provide about 30 milligrams daily, and many much less. United States authorities have been slowly reducing their recommendation, which now stands at 60 milligrams daily. There is still disagreement on the matter of vitamin C intake, and in 1970 a Nobel Laureate, Linus Pauling, published a book on vitamin C in which he recommended a daily intake of relatively large amounts. His arguments were considered by some to be only theoretical; others appear to agree.

HUNGER AND FEEDING BEHAVIOUR

Man, like other animals, evolved in an environment in which food was scarce. Hunger is a sensation associated with various physiological changes that stimulate the drive to search for food. Feeding behavior depends on the activity of nerve centres in the hypothalamus, situated at the base of the brain. If, in a rat or other experimental animal, the medial hypothalamic nuclei are destroyed, the animal will begin to eat voraciously as soon as it has recovered from the anesthetic, and in a few weeks will become obese. If the lateral hypothalamic nuclei are destroyed, however, the animal may refuse to eat and, unless force-fed, may die of starvation. These effects are assumed to be due to the destruction of a "satiety centre" on the one hand and a "feeding centre" on the other.

Types of hunger stimuli

The stimuli activating the feeding centre may be speculated as being: (1) chemical; *e.g.*, a rise in the level of free fatty acids or a fall in the level of glucose in the blood; (2) nervous; *e.g.*, the hunger contractions that occur in an empty stomach; or (3) thermal; *e.g.*, the slight fall in the temperature of the blood that may occur in starvation. Satiety may be signalled by gross distension of the stomach and alimentary canal. (This, however, does not explain hunger in a gastrectomized individual.) The capacity of a hungry man for feeding is sometimes enormous. Soldiers after a period on half rations have been observed to eat 9000 kilocalories in a day, the equivalent of nine large meals. There are many tales of how quickly a group of Africans can dispose of the meat on a dead elephant. On the other hand, individuals deprived of food for long periods of time may require days or weeks of semisolid feeding before being able to eat a normal meal.

It is only relatively recently in human history that large numbers of people have been able to obtain their food with little or no physical effort. New sources of power do the work formerly carried out by human muscles, and now large numbers of people spend the greater part of their days sitting. Members of the "affluent society" are seldom really hungry, although they may have specific appetites; usually their feeding times are determined by social customs and convenience rather than by physiological need, and they readily become obese.

The nature of the control system that regulates the

Short- versus long-term calorie requirements

amount of energy reserve in the adipose tissue and, in turn, the body weight is not understood. Over long periods the system appears to be precise. An individual's weight, for example, may remain in the range 60–65 kilograms for 40 years, during which time he will have eaten about 20 tons of food. Yet, control over short periods is imprecise. In many field surveys the daily energy intake in food and the energy output in physical activity have been measured simultaneously. The results indicate that few people adjust their food intake to their needs on a daily basis, but nearly all do so over about a week. It is not unusual to accumulate a surplus or deficit of 2000 kilocalories, the equivalent of about three normal meals. Dietary habits are sometimes abruptly changed at the weekend. It is difficult to see how any of the physiological changes associated with hunger could be stimuli for coordinating the long term regulation of the reserves of energy. Presumably, the centres in the hypothalamus receive information about the size of the energy reserve in the fat stores, but how this information is conveyed is not known.

The regulatory mechanism is apparently altered in pregnancy. It is normal for a pregnant woman's weight to rise by about 12 kilograms in the 40 weeks of gestation; of this about four kilograms is fat in the adipose tissue—an extra energy reserve that presumably has survival value and is lost during lactation. Possibly the hormones responsible for the maintenance of the fetus in the uterus also modify the setting of the energy balance in pregnancy. Similar steroid hormones might have a regulatory function in the nonpregnant state (see also HORMONE).

There is no apparent marked difference, however, between functions of the endocrine glands in healthy people, both thin and fat. There is also no explanation of how some people remain thin while eating well and without restraining their natural appetite; others readily become obese, unless they diet continuously. Writers on this subject usually assume that the diet is adjusted to meet the demands of physical activity; the reverse possibility that physical activity is adjusted to meet the dietary intake is seldom discussed. Children obviously have a drive to play as well as a drive to eat. In contemporary urban society, opportunity for physical recreation is greatly restricted, and lack of exercise can contribute to the condition of obesity.

It is important to appreciate how little the regulating system has to be offset for obesity to follow. Thus a man who, without changing any of his other habits, began to eat each day an extra half slice of bread at breakfast or started to drive his car to work instead of walking briskly for five minutes each way, would put himself in energy surplus by about 50 kilocalories daily; after a year he theoretically would have gained over 2 kilograms in weight and in 10 years would be seriously obese.

THERAPEUTIC DIETS

Therapeutic diets may be restorative and designed to restore losses resulting from wasting disease. Alternatively, they may be designed to remove previous excess or to reduce the load on the functional capacity of an organ or on tissue damaged by, or susceptible to, disease.

Restorative diets. Any severe infectious disease or trauma from injury or major surgery results in wasting. Once the infection is overcome and the injury repaired, convalescence is aided by adequate nutrition. If infection persists, or if wounds heal slowly, appetite is often impaired, and the patient will not receive adequate nutrition without medical assistance. Nutritional problems are also present when patients are too ill to feed themselves, or are unconscious, or have diseases affecting the mouth or alimentary canal that interfere with the intake or retention of food.

Nutrition and the repair of injury

When normal feeding is possible but appetite is impaired, much can be accomplished by the use of food concentrates rich in protein and energy. Soups, souffles, jellies, cakes, and ice creams, for example, can be enriched with dried milk, casein, fat emulsions, or sugar. Supplements of vitamin preparations and minerals also may be supplied.

When normal feeding is difficult or impossible, nutrition can be maintained in a number of ways: by feeding through a tube passed into the stomach through the nose (nasogastric feeding), through a tube inserted surgically into the stomach or intestine, or into a vein. For intravenous feeding, mixtures of amino acids, fat emulsions, simple sugars, vitamins, and other substances may be used. A patient may be nourished in one or other of these ways for many weeks.

Restrictive diets. *Low-energy diets.* All reducing regimens owe what success they achieve to restricting the dietary energy below the level of energy expenditure. If a person is not more than 10 percent overweight, then weight loss may usually be achieved by reducing intake of carbohydrates, fats, and alcoholic beverages. If an individual is more than 10 percent overweight, it is best to get medical advice. Most obese people, if sufficiently motivated, can keep to a 1,000 kilocalories daily diet, and on this should lose a little over a kilogram (about two pounds) per week. Such a reducing diet should contain sufficient meat, fruit, and vegetables to ensure that needs for protein, minerals, and vitamins are met. This means restriction on other foods, particularly those rich in carbohydrates. A good hospital dietitian can advise an individual how best to achieve this in relation to his normal dietary habits. People need constant advice and encouragement and, if they are outpatients, should see their physician at regular intervals. Those who are seriously overweight (more than 15 kilograms in excess, even in someone young and otherwise healthy) should not undertake starvation diets without strict medical supervision.

A low-calorie diet greatly benefits overweight patients with diabetes or high blood pressures. Indeed, for many patients with these diseases, such a diet may give marked relief from symptoms and, in some cases, no other therapy may be needed.

Low-protein diets. Dietary protein restriction is indicated when disease of the kidney impairs its ability to excrete urea and other nitrogenous waste products. A diet providing 45 grams of protein daily is frequently recommended when there is evidence of renal failure. The reduction in protein intake substantially lowers the load on the kidneys but still provides sufficient amino acids to meet minimal requirements. Such a diet can be made appetizing and attractive; kidney patients can live on it for years. Further protein restriction is possible and a diet that provides only 20 grams of protein daily is sometimes prescribed for individuals with severe renal failure. Some manage well with this diet, and its use may lead to improvement in renal function, but for others it is not only unappealing but also provides insufficient dietary protein for maintenance of tissue integrity. Whether or not manipulation of the diet in treatment of kidney disease is useful depends to a great extent on the facilities for other methods; *e.g.*, hemodialysis, for treating the renal failure.

Low-salt diets. Wherever there is edema, or an accumulation of fluid in the tissues, an excess of salt in the body fluids must be suspected because excess sodium chloride "holds back" tissue fluid. In patients with cardiac failure, or kidney or liver disease, edema can often be markedly reduced by severely restricting salt intake. Salt-free, or extremely low-salt-content diets are most unpleasant. There are now available, however, salt substitutes the flavour of which closely resembles that of table salt, and low-salt diets, coupled with the use of diuretics to increase the flow of urine and consequently lower the body water content, are effective in promoting excretion of the excess fluid. All who are susceptible to edema are usually advised to restrict their salt intake by taking no table salt and avoiding salt-rich foods, such as cured meats, cheese, and most sauces, and to use canned goods processed without salt.

Restricting the salt intake has a tendency to lower blood pressure, even in health, and is part of the regimen for most patients with high blood pressure.

Low-fat diets. Before fat can be utilized by the body it first has to be emulsified and digested, for which bile and pancreatic juice are required (see DIGESTION, HUMAN).

Diseases of the pancreas, liver, and biliary passage may impair digestion, causing fat to appear in the feces, a condition known as steatorrhoea. In these circumstances a low-fat diet is needed. It is not difficult to reduce the fat intake from the normal figure of about 100 to 50 grams per day and to keep the diet appetizing. Under certain circumstances, more severe restriction may be needed, and it is sometimes difficult to prepare diets providing a daily content of only 25 grams of fat. When a patient is on a low-fat diet, a supplement of fat-soluble vitamins is usually given.

Low carbohydrate diets in diabetes mellitus. As already mentioned, a low-energy diet is of benefit to diabetics who are obese. All diabetic patients maintain better health if they restrict their diet so that their body weight is a little below rather than above their ideal weight. There is no firm agreement as to whether the carbohydrate content of a diabetic diet should be specifically reduced, but in most the proportion of calories derived from carbohydrates is kept low.

Low saturated fatty-acid diets. Reducing the intake of fats containing a large proportion of saturated fatty acids (*e.g.*, animal fats) or replacing them in the diet with fats high in unsaturated fatty acids (*e.g.*, vegetable oils) lowers the level of cholesterol in the blood plasma. As atherosclerosis (deposition of lipid materials within the arteries) is associated with a high level of plasma cholesterol, vegetable-oil diets have been tried to see whether they might prevent the appearance or reduce the progress of clinical manifestations of this disease. The results have been equivocal. Physicians now warn patients with evidence of atherosclerosis of the dangers of excess intakes of butter, cream, or fat bacon.

Gluten-free diets. Celiac disease, which usually begins in the first three years of life, is caused by a sensitivity of the small intestine to gluten, a mixture of proteins present in wheat and rye. The affected individual has chronic diarrhea, sore tongue, frothy, fatty stools, and a blood picture similar to that of pernicious anemia. These symptoms disappear when he is put on a diet from which gluten is completely excluded. Most celiac or sprue patients must remain on a gluten-free diet throughout life, although some affected children, as they grow up, acquire a tolerance for gluten and can then resume normal diets.

Special diets for inborn errors of metabolism. Phenylketonuria and galactosemia are two examples of these relatively rare diseases (see METABOLISM, DISEASES OF). In the former there is a failure to metabolize the amino acid phenylalanine, and in the latter, the sugar galactose, a constituent of lactose in milk. Children with either of these diseases can be reared successfully through the use of synthetic diets that contain little or no phenylalanine or galactose, respectively. Commercial preparations are available.

Many elaborate dietetic regimes, formerly often prescribed, are now known to have no scientific basis. There is no specific dietary treatment, for example, for either peptic ulcer or gout; *e.g.*, milk diets and low-purine diets as cures are now part of medical history rather than practice. This does not mean, however, that patients with these diseases need no dietary help. Their condition may have been aggravated (rather than caused) by faulty feeding habits and choices of foods "incompatible" with their ailment. The celebrated spas of Europe acquired their reputation because they imposed on patients a disciplined manner of life with restrictions on dietary excess. Many patients today might require similar regimens.

PUBLIC HEALTH NUTRITION

Historically, in times of famine government held the responsibility of feeding the people; during prosperity, each man had been expected to grow sufficient food for his family or to work for wages to purchase it; charitable persons fed the sick and the needy. Only within the 20th century have governments undertaken large-scale measures to prevent malnutrition. Wars, strangely enough, have played an important role in the evolution of this policy. In the 19th century, for example, malnutrition had become so rife that many industrial communities were not able to produce sufficient young men with the physique necessary for the armed services; moreover, the civilian population had not the working capacity needed to sustain wartime rates of production. Governments drew up wartime nutrition policies, many features of which have survived in peacetime with great benefit to the community. The enormous growth of the food industries has been beneficial to health, due principally to the cooperation of manufacturers and governments in ensuring that products are of acceptable standards. The rapid population growth, especially in many tropical countries, together with the increasing migrations from the countryside to the towns, has raised a number of public health problems concerned with nutrition. In many countries the importance and urgency of these problems are not yet sufficiently realized, and, even if they were, there are not enough people available with the technical skills to deal with them. The assessment and the mechanisms for handling nutritional problems on a national level are discussed in the paragraphs that follow.

Nutritional surveys. Statistical surveys may assess the nutritional status of a representative sample of a whole community or of a special group; *e.g.*, preschool children, elderly people, or the armed forces. There are three complementary components to such a survey: dietary, clinical, and biochemical.

Assessment of intake

The dietary intake of each individual or family is assessed over a specific period—usually seven days. If possible, every article of food consumed is weighed. If this is impractical, reliance must be placed on an accurate dietary history. Leftover and wasted food must be accounted for. Specially trained persons, preferably dietitians, collect the data. Using appropriate tables of food analyses, intakes of individual nutrients can then be calculated and be compared with tables of recommended allowances.

A clinical examination of persons taking part in the survey is made, in which physicians look for signs known to be associated with malnutrition. The heights and weights of all subjects are recorded and, whenever possible, other anthropometric measurements made; *e.g.*, skin-fold thickness, arm, head, or abdomen circumference.

Biochemical analyses may be made of blood or urine levels of vitamins and other substances that reflect the nutritional state. These levels are then compared with standards of "normality" for indigenous persons.

The execution and interpretation of nutritional surveys is difficult. First, there is the problem of selecting and contacting a statistically representative sample. Cooperation of the subjects is essential, and a sample more often than not may include "problem" families, or individuals who are more likely to suffer from malnutrition. Recommended allowances of nutrients and the biochemical standards of normality have relatively wide safety margins. When significant members of the sample surveyed fail to reach any of the standards, it may be difficult to draw up an unbiased report. In the past, nutritionists have sometimes exaggerated the importance of failure to reach these generous standards. Even experienced school doctors find it difficult to assess clinically the nutritional status of children who show no physical signs of deficiency disease. A single measurement of height and weight is also often misleading. Successive measurements over a period of months, showing whether or not growth is proceeding normally, are good criteria of whether a child or a group of children is receiving adequate nourishment.

In so-called advanced countries, in which many of the population are either well- or over-nourished, a survey of a random sample of the population designed to detect those persons suffering from malnutrition is misleading. Thus, in Britain, for example, it is well known and much publicized that some old people are seriously undernourished. A survey covering many parts of the country showed that over 95 percent of old people received a good diet and, indeed, many were obese. Probably no more than 2 percent of the old people in the country are

undernourished. This means, however, that there are 100,000 who need extra food and care—a sizeable social problem. In prosperous countries, medical authorities receive prompt reports concerning the incidence of infectious diseases such as smallpox, diphtheria, and typhoid, but there is no comparable mechanism for obtaining information about malnutrition.

Prevention of malnutrition. *Agricultural production.* In overpopulated countries a primary nutritional need is to increase production efficiency of the staple cereal. Countries with low yields (Table 5) could triple

Table 5: Yields of Cereals in Various Countries
(quintals per hectare)

wheat		rice	
The Netherlands	44.4	Japan	51.8
United Kingdom	40.5	Italy	48.9
United Arab Republic	26.8	United States	47.6
United States	17.4	Malaysia	25.8
Australia	12.0	Ceylon	19.3
Kenya	11.4	Hong Kong	18.3
India	8.3	Thailand	16.3
Pakistan	8.1	India and Pakistan	15.3
South Africa	7.0	Puerto Rico	6.8
Iraq	4.8

Development of new varieties of staple cereals

or quadruple output by use of modern agricultural techniques. New varieties of wheat (Sonora 64 and Lerma Roja 64), and of rice (IH8), developed largely by Rockefeller and Ford foundations sponsored research, have produced a "Green Revolution," and large areas of India, Pakistan, and other countries are now sown with these new seeds. If plans materialize, the food supply in these countries should be sufficient for two or three decades, during which there might be time to give thought to checking the present alarming growth of population. High yields of staple cereal will free land for the production of other crops—*e.g.*, pulses, vegetables, and fruits—and also for improved animal husbandry. In this way, the quality of a national diet can be improved. Agricultural planning in these areas requires guidance more by human nutritional requirements than by market economy. This is possible only where there is firm governmental direction of agricultural activities and where the government has competent and influential nutritional advisors.

Food processing industries. It would be impossible to feed the populations of the large cities of the world if there were no industries capable of taking in bulk food from the farms and of preserving and processing it for distribution through wholesale and retail outlets. In all the technically developed countries the food industries employ chemists and nutritionists to see that the nutritive value of the raw food is retained as much as possible. In general, canned and frozen foods purchased in a supermarket may be of higher nutritive value than corresponding "fresh" foods in an open small-town market: the latter may have been on sale many days after harvesting. It would also be impossible to preserve and maintain the flavour of foods for the feeding of large populations without the addition, during processing, of chemicals which act as preservatives, emulsifiers, stabilizing agents, antioxidants, flour improvers, sweeteners, and flavouring agents. People in large cities may ingest small amounts daily of 100 such food additives, all of which could be potentially poisonous. The food industry and government agencies are well aware of this danger. Much effort is expended on research to determine safety margins for each additive and safety limits are set forth in legislation.

Food additives

The addition of vitamins, minerals, or amino acids can increase the nutritive value of foods. In many countries thiamine (vitamin B_1), and sometimes other nutrients are added to refined wheat flour to give it a nutritive value more closely resembling whole wheat flour. Margarines are enriched with vitamins A and D and, in general, have a nutritive value similar to that of good quality butter. Many infant foods are enriched with vitamin D and other nutrients. In some countries there is a statutory obligation to enrich some foods, while other foods may be enriched at the discretion of the manufacturers. Enrichment policies normally require legal sanctions in most countries.

Most nutritionists agree that in certain circumstances enrichment is beneficial; *e.g.*, in the manufacture of margarines. There is, however, considerable disagreement about the value of widespread enrichment.

Food rationing. Famine, war, and natural disasters, such as earthquakes and floods, may necessitate some form of food rationing. If rations, regardless of quantity, are provided regularly, the effect on morale may be excellent. A rationing scheme that does not work has a disastrous effect on morale. The supply of one pound of cereal per person per day provides about 1,600 kilocalories, approximately the basal metabolism of an adult man. With such a ration, the health and working capacity of a community does not deteriorate seriously over a period of weeks, during which the emergency may end. It may be necessary in such cases to commandeer as much of the milk supply as is possible for distribution to mothers, young children, and hospitals. Elaborate rationing schemes are possible only when the people have a strong sense of self-discipline and there are good administrative services.

Welfare foods. Young children and pregnant and lactating women form vulnerable groups, in that they are particularly susceptible to the ill effects of a poor diet. In many countries, free or cheap milk and vitamin supplements, sometimes in the form of fish-liver oils and fruit juices, are provided as welfare foods for them. Many well-controlled trials have demonstrated the benefit to young children of a small daily supplement of milk. The United Nations and other international organizations have given millions of tons of dried milk powder for distribution to children in underdeveloped countries.

Community feeding. The nutrition of an impoverished community can sometimes be improved by providing subsidized or free meals from communal kitchens. In times of famine, this is usually the most effective and practical method of giving relief. In the 19th century in Britain a few schoolteachers, realizing that it was impossible to teach effectively a hungry or ill-fed child, stimulated the formation of charitable organizations that provided school meals for needy children. Those organizations have been extended gradually to provide a national service for all children, and there was, early in the 1970s, a standard charge that approximately covers the cost of the food, but a government subsidy covers the cost of preparation and distribution. Children from poor families, about 8 percent of the total, received the meals free. School meals are a valuable preventive medicine measure in all countries. How to provide the most nutritious meals with the small amounts of money available is the enigma of nutritionists in poor countries.

School meals

Industrial workers frequently take their meals in the company canteen or cafeteria, usually run by the firm concerned but in some countries by the government. Management of most large industries appreciates the importance to employees of having nutritious meals readily available at a price well within their budgets.

Nutrition education. In many agricultural societies certain dietary patterns and food habits have been handed down from generation to generation, with traditional recipes and meals prepared today in a fashion similar to that of centuries ago. Some of these are well-balanced nutritionally, but, on the other hand, there are also national and religious taboos which, in times of other dietary restriction, could be dangerous.

Urbanization leads to changes in dietary habits, which inevitably constitute an initial retrogression. In a rapidly growing new town, for example, a fresh supply of traditional foods from the country is limited and costly; low wages can prohibit the family a free choice of food. Malnutrition became widespread in the industrial towns of Europe and North America in the 19th century, and it is becoming even more clearly manifest in the rapidly growing towns of Latin America, Africa, and Asia. Pov-

erty is, of course, largely responsible, but ignorance of food values is also an important factor. Even with a full purse and access to a well-stocked supermarket, it is possible to eat unbalanced meals. There is a degree of malnutrition among the rich as well as among the poor.

All young people, either at school or soon after leaving home and before setting up a home of their own, must know something of the general principles of nutrition and the relative nutritive values of various foods. This may be learned in many ways but perhaps most effectively in a course on health education or general biology.

During the last 50 years there has been a decline in the popularity of breast feeding of infants, particularly in Europe and North America. It is probably of no nutritional significance when there is an adequate supply of infant "formula" preparations, and the mothers know how to use them. A corresponding decline in breast feeding has begun in other parts of the world, notably in the larger cities in the tropics. There, however, suitable alternative preparations are not readily available and the women, for the most part, may be ignorant of methods of child feeding other than at the breast. As a result, early weaning often leads to malnutrition, with accompanying disastrous effects on the child. Clearly, in all countries and in all societies, instruction in nutritional mothercraft is of the utmost importance.

A community is well nourished only if it has proper nutritional services, with available advice of nutrition experts and supported by an informed public opinion. In all countries of the world there appears to be a shortage of nutritional experts. Nutrition is a broad, general subject with many technical and differing aspects. Not all universities are well equipped to teach it.

No governmental or other broad policies can survive without the backing of an informed public opinion. Food and nutrition are topics which attract faddists of all societies, and dietary "cranks" have skillfully propagated many false and dangerous ideas.

Nutritional administration. In developing countries in which malnutrition may be rife, technical resources scarce, and administrative experience limited, it may be valuable to have a central nondepartmental Nutritional Committee able to coordinate work in several departments. Where malnutrition is widespread, much of the effort must be organized and effected at local government or village level.

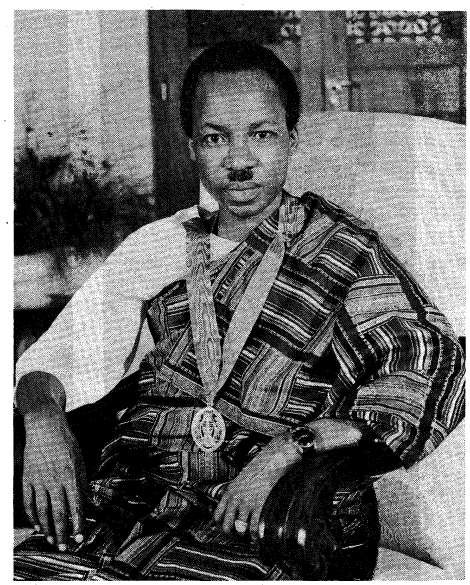
BIBLIOGRAPHY. C.M. TAYLOR and O.F. PYE, *Foundations of Nutrition*, 6th ed. (1966), an excellent introductory textbook; S. DAVIDSON and R. PASSMORE, *Human Nutrition and Dietetics*, 4th ed. (1969), a popular intermediate textbook; M.G. WOHL and R.S. GOODHART (eds.), *Modern Nutrition in Health and Disease*, 4th ed. (1968), the best advanced textbook with special reference to clinical aspects; D.B. JELLIFFE, *Child Nutrition in Developing Countries* (1968), written for field workers in developing countries; J. MAYER, *Overweight* (1968), a popular paperback describing nutritional problems in a prosperous community (written for the general reader, but technically reliable); R.A. MCCANCE and E.M. WIDDOWSON, *The Composition of Foods*, 3rd rev. ed. (1960), a good explanatory text, with tables giving analyses of 663 foods; U.S. NATIONAL RESEARCH COUNCIL, FOOD AND NUTRITION BOARD, *Recommended Dietary Allowances*, 7th ed. (1968); and DEPARTMENT OF HEALTH AND SOCIAL SECURITY, *Recommended Intakes of Nutrients for the United Kingdon* (HMSO, 1969), two reports giving a table of recommendations for nutrients with good explanatory text and many references.

(R.Pa.)

Nyerere, Julius

Julius Kambarage Nyerere became the first prime minister of an independent Tanganyika in 1961, and, when that nation merged with Zanzibar to form the new state of Tanzania in 1964, Nyerere became its first president. A strong believer in Pan-Africanism and a major force behind the Organization of African Unity, he has consistently advocated reason and moderation to achieve radical ends. From 1954 he led his country through all stages of independence without the loss of a life.

Nyerere was born in March 1922 at Butiama, Musoma District, Tanganyika, the son of a chief of the small



Nyerere.
Pictorial Parade

Zanaki tribe. He was educated at Tabora Secondary School and Makerere College, Uganda. A convert to Catholicism, he taught in several Catholic schools before going to Edinburgh University, where he was graduated in liberal arts in 1952. In 1953 he married Maria Magige, by whom he had five sons and two daughters.

By the time Nyerere entered politics, the old League of Nations mandate that Britain had exercised in Tanganyika had been converted into a United Nations trusteeship, with independence the ultimate goal. Seeking to hasten the process of emancipation, Nyerere joined the Tanganyika African Association, becoming its president. In 1954 he converted the organization into the politically oriented Tanganyika African National Union (TANU). In 1955 and 1956 he journeyed to the United Nations in New York as a petitioner to the Trusteeship Council and the Fourth Committee on trusts and non-self-governing territories. After a debate that ended in his being granted a hearing, he asked for a target date for independence. The British administration rejected the demand, but a dialogue was begun that established Nyerere as the pre-eminent nationalist spokesman for his country.

Formation of TANU

The British administration nominated him a member of the Legislative Council, but he resigned in 1957 in protest against the slowness of progress toward independence. In 1958 he accepted a plan for tripartite electoral representation of the three communities, African, Asian, and European. In subsequent elections, his organization (TANU) put up candidates from each of the three communities and won an overall majority. Progress toward independence owed much to the understanding and mutual trust that developed during the course of negotiations between Nyerere and the British governor, Sir Richard Turnbull. Once, when Nyerere had determined on a course of passive resistance involving nonpayment of taxes, he agreed to call off the campaign, though it meant jeopardizing his political leadership, in favour of constitutional steps proposed by the Governor. When Tanganyika gained responsible self-government in September 1960, Nyerere became chief minister and in December 1961 became the first prime minister of independent Tanganyika. When Tanganyika became a republic a year later he was elected president and in 1964 became president of the United Republic of Tanzania (Tanganyika and Zanzibar).

Nyerere's views and inspiration often have had effects beyond the borders of East Africa. When the white government of Northern Rhodesia threatened repressive measures against the African organization headed by Nyerere's friend, the Zambian leader Kenneth Kaunda, Nyerere took a leading part in mobilizing 5,000 unarmed volunteers to cross the border if necessary. Kaunda did not feel it necessary to call on the volunteer force and

went on to become the first prime minister of independent Zambia. Nyerere was a strong advocate of economic and political measures in dealing with the apartheid policies of South Africa. He was prominent in formulating the Lusaka Manifesto, calling for black and white cooperation in the peaceful development of all Africa.

Soft-spoken, unpretentious, small of stature, and quick to laugh, Julius Nyerere is widely credited with unusual powers of political perception. A key to his mind and understanding may be found in his two books, *Freedom and Socialism* (1968; *Uhuru na Ujamaa*) and *Freedom and Unity* (1967; *Uhuru na Umoja*), and in his choice of two plays of Shakespeare, *The Merchant of Venice* and *Julius Caesar*, for translation into Swahili. He has defended the one-party state, entrenched in his own and several other African nations, on the grounds that a young country, creating an independent political economy, cannot afford to threaten its foundations with elections. The defect of the system seemed to be illustrated by the trial in 1971 for treason of a number of Nyerere's closest colleagues and especially by the secret conclusion of the trial and imprisonment of the defendants for life. Nyerere has continued to insist, however, on an idealistic basis for his government. "We must try to find a method which will enable us in Africa to avoid the weakness of the 'national' state, and make it an instrument for the unification of Africa," he has said. "African nationalism is meaningless, dangerous, anachronistic, if it is not, at the same time, pan-Africanism." Again, addressing himself to the deep conflict of the 20th century, he has said, "The choice before the free states of the world . . . is not between peaceful change and no change. The choice is between peaceful change and conflict."

His defense of the one-party state

BIBLIOGRAPHY. For the history of Tanganyika and Tanzania and the part played in it by Julius Nyerere, see the selections from his writings and speeches collected in *Freedom and Unity* (1967) and *Freedom and Socialism* (1968). Other relevant books are ALEXANDER MACDONALD, *Tanzania: Young Nation in a Hurry* (1966); B.T.G. CHIDZERO, *Tanganyika and International Trusteeship* (1961); ROLAND OLIVER, *The Missionary Factor in East Africa*, 2nd ed. (1965); MARGARET L. BATES, "Tanganyika," in GWENDOLEN M. CARTER (ed.), *African One-Party States* (1962); MICHAEL F. LOFCHIE, *Zanzibar: Background to Revolution* (1965); and WILLIAM HAROLD INGRAMS, *Arabia and the Isles*, 3rd ed. enl. (1966). An excellent, three-part profile by W.E. SMITH may be found in the *New Yorker* (October 16, 23, and 30, 1971).

(G.M.S.)

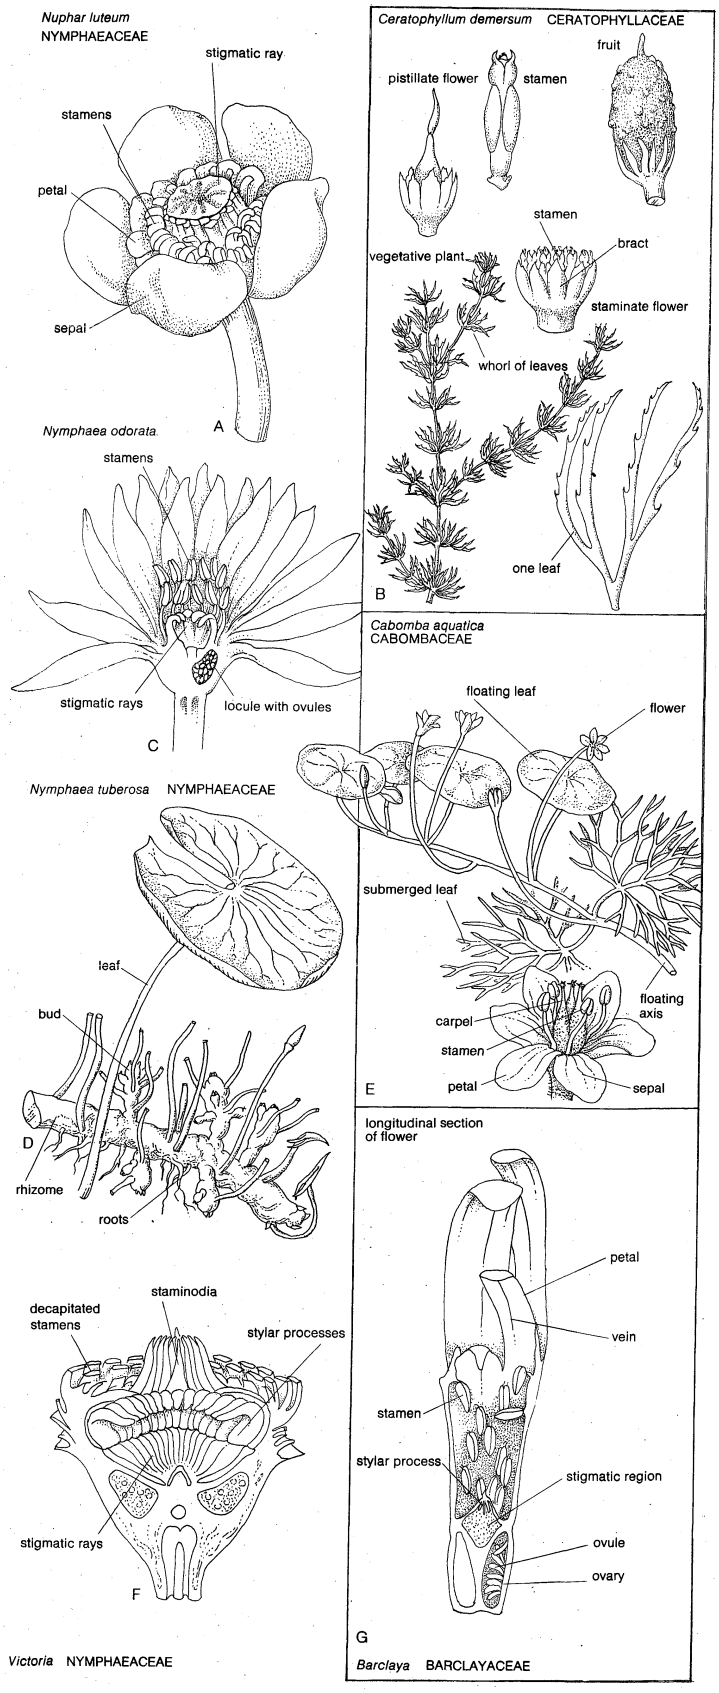
Nymphaeales

Nymphaeales is a plant order belonging to the dicotyledonous group of flowering plants. (One of two such groups, the dicots are roughly equivalent to flowering plants having broad, net-veined leaves—most trees, roses, daisies, etc., being familiar examples.) Its members are found in aquatic habitats, and its best known representatives are the water lilies, from which the order derives its common name, the water-lily order. The aesthetic appeal of the water lilies, especially those of the genera *Nymphaea* and *Victoria*, enhanced by their aquatic habitats, has led to their worldwide cultivation and familiarity. There are 4 families, 8 genera, and about 70 species.

GENERAL FEATURES

Plants of the Nymphaeales order are aquatic. In the genus *Ceratophyllum*, the plants are either rooted or free floating but submerged; in the other genera, they are attached to pond or stream bottoms, but their leaves and flowers may be either submerged, floating, or standing above the water. They range in size from the small, fragile fanwort (*Cabomba*) that has floating leaves less than an inch in diameter, to the hornwort (*Ceratophyllum*) with small leaves and richly branched stems reaching 12 to 15 feet (3.5 to 4.5 metres), to *Victoria* with its floating, circular, shieldlike leaves 6½ feet (2 metres) across and flowers 15 inches (38 centimetres) in diameter.

Representatives of the order occur, often abundantly and frequently, in quiet freshwaters over most of the earth. The genus *Cabomba*, for example, is found in the New World tropics and subtropics; *Brasenia*, the water



Representative plants from the four families of the water lily order.

Hutchinson, *The Families of Flowering Plants;* The Clarendon Press, Oxford

shield, is native to all continents except Europe; *Victoria* is found in tropical South America; *Euryale* and *Barclaya* live in the tropics and subtropics of Asia and Indonesia; the genus *Nuphar*, consisting mostly of the large yellow-flowered pond lilies, ranges over most of the Northern Hemisphere; *Nymphaea*, consisting mostly of smaller, white-flowered water lilies, is cosmopolitan, except in the Pacific islands and New Zealand; and the hornwort, *Ceratophyllum*, is also cosmopolitan.

The leaves; the starchy, horizontal, creeping stems; and the protein-rich seeds of the larger species have been used as food by man throughout his history and are used today, commonly by primitive peoples, and even more widely during famines. The seeds are eaten by fish, and all parts are eaten by grazing or browsing hoofed mammals. Several genera supply cover for fish and attachment and protection for their spawn. Fruits and seeds provide food, and the plant parts, extending above the water, provide food and cover for aquatic birds.

Cabomba, *Brasenia*, *Ceratophyllum*, and *Nuphar*, and other genera less commonly, may grow so rankly as to clog lakes and irrigation ditches. The Figure illustrates some of the structures characteristic of the order.

NATURAL HISTORY

Life cycle. All genera are perennial (*i.e.*, they live through more than one growing season) in their natural habitats, although plants of *Victoria* persist for only a few years. Those genera with creeping, horizontal stems may multiply vegetatively, as older branches die. Some species of *Nymphaea* produce detachable plantlets on their leaves.

Seed dispersal

The seeds of all genera are distributed passively. The fruits of *Nymphaea* species are thrust underwater by the arching growth of the floral stalk and are ruptured by the swelling of mucilage contained in the spaces around the seeds. The seeds of *Nuphar* species are released to float, in packets of soft tissue enclosing air, after the decay and opening of the fruit; the seeds eventually sink when released from the packets. Pulpy, bladderlike tissues produced by the seed stalks around the seeds of *Nymphaea*, *Victoria*, and *Euryale* carry the seeds until ruptured. In the genus *Ceratophyllum*, the spiny fruits are transported by submerged water currents or by fur animals, and the spines eventually anchor them in the substratum. Fish and seed-eating or fish-eating birds also distribute the seeds of various species.

Leaves, flowers, and young fruits of attached genera remain afloat or extend above water level, whichever is normal, even with rising water by means of continuing growth at the bases of leaf or floral stalks, respectively. Cutin and other waxes on floating leaves and flower parts prevent wetting of tissues and their sinking. A coating of mucilage covers the leaves and stems of species of the Cabombaceae family, probably as a protective mechanism. Sharp, strong prickles protect all exposed organs from animals in the genera *Victoria* and *Euryale*.

Ecology. The genus *Ceratophyllum* grows in stagnant or slow-moving water and may be either attached, by burial of the older end of the stem and its branches, or free-floating. All attached species characteristically grow in deep, silted, saturated soils, with little or no free oxygen, below quiet bodies of water. The creeping stems (rhizomes), submerged leaves, and roots are tolerant of oxygen-poor conditions. Air passages extending in the ground tissues from floating leaves, or leaves above the water, into the roots provide for some gaseous exchange between atmosphere and tissues. *Nymphaea* and *Nuphar* are able to withstand fairly severe dehydration without injury and can flourish in semiterrestrial, moderately aerated soils.

Insect associations

Many plant-eating insects, all of them flying types in the adult form, visit Nymphaeales species for food and to deposit eggs. No insect that lives on submerged plants or parts depends on a single species of plant; but there are specific relationships between emergent or floating plant species and flying insects. Some insects, dependent on floating plant parts, are not associated with submerged plant species since they cannot deposit eggs on them. Injury is due to sucking of food materials by bugs (Heteroptera), insertion of eggs and subsequent decay by dragonflies and damselflies (Odonata), removal of epidermis and leaf mining by beetles (Coleoptera), and gross destruction by the caterpillars of moths and butterflies (Lepidoptera). The transfer of pollen by flying insects is the usual pollinating mechanism, except in the genus *Ceratophyllum*. Pollinating visitors, also often plant-eating, are primarily beetles and flies (Diptera), but bees (Hymenoptera) and bugs have also been recorded as pollinators.

Pollination mechanisms

Natural mechanisms insuring cross-pollination and hybridization have been described for *Nymphaea*, *Nuphar*, *Victoria*, and *Ceratophyllum*. The stigmas (female pollen-receiving structures) of a flower become receptive before the anthers (male pollen-producing structures) of the same flower shed pollen. In the flowers of *Nymphaea*, *Nuphar*, and *Victoria*, the inner stamens (the male structure of the flower consisting of the fertile anther and its supporting stalk) or staminodia (sterile, petallike stamens) form a closed cone over the stigmas apparently preventing insect invasion after pollination and often trapping those insects that delivered pollen, causing them to drown in liquids present in the stigmatic cup. During the period when the female stigmas are receptive to pollen, nectar, sweet liquid in the stigmatic bowl, scent, and colour attract insects. Later, when the male anthers are ripe, pollen attracts the insects. In the submerged species of *Ceratophyllum*, male flowers are situated above female flowers. Pollen is released and sinks slowly through the water. Some of the pollen eventually slides down a groove contained in the pistil of the female flower and is thus deposited in a pit where pollen germination occurs, leading to eventual fertilization of the female ovules.

FORM AND FUNCTION

Vegetative features. Some genera have extensive, buried or surface creeping rhizomes (rootlike horizontal stem structures), especially the genera *Nuphar*, *Nymphaea*, and *Brasenia*; others have short, erect, buried stems with (in *Brasenia*, *Cabomba*) or without (in *Victoria*, *Euryale*) associated horizontal floating branches. The genus *Ceratophyllum* has long, largely floating stems with many lateral branches, but a plant may be anchored at its basal end. Branching is not understood in all genera. In the Cabombaceae family, branching is sympodial; that is, a vegetative apex is transformed into a flower, and a lateral branch continues vegetative growth. In others, branching is monopodial; that is, the main axis is continued and the flowers are laterals. In *Nuphar*, flowers arise in leaf sites, replacing leaves, but they are not directly associated with and located above leaves (the axillary position); vegetative buds arise at prospective floral sites and are axillary. In the genus *Nymphaea*, flowers and buds arise similarly, but neither is axillary. In *Victoria* and *Euryale*, the flowers arise in a successive, helical arrangement, alternating with a leaf helix. Roots, which are absent only in the genus *Ceratophyllum*, arise in clusters from the stem at leaf bases.

Vascular systems

The vascular systems in the stems of the Nymphaeaceae and Barclayaceae families are extremely complex and have not yet been satisfactorily described. In the Cabombaceae and Ceratophyllaceae families, relatively simple vascular systems are present. Very little xylem (water-conducting tissue made of special hollow cells known as tracheids and vessels) is present in the vascular bundles. Tracheids (nonspecialized supporting and water-conducting cells) are present, although scarce in the Cabombaceae family, in the organs of all genera. Vessels (specialized water-conducting cells) are usually reported as being absent, but recent studies have indicated that they may be present in the roots of some species of the Nymphaeaceae family.

Flower characteristics. Flowers are solitary in all genera of the order, except that in *Ceratophyllum* two flowers may occur in the axil of one leaf. Floral parts are arranged radially in each flower (*i.e.*, they are "regular" or actinomorphic). Anatomical studies indicate that probably floral parts are attached in complex, multiple

helical arrangements, although the helices may be nearly suppressed, and some organs appear externally to be arranged in whorls (cyclic). The flowers of the Nymphaeaceae, Barclayaceae, and Ceratophyllaceae families pose special problems in the study of their structures, which have been partly resolved by anatomical investigations. In the Nymphaeaceae and Barclayaceae families, the carpels (structures making up the female part of the flower, the ovary or pistil) are partially fused in some species of *Nymphaea*, or completely fused in a subwhorl around a central core except in the stigmatic (pollen receiving) regions. The ovary is multilocular (has several chambers) with few to many ovules attached widely over the side walls. The stigmatic region occurs as an upwardly widening cone, with a basal conical projection in some genera, and it has prominent to reduced extensions of the carpels termed stylar processes. The pollen-receptive stigmatic tissues occur on the inside surface of the stigmatic cone as laterally discontinuous, centrally grooved, radiating zones (rays), each above a locule (chamber of the ovary). Stigmatic-like tissue is continuous from the rays to the bottom of the inner lining of the locules, providing the pathway for pollen tubes. In *Nymphaea* and *Nuphar*, the perianth (flower petals and green leaflike sepals considered together) and stamens are hypogynous (attached below the carpels) and are free from one another, although some stamens are fused to the ovary in *Nymphaea*. In *Victoria, Euryale*, and *Barclaya*, the perianth and staminal organs are, reportedly, fused laterally and basally into a common tubular structure that is fused to, and indistinguishable from, the fused ovary wall. In *Victoria* and *Euryale*, therefore, the free lobes of the perianth and stamens are epigynous; that is, they arise from the top of the fused carpels. In *Barclaya*, the stamen-perianth tube extends above the fused carpels and the free staminal parts are attached to the inner wall of the tube where they hang downward. The inner stamens of *Victoria*, which assist in the cross-pollination mechanism, are, however, sterile; their basal, fused parts arch over the recurved stigmatic rays and are fused with them, and their free upper parts stand erect, after pollination.

The young female structure in *Ceratophyllum*, generally reported as being unicarpellary, is composed of two separate and unequal carpels, which fuse during development. The product is unilocular (single-chambered).

Biochemistry. Latex cells have been reported for most genera, except *Ceratophyllum*. All genera have a reddish anthocyanin pigment that turns purple instantly on exposure to air or to acid. Recent investigations have revealed an insulin-like compound in *Nymphaea nouchalii*, minute quantities of a spasmolytic alkaloid in the rhizomes of *Nymphaea alba*, and ellagitannins (dark-coloured carbohydrates) in *Nymphaea* and *Nuphar*, characteristic of other primitive dicotyledons, but absent in monocotyledons (dicots and monocots are the two great groups of flowering plants, the latter apparently derived from the former through some unknown primitive ancestor).

EVOLUTION AND PALEONTOLOGY

Origin of the order

On the basis of widespread fossil deposits of rhizomes, leaves and fruits of the genus *Brasenia* from Cretaceous deposits (about 100,000,000 years old) and of *Euryale, Nymphaea*, and *Nuphar* from Tertiary deposits (about 50,000,000 years old), apparently the Nymphaeaceae family has enjoyed a wide distribution over the earth since the early Tertiary Period, and possibly since the early Cretaceous Period. Some of the oldest angiospermous (flowering plant) pollens reported (reports not unchallenged, however) by paleobotanists are those of *Nuphar* and *Nymphaea* from the Jurassic Period (about 150,000,000 years ago).

Because of the relative lack of environmental stresses in their aquatic habitat, few striking structural changes from the ancient form have occurred in the Nymphaeales order during its long existence other than the evolution of fused carpels and enclosed ovaries (in some) to protect the seeds against plant-eating insects, and the adoption of aquatic features, including reduction of the xylem, development of air canals, and the rhizomatous habit.

CLASSIFICATION

The following characters of the Cabombaceae, Nymphaeaceae, and Barclayaceae families contrast with those of the Ceratophyllaceae family: adventitious roots (roots arising in unusual places such as along stems) are present; flowers are bisexual (male and female parts present in the same flower) and generally with differentiated petals and sepals; embryos are small; endosperm (the starch and oil containing tissue of seeds) is mealy but scanty; perisperm (tissue surrounding the endosperm) is abundant.

Annotated classification.

ORDER NYMPHAEALES

Aquatic herbs, usually perennial, from stout rhizomes or lacking roots and free-floating, juice sometimes milky, leaves simple, peltate (shieldlike, the stalk attaching near the centre of the disk), or in whorls, floating or emergent or submersed and then with dissected margins. Flowers bisexual, or unisexual, solitary, parts trimerous or numerous and arranged spirally; sepals, petals and stamens in some intergrading in structure. Sepals 3, 4, 5, or numerous; petals 3 to many, or none. Stamens 3 to many in cyclic or spiral arrangement, anthers splitting lengthwise. Carpels 3 to many or 1, usually free but sometimes coalescent; ovules 1 to 5 or many; ovary superior or inferior. Fruit a follicle, nutlet, or leathery berry.

Family Cabombaceae

Two genera, *Brasenia* and *Cabomba* containing only about 8 species. Leaves petiolate (*i.e.*, with a stalk); floating leaves of both genera are peltate. Submerged leaves of *Cabomba* are finely and dichotomously divided. Flowers small, barely floating, and hypogynous. Sepals and petals are apparently cyclic, bi- or trimerous. Stamens numerous, separate, apparently cyclic, and each is erect. Anthers split longitudinally. Carpels 3 to 6, or many, separate, unilocular, with 1 to 3 pendulous, anatropous, bi-integumental ovules attached laminally or rarely dorsally. Fruit a follicle.

Family Nymphaeaceae

Four genera (*Nymphaea, Nuphar, Victoria*, and *Euryale*), with about 53 species in all. Leaves are long-petioled, submerged, floating, or slightly emergent, peltate in *Euryale* and *Victoria*, but lanceolate (lance shaped) to orbiculate (round) with cordate (heart shaped) bases in the other genera. Flowers are relatively large, showy, generally floating or emergent, but commonly submerged and cleistogamous (not opening at maturity) in *Euryale*. The perianth is apparently cyclic. Sepals free and trimerous to 7 (*Nymphaea*), or to numerous (*Nuphar*), basally fused and epigynous (*Victoria, Euryale*). Petals showy, numerous, and separate (*Nymphaea*), basally fused and epigynous (*Victoria, Euryale*), or small, bracteate (with bracts), with abaxial nectaries (*Nuphar*). Appendages, which are transitional between petals and stamens, exist in *Nymphaea, Nuphar japonicum*, and *Victoria*. Stamens numerous, reaching 700 in some *Nymphaea*, separate, and generally hypogynous (*Nymphaea, Nuphar*), or basally fused and epigynous (*Victoria, Euryale*). Anthers split longitudinally and introrsely (directed toward the flower axis). Carpels partially fused (some *Nymphaea*) to syncarpous with 5 to 35 carpels (7 to 12 in *Euryale*), with multilocular ovaries, and with conical stigmatic regions. Ovules anatropous (*i.e.*, the ovule is bent back along the funiculus so that the micropyle opening is against it), except in *Euryale* with 2 to 3, suspended, and attached laminally. Fruit a tardily opening, leathery berry enclosing bi-integumental seeds with arils.

Family Barclayaceae

One genus, about 3 species, *Barclaya*. This family conforms to the generalized characters of the Nymphaeaceae family, except in the particular ones which follow. Leaves moderately long-petioled, floating, linear to orbicular, with cordate bases. Flower with 4 or 5 whorled, separate appendages, considered by some authorities to be sepals, at the base. Stamens basifixed (attached by their bases), pendulous, and attached to the inner wall of the extended epigynous perianth tube. Anther dehiscence longitudinal and introrse. Seeds without arils.

Family Ceratophyllaceae

One genus (*Ceratophyllum*) with about 6 species. Leaves sessile, 2 to several times coarsely and dichotomously divided, the margins serrulate. Roots absent. Flowers small, submerged to floating, unisexual (plants are monoecious), and lacking perianth. Each flower has an involucre (a whorl of bracts at the base of the flower) of 10 to 15 basally fused bracts (small leaflike appendages). Stamens 5 to 27, erect, with nearly sessile anthers. Anther dehiscence longitudinal and extrorse. Carpels 1 with 1 essentially orthotropous ovule which is

pendulous from near the top of the single locule. Fruit a spiny nutlet, tipped by a long style, containing 1 seed with 1 integument and no aril.

Critical appraisal. The delimitation of Nymphaeales, as presented here with the exclusion of the genus *Nelumbo*, frequently placed with this order, seems to be sound. The order is considered to consist of related groups, derived from a ranalian (*i.e.*, a group of dicotyledonous flowering plants showing certain primitive characteristics) ancestor, but semiherbaceous, rather than woody and treelike. The two genera *Victoria* and *Euryale* of the Nymphaeaceae family, with their massive connation (fusion) of floral parts, epigyny (*i.e.*, ovary enclosure by the fused bases of the sepals, petals, and stamens), and petal-like stamens, seem rather segregated from *Nuphar* and *Nymphaea* of the same family; on recent biochemical evidence this segregation is more justified than that of the genus *Barclaya* into its own family separated from *Victoria* and *Euryale*. Although *Ceratophyllum* seems closely related to the Cabombaceae family, the pollen types do not support such a relationship. Recent considerations based on biochemical, serological, and anatomical researches do not support the derivation of monocotyledons from the Nymphaeales order.

(M.F.Mo.)

Ob River

One of the greatest rivers of Asia, the Ob flows across Western Siberia in a twisting diagonal from its southeastern sources in the Altai Mountains to its northwestern outlet through the Gulf of Ob (Obskaya Guba) into the Kara Sea of the Arctic Ocean. It is a major communications artery, crossing territory at the heart of the Soviet Union that is extraordinarily varied in terms of physical environment and the character of its peoples: even allowing for the barrenness of much of the region surrounding the ice-threatened lower course of the river and the inhospitable waters into which it discharges, it drains a region of great economic potential, much of which is being realized under long-term Soviet development plans.

The Ob proper is formed by the junction of the Biya and Katun rivers, in the foothills of the Soviet sector of the Altai, from which it has a course of 2,287 miles (3,680 kilometres); but, if the Irtysh River is regarded as part of the main course rather than as the Ob's major tributary, then the maximum length, from the source of the Black (Cherny) Irtysh in China's sector of the Altai, is 3,362 miles (5,410 kilometres) or, if the Gulf of Ob be included, 3,959 miles (6,370 kilometres). The catchment area is approximately 1,150,000 square miles (2,975,000 square kilometres) down to the delta's end or 1,343,000 square miles (3,479,000 square kilometres) if the gulf be included—the aggregate 172,000 square miles (445,000 square kilometres) of undrained land in the south of the basin being included in both totals. The Ob's catchment area constitutes about half of the whole Kara Sea; it is the largest Soviet catchment area and the sixth-largest in the world.

The Basin. The West Siberian Plain covers about 85 percent of the Ob Basin, the rest of which is occupied in the south by the terraced plains of Turgay (Kazakhstan) and the small hills of northernmost Kazakhstan, and in the southeast by the Kuznetsky Alatau, by the Salair Range (Salairskoye Kryazh), by the Mountains of Shoria, and, behind them, by the Altai Mountains.

There are more than 1,900 rivers within the basin, their aggregate length being about 112,000 miles. The Irtysh, a left-bank tributary 2,639 miles long, itself drains 634,362 square miles (a somewhat larger area than that drained by the Upper and Middle Ob before the Irtysh confluence); and some 70 percent of the whole basin is drained by left-bank tributaries.

The huge basin of the Ob could be taken, geographically, as a representative cross section of Soviet territory: in the far south, around Lake (Ozero) Zaysan (recipient of the Black Irtysh and source of the Irtysh proper), there is arid semidesert; in the central regions of the West Siberian Plain—that is to say, over more than half of the basin—there is the swampy coniferous forest known as taiga, with very large expanses of marshland; and in the north there are vast stretches of the icy, treeless plains known as tundra.

The mainstream and its tributaries. The Upper Ob runs from the Biya–Katun junction to the confluence of the Tom, the Middle Ob from the Tom confluence to the Irtysh confluence, the Lower Ob from the Irtysh confluence to the Gulf of Ob.

The Biya and the Katun both rise in the Altai Mountains: the former in Lake (Ozero) Teletskoye, the latter to the south, among the glaciers of Mount (Gora) Belukha. From their junction the Upper Ob at first flows westward, receiving the Peschanaya, the Anuy, and the Charysh tributaries from the left; for this reach, the river has low banks of alluvium, a bed studded with islands and shoals, and an average gradient of one foot per mile. From the Charysh confluence the Upper Ob flows northward on its way to Barnaul, receiving another left-bank tributary, the Aley, and widening its floodplain as the valley widens. Turning westward again at Barnaul, the river receives a right-bank tributary, the Chumysh, from the Salair Range: the valley hereabouts is three to six miles wide, with steeper ground on the left than on the right; the floodplain is extensive and characterized by diversionary branches of the river and by lakes; the bed is still full of shoals; and the gradient is reduced, but the depth increases markedly. At Kamen-na-Obi, however, where the river begins to loop northeastward, the width of the valley shrinks to two to three miles and that of the floodplain to less than one mile, and reefs of rock emerge in places from the bed. Just above Novosibirsk another right-bank tributary, the Inya, joins the Upper Ob; and a dam at Novosibirsk forms the great reservoir known as the Ob Sea. Below Novosibirsk, where the river leaves the region of forest steppe to enter a zone of aspen and birch forest, both valley and floodplain broaden notably, till at the Tom confluence they are respectively 12 and three or more miles wide. The depth of the Upper Ob (at lower water) varies between six and a half and 20 feet.

The Upper Ob

The Middle Ob begins where the Tom flows into the mainstream, from the right. Taking at first a northwesterly course, the river henceforth becomes much deeper and wider, especially after receiving its mightiest right-bank tributary, the Chulym, shortly below the confluence of the Shegarka from the left. Successive tributaries of the

The Middle Ob

northwesterly course, after the Chulym, include the Chaya and the Parabel (both left), the Ket (right), the Vasyugan (left), the Tym (right), and the Vakh (right). Down to the Vasyugan confluence the river passes through the southern belt of the taiga (marshy forest country); thereafter it enters the middle belt. Below the Vakh confluence the Middle Ob changes its course from northwesterly to westerly and receives more tributaries: the Tromyegan (right), the Great (Bolshoy) Yugan (left), the Lyamin (right), the Great (Bolshoy) Salym (left), the Nazym (right), and finally, at Khanty-Mansiysk, the Irtysh (left, as has been said). In its course through the taiga the Middle Ob has a minimal gradient, a broadening valley (18–30 miles wide), and a correspondingly broadening floodplain (12–18 miles), through which it flows in a complex network of channels, with the main bed widening from less than one mile on the higher reaches to nearly two miles at the end and becoming progressively free of shoals. Low-water depths vary between 13 and 26 feet; and at high water there are great floods every year, sometimes spreading from 15 or even 50 miles across the valley and lasting from two to three months.

The Lower Ob

From its start at the Irtysh confluence the Lower Ob flows northwestward as far as Peregrebnoye and thereafter northward, crossing the northern belt of the taiga till it enters the zone of forest tundra in the vicinity of its delta. The valley is wide, with slopes steeper on the right than on the left, and the vast floodplain is much intersected by channels of the river and dotted with lakes. Below Peregrebnoye the river divides itself into two main branches: the Great (Bolshaya) Ob, which receives the Kazym tributary and the Kunovat from the right; and the Little (Malaya) Ob, which receives the Northern (Severnaya) Sosva, the Vogulka, and the Synya from the left. These main branches are reunited below Shuryshkary into a single stream nearly 12 miles wide; but after the confluence of the Poluy (from the right) the river divides itself again to form a delta, the two principal arms of which are the Khamanelskaya Ob, which receives the Shchuchya from the left, and the Nadymskaya Ob, which is the more considerable of the pair. At the base of the delta lies the Gulf of Ob, which represents a 500-mile extension of the river's valley invaded by the sea, with a width reaching 50 miles at certain points and its own catchment area (forest tundra and tundra proper) of more than 40,000 square miles.

Climate and hydrology. The Ob Basin has short, warm summers and long, cold winters. The average temperature for the year ranges from 14° F (−10° C) on the shores of the Kara Sea to 34° F (1° C) and 36° F (2° C) in the forest zone and to 38.8° F (3.8° C) on Lake (Ozero) Zaysan. The absolute maximum temperature, in the arid south, is 104° F (40° C); the minimum, in the Altai Mountains, is −76° F (−60° C). Rainfall, which occurs mainly in the summer, varies between averages of 12 inches a year in the north to 20 inches in the taiga zone and 100 inches on the steppes, but the western slopes of the Altai may receive as much as 62 inches a year. Snow cover, which lasts for 240–270 days in the north and for 160–170 in the south, is deepest in the forest zone (24–36 inches) and in the mountains (80 inches), much shallower on the tundra (12–20 inches), and very thin on the steppe (8–16 inches).

Annual flooding

On the Upper Ob the spring floods begin very early in April, when the snow on the plains is melting; and they have a second phase, ensuing from the melting of snow on the Altai Mountains. The Middle Ob, scarcely affected by the Upper Ob's phases, has one continuous spring–summer period of high water, which begins in mid-April. For the Lower Ob, high water begins later in April or early in May. Levels in fact begin to rise when the watercourse is still obstructed by ice; and maximum levels, which will have been attained by May on the Upper Ob, may not be attained till June, July, or even August on the lower reaches. For the Upper Ob, the spring floods are over in July, but autumnal rains bring high water again in September–October; for the Middle and for the Lower Ob, the spring–summer floodwaters gradually recede until freezing sets in (on the lower reaches, flooding may last four or five months). The rising of levels on the Ob proper and on the Irtysh obstructs the drainage of the minor tributaries' individual catchment areas.

The autumnal ice drift on the Ob lasts from about October 31 to November 10; then the lower reaches begin to freeze solid; by November 25 the whole river is frozen; and the upper reaches remain so for some 150 days, the lower for 220. The thawing of the ice, which takes longer than the freezing, lasts from the end of April (upstream) to the end of May; and the spring drift (about five days in duration) produces considerable ice jams.

The difference of level between high water and low is approximately ten feet on the Upper Ob; 36 feet on the Middle Ob down to Aleksandrovskoye, but only about 28 feet between Surgut and the Irtysh confluence; and at most 39 to 40 feet on stretches of the Lower Ob, but less than 20 feet at the mouth of the river.

The water is warmest in July, reaching a maximum of 82° F (28° C) in the vicinity of Barnaul.

In terms of drainage, the Ob is the third-greatest river of the U.S.S.R.—after the Yenisey and the Lena. Every year it pours about 515,000,000,000 cubic yards (394 cubic kilometres) of water into the Arctic Ocean—about 12 percent of that ocean's total intake from drainage.

The volume of flow at Salekhard, just above the delta, is nearly 56,000 cubic yards (42,800 cubic metres) per second at its maximum, 2,600 (2,000) at its minimum, while for Barnaul, on the Upper Ob, the corresponding figures are 12,673 cubic yards (9,690 cubic metres) per second and 211 (161). Most of the water comes from the melting of seasonal snow and from rainfall; much less of it comes from ground drainage, from mountain snow, and from glaciers.

The waters of the Ob are only slightly mineralized: dissolved substances account for an annual outpouring of 30,200,000 tons of ions into the Kara Sea. The total amount of solid matter brought down by the Ob every year amounts only to 50,000,000 tons.

Vegetation and animal life. Rich meadows extend in bands one to two miles wide for great distances along the banks of the Ob and cover many of the numerous islands. Pine, cedar, silver fir, aspen, and birch also grow on the banks and occasionally constitute isolated forests on the higher ground of the floodplain; and large areas near the river are covered with willow, snowball trees (*Viburnum*), bird cherry (*Prunus padus*), buckthorn (*Hippophaë*), currant bushes, and wild roses. Arable crops and vegetables are cultivated on some stretches of the banks.

Of some 50 species of fish to be found in the river or in the gulf, the most valuable economically are sturgeon, sterlet, and such "whitefish" as nelma (*Stenodus leucichthys nelma*), musksun (*Coregonus muksun*), chir (*C. nasus*), and pelyad (*C. pelea*); pike, burbot, Siberian dace, carp, and perch are also caught. For lack of oxygen in the water, however, many fish die every winter in the reaches between the Tym confluence and the delta.

Fur-bearing mammals of the Ob Valley include European and Siberian mole, Siberian and American mink, ermine, fox, wolf (in the taiga), elk, white hare, water rat, muskrat, otter, and beaver. Among more than 170 species of birds breeding in the floodplain are grouse, partridge, goose, and duck.

The human imprint. Politically, most of the Ob Basin belongs to the Russian S.F.S.R., but the south of it forms the northernmost part of Kazakhstan. Russians, Ukrainians, and Belorussians constitute the majority of the population, but there are, of course, numerous non-Slavic peoples also. These include the Kazakhs in the south, the Altay and Shorian peoples of the mountains, the Tatars of the Irtysh Basin, the Khanty and the Mansi, whose *natsionalny okrug* (national area) occupies part of the taiga; and the Nenets, Nganasan, Enets, and Selkup peoples of the north. The valleys of the river are more densely populated than other parts of the basin.

The earliest known sailing directions for the Lower Ob are those appended to Pyotr Ivanovich Godunov's *Chertyozh* ("Chart") of Siberia (1667); further details were

Exploration and development

provided by Semyon Ulyanovich Remezov in his *Chertyozhnaya Kniga Sibiri* ("Chart-Book of Siberia"; completed 1701); and the Russian scientists of the Great Northern Expedition (1733–43) investigated the Lower Ob as well as other Siberian rivers. For the next 150 years the river system was investigated chiefly for purposes of communication within the basin. Hydrological studies, however, were inaugurated by the end of the 19th century and were pursued intensively in the 20th; and during the Soviet period the hydroelectric potential of the rivers was not only studied but also developed.

The Ob's total hydroelectric potential is estimated at 250,000,000,000 kilowatt-hours. There were three stations operative in the early 1970s: one on the Ob proper, at Novosibirsk (400,000 kilowatts, its reservoir having an area of 410 square miles and a capacity of 11,500,000,000 cubic yards [8.8 cubic kilometres]); the other two on the mountainous reaches of the Irtysh, at Bukhtarminsk and at Ust-Kamenogorsk.

The Ob, one of Western Siberia's principal means of communication, is navigable for 190 days of the year on its upper reaches, for 150 on its lower. It serves the basin both for importing and for exporting. The Trans-Siberian Railway crosses the Irtysh at Omsk and the Upper Ob at Novosibirsk. Railways going into Kazakhstan from Novosibirsk and from the foothills of the mountains cross the Upper Ob at Barnaul.

Several benefits would accrue if more dams were built on the Ob: (1) its hydroelectric productivity would be augmented, (2) its floods would be less extensive, (3) its navigation facilities would improve, and (4) some of its water might be diverted to irrigate the arid parts of Kazakhstan and Central Asia.

(L.K.M.)

Ocean Basins

The ocean basins and the continents constitute the largest relief features on Earth, with the ocean basins, covering three-fifths of the Earth's surface, dominant. Water, including that of the shallow seas, actually covers 71 percent of the Earth, but only 60 percent of this overlies the deep ocean basins, which occur below the 2,000-metre (6,500-foot) contour line. The average depth of the sea is 3,800 metres (12,500 feet), whereas the average height of the continents is 840 metres (2,760 feet). Thus, the total relief contrast is 4,640 metres (15,220 feet).

The distribution of ocean basins and continents is asymmetrical. Continents are generally antipodal (diametrically opposed) to ocean basins. The antipodal position of Australia, for example, is within the North Atlantic Basin, and Antarctica opposes the Arctic Basin. The ocean basins lie principally in the Southern Hemisphere, and the Antarctic Basin encircles the Earth. In a sense, the three major oceanic basins (Pacific, Atlantic, and Indian) may be regarded as huge gulfs that extend off the Antarctic Basin, with the Arctic Basin being a secondary northward extension of the Atlantic. Thus, unlike the separated and isolated continents, the ocean basins are all interconnected, so that there is really only one worldwide ocean basin. This ocean basin is subdivided into a number of individual ocean basins largely as a matter of convenience.

A classical view of natural philosophers held the oceans to be as deep as the mountains are high, which is roughly correct if only the greatest mountains are considered. The first deep-sea sounding was made in the central South Atlantic in 1840; a heavy plummet was lowered 2,425 fathoms (4,435 metres [14,500 feet]) on the end of a long line. The first generalized map of the ocean basins was fashioned in 1895, using the 7,000 oceanic soundings deeper than 2,000 metres (6,500 feet) that were then available. The advent of the echo sounder in 1920, with which precisely timed echoes are bounced off the bottom, revolutionized deep-sea soundings. A modern survey ship can obtain a sounding every second along its track. The problem of obtaining accurate position control, or fixes, under all conditions of weather and in any part of the world was solved recently through satellite navigation, determination of fixes continuously from low-orbited satellites. The bathymetry (depth measurement) of the entire ocean floor is rapidly being revealed and charted in the 1970s with literally millions of soundings.

Before about 1930 the ocean floor was regarded as flat, monotonous, and generally featureless. Charts since then show a topography remarkably varied in both shape and relief. Some seamounts (isolated conical submarine peaks) and escarpments (steep slopes) are higher and more rugged than any on land, whereas the abyssal (deep-sea) plains are the levelest surfaces on the face of the globe. It has also been learned that the ocean floor, like the surface of the Moon, is a distinct geomorphic domain (*i.e.*, occupied by distinctive landforms); constructional and depositional physiography are quite unlike that on land. Erosional landforms on the continents are sculptured by wind, ice, and running water, but only sluggishly moving water modifies the deep ocean floor. Terrestrial stream action is imitated beneath the sea by turbidity currents, mud-laden tongues of water that periodically pour down the continental shelves and slopes to the ocean floor. Weathering (rock disintegration by chemical and mechanical processes), as well as erosion, proceeds slowly beneath the sea, so that the sea-floor morphology (fault scarps, volcanic knolls, and other features) tends to retain a pristine appearance.

Undersea constructional topography commonly differs from that on land. There is, for example, no undersea equivalent of folded sedimentary mountains. The major features of the ocean floor are deep-sea trenches, rifts, and fracture zones that are created by the interaction along their boundaries of shifting rigid crustal plates. The giant volcanic cones that create seamounts are especially spectacular. The smaller features represent a variety of volcanic topographic forms, related mainly to fissure eruptions (along linear cracks rather than through a central vent) and rifting of the ocean floor.

Mineral resources

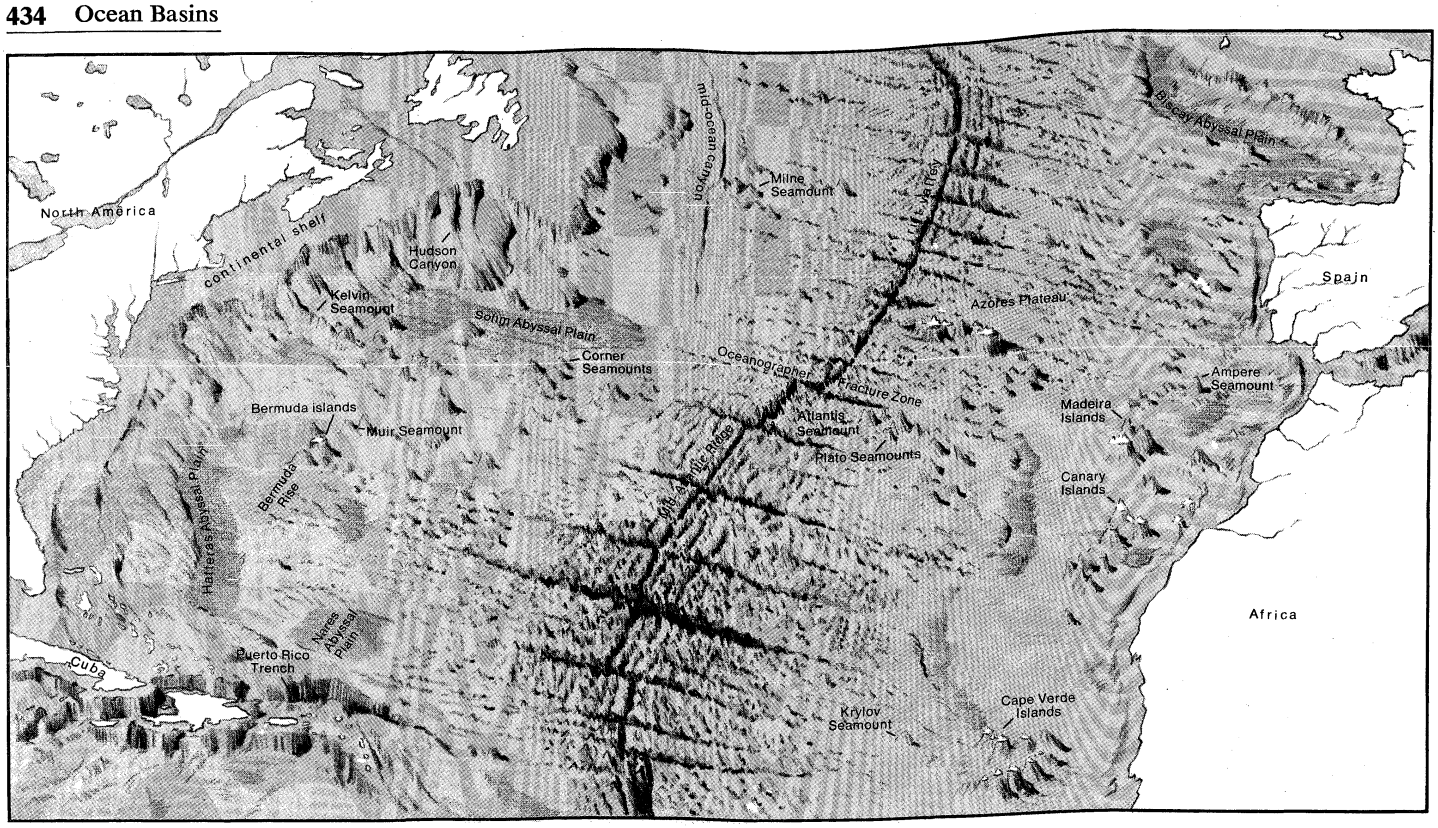
The mineral-resource potential of the deep ocean floor commonly has been considerably overstated. Basalt, which is the common rock of the oceanic crust and of seamounts, offers uninteresting mineral prospects. Iceland and Hawaii provide subaerial examples of oceanic rocks, and these, like all oceanic islands, have little to offer in the way of useful minerals. On the other hand, much interest has been accorded to marine phosphorites and manganese nodules, both of which are formed on the sea floor. The manganese nodules may someday be commercially recovered because of their high content of copper, nickel, and cobalt. Metalliferous sediments beneath pockets of hot brine in the Red Sea are another possibility. Also a highly mineralized layer commonly lies between the sediments on the sea floor and the underlying oceanic crust.

With the exception of precious coral, there is no mining of the deep-sea floor today. Precious coral occurs primarily around some of the coral atolls and seamounts of the central western Pacific, where it is gathered from deep crevices by the Japanese.

This article treats the geologic and geographic features of the ocean basins and includes a section on their origin. For further information on the areas marginal to ocean basins, see CONTINENTAL SHELF AND SLOPE, and for treatment of sediment transport from these areas to the ocean basins see CANYONS, SUBMARINE; DENSITY CURRENTS. See also OCEANS AND SEAS; OCEANIC RIDGES; and SEA-FLOOR SPREADING for additional detail on oceanic processes of relevance and EARTH, PHYSIOGRAPHY OF for an overview of the dimensions and interrelations of land and sea areas.

COMPONENTS OF OCEAN BASINS

The oceanic crust. The oceanic crust contrasts sharply with the granitic crust that makes up the continental blocks. The ocean floor is separated from the Earth's upper mantle (zone beneath the crust) by three distinct layers, which have been revealed by seismic refraction studies. These are: Layer 1 (zero–two kilometres [zero–one mile] thick), consisting of unconsolidated sediments that have been derived from the continents by submarine density currents or surface transport; Layer 2,



Midoceanic ridge, fracture zones, and sea-floor topography of the North Atlantic.
Drawing by E. Derdeyn

comprising Layer 2a (0.5 kilometre [0.3 mile] thick), consisting of pillow lava, a submarine form produced by the rapid quenching of lava as it poured from fissures onto the ocean floor, and Layer 2b (two kilometres [one mile] thick), a series of feeder dikes (dikes are solidified sheets of lava that intrude pre-existing rocks) that originally provided passages for the lavas onto the ocean floor; and Layer 3 (five kilometres [three miles] thick), consisting principally of gabbro, a coarse, crystalline, basic intrusic rock, a form of olivine basalt. Unlike the sediments that are added by deposition from above, these igneous rocks are all injected from below. They are derived by the partial melting of the primitive iron- and magnesium-rich rock of the upper mantle.

Relation of rocks and features to plate tectonics

The nature of the igneous crustal layers found below the sediments is in accord with the concept of sea-floor spreading (*q.v.*). As 100-kilometre- (60-mile-) thick lithospheric plates move apart at midocean rifts, mantle rock moves up from below to fill the void. Much of this injection takes place by viscous-solid flow, but there is also some molten rock present that is squeezed to the top. Outpouring of lava onto the sea floor is quickly chilled into bolster-shaped pods with glassy surfaces that are called pillow lavas (Layer 2). Beneath these pillow lavas are feeder dikes, along which the lava rose to the sea floor. With sea-floor spreading these dikes are pulled apart and injected with new dikes, forming a complex system of dikes (Layer 2b). These dikes are derived from an underlying layer of magma that cools slowly and crystallizes to form gabbro (the intrusive equivalent of olivine basalt) and associated suites of rocks.

This interpretation of the oceanic crust is not fully agreed upon by all authorities. According to this interpretation, however, all of the oceanic crustal rocks have the general composition of olivine basalt.

Major features. The major features within the ocean basins are the midocean ridges (rises), trenches, and fracture zones. These grand features are related, because they are all associated with the boundaries of the Earth's major crustal plates. These boundaries almost invariably lie within the ocean basins rather than on the continents. The trenches mark zones of underthrusting associated with the descent of the crust into the mantle; the midocean ridge forms along the pull-apart zones; and the fracture zones reflect lines of crustal disruption associated with great shearing action where one crustal plate has slid past its neighbour. Thus, the concept of plate tectonics (that the Earth's surface consists of a small number of crustal plates the boundaries of which are sites of major deformation) accounts for these three major types of features that dominate the ocean basins.

Midocean ridges. The midocean-ridge system actually forms a continuous swell throughout the world oceans with an overall length of 60,000 kilometres (37,000 miles), or more than the circumference of the Earth. It is a broad arch one to three kilometres high which may be either exceedingly rough or quite smooth. It is by far the largest and most extensive mountain range on the face of the Earth. Nearly everywhere it is deeply submerged, with only an occasional small island, such as Saint Helena or Ascension, marking its presence. Iceland alone is an exposed broad expanse of the spine of a midocean ridge. The expansion of rocks when hot apparently accounts in large part for the relief of the ridge above the normal level of the ocean floor. As the Earth's mantle loses this excess heat away from the ridge crest, the sea floor subsides to its normal depth, but this process of cooling takes several tens of millions of years.

This broad swell in the ocean floor forms a median ridge through the Atlantic and Indian oceans. This median position is almost precisely true for the Atlantic, where it faithfully follows the contours of the opposing continental slopes. The feature was first described and studied in the Atlantic and was appropriately termed the Mid-Atlantic Ridge. It is high, rugged, and marked by a prominent dorsal cleft, or rift valley. The ridge has a similar aspect in the Indian Ocean, although it is considerably more complex. Its overall form is like that of an inverted Y, but nevertheless the ridge maintains a roughly mid-ocean position relative to the surrounding continents.

The East Pacific Rise

The midocean-ridge system of the Atlantic and Indian oceans south of Australia joins with the East Pacific Rise (Albatross Cordillera). In the Pacific it is common practice to use the term rise rather than ridge, because, although this rise is simply an extension of the midocean-

ridge system of the other oceans, the Pacific swell has a smooth, low silhouette and generally lacks an axial rift valley. The East Pacific Rise also does not occupy a mid-ocean position but runs north–south, paralleling South America and intersecting North America at the mouth of the Gulf of California. This rise remains deeply submerged, and its presence is suggested by only a single volcanic island rising from its crest, Easter Island.

The difference in topographic expression between a ridge and a rise has been explained in terms of plate tectonics. Fast spreading, defined as the opening of the sea floor at a rate faster than six centimetres (two inches) per year (or three centimetres [one inch] per year on each spreading limb), as is characteristic of the Pacific, produces a rise. Slow spreading, on the other hand, results in the formation of a ridge. Sea-floor spreading is a symmetrical process that accretes new ocean floor equally to both flanks of a rift; when a former landmass splits apart, the ridge maintains a median position as the newly created ocean basin increases in size. This phenomenon occurred in the Atlantic and Indian oceans, but, in contrast, the rise in the Pacific did not rift a landmass when it was formed, and consequently there is no reason for it to be median.

Trenches. Oceanic trenches are long, narrow, arcuate depressions in the ocean floor. They occur principally around the periphery of the Pacific Basin, but examples are also found in both the Atlantic and Indian oceans. Individual trenches have lengths of thousands of kilometres, widths of roughly 100 kilometres (60 miles), and depths of two to four kilometres (one to two miles) below the adjacent ocean floor. Nearly all of the hadal regions, which are those deeper than 6,000 metres (20,000 feet), lie within trenches. Their continuity is remarkable—9,000-metre- (30,000-foot-) deep Tonga Trench is about five kilometres (three miles) wide, but it is continuous for 700 kilometres (400 miles). Typically, trenches have an asymmetrical V shape with a steeper slope toward land and a gentle slope toward the ocean basin; a low arch sometimes intervenes before the normal deep ocean floor is attained. Trenches and their associated island arcs, surmounted by explosive volcanoes, are the most active geological features on the face of the Earth. The great earthquakes and tsunamis (great sea waves produced by submarine earth movement or volcanic eruption) generated from them are invariably associated with trenches.

Greatest ocean depths

The greatest depths are found in trenches and so are near continental margins or island arcs rather than in the middle of the ocean basins. The deepest depression is the 10,850-metre (35,600-foot) Challenger Deep, discovered by HMS "Challenger II" in 1948, in the Mariana Trench not far from Guam. Some greater depths for this deep have been claimed, but they remain unsubstantiated. The oceanographers Jacques Piccard and Don Walsh descended to the bottom of the Challenger Deep in 1960 aboard the bathyscaphe "Trieste," a feat comparable to the ascent of Mt. Everest. Some other great deeps of the Pacific are Tonga Trench, 10,800 metres (35,400 feet); Kermadec Trench, 10,800 metres (35,400 feet); and Philippine Trench, 10,030 metres (32,900 feet). The greatest depth in the Atlantic Ocean is 9,200 metres (30,200 feet), found in the Puerto Rico Trench, just north of that island.

It is now commonly agreed that trenches are subduction zones—that is, zones where the outer, 100-kilometre- (60-mile-) thick outer shell of the Earth plunges into the mantle at angles from 30° to nearly vertical. The bending of this rigid crustal plate in adapting to the spherical geometry of the Earth is the cause of the arcuate shape of the trench. The descending lithospheric plate contains numerous rock types that are unstable in the regime of high pressures and temperatures that exists in the mantle. Hence, they cannot be consumed and are melted and returned to the surface as magmas and lavas that build up the arc behind the trenches. The Aleutians–Alaska Arc, which lies behind the Aleutian Islands, is a prime example; the Kuril and Mariana arcs are others (see further ISLAND ARCS).

Fracture zones. Since the early 1950s, bathymetric surveys have revealed a large number of horizontal lineations of high and rugged topography called fracture zones. These are long, narrow ridges and depressions that usually separate oceanic ridges of different depth. The fracture zones may be as much as 100 kilometres (60 miles) wide and 2,000 kilometres (1,000 miles) long. The first to be described was the Mendocino Fracture Zone, extending westward for 3,300 kilometres (2,100 miles) from Cape Mendocino, California. Subsequently, three other almost parallel extensive fracture zones have been surveyed off western North America—namely, the Murray, Molokai, and Clarion fracture zones. These appear to be scarps associated with offsets of a former extension of the East Pacific Rise, which was overridden by the westward drift of North America. In the Atlantic Basin there are also numerous fracture zones that offset the axial rift of the Mid-Atlantic Ridge. These fracture zones also extend far beyond the limits of the offsets and, in some cases, can be traced nearly to Africa or North America before their trace is lost beneath the thick-lying blanket of sediments along the continental margins.

Earthquake activity indicates that these fracture zones are actively shearing (moving) today only where they connect segments of actively spreading ridges or where they connect a rift to a trench. The extensions of the fracture zones onto the adjacent segments of the ocean floor are dead (immobile), although the rugged relief along their trends remains as evidence of earlier faulting and crustal slippage.

Mountains beneath the sea

Seamounts and guyots. A seamount is a mountain beneath the sea, generally in the form of an isolated, conical elevation of the sea floor at least one kilometre high. Seamounts are the most prominent and striking features on the ocean floor. More than 2,000 seamounts have been reported, and many more await future discovery. There remains no doubt that seamounts are nearly all volcanoes (mostly extinct), because when dredged the bedrock is always basalt, and their shapes and slopes are like that of a volcano on land. They are composed of alkaline basalts derived from depths of 150 kilometres (90 miles) or more within the deep portion of the upper mantle.

The Northeast Pacific Basin is especially rich in seamounts that commonly trend northwest to southeast in long festoons. Many of these chains are entirely submerged, such as the Magellan Seamount Group in the far western Pacific. Others, such as the Hawaiian chain, are mixed groups of islands, banks, and seamounts. Forming an extension of this chain is the giant, deeply submerged Emperor Seamount Chain off Japan. Each of these seamounts is named after a semi-mythical Japanese emperor.

Oceanic islands, those rising from the deep ocean bed beyond the continental shelves, may be classified as either high islands or low islands. High islands are simply the tops of giant seamounts that are both tall enough to pierce the surface and young enough not to have been eroded away by wave action. These are nearly all active, dormant, or recently extinct volcanoes, because erosion reduces an island to a shallow bank after a few million years. Strings of islands, such as the Hawaiian chain, may be formed when the Earth's outer crust drifts over a deep, stationary lava pipe. Thus, the volcanically active island always lies at one end of the chain. Low oceanic islands, those lying essentially at sea level, generally are coral atolls in tropical latitudes. As Darwin surmised about the mid-19th century, these atolls have formed by the deposition of limestone upon a subsiding, extinct volcano. The upward growth by corals and lime-secreting algae offsets subsidence and maintains the atoll precisely at sea level, so that these limestone edifices are "the gravestones of departed volcanic islands."

Some large, deeply submerged seamounts, especially in the central North Pacific, are flat-topped and are termed guyots, after Arnold Henry Guyot, a 19th-century Swiss–U.S. geologist. An especially large cluster of guyots is that of the Mid-Pacific Mountains, which stretch from west of Hawaii to Wake Island.

Because truncation of a seamount can occur only by wave action at sea level, guyots are thought to be

drowned ancient islands that have subsided one or more kilometres beneath the sea surface. They are found in regions unfavourable to coral growth, so that no atoll was built up to offset their subsidence. This sinking usually is largely a result of regional subsidence of the ocean floor and of the horizontal drift of the seamount as the ocean crust moves down the flank of a rise. Local subsidence, or foundering, caused by the load emplaced on the crust by a volcanic seamount, may also play a role, but sinking caused by a relative rise of sea level (addition of new water to the oceans) apparently is not important. Although the oceans probably are growing deeper with time as new water is squeezed out of the Earth's mantle, this deepening is exceedingly slow, probably not more than a few centimetres per million years.

Abyssal hills and plains. Hills and knolls on the ocean floor are termed abyssal; they are protuberances smaller than seamounts, rising to heights from a few tens to several hundred metres above the ocean floor in regions largely devoid of sediment. Extensive regions of chaotic roughness especially characterize the Pacific floor along the flanks of the midocean ridges. Where careful surveys have been made, these hills commonly display an elongate form. They are caused by faulting of the oceanic crust, volcanic extrusions, and other kinds of deformation.

Featureless plains on the sea floor

Extensive regions of the ocean floor are abyssal plains, flat, featureless, sedimentary plains with slopes of less than one part in 1,000. Over broad reaches these plains will not vary in depth by as much as one metre, and they are the levelest regions on the face of the Earth. This nearly perfect flatness is derived by the long-continued deposition of sediments by muddy bottom flows, which pond in the deepest hollows, burying any existing irregularities. These plains are found in all ocean basins but are best developed near continental margins and in the Atlantic Ocean, where deposition rates are high. Fine examples off the eastern United States are the Hatteras and Nares plains, lying at 5.5 kilometres (3.4 miles) depth, which have been developed by sediments shed from North America. The world's greatest abyssal plain is probably that underlying the Bay of Bengal, which has been built up by the muddy Ganges and Irrawaddy rivers.

Sediments of the ocean floor. The ocean floor is blanketed in most places with a sedimentary cover. Two basic types are recognized: namely, terrigenous sediments (sands, silts, and clays) that are shed from the continents or from islands and pelagic, or open-sea sediments—the finely suspended clays and remains of pelagic (floating-form) plants and animals that "rained" gently on the bottom.

The terrigenous sediments generally are deposited near the base of the continental slope as sedimentary fans or aprons. They are mostly turbidites laid down by turbidity currents (a type of density current in which the density contrast arises because of the high sediment concentration of the flow), and they attain great thickness. Although covering a larger area, the pelagic oozes form a thinner blanket (zero–two kilometres thick). The most common is globigerina ooze, composed of minute calcium carbonate shells of protozoans, mostly of the genus *Globigerina*. This ooze covers vast expanses of the Atlantic and Indian oceans. Calcium carbonate dissolves in the deeper portions of the oceans so that in much of the central Pacific Basin calcareous oozes are replaced by red clay. Diatom ooze, composed of opaline siliceous shells of marine algae, are found mainly beneath colder waters. A belt of diatom ooze cordons the world in the Antarctic region, and another zone lies across the far north Pacific. Another siliceous ooze, radiolarian ooze, is typical of tropical regions. A belt of this ooze extends across the Pacific beneath equatorial waters. It is composed of the minute remains of radiolarians, a pelagic protozoan (see further MARINE SEDIMENTS).

Basin boundaries. *Continental slopes.* The outer edge of the continental slope is marked by an abrupt brink where the sea floor plunges three to five kilometres (two to three miles) to join the abyssal floor. The continental slopes are the longest, highest, and straightest boundary walls in the world. Only the lofty Himalayan rampart facing India attains the scale of a continental slope. If the ocean waters were removed, the continents would stand as pedestals everywhere. The continental slopes are the margins of the continents and, hence, are the boundaries of the ocean basins. Their declivity is typically 3° to 5°.

Some continental slopes can be classified as accretionary, because they were created by oceanic crust underthrusting the continental margin. This origin applies to much of the Pacific margin. Other slopes are modified scarps or faults related to continental breakup and continental drift. This origin applies to much of the Atlantic and Indian ocean margins. Such slopes have commonly been extensively modified by sedimentation.

The continental rise. In many parts of the world the continental slope is separated from the abyssal ocean floor by a broad apron. This continental rise is the top of a prism of sediments shed from the continents and laid down mostly by turbidity currents on the deep ocean floor. Such rises are particularly characteristic of the Atlantic and Indian oceans. A particularly fine example is developed off the eastern United States, extending as a smoothly sloping apron for about 250 kilometres (150 miles) from the 1,000-fathom (2,000-metre [6,000-foot]) level to the deep abyssal plain. Geophysical investigations indicate that this continental-rise prism may attain a thickness of more than six kilometres. This huge sedimentary prism is regarded as a potential major oil province of the future. After initial deposition by turbidity currents, the sediments of the continental rise may be extensively reworked and are deposited by deep bottom currents. This condition is particularly true along the western sides of an ocean basin. The Blake Nose, a huge lens of sediment projecting outward from the continental rise off the south central United States, is an example of this bottom-current effect. Because the deep currents tend to move parallel to the bottom slope, they are called contour currents and their deposits contourites.

ORIGIN OF OCEAN BASINS

The new concepts of plate tectonics and sea-floor spreading have worked a revolution in the Earth sciences. Among other things, the concepts provide an adequate explanation for the origin of ocean basins. The theory holds that the Earth's outer shell is broken into about eight large, rigid, spherical caps, plus many small subplates. Except for the Pacific plate, which includes much of the Pacific Ocean, each major plate contains a separate continent embedded within it. An ideal plate may be envisioned as being rectilinear. Along one edge, where the plate is heavy, it dives into the Earth's mantle along a trench called a subduction zone. Opposing this zone of lithospheric descent, a rift is formed. As the rift grows larger, the void left behind is constantly healed by the upwelling of mantle rock that emplaces new ocean crust, a process known as sea-floor spreading. New ocean crust is presently being generated at about 1.5 square kilometres (0.6 square mile) per year, a rate sufficient to repave the entire ocean basin in 200,000,000 years. To accommodate this crustal movement, the rift and the trench are connected by large zones of shear or slippage called transform faults. Thus, crust is consumed at the trenches, created at the rifts, and conserved along the transform faults. The crustal plates and the continents embedded within them undergo drift, and this condition provides the mechanism for continental drift (*q.v.*). Typical drift rates range from one to several centimetres a year, a remarkably rapid geologic process.

Formation of ocean basins between the continents

To understand why the Earth has ocean basins, the origin of continents must be considered, because the ocean basins are simply those depressed crustal regions that lie between the isolated continents. The continental plateaus are slabs of granitic rock or sial (siliceous or acid igneous rock), and they literally float in the Earth's denser mantle like blocks of wood floating in water. Following the principle of Archimedes, the continents adjust themselves to a level at which the weight of the mantle rock displaced is equivalent to their own weight, which is called isostatic (equal-weight) equilibrium. The 35-kilometre (22-mile)

thickness of the continents and their density contrast with sima (mantle rock) is such that a five-kilometre (three-mile) relief results between oceanic and continental levels.

The generation of the granitoid rocks that form the continents requires at least two stages of melting and gravitational differentiation (separation according to density differences) of the low-density rock from the heavier rock. First, as the midocean rifts pull apart, new oceanic basalt fills in the void, repaving the ocean floor. This basalt is a partial melt or differentiate of the primitive, heavy, ultrabasic material of the Earth's mantle. Because of crustal drift this basalt is eventually consumed within trenches, subduction zones that carry the crust downward into the hot regime of the upper mantle. There the oceanic basalt is remelted, giving off sialic (lighter) rock that rises up to the surface as lava or granitic intrusions. This new rock generally forms an island arc that ultimately becomes accreted to the margin of a continent. In this manner the continents grow and the regions between these sialic plateaus become the ocean basins.

BIBLIOGRAPHY. The literature on the ocean basins is extensive and is growing at a rapid rate. Only a brief sampling of English-language publications can be included here. Some general nontechnical discussions about the ocean floor are: B.C. HEEZEN and C.D. HOLLISTER, *The Face of the Deep* (1971), a magnificent monograph of deep sea photos with explanatory text; F.P. SHEPARD, *The Earth Beneath the Sea* (1959), which emphasizes the geomorphology of the ocean floor; D.H. and M.P. TARLING, *Continental Drift* (1971), summarizes the now accepted concept of drifting continents in terms of plate tectonics; H.W. MENARD, *Anatomy of an Expedition* (1969), tells how a modern scientific expedition is organized to study a portion of the Pacific Basin. Some popular books that deal with the oceans generally are: J. DUGAN, *Man Under the Sea*, rev. ed. (1965), which concerns man's entry into the subsurface world; and J. PICCARD and R.S. DIETZ, *Seven Miles Down* (1961), a documentary account of the bathyscaphe "Trieste" and its ultimate dive to the bottom of the Challenger Deep. Some important textbooks and basic reference works include the following: The classic text on oceans generally is by H.U. SVERDRUP, M.W. JOHNSON, and R. FLEMING, *The Oceans* (1942). An excellent treatment of the Pacific is presented by H.W. MENARD in *Marine Geology of the Pacific* (1964). F.P. SHEPARD, *Submarine Geology*, 2nd ed. (1963); and P.H. KUENEN, *Marine Geology* (1950), discuss the ocean floor generally. Erosional forms are covered in F.P. SHEPARD and R.F. DILL, *Submarine Canyons and Other Sea Valleys* (1966). The mineral potential of the ocean floor is described in J.L. MERO, *Mineral Resources of the Sea* (1965). Some more general reference works are: R.W. FAIRBRIDGE (ed.), *Encyclopedia of Oceanography* (1966); and M.N. HILL and A.E. MAXWELL (eds.), *The Sea*, 4 vol. (1963–70). Charts of the coastal regions of the United States may be obtained from National Oceanic and Atmospheric Administration (NOAA), National Ocean Survey, Washington, D.C.; chart and bathymetric maps for other countries are issued by the Naval Oceanographic Office, Washington, D.C. Physiographic maps of the Atlantic, Pacific, Arctic, and Indian oceans may be obtained from the National Geographic Society; and original oceanographic data for selected regions is available from NOAA, Environmental Data Service, National Oceanographic Data Center, Rockville, Maryland.

(R.S.D.)

Ocean Currents

The great water masses that cover nearly 71 percent of the earth's surface are interconnected by a rather orderly system of ocean currents. The driving forces for this water motion are wind friction at the sea surface and horizontal and vertical differences in the density of seawater. Differential heating and cooling, precipitation, and evaporation produce differences of water density at the sea surface. Overturning of water masses, vertical convection, and mixing provide the mechanisms for distributing density differences from the sea surface into deeper layers. This creates horizontal density differences and, consequently, horizontal pressure differences and currents at all depths in the oceans. As far as the driving forces are concerned, a distinction is made between these two components of the general oceanic circulation (wind friction and differential density); they are not independent of each other, however.

Because the oceanic circulation is so closely linked to the atmosphere and its behaviour, the great oceanic current systems cannot be as stable or as steady as might be expected. The usual charts depicting ocean currents show only the prevailing current directions and speeds, not their variability. Such charts represent the average trend of water displacements and are comparable to climatic wind charts.

This article treats the nature, distribution, and causes of ocean currents and oceanic circulation, and oceanic–atmospheric interactions, including climatic effects. Related aspects of these topics are discussed in the articles WATER WAVES; TIDES; OCEANS AND SEAS; ATMOSPHERE; WINDS AND STORMS; and CLIMATE.

DISTRIBUTION OF OCEAN CURRENTS

Charts that show the horizontal distribution of ocean currents are based on a large number of direct and indirect current observations. Most of the data are obtained from ship drifts, however. If careful record of the course and speed of the ship is made then a "dead reckoning position" is established. This would be the true position if no drift by currents has affected the course and speed of the ship. The difference between dead reckoning and the actual position as determined by astronomical or electronic means indicates the average current. Whenever possible, these differences are determined at least 24 hours apart.

The general pattern of currents throughout the world's oceans is shown in Figure 1 for the Northern Hemisphere winter. More detailed maps are available for individual oceans or for parts of the oceans, and the adjacent seas. Figure 1 shows that the distribution of currents in the upper strata of the oceans tends to coincide with the prevailing winds of the world. It should be recognized, however, that this smooth, average representation of the oceanic circulation only outlines the general trend of horizontal water movements.

Vertical components of currents

Because ocean currents are three-dimensional water displacements, the vertical components of currents are also of interest. In general, vertical speeds are much smaller than horizontal speeds. Nevertheless, vertical motions are important for an accurate description and explanation of the oceanic circulation system. Significant vertical branches in the current structure occur mainly where horizontal currents either diverge or converge. The phenomenon of upwelling water in the surface strata of the oceans is caused by diverging surface currents in the open ocean, or near the coasts of continents where a supply of water from deeper layers is required to compensate for the seaward motion of surface currents. The formation and spreading of water masses in the deep sea also depends upon vertical branches in the current system for explanation.

THE CAUSES OF OCEAN CURRENTS

The equations of motion in hydrodynamics make use of one of Newton's fundamental laws of mechanics when applied to a continuous volume of water. They state that the product of mass and current acceleration equals the vector sum of all forces that act upon the mass.

Besides the external force of gravity, the most important forces that cause and affect ocean currents are horizontal pressure gradient forces, the Coriolis forces, and frictional forces.

Pressure gradients. The hydrostatic sea pressure, p, at any depth below the sea surface is given by the product $\rho = g\,\rho\,z$, where g is the acceleration of gravity, ρ is the density of seawater, and z the depth below the sea surface. Because differences in density at any fixed depth are due to differences in temperature and salinity, the sea pressure, p, will vary correspondingly from region to region. This part of the total internal pressure field in the oceans is called the relative field of pressure.

In a homogeneous ocean of constant potential density, horizontal pressure differences are only possible if the sea surface is tilted against level surfaces. Level surfaces are everywhere perpendicular to the force of gravity (the plumb line). In this case, surfaces of equal pressure, called

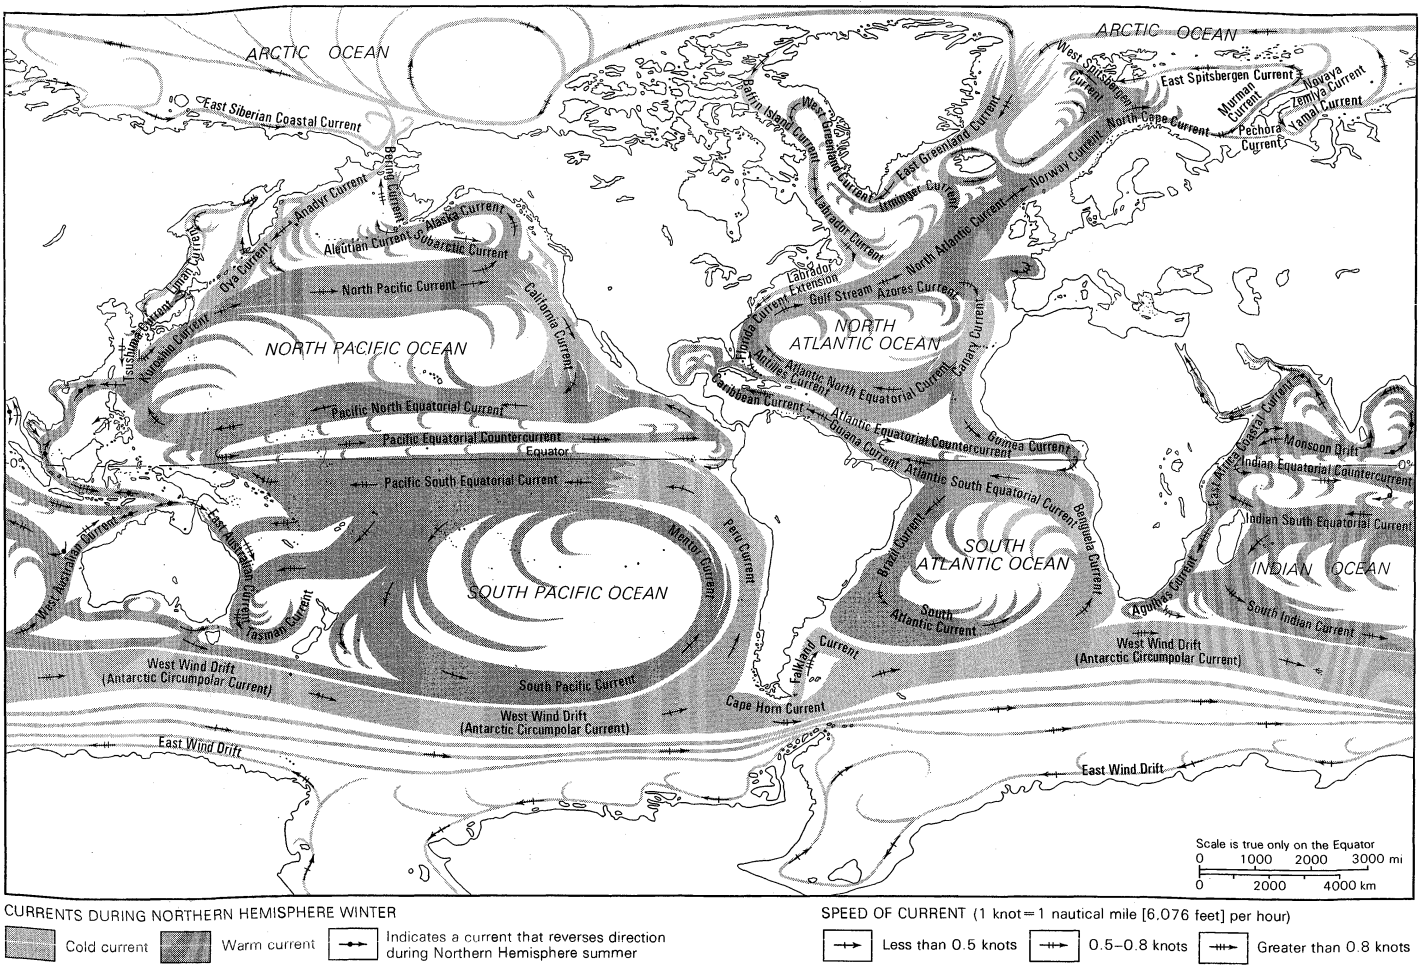


Figure 1: Major ocean current systems of the world.

isobaric surfaces, are also tilted against level surfaces in the deeper layers. This part of the internal pressure field is called the slope field. Thus, the total oceanic pressure field is composed of two parts: the relative field and the slope field. The slope field of pressure can be the result of the wind, for example, when wind-driven surface currents pile up water against a coastline or between opposing winds in the open sea.

The rate of change of pressure, Δp, along a horizontal distance, Δn, is called the horizontal pressure gradient, $\Delta p/\Delta n$. Although much smaller than the vertical pressure gradient, $\Delta p/\Delta z$, the horizontal pressure gradient nevertheless is most important with respect to ocean currents.

Coriolis effect. To an observer in space a moving body would continue to move in a straight line unless the motion were acted upon by some other force. To an earthbound observer, however, this motion cannot be along a straight line because the reference system of coordinates is fixed to the rotating earth. This is similar to the effect that would be experienced by an observer standing on a large turntable if an object moved over the turntable in a straight line. An apparent deflection of the path of the moving object would be seen. If the turntable rotated clockwise, this apparent deflection would be to the left, relative to an observer looking in the direction of the motion.

Because the earth rotates from west to east about its axis, an observer in the Northern Hemisphere would notice a deflection of any moving body to the right. In the Southern Hemisphere this deflection would be to the left. At the Equator there would be no apparent horizontal deflection but only a vertical deflection for zonal currents. This most remarkable effect of the earth's rotation, the Coriolis effect, is named after Gaspard Coriolis, a 19th-century French mathematician.

It can be shown that the Coriolis force always acts perpendicular to the motion. Its horizontal component, CF, is proportional to the sine of the geographical latitude and the speed, c, of the moving body. It is given by $CF = 2\omega c \sin \varphi c$, where ω (7.29×10^{-5} radian per second) is the angular velocity of the earth's rotation. Coriolis forces affect all motions on or near the earth's surface, including missiles in flight, a Foucault pendulum, air currents, and ocean currents.

Frictional forces. A faster moving fluid layer tends to drag along a slower moving layer. A slower moving layer will tend to reduce the speed of a faster moving layer. This is the result of momentum transfer between layers of different velocity. Also, the wind blowing over the sea surface transfers momentum to the water and causes a drift of water. This frictional drag at the sea surface (the wind stress) is transmitted to deeper layers by friction within the water. Together with the Coriolis force this friction causes pure wind-driven currents.

Geostrophic currents

A simple equation of motion can be derived for the case where friction is insignificant, the currents are nonaccelerated, and the driving forces for ocean currents are due to horizontal pressure gradients only.

On a nonrotating earth, water would be accelerated by the pressure gradient and would flow, as in a river, from higher to lower level, or from high pressure to low pressure. On a rotating earth, however, the Coriolis force deflects the motion, and the acceleration ceases only when the speed, c, of the current in a given latitude is just fast enough to produce a Coriolis force that can exactly balance the pressure gradient force. Therefore: $\Delta p/\Delta n = 2\rho\omega c \sin \varphi$. From this balance, it follows that the current direction must be perpendicular to the pressure gradient, because the Coriolis force always acts perpendicular to the motion. In the Northern Hemisphere this direction is such that the high pressure is to the right when looking in

current direction, in the Southern Hemisphere it is to the left. This type of current is called a geostrophic current. If the pressure gradients are the result of differences in density of ocean water, this simple equation provides the basis for an indirect method of computation of ocean currents.

If $\Delta p/\Delta n$ is known, the velocity, c, of the resultant current can be computed. Because $\Delta p/\Delta n = g\rho(\Delta z/\Delta n)$, where $\Delta z/\Delta n$ is the slope of an isobaric surface, the speed, c, of the current is obtained from $c = g(\Delta z/\Delta n)/2\omega \sin \varphi$.

Across the Gulf Stream, the slope of the sea surface over a distance of 100 kilometres is about one metre, thus $\Delta z/\Delta n = 10^{-5}$. With $g = 9.8$ metres per second squared and $2\omega \sin \varphi = 10^{-4}$ in middle latitudes, it follows that $c = 0.98$ metre per second, or about one metre per second. This is a reasonable average surface speed of the Gulf Stream. Because the Gulf Stream often is less wide and somewhat "streaky," however, its speed in some parts of its course can be higher.

Wind-driven currents

The frictional drag of the wind at the water surface, and between layers of water, sets ocean water in motion. If a steady wind blows long enough over a large ocean, pure wind-driven currents are the result. They show some remarkable properties. The currents do not follow the wind direction, but are deflected at the sea surface by 45° to the right in the Northern Hemisphere, and to the left in the Southern Hemisphere. With increasing depth this deflection increases while the current speed decreases. At a certain depth, roughly around 75 or 100 metres in middle latitudes, the current even flows against the surface current; however, its speed has reduced to about $\frac{1}{23}$ of its surface speed.

In 1902 the Swedish oceanographer V. Walfrid Ekman deduced these results in a theoretical model. He considered a homogeneous ocean where frictional forces are balanced by Coriolis forces, and where resulting currents are nonaccelerated. His results show that the end points of the current vectors from surface to bottom, when vertically projected on a horizontal plane, produce a logarithmic spiral, now termed the Ekman spiral.

Pure wind-driven currents of this type do not penetrate deeply into the ocean. Essentially, they occupy a surface layer called the Ekman layer, about 100 metres deep. The average total water transport in the Ekman layer is 90° to the right of the wind direction in the Northern Hemisphere, to the left in the Southern Hemisphere, and proportional to the wind stress. In the ocean these drift currents must either converge or diverge because they will meet coasts or, in the open ocean, winds of opposing direction and speed. In regions of surface water convergence, water is not only piled up but also is pushed down. In regions of divergence the sea surface is lowered and deeper water rises to the surface. This produces slopes of the sea surface and slope currents. Superposition of pure wind-driven currents and slope currents can result in a complicated current system. If density differences contribute to a relative pressure field in addition to a slope field, ocean currents are further modified.

Since 1946 considerable progress has been made in the study of the wind-driven ocean circulation and the thermohaline circulation produced by density differences. One of the most modern theoretical models that tries to take into account all of the driving forces, wind-driven and thermohaline, is the numerical model by Kirk Bryan and Doak Carey Cox (1967). It has succeeded in explaining many of the major features of the general oceanic circulation, for the wind-driven surface strata and for the deep sea. Laboratory models such as those conducted by William Sterling von Arx that employ rotating water basins have helped to substantiate theoretical results on the dynamics of ocean currents.

GENERAL SURFACE CIRCULATION

The system of surface currents. The circulation of the upper strata of the oceans divides into gyres that rotate either clockwise or anticlockwise (Figure 1). A clockwise rotation in the Northern Hemisphere with higher pressure in the centre of rotation is called anticyclonic. An anticlockwise rotation with lower pressure in its centre is called cyclonic. In the Southern Hemisphere the sense of rotation is opposite, because the effect of the Coriolis force has changed its sign of deflection.

This system of surface currents corresponds closely to the average climatological wind system over the oceans. It is, however, affected by the interference of coastlines with respect to the winds.

Westward intensification of currents

The tendency of ocean currents in big, elongated, anticyclonic gyres is to displace their centres of rotation to the west, and to form strong western boundary currents like the Gulf Stream and the Kuroshio. This westward intensification of ocean currents was explained by Henry Melson Stommel (1948) as a result of the fact that the horizontal Coriolis force increases with increasing latitude.

Walter Heinrich Munk (1950) and others explained theoretically many of the major features of the wind-driven ocean circulation by using the mean climatological wind stress distribution at the sea surface as a driving force.

Effects of bottom topography or of a restricted vertical extent of wind-driven currents by strong vertical density gradients in the oceans have not been considered in these models, however. These additional effects may help to explain why the westward intensification of ocean currents is not equally strong in the Southern Hemisphere.

Western and eastern boundary currents. Individual branches of the surface current pattern are indicated by their geographical names in Figure 1. The poleward flow on the western side of the great subtropical gyres in the North Atlantic and North Pacific, the western boundary currents, is fast, narrow, and deep; whereas the return flow toward the Equator, the eastern boundary currents, is slower, broader, and less deep. In the Southern Hemisphere, however, western boundary currents like the Brazil Current and the East Australian Current are not as strongly developed as their Northern Hemisphere counterparts.

Western and eastern boundary currents associated with subtropical gyres in the world's oceans are listed in the Table.

Western and Eastern Boundary Currents of the World's Oceans

boundary currents	Atlantic Ocean		Pacific Ocean		Indian Ocean
	north	south	north	south	
Western	Gulf Stream	Brazil Current	Kuroshio	East Australian Current	Somali Current
					Mozambique Current
					Agulhas Current
Eastern	Canary Current	Benguela Current	California Current	Peru Current	West Australian Current

Gulf Stream and Kuroshio currents

The best explored western boundary currents are the Gulf Stream and the Kuroshio. The Gulf Stream system is composed of the Florida Current, the Gulf Stream proper between Cape Hatteras and the Grand Banks, and the North Atlantic Current. The corresponding divisions of the Kuroshio system are the Kuroshio, south of 35° N, the Kuroshio Extension, and, farther east, the North Equatorial Current.

The Gulf Stream and Kuroshio are usually sharply defined by an oceanic front along their continental side that marks a transition between the warm and more saline water masses of these currents and the cooler, less saline water of coastal regions. This front, often called the cold wall, is distinguished by a sudden change in temperature and sea colour.

Recent observations have shown that both currents are much narrower and faster than previously supposed. Sometimes they break up into two or more streaks that are considerably variable in their position and speed, often forming meanders and eddies that may detach from the main current.

Eastern boundary currents are relatively shallow and often indicate the presence of numerous eddies and countercurrents. These currents are closely connected with the process of upwelling water in coastal regions. Outstanding areas for this phenomenon are the coasts of northwest Africa, southwest Africa, California, and northern Chile and Peru. The upwelling water is usually restricted to the upper layer of 200 metres or 300 metres depth.

The equatorial current system. The circulation of the upper ocean strata in tropical and subtropical regions is dominated by the North and South Equatorial currents, Equatorial countercurrents, Equatorial undercurrents, and in some parts by Monsoon currents. Pronounced seasonal variations of the equatorial current system are the result of strong seasonal changes of the wind system, particularly in the Indian Ocean. This wind system is governed essentially by the trade winds and in some areas by monsoon winds. Between the fairly steady trade winds of both hemispheres a more or less broad belt of light variable winds or calms develops, often called the doldrums.

From G. Neumann, "Oceanography of the Tropical Atlantic," *Anais da Academia Brasileira de Ciencias*, vol. 37, Supplement, pp. 63–82 (1965)

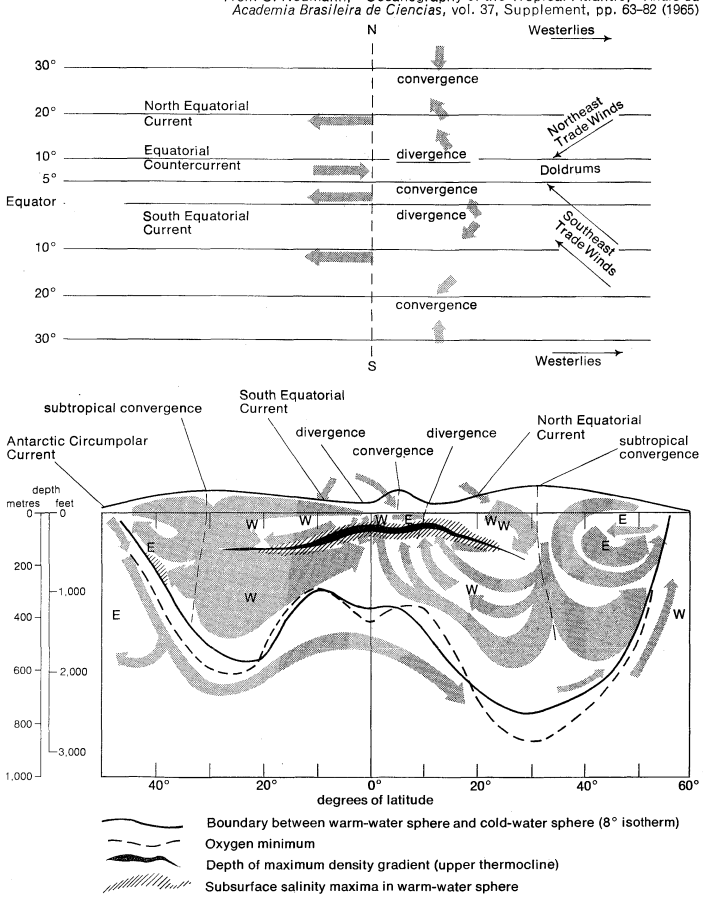

Figure 2: (Top) Explanation of equatorial and subtropical current system. (Bottom) Cross-sectional view of warm-water sphere (equatorial and subtropical regions) showing meridional circulation by arrows and zonal currents by W and E, respectively. Main features of stratification as related to currents are also shown.

Equatorial countercurrents

Among the outstanding branches of the equatorial current system are the Equatorial countercurrents. The most impressive is the North Pacific Equatorial Countercurrent. The Equatorial Countercurrent of the Atlantic is fully developed only during the Northern Hemisphere summer when it extends from about 50° W longitude into the inner Gulf of Guinea. During winter (Figure 1), it occupies only the eastern part of the tropical Atlantic.

In the Indian Ocean, during the time of the northeast monsoon (Northern Hemisphere winter), a strong countercurrent is found between about 2° S and 8° S, embedded in the westward flowing North and South Equatorial currents. During this season, the Somali Current, near the African coast, flows southward, where at about 7° S it feeds part of its water into the countercurrent (see Figure 1). During the Indian southwest monsoon (Northern Hemisphere summer), however, currents have completely reversed their direction in the tropical western and northern part of the Indian Ocean. The Equatorial Countercurrent has disappeared and the Somali Current has reversed its direction and flows northeastward, sometimes even faster than the Gulf Stream. This remarkable current now feeds its water masses into the eastward flowing Southwest Monsoon Current in the northern Indian Ocean.

The doldrums

The locations of the Equatorial countercurrents are closely related to the locations of the doldrums. A qualitative explanation of the tropical current system for the case where doldrums occupy latitudes between 5° N and 10° N is as follows. Wind-driven water transport in the Ekman layer leads to convergences and divergences of surface water between the major winds and to a piling up or depression of the sea surface, respectively. The resulting slopes of the sea surface in a meridional section from about 25° N to 10° N are downward. Between 10° N and 5° N it must be upward because of the convergence at 5° N. Near the Equator is a region of divergence and, therefore, the sea surface must rise from the Equator not only toward 25° S but also toward 5° N.

These slopes of the sea surface produce horizontal pressure gradients and slope currents that superpose the pure wind-driven currents. Because the resultant currents must always flow in such a direction that the higher pressure is to the right in the Northern Hemisphere and to the left in the Southern Hemisphere, westward flowing currents must occur between 25° N and 10° N, and between 5° N and 25° S. These currents represent the North and South Equatorial currents. The surface slope in the doldrums belt between 10° N and 5° N, however, requires a narrow, eastward flowing current, the Equatorial Countercurrent.

Equatorial Undercurrent and the Cromwell Current

The Equatorial Undercurrent is another extremely narrow, eastward setting current branch in the equatorial current system. It is centred on the Equator with a width of about 200 to 300 kilometres and a vertical extent of 200 to 300 metres. Most often, it does not reach the sea surface and is, therefore, not represented in surface current charts. Maximum eastward speeds of 100–150 centimetres per second may occur at depths between about 50 and 150 metres, while at the sea surface westward setting currents are observed. This current was first extensively studied in the Pacific Ocean where it is named the Cromwell Current. During recent years, oceanographic work in equatorial regions has established the worldwide existence of this remarkable current. In 1960 G. Neumann pointed out evidence for an Equatorial Undercurrent in the Atlantic Ocean.

The Antarctic Circumpolar Current. Currents around Antarctica flow mainly from west to east. Only in a narrow zone close to the continent are westward flowing currents observed (Figure 1). Both currents are largely a response to the prevailing winds.

The great eastward flow is called the Antarctic Circumpolar Current. In contrast to the wind-driven currents in tropical and subtropical regions, this current is deep and in some parts of the ocean it reaches the bottom at 3,000–5,000 metres depth. Therefore, its course is strongly affected by bottom topographic features, like submarine ridges. The surface speeds are rather small (15–20 centimetres per second), but as a result of the great depth, the water volume transported exceeds that of any other oceanic current system. V.G. Kort (1962) estimated the Antarctic Current transport to be 150,000,000 and 190,000,000 cubic metres per second. This is about twice the rate of transport of the Gulf Stream. The Antarctic Circumpolar Current constitutes an important link between the Atlantic, Indian, and Pacific Oceans, with respect to the oceanic deep-sea circulation and stratification.

DEEP-SEA CIRCULATION

Knowledge of the deep-sea circulation is essentially based on indirect methods. The German oceanographers Albert J.M. Defant and George A.O. Wüst used such methods extensively to analyze the deep-sea currents in the Atlantic

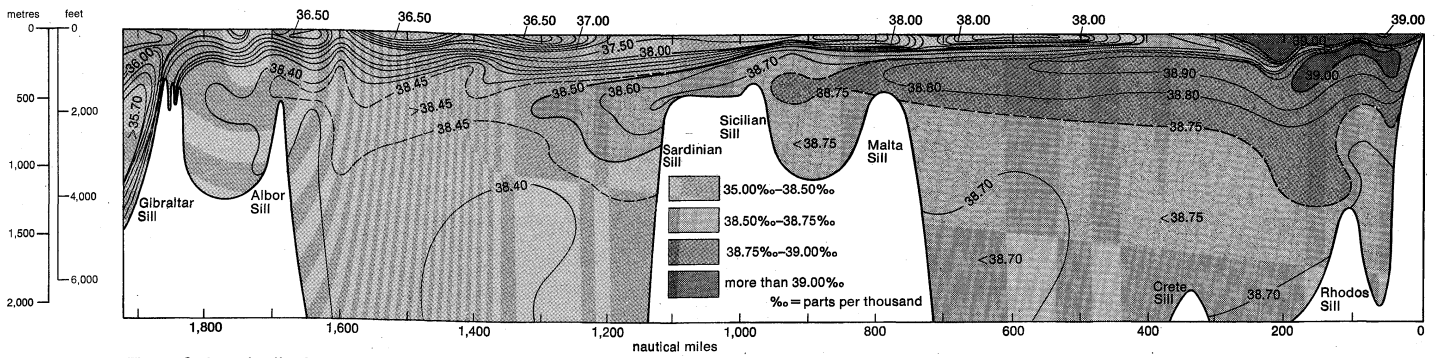

Figure 3: Longitudinal sections of summer salinity in the Mediterranean Sea along the axis of the Levantine Intermediate Water, showing the origin of the water that forms the so-called Upper Deep Water in the Atlantic Ocean.
From Wust (1961) in G. Neumann and W.J. Pierson, Jr., *Principles of Physical Oceanography* (1966); Prentice-Hall, Inc.

Ocean. The distribution of temperature, salinity, oxygen, and other chemical factors have provided much information on currents and water mass transport throughout the oceans. Some direct current measurements from the deep sea also have been used and it has been concluded that the deep-sea circulation is essentially a thermohaline circulation that depends on differences of temperature and salinity. It is not independent of the wind-driven circulation, however.

Influence of highly saline waters

Compared to the Pacific and Indian oceans, the vertical structure of temperature, salinity, and oxygen in the Atlantic is more differentiated. This is because the exchange of water with the Arctic Ocean is many times greater than that of the Pacific. Moreover, the Atlantic is bordered by a number of adjacent seas, among which the Mediterranean Sea is the most important. Small, but continuous, intrusions of Mediterranean water of high salinity and relatively high temperature through the Strait of Gibraltar create a special "climate" in the Atlantic deep sea.

The Mediterranean Sea, in general, is located in an arid climate zone. Evaporation exceeds precipitation, and this causes an increase of surface salinity, especially in its eastern parts. This high salinity water near Asia Minor sinks into subsurface layers because of its higher density. From there, it moves with subsurface currents at about 500 metres depth westward and, finally, flows through the Strait of Gibraltar into the Atlantic Ocean. This Mediterranean water sinks quickly to about 1,500 to 2,500 metres depth and spreads out into the Atlantic. It can be traced across the Equator as far south as the Antarctic Ocean, where it is entrained in the Antarctic Circumpolar Current. Along its path this water mass, termed Upper Deep Water, gradually decreases in salinity while mixing with less saline water above and below its level of spreading. In the Indian Ocean a similar water mass originates in the Red Sea and the Persian Gulf, whereas it is missing in the Pacific Ocean.

A schematic block diagram (Figure 4) for the western part of the Atlantic Ocean summarizes knowledge of its surface currents and deep-sea circulation. The spreading of the Mediterranean water from about 30° N and 1,500 metres depth is indicated.

Middle and Lower Deep Water masses

Other important deep-sea movements from north to south are associated with the spreading of Middle and Lower Deep Water masses. These water masses originate near Greenland. They are cooler (3°–4° C) than the Upper Deep Water and can be traced by their higher oxygen content while spreading southward between about 2,500 and 4,000 metres depth. Wüst estimated current speeds of 10–15 centimetres per second at about 3,000 metres depth in western equatorial regions. There seems to be no source of cold deep water in the North Pacific.

Deepwater movements from north to south in the Atlantic are sandwiched between water masses that spread northward with relatively low salinities (less than 34.85‰ [parts per thousand]; see Figure 4). The upper water mass is called the Antarctic Intermediate Water. It is formed at the sea surface near the Polar Front, or Antarctic Convergence, around 50° S. From there it spreads northward at about 700 or 1,000 metres depth, mainly in the western part of the Atlantic, where it is characterized by low salinities. It can be traced as far north as 25°–30° N.

Antarctic Bottom Water

The deepest water mass of all, Antarctic Bottom Water, originates on the shelf of the Antarctic continent. Because of its high density, it slides down to the ocean bottom and then spreads northward and eastward. Its movements are channelled by submarine ridges and troughs, and it spreads mainly along the western half of the Atlantic (West Atlantic Trough), crossing the Equator while passing some of its water through a narrow pass (the Romanche Trench) in the Mid-Atlantic Ridge. Average velocities of 10–15 centimetres per second near South America have been obtained from geostrophic current computations. Bottom-water current speeds can be more than twice as great on occasion, however. Relatively strong bottom-current speeds, up to 60 centimetres per second, have been inferred by marine geologists from ripple marks, scour marks, and rock outcrops beneath the Antarctic Bottom Water, in the Drake Passage south of Cape Horn, and in other parts of the oceans, including the Pacific Ocean.

OBSERVATION OF OCEAN CURRENTS

Meaningful current measurements require knowledge of a fixed point in the open ocean or accurate determination of the geographical position from which the measurements are made. The fixed point can be an anchored ship, a moored buoy, or a platform construction. Submerged deep-sea diving vessels like the bathyscaphe "Trieste II" also can be used to make current observations near the sea floor while the ship has settled on the bottom.

Methods of measuring ocean currents can be divided into two basic groups. The Eulerian method measures the speed and direction of currents at fixed points by means of current meters. If observations of this kind are available for many points, current charts can be constructed that depict the instantaneous movement of the water in a given area. The current can be shown by a current vector at each observation point that indicates direction and speed. The combination of many of such current vectors in a chart gives a streamline representation of currents, where at each point the current vector is tangent to the streamline.

Drift measurements

The second group of observational methods is termed Lagrangian; basically, the path of a drifting water parcel is followed over a longer time interval. The traced path of a water particle or of a freely floating object is called a trajectory, and the combination of many of such trajectories permits construction of a trajectory chart, in distinction to the streamline chart obtained by the Eulerian method. Only when currents are stationary, where they do not change with time at a given place, will trajectory charts agree with streamline charts.

Trajectories of ocean currents usually represent only horizontal trajectories, and the vertical motion of water is neglected. This is because the observations are taken by means of drifting objects, called tracers, and these are bound to a certain water layer and, therefore, do not follow exactly the three-dimensional path of drifting water.

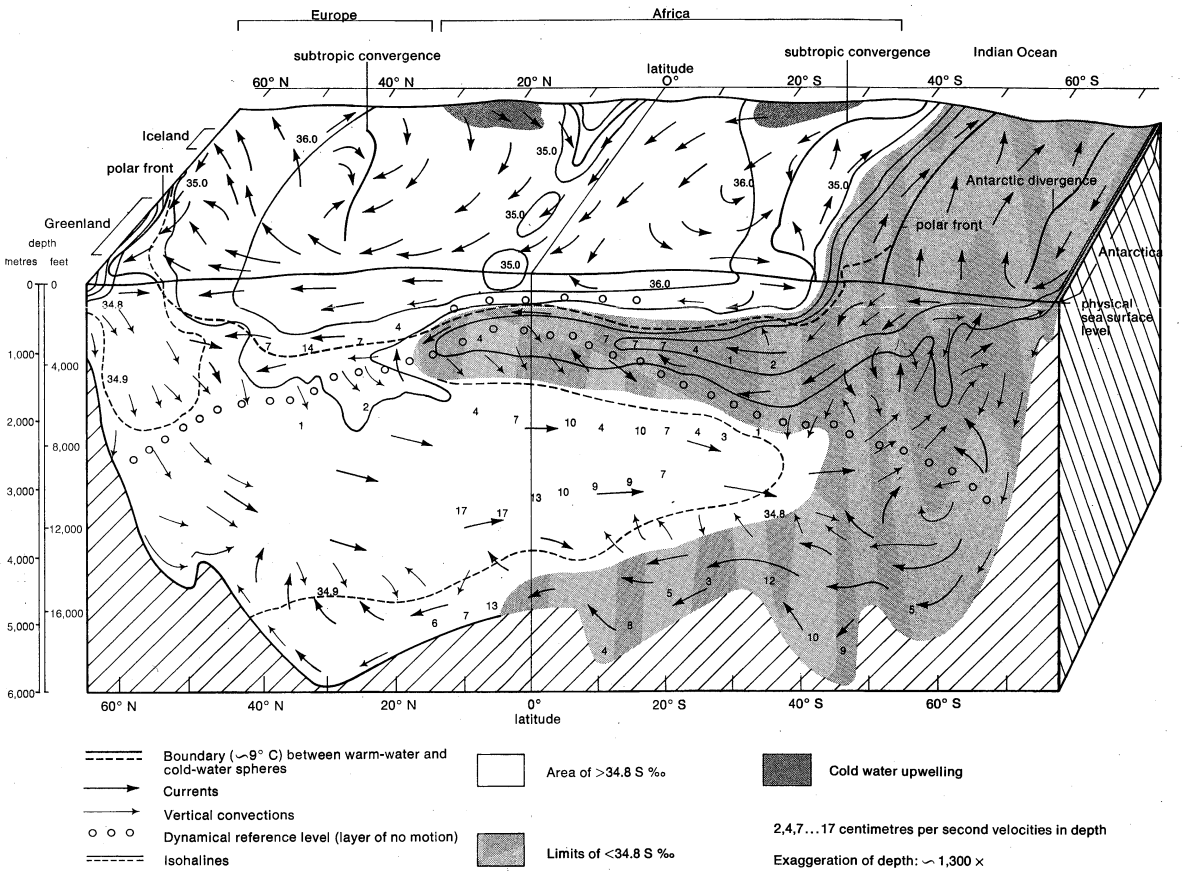

Figure 4: Essential aspects of deep-sea circulation and spreading of water masses in the Atlantic Ocean.
From Wust (1961) in G. Neumann and W.J. Pierson, Jr., *Principles of Physical Oceanography* (1966); Prentice-Hall, Inc.

The oldest method of drift measurements involves the use of drift bottles or drift cards. Together with ship drift observations, where the ship itself is used as a tracer, these simple methods have helped to describe many of the main features of the surface circulation in the oceans. Because drift measurements require the continuous tracing of freely floating objects along their path, the obvious disadvantage of the method is that in many cases only the end point of drift can be related to the starting point. Modern radio buoys can be traced continuously by radio direction-finding receivers from shore stations, ships, or aircraft.

Deep drogues to measure the path of moving water can be either canvas, wood, or metal crosses or sheets that offer the largest possible drag at the level of current measurement. Parachutes that are designed to open at a prescribed depth of measurement have been widely used. These deep drogues are attached to a small surface float that can be followed by an attending ship.

The first successful subsurface current drift tracer without surface connection was developed and used in 1955 by J.C. Swallow. It is a neutral buoyancy float, properly balanced to float freely at a predetermined level, where the weight of the displaced water equals the weight of the float. The subsurface float acts as an acoustical source, and sends signals to the surface ship. These signals or "pings" can be followed by a surface ship equipped with hydrophones suspended into the sea.

Electromagnetic and temperature–salinity methods

If seawater, which is an electric conductor, moves in the earth's magnetic field, an electric field is induced in the water. The intensity of this electric field can be measured by a pair of electrodes in tandem, about 100 metres apart, towed behind a ship. The electric potential difference between the two electrodes, e, is recorded on board the ship by means of a potentiometer. The velocity, v, of the moving water is proportional to e, and $v = ke$, where k is a factor that depends on the distance between the electrodes, the specific electrical resistance of seawater (and of the bottom in shallow water), and on the vertical intensity of the geomagnetic field. Manoeuvring the ship by 90° changes in course provides the necessary data for determining current speed and direction. The advantage of this method is that it does not require a fixed point for making current measurements.

The velocity of ocean currents also can be obtained from measurements of the temperature and salinity of seawater from surface to bottom. Knowledge of the distribution of temperature and salinity permits computation of the density of seawater. The relative pressure field that provides the driving force for ocean currents can be derived from the density field. If the pressure field in the oceans is known, certain hydrodynamic relationships can be used to compute the speed and direction of currents.

OCEAN CURRENTS, CLIMATE, AND WEATHER

The mutual influence of atmosphere and ocean manifests itself in climate and weather phenomena, as well as in the circulation and stratification of the oceans. Ocean currents are largely responsible for the temperature distribution at the sea surface, which, in turn, affects the overlying atmosphere. The difference between the temperature of the air and water basically determines evaporation rates, atmospheric humidity, precipitation, and the vertical stability of air masses moving over the ocean surface. As air cools when flowing over a cold ocean current, fog is likely to form. When cool air flows over a warm current, the air is heated from below and may rise. This leads to condensation of water vapour in the rising air, cloud formation, and often precipitation. Such atmospheric convection processes can sometimes be violent, forming towering cumulonimbus clouds and thunderstorms.

Interaction of atmosphere and ocean

Meteorological consequences of the interaction of atmosphere and ocean are obvious in regions of upwelling water near the west coasts of the continents. The upwelling water is accompanied by relatively cool sea surface temperatures. Because the air is cooled and stabilized over these regions, the climate is cool, with haze or fog, but

little or no precipitation. From the biological point of view, these coastal regions offer a striking contrast between land and sea. Off the coast of northern Chile and southern Peru, for example, the land is barren, dry, and almost wholly infertile (Atacama desert); the sea, however, teems with sea life of every type. Its cool waters provide some of the world's best fishing grounds, because water from deeper layers with a high nutrient content is brought up to the sea surface by the upwelling process.

The oceanic circulation also supports the atmospheric circulation in equalizing temperature differences between the tropics and the poles. The oceans can store great amounts of heat because of the great specific heat of water. The heat stored in tropical regions is transported over great distances, especially by western boundary currents. It is released to the atmosphere in higher latitudes chiefly as latent heat of evaporation. The fact that northwest Europe has such an agreeable climate is ultimately the result of the Gulf Stream system, a warm-water heating system that is supported by, and mutually related to, a warm-air heating system that is provided by the prevailing winds. In the Pacific Ocean, the Kuroshio Current system plays a similar role with respect to the climate of the northwestern part of North America.

Disturbances of the oceanic current system and its associated heat transport can produce far-reaching effects that are reflected in climatological anomalies; droughts or floods, abnormally cold and severe winters, or extremely mild ones are examples. Attempts at long range weather forecasting (*q.v.*) depend largely on the general oceanic circulation, its variation through time, and its effect on physical conditions at the air–sea interface.

BIBLIOGRAPHY. General textbooks, with extensive information and bibliographies on ocean currents, include: H.U. SVERDRUP, M.W. JOHNSON, and H.R. FLEMING, *The Oceans* (1942); A. DEFANT, *Physical Oceanography*, 2 vol. (1961); W.S. VON ARX, *Introduction to Physical Oceanography* (1962); G. DIETRICH and K. KALLE, *General Oceanography* (1963); H.J. MCLELLAN, *Elements of Physical Oceanography* (1965); and G. NEUMANN and W.J. PIERSON, JR., *Principles of Physical Oceanography* (1966).

Specialized textbooks on currents are H. STOMMEL, *The Gulf Stream: A Physical and Dynamical Description*, 2nd ed. (1965); L.M. FOMIN, *The Dynamic Method in Oceanography* (1964); and G. NEUMANN, *Ocean Currents* (1968), with an extensive bibliography.

Information on this subject may also be found in M.N. HILL (ed.), *The Sea*, vol. 1 and 2 (1962–63), containing technical articles on the dynamics of ocean currents, current measurements, and special current systems; R.W. FAIRBRIDGE (ed.), *Encyclopedia of Oceanography* (1966); and in R.W. STEWART, "The Atmosphere and the Ocean," *Scient. Am.*, 221:76–86 (1969).

Oceania, History of

Oceania, in its broadest sense, comprises most of the insular territories of the Pacific Ocean, but conventionally comprises four divisions: (1) the island continent of Australia; (2) Melanesia, from New Guinea eastward to Fiji; (3) Micronesia, principally the Mariana, Caroline, Marshall, and Gilbert archipelagoes; and (4) Polynesia, a triangle with many islands, such as Hawaii, Tahiti, Samoa, Easter Island, and New Zealand. In this article, the history of Oceania is limited to Melanesia, Micronesia, and Polynesia. (For Australia and New Zealand see AUSTRALIA, HISTORY OF; NEW ZEALAND, HISTORY OF.) These names were coined in the second quarter of the 19th century by the French explorer Jules Dumont D'Urville from the Greek noun *nēsos* ("island") and the adjectives *melas* ("black"), *mikros* ("small"), and *polys* ("many"). But the history of Oceania began many thousands of years before this European classification, before even the first European sightings of the islands in the 16th century. Prehistory, the period before written records survive, began in Melanesia at least 20,000 years ago, and the migrations and voyages that led to the populating of every habitable Pacific island extended from that time until the first quarter of the 2nd millennium AD. After European discovery, which extended from the early 16th century until the end of the 18th, the prehistoric world of Oceania was transformed, at first by casual visitors, then by more permanent ones, such as beachcombers and castaways, and then, at the end of the 18th century, by missionaries. From the 19th century the European impact was accelerated by missionaries, traders, settlers, and by the penetration of European governments into the area. By the 20th century, Oceania had been completely involved in the European world, even as European governments began to withdraw from the region.

Historiographical problems. Both the prehistory and the history of Oceania present problems. Prehistory is primarily dependent for its reconstruction upon archaeology. This has scarcely begun in Oceania, so that any conclusions must be tentative and subject to modification with each new site that is examined. Linguistics, upon which the prehistory also rests, is somewhat more advanced, but here, too, much remains to be done. A broad picture can be sketched, but the detail is still missing. Indeed, prehistory with a precise detailed chronology may never be possible. The period of Oceanic history for which documentary evidence is available also presents difficulties. The documents are chiefly of European origin and are, therefore, the products of people who may not accurately have recorded a culture different from their own—a culture they perceived and understood only imperfectly. This distortion can be corrected to some extent by using the findings of social anthropology and the oral traditions of the Oceanic people, but these sources are difficult because, by definition, they are contemporary. They may not describe the past accurately because they serve contemporary purposes; they do not record the past for its own sake. But the main historiographical problem of Oceania is its diversity. Some 10,000 islands scattered across 750,000 square miles of ocean, a great variety of cultures, hundreds of mutually unintelligible languages, and very diverse historical experiences make it very hard to generalize.

Geography and prehistory. The physical diversity means that contact between islands has never been easy because of the distances involved; it also means that the physical environment is not only isolated but varied. The large continental islands of Melanesia—such as New Guinea, New Caledonia, and Viti Levu—not only have a different physical basis of life and a wide variation in climate and fertility but their rugged terrain has made for social isolation. The smaller volcanic high islands, such as Samoa and Tahiti, have greater homogeneity and, although lacking the mineral resources of the continental islands, are very fertile, supporting a life well above the subsistence level. The coral atolls, the low islands of Oceania, support a much narrower range of vegetation; they are more exposed to bad weather and support an existence much closer to bare subsistence, except for the rich marine resources of their lagoons.

Physical environment does not determine the kind of society that exists, but it does set limits to it. The large islands of Melanesia produce marked differences between people of the coast and those of the interior. Their long coastlines have acted as a filter for many different arrivals in Oceania. The valleys have perpetuated differences. Thus Melanesia is characterized by many small groups of people, divided from each other by language and custom. Political and social organization has been small in scale. The margin above subsistence has not been great enough to allow for elaborate ceremonial. The high volcanic islands of Polynesia offered no such barriers to social and political unity. Their fertility allowed the development of elaborate social, religious, and political ceremonial. The low islands also allowed homogeneity and wide social groupings, but their land resources offered no great margin for ceremonial life except as they were supplemented by skill as fishermen. These contrasts within Oceania are obvious, as they were to early European visitors, but they conceal a similarity: whether small, with leadership a matter of acquiring influence rather than hereditary position, or larger, with chiefs surrounded with awe and reverence, Oceanic societies all rested on the principle of reciprocity. Every gift or service had to be returned.

Ethnography

The diversity of Oceania not only conceals a basic similarity but it has also misled historical enquiry. The useful division of Oceania into Melanesia, Micronesia, and Polynesia has prompted a search for different origins of the people of those areas. They have been assumed to be different races—Negrito, Mongoloid, Caucasoid. They have been traced as different waves of migration out of Southeast Asia; and the Polynesians have been given, by at least one authority, a South American origin that is denied by the linguistic and botanical evidence. These earlier theories of waves of immigrants from Malaysia and elsewhere are very doubtful in the light of the archaeology. What recent archaeology suggests is that the threefold division happened in Oceania itself: it is no evidence of different origins in some area outside Oceania. New Guinea was certainly settled at least 20,000 years ago, presumably by people from Southeast Asia. But the earliest dates for the settlement of the rest of Oceania are as yet no older than the 2nd millennium BC, and this settlement extended into the Christian Era. Linguistic evidence supports this. People on the islands of Oceania speak languages of the Austronesian stock, which includes Indonesia, Malaysia, the Philippines, and the aboriginals of Taiwan and Madagascar. Languages of non-Austronesian type are found only in small numbers in the interior of the islands of New Guinea and its close neighbours.

The broad picture that the archaeological work suggests is, therefore, that there was an early human settlement in New Guinea, perhaps 25,000 years ago. Then, at some later date, there was a new complex of settlement, which was not that of hunters and gatherers but of horticulturalists who had domesticated animals. This complex was taken, fully formed, with the first settlers of other Pacific islands, together with a ground-stone technology. The pottery called Lapita ware (from the site at which it was first systematically examined in New Caledonia) indicates the track of these settlers. It has been found in New Britain, near Rabaul, and in the New Hebrides, in Fiji, and in Tonga. Its makers had settled in Fiji by 1000 BC and in Tonga by 500 BC. They were the formative influence in what has been classified as Polynesian culture. In the Marianas, in Micronesia, a related type of pottery goes back to the 2nd millennium BC. It seems, therefore, that what is distinguished as Polynesian was filtered through Melanesia to western Micronesia, and to western Polynesia, where it developed distinctive characteristics that were then taken by the original settlers to eastern Polynesia, where the Marquesas were settled about AD 500. On this evidence, the three divisions of Oceania that so struck the first Europeans originated within the islands themselves. And, in the case of some of the eastern Polynesian islands, settlement antedated that of Europeans by only a few hundred years.

Neolithic technology

Oceanic societies, at the time of European discovery, were Neolithic. They had developed a technology based on stone, bone, and shell; they cultivated tubers and tree fruits, all of which were of Southeast Asian origin, with the exception of the sweet potato, which derives from South America, and which culture had spread through most of Polynesia in pre-European times, but only marginally into Melanesia. This Neolithic cultivation was associated with three domesticated animals: the pig, dog, and chicken, also of Asian ancestry. The coastal people had developed techniques of fishing and considerable skills as sailors; although the fabulous voyages once ascribed to the Polynesians are doubtful, navigation between the closer islands was well-developed. At the same time, some skills were lost: pottery, for example, disappeared in the Samoas and the Marquesas shortly after initial settlement. And with the control of the environment that Oceanic technology offered, there is evidence of overpopulation, settlement spreading into less-favoured areas of the islands and being fortified, as in the Marquesas. (For a discussion of the cultures of the indigenous peoples, see OCEANIAN PEOPLES AND CULTURES; for further description of the geographic setting, see PACIFIC ISLANDS.)

European exploration. The Oceanic world was not a static unchanging one, but changes were slow compared with those that attended European discovery. Vasco Núñez de Balboa discovered the Pacific in 1513; seven years later Ferdinand Magellan rounded South America and sailed across the ocean, missing the main island groups but discovering one of the Tuamotu Islands and Guam; after his death in the Philippines, his expedition discovered some of the Carolines. These northern islands were further explored by the Spaniards as they established a galley trade from Manila to Acapulco (see PHILIPPINES, HISTORY OF THE). The next major Spanish discoveries were made by Álvaro de Mendaña de Neira and Pedro Fernández de Quirós. In 1567 the former set out from Peru to discover the great southern continent, which was believed to exist in the South Pacific. He found the Solomons but failed to find them again on his second journey, during which he died. In 1606 his chief pilot, Quirós, after discovering some of the Tuamotu Archipelago, found the northern Cooks, Tikopia, and the New Hebrides. One of his companions, Váez de Torres, found southeastern New Guinea and then the strait (later named for him) between that island and Australia, although the discovery was unknown to later sailors. These Spanish expeditions were motivated by the search for riches; by zeal to extend religion; and, in the case of Quirós, discovery for its own sake. But with his voyage, the Spanish effort was ended. Thereafter, the Dutch, who were already established in Indonesia, entered the Pacific. They too looked for a southern continent. In 1615–16 the Dutch navigator Jacques Le Maire came from the east through the Tuamotus to discover Tonga, the Bismarck Archipelago, New Ireland, and New Hanover. In 1642 Abel Janszoon Tasman, sailing from Batavia (now Djakarta, Indonesia), the Dutch headquarters in the East Indies, discovered New Zealand, Tonga, some of the Fijis, and New Britain. The Dutch were primarily interested in commerce; they found none. Tasman thought that New Zealand was part of the great southern continent. The effect of these visitors on Oceania was transitory. They stayed for periods of at most a few months. Their contacts with the islanders were those of simple barter, but the demands they made upon food supplies often caused hostilities in which some European and many islanders' lives were lost, as on Guadalcanal and in the Marquesas during Mendaña's visits.

During the early 18th century the extent of Oceania was further revealed. The English pirate William Dampier visited New Hanover, New Britain, and New Ireland in command of a Royal Navy ship. Dampier was the forerunner of scientific exploration, and he proved that those islands were separated from each other and from Australia. In 1722 the Dutch admiral Jacob Roggeveen crossed the Pacific from east to west on a voyage of exploration that had also commercial objects. He found Easter Island, more of the Tuamotu Archipelago, the northern islands of the Society group, and some of the Samoan islands. These voyages were not essentially different from earlier ones, but they foreshadowed the scientific interest of the later 18th century. The execution of that interest was delayed by European wars. But in 1765 the English admiral John Byron (grandfather of the poet), who was sent by the British Admiralty in search of the supposed southern continent, found more of the Tuamotus and the southern Gilberts. In 1767 Samuel Wallis and Philip Carteret followed, but their ships were separated as they entered the Pacific. Wallis discovered Tahiti, more of the Tuamotus, and the Society Islands, while Carteret found Pitcairn and rediscovered the Solomons of Mendaña, although he did not so identify them. This was left to the French following Louis-Antoine de Bougainville's visit in 1768, during which he also discovered some of the New Hebrides and Rossell Island in the Louisiade Archipelago.

These explorers were more important for the knowledge they spread in Europe than for most of their discoveries. Dampier's *New Voyage round the world* and Bougainville's description of the noble savage in Tahiti were particularly influential. The English captains had not carried out their precise instructions, but the interest their jour-

nies created was in part responsible for the instructions given to the greatest of all 18th-century explorers of Oceania, James Cook. In three voyages he left others little to do but fill in occasional details of Oceania. Cook was sent in 1769 to observe the transit of Venus at Tahiti and then to search for the great southern continent. Cook found some of the Society Islands, but he also circumnavigated New Zealand, and he defined the limits of eastern Australia. During his second voyage (1772–75), he proved that there was no southern continent, but he also made further discoveries in Oceania: in the Tuamotus, the Cooks, the Marquesas, Fiji, New Caledonia, the New Hebrides, and Norfolk Island. His third voyage (1776–79) was mainly concerned with the North Pacific, during which he found some of the Tongan group, Christmas Island, and Hawaii between. He had completed the main work of discovery with an exactitude hitherto unknown. Although his contacts with islanders were not in essence different from his predecessors, his relations with them were nevertheless more prolonged and more humane. And his exploration of eastern Australia, through the account of his naturalist, Joseph Banks, was of great importance in Oceania, for it led to European settlement close to the islands.

Importance of Cook's travels

Traders and vagabonds. With the establishment in 1788 of the Australian settlement, Oceania became a source of supply. In 1793 pigs from Tahiti were landed at Sydney, and until 1826 the trade, although subject to fluctuations due to the competition of other cargoes and Tahitian wars, was important. The competition among Europeans for sandalwood, pearl shell, and bêche-de-mer (sea cucumbers), valuable cargoes that attracted ships from the Australian colony, further involved Oceania with the European world. In 1804 sandalwood was found in Fiji and for the next ten years attracted European traders. The sealing industry drew men to New Zealand, just as the fur traders, in the 1790s, wintered in Hawaii. All of these contacts began to affect Oceanic societies because they were sustained and prolonged. Together with the castaways and beachcombers who had begun to live in the islands from the days of first European contact but who increased in numbers with commercial shipping, these European contacts began to transform Oceania.

The "Bounty" mutineers

Castaways, such as the HMS "Bounty" mutineers who went to Tahiti in 1789, began with their muskets to alter the political state of the islands they lived in by the support they gave to the chiefs who befriended them.

Missionary and trading societies. Such Europeans had an important effect, but they were dependent upon the people they lived with for their survival. Very different were the first Europeans to come to Oceania permanently and with the deliberate intention of changing Oceanic society: the missionaries. In 1797 the London Missionary Society (LMS), now the Congregational Council for World Mission, sent a party to Tahiti. After some vicissitudes it converted the chief Pomare I who controlled the area of Matavai Bay, where Europeans had called since Wallis' discovery. The LMS failed in its first attempts at Tonga and the Marquesas, although it was more successful in Huahine, the Tuamotus, the Cooks, and later in Samoa. Other missionary societies followed. In 1822 the Methodists began to work in Tonga; in 1835 they went to Fiji. In 1843 Roman Catholic missionaries began working in New Caledonia. The Church of England began to penetrate into Oceania from New Zealand in the 1840s. These missionaries encountered societies in Polynesia that already had a problem of law and order from the effects of European beachcombers and traders. Its solution was to create missionary kingdoms, in the case of British missionaries, or the establishment of direct political control, in the case of the French.

In Tahiti, Hawaii, and Tonga, native chiefs whose power was established by their access to European arms and support not only became kings but took missionary advisers and missionary-designed codes of law. In 1819 the native ruler Pomare II of Tahiti promulgated such a code. In Tonga, Taufa 'ahau took the name of George in 1833, and in 1845, when he took the Tongan title of Tu'i Kanokupolu, he became "king" of Tonga; in 1862, under the influence of the Rev. Shirley Baker, he adopted a constitution. By attempting to enforce a scriptural code of law, these missionary kingdoms were an answer to the problems of European lawlessness in the islands. If the missionaries could not prevent the sale of arms, they could at least make sure that these passed into the hands of friendly chiefs. But the authority of these "kings" was challenged from two sides. By becoming Christian they had cut themselves off from the mana (a Polynesian religious concept sometimes described as an all-pervasive energy) that came from the old gods, and this produced heathen reactions. In Tahiti there was a revolt against the new Christian order by supporters of the old ways in 1830; in Tonga there was a similar reaction in 1831. In Samoa, where the holder of the Malietoa title had embraced Christianity from Tahitian missionaries, there were heretical movements. If heathen beliefs thus resisted the chiefs and their missionary supporters, the European traders also resisted the political authority of the kings. Dissidents and heretics looked to these Europeans for leadership, and these Europeans looked to their own national governments for protection.

In Melanesia the story is somewhat different. In Fiji, the missionaries who landed in 1835, accompanied by an envoy from George of Tonga, made no headway with the rising chief Cakobau, who was not converted until 1854, when his fortunes were at a low ebb and he needed Tongan support. Elsewhere in Melanesia, the absence of chiefs meant that missionary work had to be conducted with small groups of people and repeated every few miles. There was no wholesale conversion of the kind that had happened in Polynesia. The attempt of the London Missionary Society in the New Hebrides in the 1840s came to nothing. The Anglican Melanesian mission in the Solomons made slow progress in the 1850s. In New Guinea, mission work, divided into four spheres of influence in Papua, did not begin systematically until the 1870s. Micronesia was a backwater. The Spaniards had established missionaries in the Marianas in 1668, but the missionaries in the Carolines were killed in 1733. The main effort came from the Hawaiian Evangelical Mission in the 1850s. The general effect of mission activity was, nevertheless, the same as it was in Polynesia. It dissolved the old ties of society by attacking the supernatural sanctions that supported leadership and social mores. It altered the political structure of Oceanic societies. It incidentally introduced both European goods and the desire for them. The missionaries themselves acted as intermediaries between Oceanic societies and other Europeans—as political advisers, as agents, and as interpreters.

Growth of trading communities

Beachcombers and castaways preceded missionaries in many of the islands, but the growth of trading communities was in part the result of the missionaries' work in restraining native violence. Those traders were initially pork traders in Tahiti, but European captains followed valuable cargoes from island to island. When the supply of sandalwood was depleted in Fiji by 1813, the traders then found it in Hawaii in the 1820s, in the New Hebrides in 1825, and in New Caledonia in 1840. Pearl shell attracted traders to the Tuamotus in 1807. The sandalwood trade declined as supplies were exhausted. Pearling declined as natives took reprisals for the atrocities that had accompanied both trades. The demands of the Oceanians also changed the character of trade. Once native polities were established, the demand for muskets fell off; under missionary influence, the demand for alcohol was limited. What the islanders now wanted was clothing and hardware. The exchange traders were not guilty of the cruelties as those looking for sandalwood or pearls were apt to perpetrate to obtain their cargoes, and exchange trading encouraged the growth of resident agents in the islands, a development that met the needs of the whalers who came ashore to refit their vessels. After 1840 it also met the needs of the staple trade of the islands—coconut oil. Copra trading, from which the oil came, became the mainstay of European trade because even islands that had no other resources had coconut palms. In the early 1840s new techniques enabled the oil to be used for soap and candles. Such commerce promoted the growth of the port

towns and of resident trading communities. Papeete in Tahiti, Apia in Samoa, and Levuka in Fiji became European centres, including not only respectable traders but also lawless men who might be escaped convicts from New South Wales or others escaping from the rules of settled societies. These were frontier towns and could be regulated only with difficulty by native kings or by visiting European captains. Law and order became a problem with which the Oceanic institutions were unable to cope and with which captains could deal only intermittently.

European settlement. The problem became more urgent with the advent of European settlers. In Fiji, for example, after Cakobau's first offer of cession of the islands to Great Britain in 1858, Europeans came to establish plantations, at first of coconuts, then, during the U.S. Civil War, for cotton and afterward sugar. The development in Samoa was similar. But settlers needed land on a much larger scale than traders, and they needed labour in much greater quantities to work the plantations. Both land sales and labour recruitment caused friction, for "ownership" was not an Oceanic concept; thus, land titles were disputed or resented, and the recruitment of labour often caused the breakup of Oceanic societies if too many males left their communities and the creation of foreign racial communities if they did not. The settlers were a more permanent element in Oceanic societies. By 1870 they numbered 2,000 in Fiji. Politically the settlers had an interest in stability, and economically they needed security of title to land and a supply of labour. Neither requirement was satisfied by the missionary kingdoms. Nor was it satisfied by native governments that were not missionary guided. In Tahiti, in Tonga, in Samoa, and in Fiji no native authority was able to keep order in the novel circumstances created by European enterprise; in any case, these native kings were themselves open to challenge within their own societies. Pomare encountered revolt in Tahiti, Samoan politics were always a matter of rivalry between chiefs, and Cakobau's government was threatened by the Tongan chief Ma'afu, who had established his own confederacy in the Lau Islands.

Establishment of plantation societies

Such internal conditions in Oceania began to draw in European governments, all of which acknowledged some responsibility for the protection of their nationals and their property. The French government was the first to intervene, after the expulsion of two Catholic missionaries from Tahiti in 1835. In the following year two more were deported from Hawaii. In 1839 the Archbishop of Chalcedon suggested regular association between the Catholic missions and the French navy, but the French government was also aware of the need for a good naval station for the fleet and for French commerce and for a place of penal settlement. Abel DuPetit-Thouars thus took possession of Tuahata and the southeast Marquesas in 1842 and in the same year persuaded the Tahitians to ask for a French protectorate, which was formally accepted in 1843. In 1853 the presence of French missionaries in New Caledonia led to French annexation, possibly for fear of British action, certainly to establish a penal colony (to which convicts were transported until 1897). Other European nations intervened for different reasons. In 1857 August Unselm, as agent for J.C. Godeffroy und Sohn, set up the company's depot at Apia, and Samoa became the greatest trading centre in the islands; and even when Godeffroys failed in 1879, the Deutsche Handel und Plantagengesellschaft took over, and Samoa remained the favourite colony of the colonial party in German politics. British nationals had trading and plantation interests in the islands; to give some protection to these interests, the British government had appointed consuls to those islands governed by recognizable rulers, but their powers to maintain order were limited and, except for the visits of warships, unenforceable. The United States also appointed consuls. The rivalry between these officers, between European entrepreneurs, and the involvement of both in the internal politics of Oceanic societies merely emphasized to metropolitan governments the disordered condition of the islands. In Tahiti the problem was resolved by French annexation. In Samoa, after a tripartite supervision set up by the Samoa Act of 1889 came to grief in European rivalries and Samoan factionalism over chieftainships, an agreement of 1899 divided the Samoa group between Germany and the United States; Britain received compensation elsewhere. Britain's main concern was in fact with the activity of its nationals: in Fiji, where it accepted the offer of cession of 1874, it did so primarily because native authority had broken down. But Britain also had been concerned with the labour trade by which the Queensland plantations took islanders, who were sometimes recruited under doubtful or brutal conditions. In the 1860s this trade flourished in the New Hebrides, and there was violence which led the missionaries to protest. Then the labour trade moved north to the Solomons, where again there was violence, including the murder of the Anglican bishop in the Santa Cruz group, from which five men had been taken by recruiters. The British solution was the Western Pacific Order in Council (1877), which empowered the governor of Fiji to exercise authority over British nationals and vessels in a wide area of the western Pacific. The problem still remained, however, of non-British nationals in islands that had neither native kings nor European governors, especially those of Melanesia.

Intervention of European governments

Recruitment of labour

European government, like both mission and commercial enterprise, had been slower to penetrate Melanesia. Missionary activity did not begin in New Guinea until 1873. There was not much labour recruiting. The first main activity was the gold rush of 1877, but German traders had come to the northern coast in 1873 followed by the firm of Hernsheim in 1875. Such foreign interest produced a demand in the Australian colonies for annexation for reasons quite unconnected with the internal situation in the islands. German interests were marked in Micronesia, French in the New Hebrides. A number of groups in Australia also looked on New Guinea as a rich possession. But the British government, notwithstanding Queensland's abortive attempt at annexation in 1883, would not annex unless the Australian colonies paid the cost of administration, the same argument it was applying to New Zealand's interest in the Cook Islands. When the Australian colonies agreed to pay, the British government acted. Southeast New Guinea was declared a protectorate in 1884 and annexed four years later; the Cooks became a protectorate in 1888 and were annexed in 1901. Germany annexed northeast New Guinea in 1884, including some of the Solomons, over the rest of which the British established a protectorate in 1893. In Micronesia, the Germans, after an attempt to annex the Spanish possession of the Carolines in 1885, finally bought them from Spain with the Palaus and the Marianas in 1899, having annexed the Marshalls in 1885 and, under a convention with Britain of 1886, the phosphate island of Nauru. By that convention Britain's interest in the Gilberts was recognized, although no protectorate was declared until 1892. The Ellices were added in the same year. The process of partition was completed by the New Hebrides. A convention of 1887 set up a mixed British and French naval commission, but its authority was limited, and in 1906 a Condominium was agreed upon by which such difficult legal questions as land title were settled and a joint administration set up.

Patterns of colonial government. With the exception of Tonga, which remained an independent kingdom under British protection (from 1900) with a consul who was not to interfere in internal affairs, the whole of Oceania passed under the control of European powers and the United States between 1842 and the end of the century. Having acquired colonies, these powers governed Oceania with metropolitan institutions modified to a degree by local circumstances. Thus Britain reproduced in the islands the pattern of crown colony government, which derived from its own political development: a governor who represented the king; an executive council of senior officials; and, where the European population justified it, a legislative council to advise the governor. Within this form of government, administration was adapted to local conditions. Thus, Sir Arthur Gordon, the first governor of Fiji, set up a system of native administration that incorporated

the chiefs: the island was divided into provinces and districts that, on the information available to him, represented the old divisions of Fiji, and over each he tried to select the chief to take administrative office. Even in Melanesia, where chieftainship was not highly developed, the British attempted to appoint chiefs who were men of influence. The first administrator of British New Guinea was a former officer in Gordon's government, William MacGregor, who first tried appointed chiefs and then settled for village constables. The Australians, who took over British New Guinea in 1906 and rechristened it Papua, followed the British pattern. The first Australian governor, Sir Hubert Murray, although he introduced measures of native development, still preserved the British pattern of colonial government, as did New Zealand in the Cook Islands. Beneath the governor, district administration tried to incorporate both native leadership and the technical and professional direction of specialized departments (such as agriculture and health), as well as those departments that dealt with the questions raised by European settlement (such as land and labour).

The Germans in Samoa

Other nations had different patterns. The Germans, if only because domestic German politics made colonies an incident of European policy, tried to administer their colonies through commercial companies. In New Guinea, the Neu Guinea Kompagnie was commissioned to administer the colony as a commercial enterprise. Only when it failed did the imperial government assume responsibility (1899). In the Marshalls, the German firms known as the Jaluitgesellschaft became a chartered company under a government commissioner in 1885. In Samoa, in the first decade of the 20th century, the governor Wilhelm Solf attempted to control the importation of Chinese labour for the plantations and tried to enlist Samoan interest for the government, but he was subject to the pressure commercial interests were able to exert in Germany itself. In the French territories, colonial rule meant assimilation to French institutions. The governor was analogous to the prefect of a French *département*, assisted by an administrative council and from time to time by a general council drawn from French citizens. Where such a council existed, its powers were limited to an optional section of the budget, the rest of which was obligatory. In effect, the governor ruled by administrative decree. In the United States territories, there was also a marked assimilation to United States metropolitan forms of government. When Hawaii was annexed in 1898, the president of the republic became a U.S. governor. When eastern Samoa was given to the United States under the convention of 1899, President William McKinley, in 1900, placed it under the authority of the Department of the Navy, the commanding officer of the station also becoming governor and administering the islands with the help of his technical officers and the advice of a Samoan fono, or legislature. These colonial governments were adapted to local circumstances. In the Polynesian islands and in Fiji, Britain and Germany attempted to incorporate the authority of the chiefs into their governments, both as advisers and as local officials in the districts, as did the United States in its part of Samoa. But in both Hawaii and Tahiti the old system of rank had broken down under the impact of missionaries, traders, and settlers, so that it could not be used for administrative purposes but had to be replaced by appointed local officials. In Melanesia, where there was in general no chiefly authority that could be used because influence was acquired by criteria that made it fleeting, the colonial powers had no choice but to use appointed local headmen. The Germans and the British did this in New Guinea and the Solomons, but the real instrument of government was the patrol by European officers with an escort of armed native police, who enforced peace.

The impact of World War I. This pattern of colonial rule in Oceania was altered by external circumstances. With the outbreak of World War I in 1914, an Australian force took German New Guinea, and a New Zealand force took German Samoa. Japan took the Carolines, the Marshalls, the Palaus, and the Marianas. At the end of the war these German territories were retained by the occupying powers as mandates under the League of Nations. The professed aim of colonial rule was to help the people of these territories to stand on their own feet under the strenuous conditions of the modern world.

This stress on Oceanic interests was not new, but it was now an international standard. Still, the first step was the establishment of government control and of law and order before any other measures could be taken. In New Guinea, in the Solomons, and in many parts of Melanesia, the interior was often unknown, let alone controlled. So the attention of colonial government was concentrated on this. The discovery in 1933 of the grass valleys of New Guinea presented the Australian administration with the problem of 750,000 new people. Thus in the Australian territories the resources for doing anything beyond this initial control were spread thinly. Health and education were left to the missions. By contrast, Fiji was more developed. With the importation of Indian labour to work the sugar plantations from 1879, and with the reforms in the indenture system (which came after a commission of 1909), the large Indian population of Fiji received the attention of the government in education and health matters, but the increase in this population raised the difficult question of the Fijians' future. They played a minor part in the economic life of the colony, and the trend of official policy was to preserve them within their villages under a separate system of administration, which was reorganized in 1944 as the Fijian Administration—to be virtually a state within a state. But the government's resources were not enough to introduce welfare measures and to promote development on any great scale. A good deal depended on the missions and other private organizations. In Samoa, where the old society had retained its organization, there was resistance to change. The New Zealand administration of Samoa had begun with the objective of promoting the welfare of the native race, which meant health, education, and better use of the land. By recognizing Samoan councils it tried to ensure Samoan support, but the policies broke down in execution. In American Samoa, the navy provided welfare services as part of its routine work but could do little more than that when its principal concern had to be the smooth running of the naval base. In French Polynesia native policy aimed at making the people French citizens. The welfare services were directed from Paris, but they were limited by the resources available.

Problems of health and welfare

Oceania since World War II. Such limited resources and the competition between different objectives of colonial policy plainly restricted what could be done. Mission resources were obviously limited. Moreover, they were affected by external events such as the Great Depression and the fluctuations in world markets for copra, sugar, and other products of Oceania. The principal achievements were to check population decline by control of the introduced European diseases that had ravaged the islands and by increasing control of endemic diseases (such as malaria in Melanesia) and to hold a rough balance between European and indigenous interests. But welfare policies and island administration were both interrupted by World War II. The Japanese had been established in the north of Oceania, where they had treated their mandates as part of Japan itself. In 1941 they advanced into the rest of Oceania, reaching and controlling most of New Guinea as well as much of the Solomons at the peak of their advance. New Caledonia, the New Hebrides, Fiji, and Polynesia were not occupied but the effects of the war made colonial government secondary to military operations. After the war, the Trusteeship Council of the United Nations replaced the mandates, but all of the colonial powers accepted that independence or self-government was the aim of their rule. The Oceanians themselves had been exposed to a more intensive European (and Japanese) impact; their horizons had widened. The colonial powers felt a greater urgency to promote development and to make available greater resources to achieve it.

Politically, colonial governments were reorganized to give indigenous people a part in government. In Western Samoa, the Legislative Council was given, in 1947, a

Beginning of self-government

Samoan majority and considerable powers. In American Samoa, naval rule was replaced in 1951 by civilian control, and a legislature of two houses was set up, which by 1960 became a lawmaking body of Samoans. In French Polynesia and New Caledonia, elected assemblies were given considerable local autonomy in 1956; both territories opted to stay within the French community in 1958. In Fiji the Legislative Council was reformed, in 1962 and again in 1966, to provide an unofficial majority; but elections, in view of the racial composition of Fiji, were still to be communal. In Papua and New Guinea, administered by Australia as a single territory after World War II, an elective representative assembly was introduced in 1964. The following year the Cook Islands were granted internal self-government by New Zealand. In Micronesia, the Trust Territory of the Pacific Islands, composed of the former Japanese mandates administered by the United States, the advisory congress of two houses was set up in 1964 when the islands ceased to be a strategic concern, and in 1967 a Future Political Status Commission began to discuss its relations with the United States. The Gilbert and Ellice islands received a constitution in 1967 that provided for the Governing Council and a House of Representatives, the latter having advisory powers.

The pace of political development in Oceania thus speeded up. In 1962 Western Samoa became independent; in 1968 the phosphate island of Nauru; in 1970 Fiji and Tonga. Hawaii received United States statehood in 1959. Economically, the change has been less dramatic. Since World War II the colonial powers have devoted much more money and attention to agricultural development. New crops, such as coffee and cocoa, have become important. Tourism has expanded. But copra in most islands and sugar in Fiji have remained the basis of agricultural production, even when their value has been overlaid by mineral wealth, such as copper in Bougainville. There still remains the problem of diversifying the economies of Oceania. There remains, too, the problem of education. In 1965 a university was established in Papua and New Guinea. Two years later the University of the South Pacific was set up in Fiji. Yet New Guinea still has a major problem of literacy and of elementary and secondary education; and, although a high level of literacy exists in Samoa and the French territories, education is largely still at the basic primary level. There is a shortage throughout Oceania of skilled artisans and an even greater shortage of professionally trained people.

Political development has been faster partly for external reasons. International pressure in the shape of a United Nations Visiting Mission, such as that of Sir Hugh Foot to New Guinea in 1962, forced the pace, although he was pressing an Australian government already moving in that direction. A growth of regional feeling, fostered by the international South Pacific Commission set up in 1947, increased political awareness. The main dynamic of the advance has been the governments' perception of circumstances in the islands themselves. Oceania has produced none of the mass national movements of Africa and Asia. The reaction to European rule has usually taken the form of nativistic movements, or cargo cults, in which, by ritual, Oceanians await the coming of cargo diverted from them by Europeans. There have been attempts to remedy the frustrations felt at European material superiority. But they have not been political movements, except in so far as they now underlie the electoral processes of Oceania. The Mau, or opinion, movement that declined cooperation with the government in Western Samoa in the 1920s and 1930s was more overtly political, but it was not in any usual sense a nationalist movement. The nationalism that has existed has been the work of political parties formed as a result of the creation of electoral processes and assemblies. In French Polynesia, the Rassemblement Démocratique des Populations Taïtiennes began as a political opposition but split when it became a government. In Samoa, politics have followed kinship groupings rather than nationalist principles. In Fiji, politics have been racial rather than nationalist. In Papua and New Guinea, political parties have been slow to form. The reasons for this absence of nationalism are only partly that the colonial governments have on the whole maintained native interests in the face of European pressures and thus have prevented landless, detribalized people from emerging. The reasons lie much more in the local nature of Oceanic societies, which still look on politics as a matter of kinship or conformity to correct behaviour as determined by their own standards. Locally there are exceptions, but in general Oceania has been shielded from the impact that might have destroyed its societies. All of them have changed by their involvement in the European world, but the changes have been adapted so that the new is still interpreted in terms of the old.

Nativistic movement

BIBLIOGRAPHY

Prehistory: The picture is changing so rapidly with every new site that there is no comprehensive account. The best work is J. GOLSON, *Prehistoric Research in Melanesia* (1967). A traditional view is presented by P.H. BUCK, in *Vikings of the Sunrise* (1938), now very doubtful.

Exploration: The standard work is J.C. BEAGLEHOLE, *The Exploration of the Pacific*, 3rd ed. (1966). A. SHARP, *The Discovery of the Pacific Islands* (1960), lists the first European sightings of every island. An older popular account is J.A. WILLIAMSON, *Cook and the Opening of the Pacific* (1946).

Missionaries: The only general book is A.A. KOSKINEN, *Missionary Influence As a Political Factor in the Pacific Islands* (1953); but W.P. MORRELL, *Britain in the Pacific Islands* (1960), includes accounts of missionary activity.

Traders: The trading history of Oceania has yet to be written, but studies of particular aspects of trade are well described in H.E. MAUDE, *Of Islands and Men* (1968). D.S. SHINEBERG, *They Came for Sandalwood* (1967), deals with one crucial trade.

Colonialism: Colonial rule in the Pacific has received much attention. W.P. MORRELL, *Britain in the Pacific Islands* (1960), is the standard account. F.J. WEST, *Political Advancement in the South Pacific* (1961), deals with the post-World War II political development in several territories. Individual islands so far studied are: J.D. LEGGE, *Britain in Fiji, 1858–1880* (1958); and R.P. GILSON, *Samoa 1830–1900: The Politics of a Multi Racial Community* (1970). J.W. DAVIDSON, *Samoa Mo Samoa: The Emergence of the Independent State of Western Samoa* (1967), is the view of a participant in the independence movement. R.G. CROCOMBE, *Land Tenure in the Cook Islands* (1964); and N. MELLER, *The Congress of Micronesia* (1969), discuss aspects of islands so far little studied. F.J. WEST, *Hubert Murray: The Australian Pro-Consul* (1968), gives an account of Papua under Australian rule; and S.W. REED, *The Making of Modern New Guinea* (1943), describes the mandated territory.

(F.J.W.)

Oceanian Peoples, Arts of

Art is an imprecise concept, especially if the economic connotations that accompany it in a given culture are not regarded. In the West, indeed, anything sold as art is considered such, especially whatever sells best. Well-known "aestheticians" have gone so far as to treat the bark paintings of Arnhem Land (Figure 1) as mere commercial objects and yet to regard as "art" certain pieces that, after a lengthy period in European hands, had lost their colour and acquired an "admirable" patina after being zealously waxed!

Some art historians have tried to understand Oceanic art —like other supposedly "primitive" arts that now look so modern—as rising from the same kind of inspiration that gave birth to Western and other cultures. They have spoken of magical art, then of religious art, using concepts and connotations—positive or negative, black or white —that properly belong to the religious and theological universe of the Western world. It is better to discard such hand-me-down ideas and to look at the way each piece of Oceanic art—including those objects that the West regards as beautiful and, also, those that the Oceanic peoples themselves appreciate as such—finds its place within the specific society and culture. Within the concept of Oceanic art is included not only the plastic works—sculpture, painted plaques, monumental structures—but also any object in daily use that has received a finished or intentionally fashioned form (Figure 2). It likewise in-

cludes the vocal arts, with all the forms and uses of a construed sentence, music, and many of the elaborate formal gestures of the dance.

This article is divided into the following sections:

I. General considerations

THE SOCIAL MILIEU

The influence of the social milieu on art is a constantly recurring problem in aesthetic studies, perhaps because the meaning of the term social milieu is so elusive. It is, indeed, better to question how aesthetic expression is introduced into and operates within the social group, from which it can only be detached for the sake of convenience and in formal terms; for there can be no aesthetic manifestation unless there is at least one person to serve as the public. There is, however, a permanent and balanced relationship between art and society in the sense that, while aesthetic expression profits from an organization that ensures its reproduction or transmission, the artist derives advantages that do not belong solely to the level of art: prestige or gain, if not both of them together.

Commercial values. A discovery of recent decades is that among the Oceanian peoples art has its commercial value and is bought and sold. The Melanesians, at any rate, have a system that, for want of a better term, might be called "copyright." This system is as complicated as that in the West, with both negative and positive aspects. It is forbidden under pain of supernatural punishment to take that which does not belong to you, and this extends to the arts: all stylistic elements, whether plastic forms, painted decoration, musical themes, poems, or sequences of dance steps are copyright. The usual owner is the local group or clan attached to a given area, and the group is represented by some chosen dignitary. Ownership may be by inheritance, the result of an expensive purchase, or both. Literature sells least well. This is because sung verse usually embodies the myth of a particular clan, and the recitation of a myth to which one has no right is considered theft—it is seen as an attempt to deprive the owners of their land. One does, however, come across song texts with the original music, either in the original language or in that of the borrowers, sometimes paired and sometimes not. (Chants can also be transmitted from one place to another without an accompanying translation and without the new singers necessarily knowing the meaning of the words.) Dance steps can also be borrowed and used with a different chant. The important thing is to pay for what is taken and (so that there can be no misunderstandings about this) to pay in public—ritually and with goods whose value is undisputed, such as pigs or traditional treasures.

The Oceanic conception of ownership

A work of plastic art may also be sold, but the sale need not be of the piece itself. It may be one or other of its elements that provides the attraction—an outstanding portion, an astute technique, an aspect of decoration, or a combination of all. Each legitimately bought element can be combined with others obtained elsewhere to produce a new artifact that will appeal to the customs and fashions of society.

Art and social institutions. Aesthetic expression is thus influenced by society in the wide sense and makes use of its institutions and forms of control, but there is hardly any evidence to suggest that a mode of government can have been the originating force of any particular aesthetic tradition. The combined nuances within an organized society can exert such a force, however, and a good example of how they do so is found at the level of the organization of trade. Craftsmen specialize by village in the Admiralty Islands, making a specific category of goods, and this ensures a stability of form, with variations occurring only in the fine detail. Individual gifts and abilities are not especially important. On the other hand, societies that offer a premium to initiative or to individual inspiration (as in Middle Sepik, a region of central New Guinea)

foster the means to maximum creative power, and the importance of individual talent in this situation is paramount.

But this factor alone does not seem to account for the comparative artistic richness of certain areas. Wide circulation of information and the buying or selling of artistic ideas and elements are equally important factors and favour those places where ideas and themes are most readily interchanged. Another essential factor in the situation is competition for prestige among individuals (Middle Sepik) or among groups (New Hebrides, New Ireland), which, it is generally agreed, results in some of the finest art forms of all. Where there is a frozen hierarchy of power and prestige, such as there is in Tonga, a sophisticated theological structure is evolved, but a diversity of art forms is not (though some does exist). The complex theogonies of the Maoris, for example, were not the inspiration behind sculptures and bas-reliefs of New Zealand (Figure 3); the fact that rival schools of sculpture flourished there offers a better explanation for their exuberant form.

Sexual attitudes seem to have had little connection with artistic productiveness: the New Caledonians, who are sexually reserved, have created many interesting works of sculpture; the inhabitants of the Loyalty Islands, who are permissive, have a very developed art of chanting and dancing (but know almost nothing of sculpture), whereas the Trobriand Islanders, also permissive, have not developed these arts.

DEMOGRAPHIC INFLUENCES

Coastal populations seem to be more productive than those of the interior. This is especially true of New Guinea, where distance from the coast can mean virtual isolation. Being by necessity involved in coastal trade and therefore well placed for cultural interchanges, the seafarers all knew some kind of sculpture, though of widely differing forms. But this is not a hard and fast rule. The people living inland in New Guinea, known for convenience under the designation of Middle Sepik, achieved the highest artistic levels, for instance, and the inhabitants of the highlands often produced forms, motifs, and colours of great interest. Their work, however, was either deliberately destroyed after ritual use or else decayed very quickly, for they used mainly fragile vegetable materials (Figure 4).

Works that were made to be destroyed

Works gathered by European collectors were usually taken from the coastal regions, and even these were those pieces that were most easily transported. Very little is known, therefore, about the interior from an aesthetic standpoint, and problems of transport still present a formidable obstacle in the way of learning very much more.

Isolation. The state of isolation, when it truly exists, inevitably works against inventiveness and encourages stereotyped repetition. Actually, only cases of relative isolation are known: even the people of Tikopia, for instance, travelled far in their boats, or "pirogues" as their crafts are called, along routes established by tradition, and they reached some destination. The extent to which harsh climatic conditions inhibit artistic expression is not known, if indeed they do at all—the abstract art engraved on stone plaques by aborigines of the inhospitable central Australian desert is, for example, especially fine. Nor is there much evidence that the rough or elaborate aspect of wood sculpture (Figure 5) has any relation to technological backwardness or otherwise: the basic technique of cutting wood (which is prepared by slow, controlled firing) with a stone hatchet is everywhere the same, and only the finishing tools—splinters of jade or obsidian, shells, dog incisors, and the like—vary.

Intercultural borrowings. It is the element of complexity and number of intergroup relations that seems to provide conditions most clearly favourable to aesthetic production in Oceania. Two thousand years of Western history teaches the same thing. Objects are "borrowed" by one culture from another, but the object borrowed does not always retain its original significance. The society borrowing, stealing, or plundering the object attributes to it the connotations that suit it, those that are available at the moment. A mask, for example, acquires quite a different significance from one place to another (Figure 6): it may be an object used in theatrical games, with the laughing participation of women and children; another group may use it as a symbol for the initiation of young men, with the appropriate respect (even if the oldest women know which man is hidden under the dis-

guise); somewhere else it represents a returning ancestor and is invested with emotion accordingly; and yet elsewhere it serves as the public symbol of an institution, guaranteeing a form of social control and serving to support the proclamation of decrees concerning public order. It never has the same connotations in one place as in another, and generalizing discourses on the mask, as a subject, have little basis in fact.

Western influence. The effect of the West on Oceanic culture after two centuries has been both overestimated and underestimated. During the 18th century, through the intelligence or determination of the parties concerned, the relationship between the two was much more equal than is generally believed, though at the cost of many human lives. Their artistic traditions were not stifled; indeed, when the European policy of conquest was abandoned, largely because of the territories' lack of useful natural resources, many societies underwent an aesthetic flowering (particularly in the visual arts) that has not always been appreciated. This took place because metal tools had been introduced, bringing about more efficient techniques in carving wood, and because new leisure time had been created, which had to be filled by a kind of ritual explosion and in which invention was given free rein (though the themes were, nevertheless, drawn from tradition).

Effects of Christianity on Oceanic art

In the 19th century, however, conversion to Christianity and forced colonialization brought about the progressive disappearance of all indigenous visual arts. The musical arts and the dance resisted better: despite the quickly adopted Western techniques, they displayed much originality in their reinterpretation. (Some of the most modern experiments in rhythm were foreshadowed in the orchestras of unknown villages in the mid-Pacific, where the instrument was no more than a string stretched across an empty gasoline can.)

HISTORICAL PERSPECTIVES

Oceania does not lack historical depth, though knowledge of it is not consistent, even among the people of the region: the great Tonga lineages stretch back for 40 generations, whereas some groups have difficulty in tracing themselves back more than two. Tonga is also exceptional in that its dynamism was turned outward, for it built up a maritime empire. But usually, within an insular society's stable population and fixed habitat, the complexities of family relationship were of major importance—particularly when determining an inheritance. Often the relationships worked out were not accurate, but this need not, in fact, have hindered the actual working of a system based on genealogical reference. In New Guinea, on the other hand, where a 1,000-year-old population movement had been in existence (partly from west to east, partly from the high, overpopulated mountain valleys to the less healthy coastal areas), the permanence of land tenure was never guaranteed, and the peoples there did not favour the father-to-son pattern of inheritance. This means that notions of patrimony and inheritance pertaining to other cultures must be very carefully reviewed and corrected before being attributed to Oceanic societies. Even the most specialized Western observers, in studying this phenomenon, have too often been coloured by value systems belonging to their own society.

Continuity of tradition. There has been a tendency to treat the Oceanian peoples a little as though they belong to fairy tales. The societies they constructed and made function were considered by ethnologists to be as fragile as they were precious. They were supposed to have operated rigorously and unchangingly over thousands of years until the days of European colonialism, which the specialist considered a noxious influence with an impact that inevitably destroyed the existing society. It is true that the West and Christianity made such a crushing advance that Oceanic societies appeared to be delicate structures, as easily broken as porcelain. No one imagined that they had adopted tactical, collective decisions in the face of the invader. These tactics were aimed at saving the essential structure, while letting go of the superfluous—the visual appearances that the observer so often regarded as basic. This fact helps to explain how, at different periods, mass conversions to Christianity (the missionaries' efforts being supported from afar and close at hand by irresistible naval forces) were followed after 50 years or so by an easy return to paganism (except where, disconcertingly to Western observers, the natives hurled themselves headlong into some kind of messianic movement). That societies, weak in the sense of lacking armed strength, might adopt tactical compromises when faced by a superior force ought not to be surprising, for it is a recurring feature of behaviour throughout the history of the world; Oceanian peoples, like all others, are part of the evolutionary pattern. Delicate and supple social structures can be destroyed, however, and it is little short of miraculous that Oceanic societies should still be alive and thriving, capable of independent life while preserving a cultural heritage sufficient to maintain their cohesion.

The Oceanic world view

Such a capacity for life implies that, before the arrival of the white man, Oceanic societies had a broad vision of the world that could accommodate any new situation they faced. It is not always easy to rediscover this vision through the distorting prism that now exists because of the mistaken conceptions of the first European observers and the considerable caution of their Oceanic informants. They were conscious that if they were to protect themselves, it was necessary for them to comprehend and assimilate the white man's concepts and way of thinking. The native's great gift for psychological penetration and his capacity for adaptation are thus largely responsible for the inadequate and untrustworthy evidence that stems from that time. This is especially true of the Polynesians, who quickly learned how to present themselves to romantically minded navigators as representatives of a classical culture like that of the Celts, a society with bards and hierarchies of kings and priests. As a result, they were often able—with the exception of Hawaii—to retain more of their land and to avoid collective conscription

for forced labour. The explanation of this capacity for adaptation should be sought in the very heart of traditional structures, in their permanent receptivity to any external contribution, and in their tradition of welcoming the newcomer and providing him, in the form of land, spouse, and social status, with the means of becoming a part of society. The entry of European elements must also have been facilitated by a long-standing pre-eminence given to light skins—girls of high station were kept in the shade, for example. The Europeans were therefore looked on favourably as possible fathers. The symbolic contrast between black (accentuated in time of war by means of various vegetable pigments) and white (the colour of mourning, obtained by coating oneself with ashes or lime on the hair and upper part of the body) has played a constant role in the relations between Europeans and Melanesians. Esteemed like the dead, that is to say like gods, because of the colour of their skins, the whites benefitted from the prestige that this gave them until events proved that they were mortal and fallible, so that they came to be dreaded instead for their intentions and material strength. There was a later attempt to place the phenomenon of the white man's arrival within the context of destiny. Various explanations emerged, turning around a confusion of such ancient themes and biblical outlines as the departure of a Melanesian or Papuan Noah in a pirogue, or canoe, carrying with him the elements of power that would one day be restored to his people or the idea of the "cargo," material wealth that had been sent by the dead to their descendants, in chests whose labels were changed by the whites so that they could usurp the contents.

The Old World vision first gave way before the arrival and entry of outside elements, both from the sea in pirogues and from inland by migrations that drove the people of New Guinea from west to east and from the high, overpopulated mountain valleys toward the coast. Groups were now defined socially in terms of their physical—that is, topographical—position within the general system. The universe, broken down and divided into elements that could be listed, was apportioned among the various groups. Each group had symbolic control of its part of the known world—its animals, vegetable life, atmospheric elements, mythological figures—and located on its own territory fixed spots from which this control was asserted. Thus, the soil itself was of prime importance, and it is very important to understand that in societies without writing this should be so. For the soil offers subsistence and is literally the basis of social and religious rites—it supports communication routes and provides the sacred spots (ritual or mythological or both) among the areas assigned to lie fallow or be cultivated, to

be given over to hunting or the gathering of fruit and vegetables. This fact of the soil's importance cannot be neglected in favour of an arrangement of concepts more in line with the intellectual habits of other cultures. In order to begin understanding Oceanic culture, it is essential to realize that its peoples symbolically express their very society in what may seem to others no more than a dry list of topographical detail. The "list" is an embodiment of their basic myth, and the native inherits, as it were, a "key" to its interpretation.

Culture and tradition. There is an often bewildering multiplication of languages spoken in Oceania, with several hundred separate tongues for New Guinea alone and scores for each of the Melanesian archipelagoes. In contrast, the Polynesian languages are more obviously similar, a fact that may be connected with man's comparatively late arrival there. The languages of Oceania are divided into two large groupings. One is called, at present, Austronesian, which is considered to be relatively recent, and which includes Indonesian, certain Madagascan, Melanesian, Polynesian, and Micronesian languages. Formerly this grouping was termed Malayo-Polynesian. The other group, called Non-Austronesian, is considered to be older than Austronesian, and includes many of the languages of New Guinea, of New Britain, and a few isolated languages in New Ireland and the Solomon Islands. In older terminology these Non-Austronesian languages were subsumed under the term Papuan. While the Austronesian languages seem to be historically related, the Non-Austronesian group serves as a convenient catch-all grouping, the constituent languages of which are not necessarily related to each other. The presence of so many of the older Non-Austronesian languages in Melanesia makes this region an important one for research into historical linguistic relationships between older and newer language manifestations prevalent in Oceania.

Language groupings

Symbolism, imagery, and the aesthetic tradition. It is difficult to pinpoint any common general elements within the great variety of symbolic systems that the Oceanian peoples have built up. The bird symbol appears to be the one most frequently used, as much in speech, myth, dance, and song as in visual art. It seems to represent the political group, power, high social status, and also virility. Often it is a small sea eagle, common in coastal regions, or some other sea bird, such as the frigate bird. But the symbolic meaning is attached to the species and not the genus. A predatory bird of the fields, the sultana hen supplies a female connotation—it is the symbol of illicit love. Therefore one should not invoke the whole order of flying creatures to explain the above series of symbols, inasmuch as the large fruit-eating bat that feeds on the same fruits as the sultana hen is both a male symbol and a representation of life; the lizard, the water snake, and the shark (Figure 7) have the same connotations, and those of the shark can vary to the point of overlapping those of the sea eagle. The explanation of this apparent discrepancy lies in the division between, and the appropriation by, the different groups constituting a society of the whole of the known elements of the universe. The specific significance of the recourse to such a symbol will only be understood in terms of the whole symbolic lexicon and, simultaneously, of the overall aspects and details of its adaptation.

It is, likewise, difficult to extract from the overall culture anything that might be called a common aesthetic tradition. Landscape architecture might constitute one, for it is everywhere methodically planned and executed, though with quite different aims from one archipelago to another. Here, one will find a compact, close-cropped lawn around the houses; there, everything that encroaches on the black, lustreless, volcanic soil has been carefully uprooted. Here, the hierarchy of constructions will be organized vertically as a function of their attributes; there, grassy open spaces will be used to distinguish large categories of huts. The most elaborately worked of these glades, in terms of the techniques of arboriculture used to provide shade, will be the one that contains no huts, being used as a common dancing ground by several groups.

CONTEMPORARY FEATURES

It has been suggested above that most Oceanic cultures, despite their confrontation by Western colonialists and missionaries, retained much more life and cohesion than observers generally supposed. It is, however, a fact that the expression of their culture was seen as a manifestation of godlessness by the white overlord and could not be maintained. Much opprobrium has since fallen on those missionaries who compelled the suppression of chants and dances and still more on those who burned the idols (Figure 8). But a great many Polynesian sculptures were

Figure 8: Wooden image of the war god Kukailimoku, one of the Polynesian works of art that escaped destruction by missionaries. From the Hawaiian Islands. In the British Museum. Height 76.8 cm.
By courtesy of the trustees of the British Museum

also destroyed by isolated Polynesian evangelists and their converts, who were eager to demonstrate their changed lives, and often were motivated further by the hope of attaining the evident wealth and power of the white man. Traditional dances and chants were generally condemned by Catholic and Protestant missionaries alike, but the extent to which they survived depended upon the

proximity of the missionary station and the zeal of its local representative. Many songs and dances were, in fact, preserved, often because European dignitaries expressed an interest: official ceremonies that they attended would incorporate music and dance. Tourists were also interested in folklore, and their patronage helped to keep alive some parts of it as well as to encourage pale copies and complete invention. But a tradition can only be maintained if the principals involved really desire it. Once the ritual itself has been abandoned, everything related to it has the greatest difficulty in retaining anything but a residual or revised function.

It is, however, astonishing to discover how much was not destroyed but lay dormant, eventually to emerge from an oblivion that might have been thought final as Christianity began to suffer a relative loss of prestige. Complex texts and ceremonies have been built up in a way that reveals how retentive is the collective memory.

Commercialization

The plastic arts, on the other hand, have largely succumbed to a process of commercialization whereby an ever greater number of objects—mostly of poor quality—are needed to supply the needs of a greatly expanded market (much of it touristic) that is controlled by a class of, usually, European middlemen of extraordinary rapacity.

II. Literature

GENERAL CHARACTERISTICS

Oceanian literature is oral. Its existence was discovered about two centuries ago in Polynesia, when European observers realized that complex cosmogonies and theological formulations, embodied in astonishingly long and complicated texts, were committed to memory by what they thought of as bards and priests. For a long time, however, no one felt any call to take this discovery further. The prevailing strain of European pre-Romanticism—and, later, Romanticism itself—which then tinged the outlook of most observers, unfortunately resulted in intellectual scruples being abandoned when they came face to face with attractively exotic Oceanian situations; they produced a flood of literary reconstruction, giving current European ideas free rein, so that the genuine Polynesian literary tradition was quickly swamped. To construct a "Polynesian" text it was enough to sprinkle it with proper names and a few other words or phrases borrowed from the language. Those who did not invent did translations, and the translated texts were even more dangerous because of innumerable misinterpretations and small mistakes. Few authors supplied the Polynesian text alongside their translation, a course that would be expected if the work were one of the genuine scholarship (although an early effort by serious scholars did succeed in organizing the body of New Zealand's vernacular, unexpurgated texts, presenting them in a line-by-line translation, with an arsenal of notes and commentaries, in such a way that the text could be both understood and critically appreciated). A properly serious and scientific approach to textual criticism was, on the whole, reserved to the classical and sacred texts of other cultures.

The rise of anthropological studies toward the end of the 19th century ought to have brought with it a new interest in Oceania's oral literature. But however much conditions varied from country to country, anthropology was never practically influenced by the methods of classical philology, the rigorous discipline of which it admits with the greatest reluctance even today. Vernacular vocabularies did become an object of sustained attention for certain scholars, but they were basically seeking to describe normative and conceptual systems; as a result, they preserved very little apart from those phrases that aptly served to demonstrate the truth of their own arguments and theories. The methodical collecting of documents was scarcely begun, and the task has now become one of extreme urgency before texts are completely forgotten. It is, moreover, the sort of work in which linguists and anthropologists ought to collaborate.

It is not easy for scholars belonging to other cultures to describe the content of Oceanic literature because their understanding of it is so limited. There are, however, one or two pointers. First of all, it has to be said that the purpose of literature is to communicate: it demands an audience. In the case of an oral literature, communication depends first on memory, and this usually means that such memory aids as rhythm and stock formulas and phrases are an important element of all texts. The majority of Oceanic texts keep closely to traditional forms and appear to be committed to memory and then communicated in a strictly unvarying manner. This is, however, only approximately the case because the various techniques of formalization can allow a quite fluid text. The tradition can be made evident at the lexical level, with the possibility of a great freedom of syntax. It only prevents prosodic elements from taking on primary importance. But it is these that have been studied last by modern linguistics.

Traditional forms of oral literature

Types. The literary occasions of the Oceanian peoples are, as in other cultures, reflected in sacred literature, political literature, and frivolous—even erotic—texts. This division, however, should not be taken to represent an attempt at classification; any such pigeonholing would be inconvenient, indeed, because too many texts defy neatness and straddle two categories. But there are certainly two poles between which the various forms of literary expression can be placed. On the one hand, there is a body of works that appeals to Western readers and is made accessible to them by its use of the poetic image. On the other hand, there are many texts, often brief, in which each word is frequently a complete image. This kind of text is part and parcel of the culture that has produced it and requires a veritable arsenal of commentaries of others to interpret the key words and unravel its significance. Texts are, basically, of two kinds: (1) recitatives, whose form is rigid; they can be expanded but not transformed; in this category belong all the songs or chants that accompany dances—whether the performers be standing or seated—funeral chants, songs that accompany children's games, and those with an erotic significance; and (2) public orations, in which the elements are formally but roughly organized, giving the speaker the right to vary the presentation within certain limits established for this literary genre. Such discourses, which can aptly be delivered as a high-level political oration and as a funeral eulogy or remembrance speech, can also, in a more simple form, commemorate such events as a birth or a marriage.

Themes. The themes are those that appear in other literatures of the world: love and death, defiance and hatred, nostalgia for the past, and the pleasure of the moment. Nature provides the necessary images. There is a barrier between Oceanic literature and that of other cultures because, although it presents a familiar mental universe, it does so in an often allusive manner that demands a knowledge of local place-names, local political geography, and land division before its meaning can be understood: the owl, for example, is symbolic of a given place, the lizard of some other, and the sea eagle associated with a third.

Although there is no specific body of Oceanic literature, there are fragments of different kinds that, once gathered, suggest a cultural coherence: definite conclusions cannot be drawn, but lines for further research are indicated. Even small texts, which have often been overlooked because they did not seem sufficiently elevated—such as those that were accompanied by a flute or a stringed instrument as part of individual rites for the purpose of securing a woman's favours, contribute to the total picture.

Importance of small texts

MELANESIAN LITERATURES

Melanesian literatures are better known today than Polynesian because they remained untampered with over a longer period by Western anthropologists and scholars and were, therefore, not distorted by them. Thus, they are of great interest, although they are only just being recovered. Great pioneering work was done by Maurice Leenhardt into the literature of New Caledonia, but it has scarcely been followed up. A prime difficulty is that of method. Leenhardt trained a few Melanesians, teaching

them to read and write their own language after inventing for them a system of transcribing their verbal utterances. Thus, he provided for himself scribes—and even authors—in the local language that he had chosen for study. The body of literature he assembled in this way, since published only in part, is the most complete available to date. Leenhardt's method (which had in fact been previously employed half a century earlier by British clergyman Robert Henry Codrington [1830–1922], who did not, however, leave to posterity the literature of the Mota language that had been given him by his pupils) makes it possible to obtain texts of very high quality over a long period. Written out by the trained student himself, who has had the opportunity to re-read and check for accuracy in the quiet of his hut, the method avoids the psychological tension inevitable in a dictation session. The results make for more confident study afterward, and the method is still the only sound one. Texts taken down directly on a tape recorder can too easily be garbled or abridged unless the informants are especially trained to use the machine by a linguist, so as to avoid a psychological block when faced by it.

Two generations of researchers have succeeded Maurice Leenhardt, working in the same region as he did. They have amassed a complementary body of literature astonishingly rich and have been able to establish just what the function of each text was in the life of the society they studied. The results of their work have obliged scholars to re-examine their conceptions of the oral literary tradition. It now emerges that not even words, symbols, or places have any fixed significance: the vocabulary is at once coherent and diversified, for it is used in a way that takes into account the momentary interest of the parties present.

The traditional speech. A traditional speech may be "hurled" at the crowd by a speaker perched on a flimsy platform; the crowd responds with a muffled cry at the end of each "sentence"; it is the quality of accord reached between the crowd and the speaker that comprises the "new content" of the familiar, traditional speech (henceforth becoming part of its tradition), while the accord also conveys what other cultures would call the "message"—the new stage in a rising political career, perhaps, or a declaration denoting peace between combatants or the beginning of a war. Anyone analyzing the speech itself has to search for and consider carefully all the possible interpretations and temporal conditions it might have. The traditional form of the speech is respected all the more because it allows this variation of content—within acceptable limits—to be conveyed by nuances that may easily escape observers from other cultures.

The form of the speech also presents a somewhat thorny problem. On the surface, it is a simple enumeration of the local groups and their symbols (that is, the portion of the land that is theirs, together with its animals, plants, weather conditions, and so on). The recitation of these physical realities is an affirmation of their very society, and they are stated one after the other, linked by some stock connecting phrase. Each listed item is given its precise geographical location; of special importance are the names of special places where authority is exercised or where rites are practiced. The whole constitutes a world vision, or system, in which the individual society and its members have their place. The native audience is perfectly familiar with the spatial affirmation of their society contained in the speech, and from the dry enumeration of its components, they are able to supply for themselves a history of alliances and wars and to remodel the traditional text until it fits the conditions of the present. The orator's delivery, the nuances he maintains or introduces into the speech, are a sign of his success.

The myth. Another kind of literature, less easily defined, is the one commonly understood as myth (a term that smacks of Western classical culture and thus carries overtones that are irksome from the scientific point of view). Involved here are all formalized recitatives, straightforwardly delivered, made up of narrative with pleasing scenes interpolated, whose apparent aim is to give the account of a rite, for example, or to describe the situation of some group of family lineage (perhaps in connection with land ownership or political status) or to tell of the origin of man and his culture. The recitative may involve as little as ten lines, or it may take a man three hours to dictate. In any given local culture, the rules that govern the way in which the texts' content is formalized and those that govern the way in which they are recited are consistent. The symbolic vocabulary, formally identical with that used in public speeches, carries elaborate but acknowledged references. A text may be established on the basis of a single symbol, but in general the symbolic pattern is so complex that other cultures have great difficulty in understanding it. Indeed, it is only possible to decipher its meaning if the cultural significance of every place mentioned in the text is understood, if it is known what creature or being is worshipped where and to the benefit of which group, and often only if the intineraries that are the subject of a majority of the myths are entirely familiar to the interpreter, so that old placenames—and thus their meaning—that are referred to in the text can be identified.

POLYNESIAN AND MICRONESIAN LITERATURES

Similarity of Polynesian and Micronesian literatures

Problems of interpretation. Polynesian and Micronesian literatures are similar in structure, but they vary in detail from island to island. Little is known about the Micronesian texts, however, and work on the interpretation of Polynesian literature has been hindered—first by the excesses of European Romanticism and its flights of fancy, then for nearly two centuries by well-intentioned amateurism. Authentic texts were not collected when the opportunity was at hand, and it is now often too late to do so because the traditions—especially of religion—that maintained them have not survived. A great body of mythological material was gathered in the 19th century, but it has still not been critically edited, and it cannot be overemphasized that nothing like a properly established record of their myths has yet been produced. Polynesian "priests" have been likened to those of ancient Egypt, their recitatives treated as theological monuments—interpretations that distort the situation entirely. Such textual interpretation must, in any case, be demonstrated scientifically; since the commentaries published to date do not attempt to do this, the serious investigator is suspicious also of the soundness of their attendant translations. These translations, on the slightest pretext, indulge in lyrical flights of fancy that seem to have been inspired by old memories of Sir Walter Scott or the poets of the French Parnassian school. Editions of Polynesian texts are published by the Bernice Pauahi Bishop Museum in Honolulu, and, though interesting in the absence of any other methodical work, these, too, are open to criticism. Their translations are never literal but attempt some kind of free translation, as though dating from a period when translations aspired primarily to literary beauty.

As a result, the theogonies that have been published (supplied with diagrams indicating the superposition of the heavens) are engaging, but little more. They are no more than easy summaries for the casual reader, lacking any explanation of the texts on which they are based. Because they are simplicity itself, they enjoy much popularity, even in Polynesian circles, but they are of no scientific help to the serious modern investigator. He, nonetheless, must all too often fall back on such a summary, simply because nothing else exists to help him.

The scholar must be on his guard against an outstanding storyteller. He must take the events narrated, put them into their proper place and space, and compare them with what else is known in as complete a way as possible, so that contradictions in the fabric are revealed. Such contradictions, subtle but evidently present, indicate that an entire population has sided with the storyteller to disguise the real truth, which is in itself an interesting phenomenon for study.

The legendary cycles. There are very few comparative studies of Polynesian and Micronesian literatures. The methods they employ are not always impressive—only authentic texts should be used for comparison, not simplified summaries—but they do give a glimpse of how wide-

Figure 9: Melanesian dance of spirit impersonation, Ambrim Island, New Hebrides, Melanesia.
Kal Muller—Woodfin Camp

The "trickster" figure in legend

spread certain legendary cycles were, the most frequently recurring, from a geographical point of view, being that of the trickster figure, Maui-tiki-tiki, who was a fisherman of the islands and who discovered fire. He can be recognized, on the fringes of the Polynesian area, as the god of the first fruits of the yam harvest on this or that island, sometimes revered under a symbolic manifestation or sometimes as a less abstract figure. Indications of his variety of function over such a large area makes the loss, sustained over two centuries of interpretation willfully blind to the true Polynesian cultural phenomenon, all the more frustrating.

The few scraps of knowledge available about the indigenous literatures of Australia and Micronesia, as well as those of Polynesia, indicate that the figures of their great mythological cycles were simultaneously general symbols and local divinities. The people saw no contradiction in this double manifestation: great cultural heroes were naturally assigned to a specific place when an individual within that culture would establish a reverential dialogue with any one of them. (J.Gt.)

III. The performing arts: music and dance

THE ROLE OF MUSIC AND DANCE

Music and dance in Polynesia and Micronesia are audible and visual extensions of poetry, whereas in Melanesia they are more aimed at spectacular display during times of life crisis and secret-society rituals. The differences between Melanesian and Polynesian music and dance can be related to a basic differentiation in political types that reflects differences in social structure that have been characterized as "bigmen" societies and chiefdoms.

Melanesia. The leader, or bigman, in many Melanesian and New Guinea societies is often a self-made man; he becomes a leader by creating followers, succeeding because he possesses skills that command respect in his society, such as oratory, bravery, gardening prowess, and magical powers. He amasses goods and has great public giveaways, often in connection with the erection of a bigman's dwelling or a men's house, the purchase of higher grades of rank in secret societies, the sponsorship of funeral or other religious ceremonies, or the erection and consecration of slit-gongs (or slit-drums, percussion instruments made from hollowed-out logs or living tree trunks). These ceremonies occasion spectacular displays of the visual and performing arts.

Impersonation of otherworldly beings

There are basically two kinds of dance in these Melanesian ceremonies: dances of impersonation (Figure 9) and dances of participation (Figure 10). In the first type, the dancer impersonates mythical or ancestral beings; the dance-actor becomes someone else, and his attire is usually distinctly unhuman or supernatural—consisting often of huge masks and a full otherworldly costume. The dance movements are dictated by the two considerations that the dancers are not human and that their attire is difficult to move in. Thus the movements are those of legs and swaying bodies; the arms are often covered and frequently used to steady the costume and mask or perhaps hold a drum to accompany the dance. The movements do not interpret recited poetry; however, the voices of these supernatural beings may be heard in the sounds of musical instruments.

The dances of participation are often extensions of these dramatic ceremonies, for individuals who do not impersonate spirits often join in and dance with them, imitating the steps of the supernatural. In dances celebrating headhunting, warfare, funeral rites, or fertility—in which everyone participates—the same movements are used, often to the accompaniment of drumming and communal singing. The dances have a character of spontaneity and do not require long and arduous training. Their aim is not the simultaneous flawless execution of music and intricate movements but, rather, the creation of a mass rhythmic environment that might be characterized as a visual extension of rhythm. If words are associated, they are repetitious and seem not to tell a story; they may even be unintelligible. Although the specific structure of any single dance tradition in Melanesia is not yet known, it seems probable that the isolated units of movement would be primarily those of legs and body.

Polynesia. The entirely different world of Polynesia stands in contrast. Polynesian dance is a visual extension of poetry that uses chant or heightened speech as a vehicle for the praise and honour of high-ranking chiefs or visitors (Figure 11). In Polynesia power resides in chiefly office, and texts tell of a chief's deeds and his descent from the gods. Genealogical rank is a distinctive feature of Polynesian societies, and music and dance pay allegiance to the rank-based sociopolitical structure, reflecting and validating the system of social distinctions and interpersonal relationships. In these societies, where power resides in the office and the regime is long and enduring, specialists compose poetry, add music and movement, and rehearse the performers for many months before a public ceremony. Movements are primarily those of hands and arms, and interpretation is that of a storyteller. The dancer does not become a character in a drama, and his stylized gestures do not correspond to words or ideas as they do in literature-inspired dance traditions of Indonesia and Southeast Asia. In Polynesia the dancer interprets a story orally, usually chanting or reciting metred poetry, and accompanies the words with actions. The presentation is not dramatic in the Western sense of the word, for there is no conflict. Instead, the dancer is storyteller *par excellence*, audibly and visually telling *about* a person, place, event, or emotion, Yet, although Polynesian dance texts are based on traditional stories, legends, or myths, a story is not "told" in the usual sense: traditional literature is referred to in a roundabout way, but the poetry is often the vehicle for

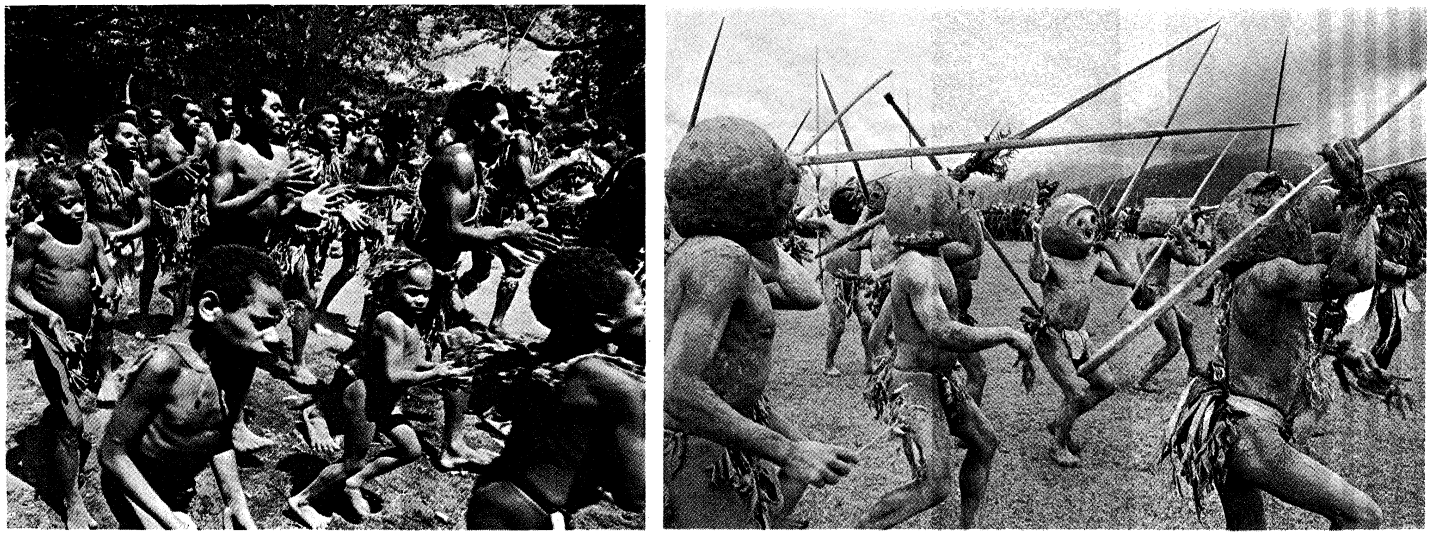

Figure 10: *Melanesian dances of participation.*

(Left) Kal Muller—Woodfin Camp; (right) © Axel Poignant

saying something else, usually something relevant for the occasion at which it is presented. In addition, the order of the dances and the choice and placement of the dancers often supply further information about the social structure.

The structure is known for at least two Polynesian dance traditions—Tongan, in western Polynesia, and Hawaiian—and the basic units of movement are primarily those of the arms. The only Polynesian dance tradition, however, that has been thoroughly studied is the Tongan. Tongan dance is a visual extension of poetry and is closely intertwined with social organization. This sung poetry is a series of references to mythology, chiefly genealogies, famous scenic places, and contemporary events. The dances, which are performed either standing or sitting, interpret selected words of the text with hand and arm movements. The distinguishing characteristics of Tongan dance are the emphasis on the rotation of the lower arm and the flexion and extension of the wrist, as well as a quick sideward tilt of the head. The legs are used mainly to keep time with sideward stepping movements, and there is a marked absence of hip or torso movement. In pre-European times the most important dance was the *me'etu'upaki*—a paddle dance performed by a large group of men in accompaniment to singing and a slit-gong, which was often played by a high-ranking chief. This dance is still performed today. Group dances called *me'elaufola* were performed by men or women separately in accompaniment to singing, long bamboo stamping tubes, and percussion sticks. The evolved form of this dance, which flourishes today, the *lakalaka*, is performed by men and women together in accompaniment to sung poetry only. Solo and small group dances performed by one, four, or eight women often follow the large group dances and are more concerned with beautiful movements than with interpretation of poetry, although the same movements are used. In the 20th century Polynesian dances are classified into six genres, three of which have survived from pre-European times. The most acculturated dance type, the *tau'olunga*, is a combination of Tongan and Samoan movements and accompanies Western-style singing in conjunction with stringed instruments.

Micronesia. Music and dance in Micronesia, though certainly not the same as their Polynesian counterparts, are closely related to them. With the exception of Truk in the central Carolines, which displays traits of Melanesian and possibly Indonesian influence, the music structure of all parts of Micronesia is predominantly word determined, as is that of Polynesia. Dance movements are mainly of hands and arms in accompaniment to poetry. In some islands, such as Yap (in the western Carolines) and the Gilberts, there is a similar concern for rank in the placement of dancers, as well as the emphasis on rehearsed execution of songs and movements. But, although movements and types of dance have a superficial similarity to Polynesia, there are differences. In the Yap Empire, for example, dances were given as tribute to Yap by Ulithi, Woleai, and other islands, and the dance texts were in languages not intelligible to the Yapese dancers—the function of movements was not to illustrate a story but to decorate it (Figure 12). Instead of acknowledging a chief's deed or genealogy, the Yapese dancers demonstrated the overlordship of Yap to the other islands. Even in Ifalik, where texts were in their own language, the movements did not interpret poetry but were apparently abstractly decorative. The same is true for the Gilbert Islands. Thus Polynesian dance could be characterized as illustration of poetry and Micronesian dance as decoration of poetry, while music in both areas serves as an elevated form of audible performance for poetry.

Dance as ornament to poetry

In many parts of Micronesia, dance and music were associated with tattooing, and with the decline of tattooing has come the virtual demise of these genres. The importance and dependence of the Micronesians on the sea is illustrated in poetry, music, and dance. In some areas dances were performed on the platform of canoes, canoe-like paddles were used in other dances, and in some areas canoe head ornaments were worn by the performers. A study of the influence of the sea on Micronesian music and dance would reveal a great deal about the underlying value systems.

Again, the specific structure of any of the Micronesian dance traditions is not known, but apparently the basic units are primarily those of hands and arms and, if early descriptions are to be believed, the head.

Australia. Music and dance of Australian Aborigines are important elements of sacred ceremonies that re-enact mythological origins of the tribes and insure the continued supply of foods through the propitiation of totemic plants and animals. Little is known about the internal structure or basic movements of the various Aboriginal dance traditions; however, in general terms there are often mimetic movements that involve the entire body to add a visual interpretative extension to the oral literature of the tribe.

MUSICAL INSTRUMENTS

Oceanic cultures have developed a large variety of sound-producing instruments. Some are unique, such as the friction blocks of New Ireland: three to four plaques carved out of a wooden block are rubbed with the hands to produce shrieking or hollow-resonant sounds, depend-

Figure 11: Welcome dance performed as a mark of respect to visitors, Viti Levu Island, Fiji Islands, Polynesia.

ing on size (eight to 80 inches for the entire instrument). Most instruments are not used in musical contexts but for other purposes—for example, to produce the voices of supernatural beings (in Melanesia), as lures (shark rattles), as toys, and for communication.

Musical instruments proper generally lack provisions for musical efficiency and easy handling. Flutes have no or few finger holes and no air ducts. Tuning devices with drums are rare, as are fixed resonators with chordophones (string instruments), which are represented only by simple types of musical bows and zithers. In general, instrumental music is culturally less important than vocal music, and in some areas it is absent altogether. In some other areas, however, such as the Solomon Islands, there are highly developed pan-flute orchestras.

Although some types of instruments—*e.g.*, conch trumpets and slit-drums—can be found in many parts of Oceania (excepting Australia), others occur only locally or are distinguishing features of certain musical areas. Open, hourglass-shaped drums with one membrane are typical of New Guinea and Melanesia, while Polynesians used cylindrical drums. Flutes of various types are usually blown with the mouth in Melanesia, with the nose in Polynesia (nose flutes), and both ways in western Micronesia. In contrast to their simple technical structure, which is the more demanding on the skills of the player, some instruments display elaborate ornamentation related to their function as cult objects in Melanesia, or they may be highly carved and finished befitting their function of honouring gods and chiefs in Polynesia.

REGIONAL STYLES AND TRADITIONS

Melanesia. Melanesia—including New Guinea—houses a multitude of regional musical styles, few of which have been thoroughly investigated. The diversity, which parallels the linguistic situation, is assumed to be a result both of migrations and the relative isolation of ethnic groups due to geographic conditions. Intergroup contacts, including European influences, mostly since the late 19th century, have had a clear influence on present styles.

Generally speaking, Melanesian music tends to be less word determined than Polynesian and Micronesian music. Melody, rhythm, and form appear to be shaped by intrinsically musical principles rather than by text structure and meaning. Song texts often use archaic or foreign languages and are thus frequently unintelligible to all participants in a performance.

Melodic characteristics. Musical scale and melodic movement have been primary criteria in the analysis of Melanesian music. The main types of melodic form are triadic, in which the melody moves exclusively or predominantly on the steps of a triad (three tones, each a third apart, as C–E–G); and pentatonic, which uses five steps within an octave, the melodic structure typically emphasizing seconds, fourths, and fifths. Other types include "narrow," in which melodic movement is restricted to an ambit (range) of a third; and "tiled," in which the melody consists of a sequence of short narrow phrases on different tonal levels, always in a descending order.

The triadic and pentatonic forms

Several attempts have been made to link these types of melodic form with specific cultures within Melanesia. The Dutch scholar Jaap Kunst attributed the tiled type found in the interior of western New Guinea, the Torres Strait, and Australia to "a people who, without doubt, emigrated from Asia to Australia—where the majority of them finally settled—by way of New Guinea and Torres Strait." Triadic melody style has been connected with speakers of non-Austronesian (Papuan) languages in New Guinea and elsewhere in Melanesia, while pentatonic structure is described as an element of Austronesian culture in Melanesia. But, whenever new data become available, previous hypotheses on the distribution of stylistic characteristics and their attribution to ethnic and cultural groupings usually have to be revised.

Also, rarely is the music of an ethnic group found to be based on one single principle of melodic structure. There is usually a mixture of several principles apparent, with one or the other prevailing.

Musical style and cultural context. This mixture of musical structures holds true for the three New Guinea groups whose music has been studied in its cultural context: the Monumbo, the Kate, and the Watut. A more detailed discussion of Kate music will illustrate the stylistic heterogeneity of the Kate, who live in the hinterland of the Huon Peninsula of northeast New Guinea and speak a non-Austronesian (Papuan) language, while some of their neighbours on the coast and on adjacent islands speak Austronesian (Melanesian) languages. A Lutheran mission was established in that area in 1886.

Music of the Kate people of New Guinea

Before the mission terminated their non-Christian religious activities, the Kate shared with their neighbours, specifically the Melanesian-speaking Jabem, Bukawa, and Tami, a secret initiation cult that provided for an exchange of music and dances among participants. The mission introduced "Christian songs" with texts in Kate language and European church tunes; but missionaries also created "Christian" adaptations of traditional Kate melodies, which were more readily acceptable than Lutheran hymns.

By about 1910 the Kate experienced a twofold cultural change resulting from the continuing contact with their Melanesian-speaking neighbours and from the impact of European colonial culture. But many aspects of their precolonial culture were then still functioning or in fresh memory.

Music and dance activities were connected with childbirth, children's games, initiation, hunting, agriculture, ceremonial bartering of pigs, warfare, and death—the

Figure 12: Festival dance, Yap, Caroline Islands, Micronesia.
Burt Glinn—Magnum

latter occasion being the only one to prohibit dancing. Consequently, initiation ceremonies, which usually extended over two years, had to be interrupted whenever a death occurred.

In addition to music and dance in ceremonial context, there were songs for entertainment and expression of individual sentiments or experiences. Most of the common social dances and dance songs were adopted from the offcoast Siassi Islands, including texts that were unintelligible to the Kate.

Structural characteristics of Kate music include triadic and pentatonic melody, both pure and in various degrees of blending; monophony (music having a single voice part); reverting and progressive strophes (stanzas) of varying lengths; basically isorhythmic organization (*i.e.*, using recurrent rhythmic patterns); and a wide range of tempi. Analysis of stylistic characteristics in relation to context and historical data revealed that triadic melody and short progressive strophes are associated with the old, non-Austronesian (Papuan) stratum of Kate culture. Pentatonic melody and longer, reverting strophes seem to represent Melanesian influence, while a specific melody style characterized by the use of several pentatonic modes in succession ("modulating pentatony"), very wide ambit, and extended strophic form can be attributed to European-culture contact.

The Solomon Islands. While the music of New Guinea and western Melanesia—particularly the Bismarck Archipelago—is predominantly vocal and monophonic, the music of the Solomon Islands is largely determined by use of highly developed panpipes. These instruments have three to nine closed tubes, usually doubled by open tubes that sound the higher octave. New instruments are tuned by comparison with old "masters," at the occasion of special ceremonies. Panpipes are used in orchestras alone and in conjunction with song. Vocal melodic style, which is characterized by triadic structure, wide melodic leaps, elaborate polyphony (several simultaneous voice parts), a specific timbre, or tone colour, and frequent change of register, is apparently an imitation of panpipe music. Types of polyphony include parallel melodic movement a third or a sixth apart, a practice most likely a result of overblowing the double panpipes, which may produce such parallels automatically.

Panpipe ensembles

The triadic melody style of the Solomon Islanders seems to have spread into adjacent western Polynesia, where similar melodic types are found in the Ellice Islands and Futuna.

Micronesia. From the Carolines in the west to the Gilberts in the east, most traditional music is accompanied by dancing in standing or sitting posture. Group singing with rhythmic accompaniment by body and ground beats or concussion sticks is the prevailing type of musical performance. Purely instrumental music was performed on nose and mouth flutes in the Carolines and Marianas.

Except in the central Carolines (Truk), where musical influences from Melanesia and eastern Indonesia are prominent, elements of chanting and metred declamation are the most conspicuous characteristics of musical structure, underlining the importance of poetry versus intrinsically musical principles. Vocal polyphony takes the forms of drone (sustained note heard against a melody) and parallel movement in a variety of intervals, with fourths most common.

Micronesia is the least known part of Oceania, as far as music and dance are concerned. On some of the Gilbert atolls, consecrations of assembly halls, races of boat models, and meetings between local groups were or still are connected with performances of dances in which both women and men participated. Active participation and choreographic role are determined by individual proficiency as dancer and singer and by social rank. The *ruoia* is a sequence of standing dances in which movements are slow and mainly those of the arms and hands. In introductory and main dances, up to six leading dancers, male or female, pose as "gliding frigate birds" in front of the other dancers, who are lined up according to status in their patriclans (kinship groups). All dancers participate in chanting long poems that are rehearsed beforehand. Endings of dance songs are frequently shouted, and texts of the final dance in a sequence are recited in heightened speech throughout. There are also sitting dances, with arm and hand movements similar to those of the standing dances, and stick dances. Dance gestures are not illustrative of the song texts, which are not generally understood by performers or audience.

The texts of traditional dance songs were "received" by composers from ancestor spirits (*anti*) in special rituals and probably in trance. Since the early 20th century, multipart singing of European church tunes has spread throughout the area. In consequence of a general culture change, social dances based on traditional movement patterns but accompanied by adaptations of Western music have become dominant.

Polynesia. Since the second half of the 18th century, all parts of Polynesia have undergone a drastic culture change that affected music and dance traditions severely. At present, adaptations of Western musical forms are predominant throughout the area. Both European church singing introduced by various missions and secular styles, ranging from the whalers' chanties to modern international entertainment music, have participated in this process. Yet, remnants or elements of precontact Polynesian music have survived almost everywhere, either alongside of or within acculturated styles—be it because of a marked traditionalism, as in Hawaii and New Zealand, or because of a delayed acculturation process, as in many of the smaller and remoter islands.

Common traits. The first useful descriptions of Polynesian music and dance come from Capt. James

Cook and his companions on his exploration voyages (1768–80). Such reports of early travellers agree with 20th-century research in suggesting that, despite regional variance, the concepts and structural characteristics of music and dance are highly similar throughout Polynesia. Music serves as a vehicle for Polynesian poetry, as dance is its illustration. The central role of the word explains why Polynesian music is primarily vocal. The only noteworthy traditional instruments used independently from song are the nose flute and the musical bow. Accompaniment of song includes body percussions (*e.g.*, slaps, claps), drums, and various idiophones (instruments the bodies of which vibrate to produce sound, such as rattles and slit-drums).

Polynesian songs

The most obvious stylistic characteristics of songs, common to all parts of Polynesia, result from word orientation. Most traditional songs can be classified as chant, as recitation in heightened speech, or as a blending of both. In some areas—for example, the Ellice Islands—the same text may be performed in either style. Chanting uses a limited number of tone levels, mostly a third or a fourth apart, and numerous tone repetitions. Rhythmic organization varies from recitative bound to the accents of the words to strict repetition of rhythmic patterns. Vocal polyphony is widespread throughout Polynesia and indisputedly indigenous. It was noticed and described by 18th-century explorers at a time when foreign influence could hardly have affected the style of music. The most common form of polyphony, reported from almost all Polynesian groups with the marked exception of the Maori (of New Zealand) and Hawaiians, is drone produced by a second part that follows the melody rhythmically while repeating one—usually the basic—tone. All authorities agree that pure drone is a precontact element of Polynesian music. Other forms of polyphony occur locally and are believed to be a result of European influence; especially notable among these is imitational counterpoint (simultaneous, interwoven melodies using melodic imitation among the voice parts).

Beyond these basic common traits, Polynesian peoples have developed musical forms and stylistic characteristics that are distinctive for individual groups of islands.

Hawaii. What is generally known as "Hawaiian music" is the result of the acculturation that began in the early 19th century and that was greatly enhanced by the introduction (*c.* 1820) of Christian hymn tunes. The ukulele, so closely connected with this almost entirely Western style of singing, is a local adaptation of the Portuguese *bragha*, a small guitar imported to Hawaii about 1879. The Hawaiian guitar is a way of playing the European instrument by stopping the strings with a metal bar.

Despite the predominance of Western—and, more recently, Asian—influences, some evolved forms of precontact Hawaiian music and dance have been preserved. Their stylistic characteristics fall well within the limits of what has been described as common Polynesian elements.

The Society Islands. The inhabitants of the Society Islands, whose ritual and profane dances accompanied by polyphonic chanting, nose flute, and drum playing were admired by 18th-century explorers, experienced a particularly rapid and thorough Westernization of their music. A visitor to Tahiti, the largest of the Society Islands, stated in 1838: "If they ever had any native music, it has long been forgotten and no other singing is now heard but hymns and sailors' songs . . ." (Capt. Charles Wilkes, U.S. Navy; see Burrows, 1934). Still, the modern Tahitian *himene,* contrapuntal compositions in as many as six voices, retain some indigenous elements of music structure derived from polyphonic chant. These *himene,* which deal with various subjects besides the Christian sentiments (from which their name is adopted), represent a highly developed form of a hybrid Polynesian–European music style.

The Tahitian *himene*

The Maori. The Maori of New Zealand have lost most of their instrumental music in the process of acculturation but have preserved many of their traditional chants and dances. Traditional chants and dances are classified according to function and contents of the text. Among the more prominent types are the lullabies (*oriori*), the laments (*tangi*), the incantations (*karakia*), the love songs (*waiata aroha*), the historical or genealogical recitations (*patere*), and the dance songs (*haka*). They are either recited in heightened speech or sung on narrow melodic lines undulating around a central tone, *oro.* Rhythm is largely word-bound. Any polyphony is considered a fault of performance. One important aesthetic concept requires a performance to be uninterrupted even by breaks for breathing. Consequently, chants are usually performed by two or more singers who will take breath at different moments. As in all of Polynesia the younger generations favour adaptations of Western music.

Western archipelagoes. Very little is published on the music of the large archipelagoes of western Polynesia such as Tonga and Samoa, whereas for some of the smaller groups—Uvéa, Futuna, and the Ellice Islands—published studies are available.

Before Western contact, music on the Ellice Islands was closely connected with social rank, religion, and magic. There are no detailed descriptions of dances; vocal styles included recitation in heightened speech and chant with drone polyphony (common to most of Polynesia), and triadic melodies resembling those of the Solomons. The Samoan emissaries of the London Missionary Society who converted the Ellice Islanders to Christianity (1861–76) destroyed the traditional social hierarchy and suppressed dances and songs either related to non-Christian beliefs or simply not fitting for their concepts of morality. They introduced pentatonic Christian songs characterized by two-part contrapuntal polyphony resulting from overlapping antiphony (contrasting groups of singers). This "pentatonic antiphony" is believed by some authorities to have developed in Samoa under European influence. By 1900, it seems to have become the predominant musical style on the Ellice Islands for both religious and secular topics. Since 1914, church hymns and school songs in four-part European harmony began to replace "pentatonic antiphony" as the favourite style. By 1960, four-part harmony was the almost exclusive style of church, school, and dance tunes. International "Hawaiian" music is gradually penetrating the islands as mass media and Western musical instruments such as guitars and ukuleles become available. Remnants of the earlier traditions persist only with members of the older generations, although outside interest has stimulated a modest revival movement.

STUDY AND EVALUATION

Music. Although valuable descriptions of music and dance date back to the three voyages of Captain Cook (1768–80) and other early explorers, systematic studies of music structure were hardly possible before introduction of the phonograph as an anthropological and musicological research tool. The Austrian anthropologist Rudolf Pöch was the first to record Oceanic music, during his field research in New Guinea (1904–06). He was followed by many anthropologists, mostly German, who visited Melanesia, western Micronesia, and Samoa during the next ten years. Similar recording activities began in eastern Polynesia only in the 1920s. Proper ethnomusicological evaluation of these early recordings began only much later and is still far from advanced.

The first comprehensive study of one Oceanic music culture (*i.e.,* music, underlying concepts, social role) based on a musicologist's own fieldwork is Helen H. Robert's 1926 study of Hawaiian music, followed in 1945 by Edwin G. Burrows' study of Uvéa and Futuna. Almost all other musicological descriptions and analyses are based on archive materials rather than the authors' own field research. Only in most recent years have ethnomusicologists resumed direct investigations in Oceania, allowing studies to extend in scope beyond solely musical analysis.

Dance. Even fewer scholarly significant descriptions and analyses of Oceanic dance exist. For some island groups, reports from the voyages of Cook and other early explorers furnish largely untapped raw materials for studies in the ethnohistory of dance as well as for culture change. Much of this early journal material on dance has been extracted and included by Johannes C. Andersen in

his 1933 study of Maori music. Some of the Micronesian literature was reviewed by Mary Browning in 1970 (in *Dance Perspectives*). Nothing comparable has been done for Melanesia or Australia. Scattered references can be found in the "classic" ethnographic studies, such as the Thilenius Expedition for Micronesia, John Layard for Malekula, and Margaret Mead in Samoa.

It was only in the 1960s that a few adequate, systematic studies and film documentations began to appear. Several excellent films of Australian Aboriginal dance in its ceremonial context have been produced by the Institute of Aboriginal Studies, Canberra, Australia. The only scholarly study of dance in Melanesia is Allison Jablonko's 1968 study of the Maring people of New Guinea, accompanied by a film, *Maring in Motion.* There are also dance films and descriptions for the Gilbert and Ellice Islands by Gerd Koch. On Polynesian dance, two excellent films of Hawaiian dances have been produced, and the structures of Hawaiian and Tongan dances have been analyzed by Adrienne Kaeppler. On the whole, both systematic documentation and penetrating interpretation of Oceanic music and dance still remain promising fields for future research. (Di.C./A.Ka.)

IV. The visual arts

GENERAL CHARACTERISTICS

Form and technology. It has often been suggested that the arts of Oceania go back to the cut or polished tool phases of the Stone Age. There is every reason to regard this as an untenable approximation. An early hypothesis that the Polynesians, for example, or at least certain components of their population, were descended from a society that had known metals is not at all unlikely. Oceanic solutions to technological problems in no way suggest the residue of a prehistoric age. On the contrary, they appear to be the result of rational choice, aiming at efficiency and economy. The "progressive" methods later brought by Europeans all too often proved to be clumsy, costly, and deceptive, as far as the organization of daily life and agricultural production were concerned. There are many convincing examples of the Oceanians' capacity for scientific reflection and deliberate experimentation, such as their adaptation of traditional fighting techniques in order to resist the Europeans and their organization of efficient methods of cultivation without the slightest assistance from their conquerors.

Materials. Oceanic art was largely governed by what material means were at hand (Figure 13). In a physical environment whose vegetation, though not luxuriant, was thoroughly understood and utilized, the people there developed a variety of working textures such as Western industrial society, for example, cannot match. Locally established Westerners have turned with immense satisfaction to the materials available there, adopted them as their own, and even transformed them into luxury items. Both as working materials and as a source of colour, the vegetable compounds available to the Oceanian artist could satisfy all of his creative requirements (especially if it is borne in mind that his artifact was never intended to stand in a home with central heating). Contemporary Western experiments in new means of artistic expression do not rival the multiplicity and complexity of Oceanic art. Today in the West, for instance, works of art are being produced by a collage of nonmetallic materials—a process long familiar to the Oceanic artist, who knew how to combine a wide variety of materials using special vegetable glues. These artists discovered many techniques for physically tranforming plant materials, including pounding, chewing, and cooking. The soft paste they obtained was used to remedy any deficiencies on the surface of the principal support (which might be wood, stone, tree fern, rattan basketwork), and it also furnished an absorbent surface to receive vegetable pigment (Figure 6). The form of the finished work was thus not determined by the size of the wood or piece of stone; the work could be extended in any or all of its dimensions to whatever proportions were required to harmonize with, for example, the architecture of the great ceremonial houses.

Techniques of transforming plant materials

MELANESIAN VISUAL ARTS

Knowledge of metals. The Melanesians have long suffered from a prejudice whereby people who only wish to remain themselves are thought of as barbarians. Their determination, however, kept their culture alive—at least until the mid-20th century, for now it is being swept away by an accelerated process of economic development imposed and controlled by foreigners. This longer duration (outlasting traditional Polynesian art by a century) has allowed observers to discover some perhaps unexpected factors concerning the Melanesians—for example, their adaptation to iron, introduced by Europeans at the end of the 18th century. Hoops from empty barrels, which had contained wine or salted meat, were collected and cut up; the pieces were sharpened and made into carpenters' adzes. These homemade tools were distributed more widely than the "proper" axes sold at a higher price by the crews of Western warships. The technique and form of wood carving was not fundamentally affected, but the results were. First of all, the slow, carefully controlled process of firing green wood to produce a material that could be carved easily was no longer necessary: with the metal axes, wood fibres could now be cut cleanly. Next, there was the new possibility of achieving a right angle—or even an acute one—instead of being obliged to have only obtuse angles (as had previously been the case, at least in the larger works; small pieces, which could be carried by hand, might always be shaped as desired by using stone splinters or animal teeth).

Although this theory of the introduction of metal seems attractive by reason of its neatness and the cultural area in question has enough consistency to lend itself to a linear analysis of its development, it is well to proceed with some caution. The coastal populations adapted with suspicious speed to the relatively massive introduction of metal at this time, and it is as well to remember that the whole area of Serera (Geelvink) Bay, New Guinea, could not have been totally unaware of metals (indeed, bronze blades have occasionally been unearthed there, which indicates a lengthy period of contact with metal). European vessels during the 17th and 18th centuries took on fresh water and provisions there; some of them must

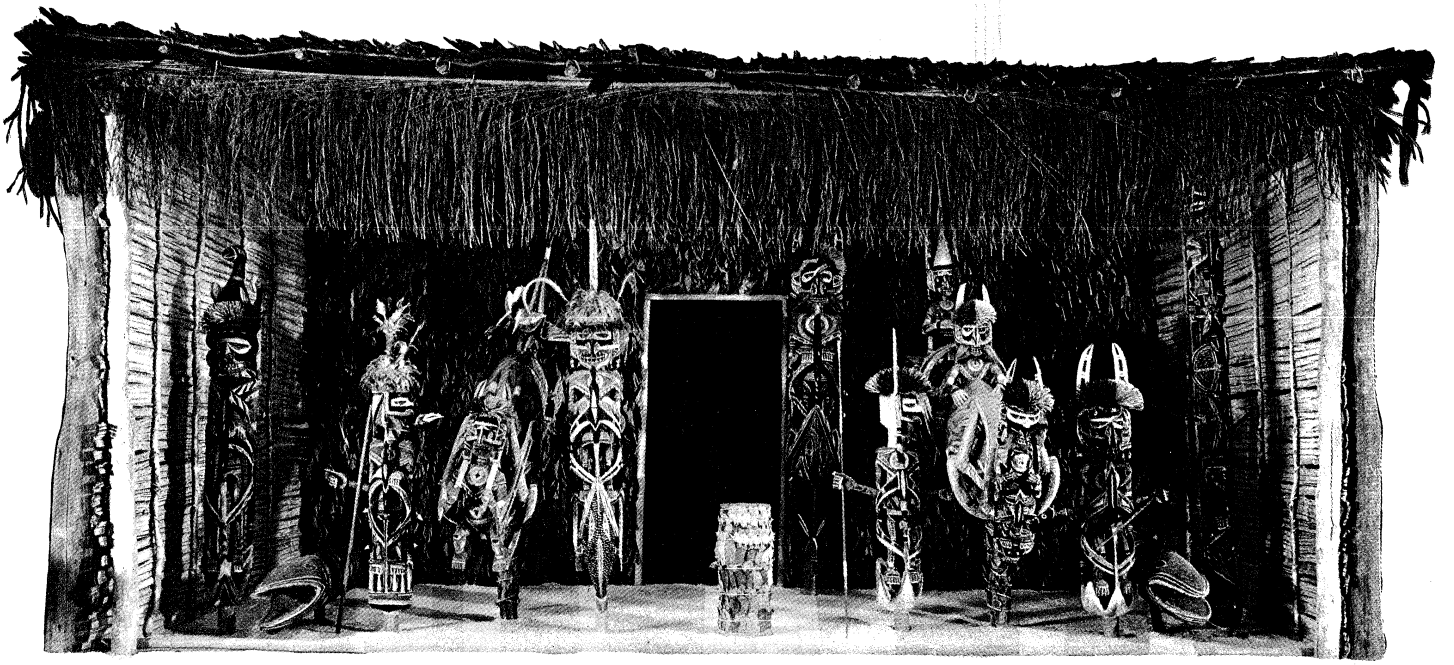

Figure 14: Cult house with *malanggans* from Medina, New Ireland. The house is made of wood, bamboo, small palm leaves, and croton leaves. The figures are carved in wood and painted with earth pigments and yellow oil colour. The house was erected to commemorate 14 deceased persons from the village. also have been shipwrecked, and the debris washed ashore would undoubtedly contain pieces of metal. Earlier still, Malay *proas* (boats) and even Chinese junks had sailed along the coasts of New Guinea; and how far the trading in objects of Chinese origin was carried on (it occurred principally along the northern coast of western New Guinea, from Indonesia) is not known. The Polynesians, at least, seem to have been already familiar with metal by the time it was "introduced" at the end of the 18th century.

Diversity and range. It is impossible to define "Melanesian art." Melanesia is a geographical concept only, designating an arc of islands—thousands in number—between New Guinea and New Zealand. Its cultural diversity is extraordinary and absolutely defies classification. Its art is no exception. Distinct regions must be treated separately; for local artists, like those of other cultures, have different ways of transforming various components into an original work. Even in the interior of one island there are many quite different plastic traditions, though there are, of course, also elements in common, such as the *uli* and *malanggan* carving traditions of New Ireland (Figure 14). Aesthetic elements are absorbed and diffused so quickly that an alteration of the distribution map of themes and methods would be necessary at least every 50 years. Striking similarities in palette and the use of comparable vegetal materials—as used, for example, in Papua and Arnhem Land (northern Australia)—have not led to a similarity of artifact or style. Even if an influence of one on the other or even an interchange of cultural elements can be supposed as taking place between New Guinea and the area of Australia opposite, the artistic products of each side certainly have no need of this proximity to explain their own existence. Ignorance on the matter is, indeed, considerable, because no one observed the technology behind the production of these objects at the time they were being made, and there is no museum equipped for the scientific study of this essential aspect. The efforts that have been made to understand everything about easel painting have not yet been extended to what is called primitive art.

Cultural diversity of Melanesian art

If, however, the plastic art of Melanesia is to be characterized on the basis of very slim knowledge, attention might first be called to its wide range, which takes in the most durable, finished stone sculptures as well as pieces so delicate that they could be rightly called arachnidean, for they actually use cobwebs as material. Broadly speaking, however, there are two tendencies to be distinguished. One leads to stereotyped art in which the individual variations of each piece lie in the small detail, discernible only on careful examination. The other favours a form of continuous creation, much of it achieved by wholly original plastic innovation, the rest by a double process of first analyzing existing formal elements and then constructing new ensembles by a partial or total regrouping of these same elements.

Stereotyped art. The first tendency can operate best within the framework of a society itself unconcerned with innovation, whose local artists specialize in a way that makes it possible instantly to recognize a piece of their work, regardless of where it may be found. This specialization need not be artistic so much as a matter of craftsmanship. The Huon Gulf and the island of Tami and the Admiralty Islands, especially, have organized specialization by village for the production of useful articles—ladders, house posts, bedsteads, mortars and pestles and spatulas for preparing and spreading lime, and obsidian dagger handles and spear points, wood and coconut-shell spoons, amulets of war or the dance, pirogue (canoe) prows, and platters of various sizes (Figure 15). Each individual member of the given society is a more or less skillful producer of one category of objects.

Innovative art. Sometimes the specialization is a prerogative of individuals because of heredity (as in the case of Big Nambas, the sculptor of tree-fern ridgepieces, or *ponarat*, of North Malekula in the New Hebrides), and sometimes because of a personal vocation (as on Ambrim in the New Hebrides). In these cases, products, though less numerous, become more accessible to classical aesthetic analysis—because of their artistic coherence and style rather than their finish. It also becomes less difficult to attempt tracing a chronology of these works with the help of the oral tradition and, sometimes, of archaeological discovery.

Individual specialization

There are many obstacles to be overcome in analyzing the aesthetics of Melanesian art. There is not even a documentary language adequate to describe the human body, so often the essential theme of plastic representation. A simple description of an object has no value at the level of scientific interpretation unless it is closely linked

Figure 15: *Melanesian articles of everyday use.* (Left) Wooden lime spatula. From the Trobriand Islands, New Guinea. In the Ethnographical Museum, Budapest. Length 30.5 cm. to the most exhaustive iconography possible. The more prominent characteristics of a work cannot meaningfully be isolated from the piece as a whole. The terms of the art historian's vocabulary have proved inadequate to convey the inventiveness and refinement of these artists. The eye, framed by some orbital motif—circular, oval, lozenge-shaped, double- or triple-comma-shaped—is a characteristic of the area that includes the Sepik Valley and the northeast coast of New Guinea (Figure 16). But the

Holle Bildarchiv, Baden-Baden, West Germany

variations are countless; and the only scientifically useful definition of them would be a list of every known case, with statistics of each variation and a comprehensive index. The result would be unreadable and probably useful only in the task of settling the origin of pieces that, stylistically, might belong to more than one region.

Classification by natural materials. It is perhaps the factors of environment that offer the best means of classification. There are, for example, elements common to all the areas forming the immense marshy stretches of New Guinea: palm leaves, interlaced and stitched together, are used as a surface to be painted (Figure 17); trees, whose outer wood at least offers enough resistance to the chisel, are used by sculptors such as those of the Asmat coast (Figure 5, left); beds of coloured clay along the raised banks of the rivers provide a plentiful supply of pigments. There are, of course, local variations of material and technique. In Papua the bark of the mulberry tree is treated and used to make masks, both secular and ceremonial (Figure 6, top left), whereas this material is not seen in works from Sepik and the Asmat coast. The bark, however, is again used for masks made in the mountainous regions toward the northern coast of New Guinea, as well as on the islands between that coast and New Britain, and also in the Walonga (Baining) masks of northern New Britain itself (Figure 17).

Limited knowledge of art in the New Guinea interior

Perishable art of New Guinea. The high plateau and mountain valleys of the New Guinea interior have yielded so little that they might seem to constitute an aesthetic void. Such a judgment does not, however, take into account some fragile, perishable works that are made to be destroyed immediately after use. Beyond the fact that such objects are indeed made, little else is known about them.

The archipelagoes. More information about the archipelagoes—which are, properly speaking, Melanesian—awaits proper research into a number of historical collections, especially that of the British Museum, which have yet to be made public. Representations of human, beast, and fish figures from the Solomon Islands (Figure 7), notable for their austere, stylized simplicity, suggest an area of common influence that includes Merat Island (north of western New Guinea); the Huon Gulf and Tami; the Massim area; and the Admiralty Islands, even extending to western Polynesia (including Fiji) and central Polynesia. The figures also have features in common with some that have been dug from peat bogs in New Zealand.

Southern Melanesia. At the southern end of the Melanesian arc, however, from New Caledonia to the New Hebrides, there exists the familiar contrast between some areas, where there is a stable tradition of sculptors specializing in one or another type of mask or in monumental decorative pieces for the large clan house, such as doorjambs (Figure 18) and lintels, posts, ridge pieces, and other areas where there is an inventive culture whose aesthetic coherence is closely connected with public or partly esoteric rituals and where the art of carving is linked to a right that is sold and bought, but not inherited. Technological ingenuity, using vegetal elements, is greatest in the New Hebrides, especially in south Malekula (Figure 6, right). The Loyalty Islands, however, and the southern New Hebrides (Aneityum, Tana, Eromanga) offer little of interest other than monumental architecture (Loyalty Islands), weapons for close combat, plaited articles, and elements of body decoration.

MICRONESIAN VISUAL ARTS

Micronesia is culturally an area of transition in every way. Known facts and common sense link Micronesia—with the exception of such Polynesian islands as Kapingamarangi, or the southern Gilberts, and the Ellice Islands, where there is Samoan influence—with the aboriginal cultures of Taiwan, the Philippines, and the islands situated off the northern coast of New Guinea, with which there were continuing relations in both peace and war. Micronesian pirogues reached the Solomon Islands (especially the "Polynesian outliers," where Micronesian components form an important part of the basic population) and the northern New Hebrides. Little is known of the countless comings and goings between Micronesia and Indonesia, though Spanish archives give some account of these contacts.

Because this was a warrior civilization, living in fear of powerful enemies likely to come from the east, either

expecting or actively preparing for warlike expeditions within their perimeter, art tended toward the monumental (raised stones, monumental doorways) rather than the figurative. The technique in wood was, however, that of cabinetmakers, and household articles, such as the platters and stools used when grating coconuts, show modern functional forms. The artists knew how to work with mother-of-pearl inlay (Palau Islands), and their technique of plaiting ribbons cut out of pandanus leaves resulted in a delicacy of work that has something in common with certain Indonesian fabrics. The large gable figures of the Caroline Islands representing the human face (Figure 19, left) and the standing *tino* statuettes (Figure 19, right) seem, by their perfection, to be the result of a very long cultural development. In the final period, the Micronesians devoted their energies and ingenuity to organizing complex political systems, establishing a hierarchy of their islands, so that there was perhaps no longer a place for artistic creativity.

POLYNESIAN VISUAL ARTS

General characteristics. Polynesia is a world that ought to be better understood than it is. The West, for instance, has been aware of it since the 18th-century voyages of Capt. James Cook and Louis-Antoine de Bougainville. But it is difficult to sort out from old documents what is useful information and what stems from the romantic imaginations of 19th-century observers. Later research, such as that undertaken by the renowned Bernice P. Bishop Museum in Honolulu, though seriously intended, too often produces only unrelated items of information, bits and pieces of folklore, which never cast much steady light on how the society under consideration functions.

In addition, much essential information was early destroyed, partly by Western missionaries, some of whom were bigots, and partly by the Polynesians themselves, who gave way with such alacrity before the power and wealth of the West that they became iconoclasts, destroying their own culture. An early-19th-century missionary, the reverend John Williams, managed to preserve some of their religious sculptures by hanging them from the yards of his ship, as "testimony" to the destruction of the devil's reign, so that the Polynesian evangelists would agree to spare the "pagan idols" from the pyre they had already prepared. These sculptures are now in London (Figure 8). But many specimens of plastic art did not escape. There is no way of knowing whether what has been preserved is wholly representative, or, if so, of what.

Making do with what is known and awaiting the publication of scientifically inferred catalogs, it is possible to advance the idea cautiously that Polynesia offers the most stereotyped—and in many ways the least colourful—visual arts culture of the whole Oceanic area. There are striking exceptions: Hawaiian wickerwork (either hard—to make representations of gods—and supple—to provide royal cloaks), with its outer covering of coloured feathers, displays an extraordinary iridescence (Figure 20).

Protective function of violent colour

New Zealand. Violent colours—red, black, jade green—are also employed in the indigenous art of New Zealand but with little subtlety. Their function is rather to provide a coloured background or even to protect perishable surfaces such as wood or interwoven reeds.

Using hardwoods and volcanic stone—materials that would not so easily be destroyed by time—and patiently carrying out the arduous task of carving with their inadequate tools, the Maori became meticulous sculptors (Figure 3). They showed a preference for squat human figures approximating the fetal position, whose faces, with their globular eyes, recall the people's dread of miscarriage and were indeed a reverent symbol of that to which life has been denied. These works display an astonishing mastery of technique: the Maori sculptor, for example, passing from the representation of the face to that of the profile in the bas-reliefs adorning the great reception houses found a technical solution to the problem more advanced than that of the ancient Egyptian sculptor. Maori art remained alive the longest, though basic changes and innovations were produced by the introduction of iron. Thanks particularly to the results of a half

century of local archaeology, Maori art is perhaps the best documented in the Oceanian area.

Marquesas Islands. Like New Zealand, the Marquesas Islands offer both monumental sculptures and small objects, the latter often more valuable for the study of style. Nothing like the exquisite boxes for feathers or the votive statuettes of the Maori are to be found there; but the minute scenes that are represented in filigree on ear ornaments and, with less animation, on Marquesan tortoiseshell plaques or fan handles (Figure 2), are very attractive. Also of great interest is the art of tatooed body decoration practiced there. Decoration may cover the whole body, especially the man's, with contrasting light and dark lines and bands and elaborate designs. Stone sculpture is not used so much to represent gods as to elaborate the main structural points of an open architecture consisting of terraces that are raised one above the other.

Easter Island. Easter Island will always arouse astonishment for the ingenuity of a people on a barren windswept island who, by managing volcanic tufa and utilizing the strength of hundreds of men, erect huge, heavy sculptures (Figure 21). Many of them are adorned with tufa hats, and their angular faces top bodies that were unknown for a long time afterward because they were buried in the Earth. The Easter Islanders also carved twisted forms from the branches of the only available shrubs. The forms are human representations that reflect the harsh conditions of life in a climate in which men are poised between life and death each time a prolonged dry spell scorches all cultivation, leaving only seafood as possible nourishment—and this only on days when rough seas do not make fishing an impossibility. The peoples of this inhospitable island also produced ideographic signs that are still in the process of being deciphered. They seem, as much as anything, to have been devices that were used to aid the memory during religious recitals.

Nonfigurative art of Tahiti

Tahiti and the surrounding islands. In eastern Polynesia, Tahiti experimented in nonfigurative art: a bundle of coconut fibres, with shell pendants, would represent the figure of the god; tapa cloth, obtained from the bark of the mulberry tree, would be given a thin wash of colour obtained from fern leaves and enjoyed simply for its decorative value (Figure 22). Art in the surrounding islands, and also in the Îles Tubuai (Austral) group, is related to that of the Cook Islands, where a considerable part of the population claim to have come from the Society Islands. Sculptures of humans are not common; but the decoration of fan handles (Huahine), of votive axes (Mangaia in the Cook Islands), of ceremonial ladles and vertical drums (Îles Tubuai) displays great subtlety. Designs, both engraved and in relief, are made up of repeated, stylized representations of a figure with outstretched arms and legs. The statuettes of Rarotonga (representing the god Te Oro and his sons) or the representation of Tangaroa (Figure 23) creating mankind from the human forms that burgeon from his own body (Rurutu, Îles, Tubuai) show the mastery of relief that Polynesian sculptors achieved, especially considering the limits that were imposed by the myth itself on its plastic representation. The perfection of form and decoration of ordinary objects—pestles to crush the taro root in preparing poi, or the countless fishing weights bearing a human face or fish form—ought also to be noted.

AUSTRALIAN VISUAL ARTS

In many parts of Australia man has had to make a great effort to survive, especially when faced by the desert conditions of the centre or the semidesert conditions to the north during the dry season. Iron was not known, and the camel was introduced only in recent times. Incomparable walkers, their naked bodies tough and resistant to hardship, the Australian Aborigines strove to maintain their culture against colonial contempt and the repugnance of Christian missionaries, with the result that much more is known today about them than about the Polynesians, who were treated infinitely better by white colonialists.

Since Sir Baldwin Spencer and Francis James Gillen (late-19th–early-20th-century British ethnologists), a host of researchers have carried out a thorough survey of the aboriginal cultures. Although not so much attention was paid to material culture and art as to other aspects of their societies, local museums display rich collections, both old and new, which are somewhat better documented than in other cases. A substantial amount of work remains to be done, but there are qualified informants still living who could give more information. It has been possible, however, thanks to the persevering efforts of Karel Kupka, to discover that colours and motifs were appropriated by certain social groups (the Dua and Yiritya dualities) but that the superposition on this normative framework of systems of relations and interpersonal exchanges, implying, from one bark painter to another, prestations in the form of license to use colours and themes belonging to others, means that no work is strictly what it should be and that to decipher it one must be familiar with the men and groups involved (Figure 1).

Abstract art of the central desert. Similarly, it is known that in central Australia, the engraved decorations to

The *tjurunga*

be found on stone plaques (*tjurunga*) served the Aborigines as an aid in reciting their myths of origin. The art is abstract, and the various elements—stippled decoration, half circles, concentric circles, and parallel lines—can be understood to represent specific themes, such as seated man, tree, footprints, water hole, mythological figure, and so forth. It does not, however, represent a coherent ideographic language that can be deciphered without consulting those Aborigines who inherit a knowledge of its significance.

Ritual structures. An important part of Australian Aboriginal art consists of ritual structures, usually planted in the soil, made from a wooden framework on which strands of human hair are strung, stuck on with human blood often drawn from the male sex organ. Other works, using the same materials, were laid out over the surface of especially prepared ground. Both kinds of art were destined to be destroyed immediately after the rite, and only rare examples are known.

Rock art. Australian rock art is certainly the richest in Oceania, perhaps because ecological conditions, including the dryness of the climate, have ensured a better state of preservation for these works (Figure 24). Another factor, this time a ritual one, explains this good state of preservation. It is now known that, in a great many cases, paintings that are to be seen in caves and rock shelters are restored each year at the end of the dry season, on the occasion of what is known as a multiplication rite. To retrace the outlines of the figures, say, of a kangaroo, ensures the multiplication of that species and thus a fruitful hunt during the rainy season—the season of full stomachs. The same is true of other animal figures, including human representations, as an assurance that the group will not be in danger of extinction. (J.Gt.)

BIBLIOGRAPHY

Literature: There are no comprehensive surveys of the literature of the Oceanian peoples. The following are representative of the types of works available: JOHANNES C. ANDERSEN, *Myths and Legends of the Polynesians* (1928, reprinted 1969); CARL STROVEN (ed.), *The Spell of the Pacific: An Anthology of Its Literature* (1949); PHILIP SNOW (comp.), *Best Stories of the South Seas* (1967); JAMES NORMAN HALL, *The Forgotten One, and Other True Tales of the South Seas* (1950); WILLIAM ARMAND LESSA, *Tales from Ulithi Atoll: A Comparative Study in Oceanic Folklore* (1961); JOHN FRANCIS STIMSON, *Songs and Tales of the Sea Kings: Interpretations of the Oral Literature of Polynesia* (1957); BACIL F. KIRTLEY, *A Motif-Index of Traditional Polynesian Narratives* (1971); INEZ HANES, *Folk Tales of the South Pacific* (1969).

Music: WILLIAM P. MALM, *Music Cultures of the Pacific, the Near East and Asia* (1967), a general survey useful as an introduction; HANS FISCHER, *Schallgeräte in Ozeanien* (1958), the only comprehensive study of sound instruments in Oceania. (*Melanesia*): JAAP KUNST, *Music in New Guinea* (1967), three authoritative studies covering western New Guinea (West Irian); DIETER CHRISTENSEN, *Die Musik der Kate and Sialum* (1957), a treatise on the music of two northeastern New Guinea tribes, based on data collected 1908–10; HERBERT HUEBNER, *Die Musik im Bismarck-Archipel* (1938), the only extensive study of Melanesian music styles outside New Guinea, but the approach and conclusions are now obsolete. (*Polynesia*): JOHANNES C. ANDERSEN, *Maori Music with Its Polynesian Background* (1934), covers Polynesia in general, with an emphasis on the Maoris of New Zealand—a useful compilation of relevant excerpts from the travelogs of 18th- and 19th-century witnesses; HELEN H. ROBERTS, *Ancient Hawaiian Music* (1926, reprinted 1967), a thorough, comprehensive study; EDWIN G. BURROWS, *Native Music of the Tuamotus* (1933), a study of Tuamotu chant in its cultural context; and *Songs of Uvea and Futuna* (1945), a study of the music cultures of two small West Polynesian islands, based on the author's field work in 1932; DIETER CHRISTENSEN and GERD KOCH, *Die Musik der Ellice-Inseln*

(1964), a study of the music history of this West Polynesian archipelago, based on field research in 1960–63. See also JAAP KUNST, *Ethnomusicology*, 3rd ed. (1959, with suppl. 1960), the largest and most comprehensive ethnomusicological bibliography, with indexes—covers Oceania very well.

Dance: GERD KOCH, in the *Encyclopaedia Cinematographica* (E-415–418, 915–920, 1962–68), dance films and descriptions of Gilbert and Ellice Islands groups; MARY BROWNING, *Micronesian Heritage* (1970), a review of early descriptions of and writings on Micronesian dance.

Visual arts: GILBERT ARCHEY, "South Sea Folk," *Handbook of Maori and Oceanic Ethnology*, 2nd ed. (1949) and "Sculpture and Design: An Outline of Maori Art," *Handbook of the Auckland War Memorial Museum* (1955); TERRY BARROW, "Maori Decorative Carving: An Outline," *Journal of the Polynesian Society*, 65:305–331 (1956); TIBOR BODROGI, *Oceanian Art* (Eng.. trans. 1959) and *Art in Northeast New Guinea* (1961 Eng. trans.); ALFRED BUHLER, TERRY BARROW, and CHARLES P. MOUNTFORD, *Ozeanien und Australien: Die Kunst der Sudsee* (1961; Eng. trans., *Oceania and Australia*, 1962); STEPHEN CHAUVET, *Les Arts indigènes en nouvelle Guinée* (1930) and *L'Île de Pâques et ses mystères* (1935); B.A.L. CRANSTONE, *Melanesia: A Short Ethnography* (1961); DANIEL SUTHERLAND DAVIDSON, *A Preliminary Consideration of Aboriginal Australian Decorative Art* (1937); ADOLPHUS PETER ELKIN and CATHERINE and RONALD BERHDT, *Art in Arnhem Land* (1950); JEAN GUIART, *Océanie* (1963); KAREL KUPKA, *Un Art à l'état brut: peintures et sculptures des aborigènes d'Australie* (1962; Eng. trans., *Dawn of Art: Painting and Sculpture of Australian Aborigines*, 1965); MAURICE LEENHARDT, *Arts de l'Océanie* (1947; Eng. trans., *Arts of the Oceanic People*, 1950); RALPH LINTON and PAUL S. (J.Gt./Di.C./A.Ka.)

Oceanian Peoples and Cultures

The peoples and cultures of Oceania are spread from the Hawaiian Islands in the north to New Zealand in the south and from New Guinea and Australia in the west to Easter Island in the east. Most of the islands of Oceania lie in the central portion of the Pacific Ocean, bounded on the north by the Tropic of Cancer and on the south by the Tropic of Capricorn. There is no accurate count of the number of islands in Oceania; tabulations vary because the definition of what constitutes an island is not consistent. Estimates range from 7,500 to 10,000; many of these islands have never been inhabited by man.

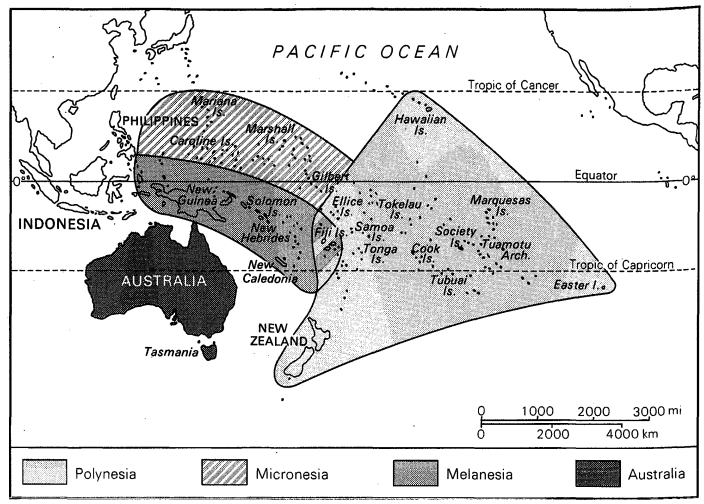
Major subdivisions of Oceania

Oceania is often subdivided into four main divisions or culture areas: Polynesia, Micronesia, Melanesia, and Australia. This classification system developed out of early-19th-century usage. Early European explorers often referred to the native Pacific islanders as Indians, grouping them conceptually with the inhabitants of the New World. Later observers noted that certain Oceanian peoples, although sometimes separated by vast expanses of water, were similar in appearance, language, and custom. An areal typology was devised that recognized both the commonly held characteristics of these peoples and the geographical locations of their island homes. The people of a large area, such as Polynesia, were seen to exhibit considerable variation, some groups even appearing atypical for the region in which they lived. Thus, geographical location alone was not a determining factor in the genetic heritage, language, and customs of its residents. The people living on an island in Melanesia, for example, were not necessarily Melanesian culturally, and Polynesian peoples were found residing on a few islands in Micronesia and Melanesia. These islands later came to be referred to as Polynesian "outlyers." The terms Polynesia, Melanesia, Micronesia were formulated by Europeans using the Greek words *polys* ("many"), *melanos* ("black pigment"), *mikros* ("small"), and *nēsos* ("island"). The term Australia was taken from *terra australis incognita*, the "unknown southern land," a long-sought hypothetical region whose existence was first postulated by early Greeks and Romans.

The islands of Polynesia are contained within a great triangle with apexes at New Zealand, Easter Island, and the Hawaiian Islands. Included are such groups as the Marquesas, Cook, Tubuai, Society, Tuamotu, and Ellice Islands, as well as the Samoa and Tonga Islands. The Fijian islands are situated on the imaginary line separating Polynesia and Melanesia, and Fijians reflect their medial position, sharing physical features and cultural and linguistic ties with both regions.

Melanesian islands include New Caledonia, the New Hebrides, the Solomon Islands, New Britain, New Ireland, and other small islands of the Bismarck Archipelago, stretching in an arc to the Admiralty Islands and including New Guinea—after Greenland, the largest island in the world.

Micronesia includes the widely dispersed islands of the western and eastern Carolines (principally the Palau Islands, Yap, Ponape, Truk, and Kusaie), the Marianas, the Marshalls, and the Gilbert Islands.



The culture areas of Oceania.

THE PEOPLE

Archaeologists have undertaken more research in Oceania since 1960 than ever before and are providing new conclusions about migration and settlement patterns. Yet there is an irregularity in the distribution of field research, and many important key sites are yet to be worked. The area of Oceania first penetrated by human immigrants was limited to New Guinea (and a few adjacent islands), Australia, and Tasmania. The earliest known occupation dates are all from Australian sites and are late Pleistocene: several excavations have produced materials that date from more than 30,000 years ago, and sites 40,000 years old are expected to be found. Some prehistorians believe that man reached Australia via New Guinea as early as 50,000 years ago. It is even possible that certain hominid forms in Australia were coeval with these early in-migrating *Homo sapiens* groups.

Earliest occupation dates

Racial groups. The reconstruction of the racial history of Oceanian peoples has been productive of many theories and explanations. The opportunities for breeding groups to develop in isolation and evolve adaptive responses to special conditions were numerous, and just as important to the racial diversity of the area is the hybridization produced by centuries of ebb and flow of migrating peoples. Such diversity is certainly the combined result of isolation or its lack, adaptation to differing environments, mating patterns, and natural selection.

Authorities still disagree over whether early hominid forms known from fossil finds to have inhabited Indonesian, Melanesian, and Australian areas were progenitors of peoples found there in recent time. There is similarly a great diversity of opinion on just which groups may have been antecedent—the Australoid, Veddoid, or Negritoid peoples found in the insular projection of lands south of Asia. Some specialists once proposed commonality of origin or at least some link between the Negroid peoples

of Africa and the darkly pigmented, sometimes frizzly haired groups found in Melanesia. Recent blood group research studies, however, show no evidence for such claims. In general, notions of a series of massive migrations, of relatively "pure" racial types from the Asian continent, and their miscegenation with antecedent peoples, seem to most specialists today to be simplistic. A quarter century of blood-group genetical studies produced no definitive conclusions about Pacific migration theory and little definitive information about the racial composition of Oceanian peoples.

Main racial elements

The racial composition of the peoples of Oceania is a composite of Caucasoid, Mongoloid, and Negroid elements; the Negroid peoples have survived or been reported in remote areas of Melanesia, the Philippines, Australia, and Tasmania. The Australian Aborigines may be described as a subcontinental isolate. Generalizations about the normative racial type of a particular culture area may be misleading. There are general tendencies, of course, but there are also such ranges of characteristics within virtually all areas that a representative of one area could easily be assimilated in one or more other areas.

Hair form among certain Melanesians is kinky, and many Polynesians have wavy to straight hair; but kinky hair is also to be found in Polynesia, as is curly to straight hair in Melanesia. The epicanthic eye fold, which distinguishes Mongoloids, is found in abundance in Micronesia, but it occurs elsewhere as well. Recognizing the difficulties of generalization, then, it may still be noted that Tongans, Fijians, Samoans, and Hawaiians are often tall and inclined to corpulence. Pigmentation generally tends to be darker among Melanesian groups than is normal in Polynesia or Micronesia. In some of the Melanesian islands, such as the Solomons and New Britain, colour is virtually blue black in some individuals. The ruggedness of Australian Aborigine facial characters exceeds that of other regions of Oceania. The people of the New Guinea highlands are of relatively short stature and have facial features of distinctive quality.

Migration sequences. The influxes of population into the area of New Guinea, Australia, and Tasmania continued until at least the end of the Pleistocene (10,000 years ago). Migration to Micronesia and Polynesia, however, appears not to have begun until 3,000 or 4,000 years ago: the islands of the Pacific were thus the last habitable portions of the earth to be populated.

Chronological sequences based on pottery styles, types of fishhooks, and other dating techniques suggest that man's presence in Micronesia was earlier than the oldest radioactive-carbon date yet found there of approximately 3,500 years ago. The evidence points to the entry of people into central Polynesia from eastern Melanesia. In due course, migrations radiating from both western and eastern central Polynesian island groups are thought to have settled the more distant reaches of Polynesia. Current opinion is that Hawaii was first reached midway to late in the 1st millennium AD by voyagers from the Marquesas, who were followed several centuries later by those from the Societies. The Societies also appear to have been the point of origin for the Polynesians who settled in New Zealand prior to AD 1000. Although the validity of the radioactive-carbon dates that have been recorded for Easter Island, indicating human presence by 400, has been questioned, it is in accord with dates of 100 to 300 in the Marquesas.

In Pleistocene times, when man first made his way out of Asia, the polar regions of the earth are believed to have held so much ice that the surface of the seas was several hundred feet lower than is the case today. Many areas that became submerged with the melting of the ice caps were then dry land and rendered migration easier.

The watercraft used by the ancient migrants from Asia were probably crude rafts or coracles: it is likely that the highly sophisticated sailing vessels so distinctive of the cultures of Oceania developed over a long period. However simple the early craft, those that men used thousands of years later to explore and settle the far reaches of Micronesia and Polynesia were impressive indeed. These were great double-hulled craft, capable of carrying a hundred or more voyagers and their provisions for a voyage of a month or longer, as well as domesticated animals and plants for propagation in a new homeland.

The issue of deliberate versus accidental voyages of discovery in the Pacific has prompted an impressive array of arguments from specialists on both sides. There is considerable evidence that some islands were, indeed, populated by seafarers who, because of a storm or mere random sailing, came unexpectedly upon their new home. There is also a great deal of evidence, however, of the navigational skills and abilities of Oceanian peoples and of certain deliberate voyages of discovery. It is also clear that return voyages were made to points of origin.

Language groups. The study of Oceanian languages sometimes requires generalizations that are no more than statements of probabilities. Many Oceanian languages have yet to be studied, and some are beyond study because they are extinct. Nevertheless, linguists offer the following characterization.

Two major language classifications

The languages of Polynesia, Micronesia, Melanesia, and Indonesia may be divided into two major groups: the Austronesian (sometimes called Malayo-Polynesian) and the Non-Austronesian (also called Papuan). Virtually all of the latter group are found on New Guinea and islands to the east and west of it. It is estimated that there are at least 500 Non-Austronesian languages spoken today. The number of Austronesian languages probably exceeds 500. Their geographical distribution extends from Easter Island to Madagascar and from Hawaii and Taiwan to New Zealand, and they are spoken in New Guinea, except for the south coast area. There are even some Austronesian languages found in southeast Asian mainland communities.

Most of the more than 200 languages of Australia, although in some instances quite different from each other, are thought to be related to one another—more than 85 percent being closely related. Common structural features strongly suggest a single original linguistic stock. Attempts to trace the Australian languages to those of other areas, even to contiguous ones, have proved fruitless; this probably indicates the great antiquity of the languages of Australia and the long isolation of the Aboriginal population (see also AUSTRONESIAN LANGUAGES, PAPUAN LANGUAGES; and AUSTRALIAN ABORIGINAL LANGUAGES).

Population trends. The nature and number of the various Oceanian peoples at the time of their discovery by Europeans are uncertain. The period of discovery was spread over several hundred years, beginning in the 16th century and becoming intense by the 18th and 19th. It was 1788, for example, before colonists from Europe settled in Australia. The number of Aboriginals at that time is not known, and their widely dispersed and seminomadic hunting and gathering groups are estimated to have been organized into from several hundred to nearly a thousand tribes. Tribal groups were generally associated with a given territory in which they eked out an existence from a relatively inhospitable land. Theirs was a simple yet highly functional material culture, which contrasted with a complex social system and a rich ceremonial life, featuring ancestor worship and totemic beliefs. They had rudimentary, impermanent shelters, went unclothed but for personal adornment, and foraged, hunted, and fought with simple but efficient implements and weapons. Some have estimated an Australian Aborigine population of 300,000 at time of European contact, but this is at best a guess. It is thought that the population had over time stabilized in relation to the ecology of the subcontinent and that, as a food-gathering and hunting culture, it was in balance with the environment. Like many other Oceanian peoples, the Australian Aborigines suffered severe population loss as a result of contact with the Western world. Only recently has the population of Aborigines begun to expand significantly. There are about 50,000 Australian Aborigines today, as well as a similar number of individuals who are part Aboriginal.

The island of New Guinea dominates the rest of Mela-

Populations of the major culture areas

nesia; 1,300 miles (2,100 kilometres) in length and more than 300,000 square miles (800,000 square kilometres) in extent, it has a mountainous spine rising to cloud-shrouded heights of 15,000 feet (5,000 metres). It was named in the 16th century by European explorers who were reminded by its dark-skinned inhabitants of those they knew from the Guinea Coast of Africa. Among the least altered portions of Oceania, it dominates Melanesia and Oceania not only in geographical size but also in population: estimates range from 2,500,000 to 3,000,000. The native population of the rest of the Melanesian islands, together with that of Micronesia and Polynesia, is a third to a half of that of New Guinea.

The native population of Micronesia (Guam, Trust Territory of the Pacific Islands, and the Gilbert Islands) is close to 200,000 or 225,000; that for Polynesia 1,000,000 to 1,200,000; and for Melanesia (including all of New Guinea) 2,700,000 to 3,200,000. Australian Aborigines number from 50,000 to 100,000. Therefore, all of Oceania probably contains somewhere between 3,750,000 and 4,725,000 indigenes. It must be pointed out, however, that reliable census data (or data for comparable years) is far from adequate.

CULTURE PATTERNS

The people and cultures of present-day Oceania differ greatly from those of the days when the areal classification into Polynesia, Melanesia, Micronesia, and Australia was devised. The Tasmanians have been extinct since 1876. Others, such as those living in the Mariana Islands and on Easter Island, often are more Spanish and Chilean, respectively, than they are Micronesian or Polynesian. With few exceptions, such as in remote areas of New Guinea, the peoples of Oceania have been exposed intensively to Western civilization and have adapted their ways to it either by choice or by necessity. Only certain features of their traditional cultures remain. There are, in greatly varying numbers, native inhabitants of all regions who manifest the physical types commonly associated with their culture areas. In some places, however, the native population is in the minority. It is, therefore, no longer accurate to say that the people of the Hawaiian Islands or of New Zealand possess a Polynesian culture or that those of New Caledonia are Melanesian culturally. Nevertheless, the fourfold typology of Oceanian peoples and their cultures continues to be used with reference to the contemporary inhabitants as well as to the traditional people of Oceania and their ways of life.

Stratification. Highly stratified social structures are typical of the aboriginal cultures of Polynesia and Micronesia. Hereditary chieftainship was closely related to supernatural beliefs that incorporated concepts of power (*mana*) and avoidance (*tapu*). Features of these two culture areas include an elaborate mythology; specialist craftsmen; distinctive artistic styles produced in part by isolation; pandemic and sometimes savage warfare; strong bonds of kinship and a related emphasis on genealogies; and, in places, strong trading or tributary relationships between island communities.

Melanesian societies are, because of their great diversity, less easily characterized. They were in general less concerned with social rank based on birth than with prestige gained through manipulation of resources. Root-crop agriculture (principally yams, sweet potatoes, and taro) was practiced as in many parts of Micronesia and Polynesia, and the resources of the sea were widely exploited. Ancestor worship and a rich ceremonial life were combined to produce a wealth of religious practices; they marked life crisis situations and incorporated both venerative and propitiative behaviour. In many areas complicated and highly ritualistic trading relationships were developed, and there were usually distinct differences between coastal and inland societies. Personal adornment was often elaborate; warring raids, in which heads were taken and cannibalism was sometimes practiced, were common; stone tools were polished; and animism was featured in supernatural beliefs. Its domesticated animals were those found elsewhere in Oceania, but pigs were vastly more important in the pursuit of personal prestige.

Technology. Most of the people of Oceania, prior to contact with the Western world, were at the Neolithic stage of technological development; that is, they worked stone by grinding rather than by chipping and flaking as in the Paleolithic stage. Some areas also had various other cultural features of the Neolithic such as agriculture, a few domesticated animals, pottery, and watercraft.

Utilization of materials

Seashells were used generally both as ornaments and as cutting tools. Shark, snake, and lizard skins were used as heads for drums. Bird, whale, and human bone, as well as fish vertebrae, were used for ornamental purposes and for tools, implements and weapons. Basalt, obsidian, jadite, chalk, coral stone, and other lithic materials are irregularly distributed throughout Oceania. Where these materials were available craftsmen produced a bounty of objects—adz blades, ornaments, images, and weapons —by skillfully chipping and grinding. Native woods of both hard and soft varieties were used to produce finely executed weapons, drums, masks, images, and building ornamentation. Great logs of pine were felled in New Zealand to produce flotillas of war vessels that could carry more than 100 men. Other islanders, without suitable timber for such canoes, scoured the beaches for driftwood logs or devised canoes from smaller trees, fastening planks together with cordage and caulking the seams with gum. Polynesian ironwood provided a source for some of the most intricately carved and heaviest of weapons. Ebony, bamboo, tree fern, and palm all added to the lumber supply of the Oceanian carver. Feathers of colourful birds were woven into garments and effigies in some places. Headdresses of feathers appeared in many parts of Oceania, but only the Hawaiians devised beautiful feather helmets. The kiwi, the tropic bird, the parrot, and the cassowary were but a few of the birds that added their plumage to the artisan's kit. Fibres and barks were used abundantly, particularly Orchid fibre, hibiscus, banana, flax, pandanus and ti leaves, and coconut-husk fibre. Pigments such as turmeric were obtained from plants. Earth and burned coral provided others. Among the countless other items that were utilized by the Oceanian craftsman were resins, gums, seaweed, spider webs, flying-fox fur, human hair, dog skin, kangaroo fur, boar tusks, vegetable seeds, shells, and teeth from humans, dogs, fish, and fruit bats.

The environment in which the traditional Oceanian native lived provided the setting for his culture. If there was little suitable land for agriculture, he had only tree crops such as coconut or pandanus; yam growing could thus not become a factor in social prestige nor tapa making a fine art. Although environment did not absolutely determine the nature of the culture that evolved in a given location, it served as a limiting factor; the technology of a people was in direct consonance with the surrounding region. The peoples who lived on continental islands (that is, on islands geomorphologically connected with a continent) had at their disposal a variety of minerals, a diversified flora and fauna, and, usually, a good freshwater supply. By contrast, the resident of a small coral atoll was preoccupied with securing an adequate supply of potable water and had fewer species of plants and animals. The type of island, its age, composition, and elevation, as well as its location and climate were vital factors in the development of a particular culture. Oceanian peoples had to adapt to a broad range of extremely diversified environments—tiny Micronesian atoll, humid New Guinea forest, or arid Australian desert. An artisan used the materials at hand for the most part. At times primitive trading systems allowed him to secure some materials he did not already possess, but he was mainly dependent upon his surroundings.

MODERN DEVELOPMENTS

Oceanian cultures are today blended of many elements. The number and strength of residual Aboriginal cultural traits vary greatly with the particular history of contact with non-Oceanic cultures. Much of the Polynesian cultural heritage of present-day Society Islanders has been supplanted by French influences. At the other extreme, certain remote natives of the New Guinea highlands,

whose exposure to alien influences has been negligible and whose very existence was unsuspected until a few decades ago, live much as their stone-age ancestors did for thousands of years. Even there, however, modern society is penetrating. Everywhere the time-honoured usages succumb to newly introduced supernatural beliefs, to contemporary social, economic, and political practices, and to modern technology.

The world of Oceania has been a world in flux since the great voyages of discovery by Europeans began in the 16th century to expose the peoples to new customs, values, ideas, diseases, and genes. The particular blend found in any corner of Oceania today is a unique amalgamation of surviving ancient cultural roots and modern influences.

Variety of foreign cultural imprints

Thus, an Oceanic community that has been primarily in contact with representatives of French culture (the Society or Marquesas Islands or New Caledonia, for example) differs greatly from that of a community largely exposed to British cultural influences (Gilbert or Solomon Islands, New Zealand, or the Cook Islands). The educated Fijian civil servant speaks in cultured Oxford accents. The Papuan presiding officer of the House of Assembly in Port Moresby is attired in black robe and white wig. The American Samoan policeman is uniformed in a manner like his counterpart in the United States, but the gendarme in Papeete is attired in the French tradition. Micronesians schooled under the Japanese mandate of their islands between World Wars I and II often speak and read Japanese, have a preference for Japanese cuisine, and may name a child Yoshio or Hiroshi. Spanish influence in the Mariana Islands has made Catholicism strong, whereas Protestant missionaries brought Calvinist beliefs and traditions to the Samoa and Tonga Islands of Polynesia.

Modern Oceania has many of the same concerns, problems, and responsibilities that face other areas of the world. There is concern over the environment, population control, urbanization and its attendant ills, and the need to develop viable economies. People must sometimes cope with severe problems in transportation, communications, food production, public health, and education. Their responsibilities involve the training of indigenous persons for specialized professional, technical, and administrative positions once held by representatives of governing powers or foreign entrepreneurs. They seek more self-government and political autonomy, higher levels of general education, and economic self-sufficiency.

Problems of health and welfare

Some commonly shared achievements that transcend cultural and national boundaries in the Pacific relate to public health and human welfare. Generally, people are healthier and live longer than formerly because of improved health services and preventive and remedial treatment. Controls have been effective—sometimes dramatically so—in the treatment of yaws, tuberculosis, malaria, filariasis, and leprosy. Infant mortality is greatly reduced, and immunization programs as well as village sanitation procedures have had a positive effect upon most island communities. Despite these gains, physical facilities often tend to be substandard, and trained medical practitioners are in short supply. The very success of health programs and the reversal of depopulation trends that began with epidemics started by early European voyagers, kidnapping of natives for slaves, and warfare with firearms have brought about one of the most severe problems of modern times. In most island communities, population doubled in the two decades following World War II. Today, great numbers of people cluster in port cities and towns, seeking employment, captivated by the colour and novelty of 20th-century technology. There are slums in Papeete and in Port Moresby. Sometimes, in a quest for the accoutrements of latter-day society, a people emigrates to a metropolitan centre en masse. The people of the Tokelau Islands of Polynesia, for example, have virtually transplanted themselves to New Zealand.

Human crowding occurs elsewhere, as in Fiji, from the immigration of "outsiders." The Indian population of Fiji, which settled in the islands first as labourers on sugar plantations, today dominates much of the commercial activity in Fiji and seems destined to vastly outnumber the indigenous population. Settlers from Europe clearly are predominant in New Zealand and Australia, and native Hawaiians represent a small proportion of the population of Hawaii. French business interests control the mining industry in New Caledonia, to which Europeans and islanders from Wallis and Futuna and from French Polynesia have been attracted in great numbers. Urban crowding is attended by the social ills found in cities elsewhere in the world—delinquency, crime, poverty, fragmented family life, mental illness, and ennui.

Social change brings mixed blessings. Literacy rates are higher today than ever before, but industrial development pollutes the environment dramatically in places such as Nouméa. The building of a jet airport can cause tourism to quadruple in two or three years. Tourism produces income, but many island leaders are concerned with the impact of such repetitive invasions upon their societies. More secondary school graduates are produced each year, yet there are too few opportunities for employing educated individuals when they return to their villages.

Economic issues and political aspirations

The economies of most island communities are highly dependent on the activities of external administering authorities, whose stewardship most islanders are striving to escape. The key to independence is undeniably in a greater degree of economic self-sufficiency than many Oceanian societies can manage. Most seek the development of fisheries and agricultural projects. They strive to improve livestock, crop, and forestry production. Mineral resources also are looked to for income. Markets for copra, sugar, cocoa, coffee, and bananas tend to vary, and there are some severe pests, such as rats and the coconut rhinoceros beetle, as well as devastating typhoons, which make crop production undependable. Nauru, which is rich in phosphate, has mined this resource so assiduously that its people will soon face a soil shortage. Similarly, mining exploitation in the Solomon Islands and lumbering and petroleum operations in New Guinea threaten a profound disruption of natural resources.

In attempting to cope with the problems of the modern world, the Oceanian peoples have worked with international organizations such as the Food and Agriculture Organization, the World Health Organization, the United Nations Development Programme, the United Nations Educational, Scientific, and Cultural Organization, and the South Pacific Commission. The nations that for so long dominated the Pacific world are withdrawing and are imposing their controls and initiatives less and less, and the Oceanian cultures are returning to autonomous self-government. The difference is that they cannot now live in a world of relatively splendid isolation as before. They face an earth grown smaller through technological change, and in which new dimensions have been added to old problems.

BIBLIOGRAPHY. F.R. FOSBERG (ed.), *Man's Place in the Island Ecosystem* (1963), is the most valuable source of its kind to date. SHERWIN CARLQUIST, *Island Life* (1965), treats the natural history of islands in great detail. The most complete compilation of information on the geographical exploration of the Pacific is provided by HERMAN R. FRIIS (ed.), *The Pacific Basin* (1967). Two recent readers offer a comprehensive sample of cultural diversity in Oceania: ANDREW P. VAYDA (ed.), *Peoples and Cultures of the Pacific* (1968); and THOMAS G. HARDING and BEN J. WALLACE (eds.), *Cultures of the Pacific* (1970). A number of important original contributions on Pacific migration theory, archaeology, linguistics, and ethnography are found in GENEVIEVE A. HIGHLAND *et al.* (eds.), *Polynesian Culture History* (1967). Australia's past is expertly covered by D.J. MULVANEY, *The Prehistory of Australia* (1969). Summaries of recent research in linguistics and archaeology are included in R.C. GREEN and M. KELLY (eds.), *Studies in Oceanic History*, vol. 1 and 2 (1970–71). No work on the coming of Europeans to the Pacific surpasses that of J.C. BEAGLEHOLE, *The Exploration of the Pacific*, 3rd ed. (1966). Two exceptionally well-illustrated books on Oceanic art are JEAN GUIART, *The Arts of the South Pacific* (1963); and ROLAND W. and MARYANNE FORCE, *The Fuller Collection of Pacific Artifacts* (1971). For a series of treatments of contemporary Oceania, see ALEXANDER SPOEHR (ed.), *Pacific Port Towns and Cities* (1963); and ROLAND W. FORCE (ed.), *Induced Political Change in the Pacific* (1965). Helpful statistical and

other summaries may be found in the *Pacific Islands Year Book and Who's Who* and *The Far East and Australia* (both issued annually).

Oceanic Ridges

Nothing was known of the depth or shape of Earth's ocean floors until 1840, when Sir James Ross of the British Royal Navy made the first deep soundings. By 1855 Commo. M.F. Maury had discovered a broad zone of shoal water in the North Atlantic, indicating the presence of an oceanic ridge, and evidence slowly accumulated thereafter that confirms the existence of other submerged ridges in all the oceans. But soundings made by lowering a weight on a rope or wire took so long that only a few were made, and the ocean floor was considered to be generally smooth. After 1920, however, the use of echo sounding—in which sound signals are beamed toward the ocean bottom and the time each takes to return is recorded—by British, Danish, German, and United States ships demonstrated that a great ridge extends along the axis of the North and South Atlantic oceans. They showed that another lies in the centre of the Indian Ocean, and that some parts of the Eastern Pacific Ocean were shallower than others.

Since 1954, refined techniques have permitted the recording of continuous profiles of the ocean floor beneath a ship's track, with an error of only one or two metres. Large uncertainties in the precise location of the ships while making the surveys remained a problem and were the chief source of error until after 1960, when methods of satellite navigation were introduced. In recent years the number of expeditions has increased to such an extent that no large parts of the ocean remain unexplored, and the pattern of major ridges has been established, although many details have yet to be deciphered. It is recognized today that oceanic ridges comprise one of the major features on the Earth's surface, rivalling the subaerial mountain systems in magnitude.

This article treats the classification, properties, origin, occurrence, and distribution of the oceanic ridges. For further information on the landforms and general topography beneath the oceans see OCEAN BASINS; CONTINENTAL SHELF AND SLOPE; and EARTH, PHYSIOGRAPHY OF. Additional treatment of the mechanisms that produce oceanic ridges and the significance of both the mechanisms and the ridges in Earth history is provided in the articles SEA-FLOOR SPREADING; CONTINENTAL DRIFT; ROCK MAGNETISM; ISLAND ARCS; EARTH, STRUCTURE AND COMPOSITION OF; and MOUNTAIN-BUILDING PROCESSES.

CLASSIFICATION OF RIDGES

The charting of the ocean floors has shown that they are not smooth and that many long and prominent ridges divide them into separate basins. These ridges can be classified into a few types on the basis of their properties and their relationships to one another and to the adjacent continents. The most important question is whether or not a ridge is active; that is, whether earthquakes occur along its axis. This distinction, combined with bathymetry, or the delineation of submarine topography, suffices to provide a classification that is confirmed by other geophysical and geological properties. Only the midocean ridge system and the island arcs of the world are active; all others are aseismic or quiescent.

The midocean ridge system. In 1956 the U.S. scientists Maurice W. Ewing and Bruce C. Heezen proposed that the several great sections of the known active ridges might form a continuous system. In support of this proposition it was pointed out that earthquake focuses in the southern Atlantic, Pacific, and Indian oceans join together and might mark the course of connections that had not been detected because of the paucity of soundings in Antarctic waters.

Continuity and dimensions

Expeditions sent for the purpose soon confirmed that the midocean ridge is indeed continuous and that it winds for 60,000 kilometres (40,000 miles) through all the world's oceans. It extends down the axis of the entire Atlantic Ocean, passes midway between Africa and Antarctica, and turns north to the centre of the Indian Ocean, where it branches, the main ridge continuing midway between Australia, New Zealand, and Antarctica to cross the east side of the Pacific Basin, running all the way to the mouth of the Gulf of California.

Because the system is so large and the behaviour and properties of different sections vary, several sections have separate names, such as the Mid-Atlantic Ridge, the Carlsberg Ridge, or the East Pacific Rise (Albatross Cordillera). Nevertheless, the system has an essential unity and is called the midocean ridge because of its generally axial position. Seismically active branches of the ridge system join the Azores to Gibraltar, the centre of the Indian Ocean to the Gulf of Aden, and other points on the crest to New Zealand and to Chile. A few short sections occur independently, for example, off the coast of Oregon.

The essential characteristic of the midocean ridge is that it is a broad and enormous uplift along the axis of the ocean floors. The floors slope up from depths of over 6,000 metres (20,000 feet) in marginal basins to the crest of the ridge, which is almost everywhere less than 4,000 metres (13,000 feet) in elevation, with crestal mountains commonly rising to depths of 2,000 to 3,000 metres (7,000 to 10,000 feet) and sometimes reaching above sea level.

Profiles of the East Pacific Rise show that the central portion is fairly smooth. In contrast, in the North Atlantic Ocean the crest is marked by a rift valley averaging 30 kilometres (20 miles) in width and up to 1,500 metres (5,000 feet) deep, and the inner flanks are rough and block faulted. The crest is, of course, the highest part of the ridge, but it does not lie at a uniform depth; rather, it rises towards a number of well-separated peaks or domes. In the Atlantic the crest rises above the sea to form seven groups of islands, of which Iceland and the Azores are conspicuous examples.

At the crest the basalt floor is everywhere exposed, but sediments increase steadily in thickness down the flanks and fill depressions until only abyssal (deep-sea) hills project, and finally all the bedrock is hidden beneath flat abyssal plains. But the essential structure of the ridge continues beneath the sediments to continental margins or to boundary ridges.

Fractures and earthquakes

At intervals the ridge is crossed, usually at right angles, by large topographic disturbances called fracture zones that offset, or displace, the crest. These offsets are called transform faults. Major ones, many of the largest of which cross the ridge close to islands on the crest, show offsets of as much as several hundred kilometres, but small ones cross the Mid-Atlantic Ridges every ten to 30 kilometres (five to 20 miles).

Shallow earthquake focuses follow the crest, and it has been demonstrated that those along the axis of the ridge are caused by normal faulting (one block moves downward, relative to the other, along a steeply inclined fault plane), while those on fracture zones are due to shearing (involving horizontal movements). Further, all the earthquakes have directions of motion compatible with tension and the spreading of the crest.

The midocean ridge system is the largest feature of the Earth's surface after continents and ocean basins. Its volume exceeds 100,000,000 cubic kilometres (25,000,000 cubic miles), and, if it did not exist, sea level would occur at more than 250 metres (800 feet) lower than it does.

Other ridges. *Lateral ridges.* Aseismic ridges that extend wholly or partly from uplifted islands on the axis of the midocean ridge to coasts of adjacent continents are called lateral ridges. Usually they occur in pairs and are perpendicular ("normal") to or make large angles with the midocean ridge. For example, broad ridges whose crests are everywhere less than 2,000 metres (6,500 feet) deep extend in opposite directions from Iceland to the coast of Greenland and to the continental shelf of Europe near the Faeroes and Scotland. Also, the Walvis Ridge and Rio Grande Rise make a nearly complete chevron-shaped pattern about the Tristan da Cunha group, in the South Atlantic Ocean.

Linear chains. Nearly straight ridges that terminate at one end in a young or active volcanic island are called

linear chains. The other islands of the chain appear to get steadily older away from the volcanic end. Except for local earthquakes connected with volcanism, these chains are aseismic. The Hawaiian Islands are an excellent example.

Boundary ridges. In the Atlantic Ocean the midocean ridge system lies near the centre of the ocean, except in the Arctic Ocean, where its continuation is much closer to the Siberian coast than to North America. On the other hand, the ridge does occupy a symmetrical position halfway between the Siberia coast and the Lomonosov Ridge. The latter is a great submarine mountain system that cuts right across the Arctic Ocean from north of Greenland and Ellesmere Island to the delta of the Lena River. It is generally supposed that this aseismic ridge marks the boundary of the present Atlantic system with an older section of sea floor north of Alaska.

Microcontinents. The Seychelles archipelago in the Indian Ocean resembles a continent in everything but size. The rocks of these islands are Precambrian (older than 570,000,000 years) gneisses (metamorphic rocks, formed under high temperatures and pressures); the crust beneath them is thick and continental, and the flora and fauna are of continental rather than insular types. There is complete agreement that this archipelago constitutes a microcontinent. There is also good evidence from deep-sea drilling and geophysical investigations that some submarine rises, notably the Rockall Bank, off the British Isles, are also submerged microcontinents, and many other banks and islands, including the Lomonosov and Walvis ridges and Kerguelen Island, have also been considered to be continental, but the evidence in many cases is still uncertain.

ORIGIN AND GROWTH OF RIDGES

Gravity, seismic, and magnetic data

General geophysical properties. Gravity measurements show that the midocean ridge is in isostatic equilibrium —*i.e.*, its height above the seabed must be held up by lighter material below. Seismic refraction studies show that the upper mantle (zone immediately beneath the Earth's crust), to depths of 100 or more kilometres beneath the crest, has low seismic velocities (speed of travel of earthquake waves) of about 7.6 kilometres (4.7 miles) per second, compared with normal values of about 8.2 kilometres (5.1 miles) per second. Velocities measured perpendicular to the rise are as much as 8 percent higher than those measured parallel to it. Other measurements show that the heat flow along the crest is higher than normal. To explain these observations it has been proposed that hot matter from the deeper mantle is upwelling toward the surface (the ocean floor) along the axis of the ridge.

Another remarkable geophysical feature of the ridge is that everywhere along it a pattern of magnetic anomalies occurs as long strips, each a few kilometres wide and parallel to the axis. This can be explained if the lava in successive strips on the sea floor is alternately normally and reversely magnetized. It has been proposed that along the locus of the crest of the midocean ridge the ocean floor has been spreading apart and that the natural reversals that occur in the Earth's magnetic field cause the pattern of alternating strips of magnetic anomalies. This proposal fits the assumption that hot material is welling up under the ridge.

The theory of plate tectonics. The pattern of ridges is so regular and their properties are so constant that these features cannot be caused by chance. The only theory advanced that explains their characteristics satisfactorily is that of plate tectonics. Because this hypothesis has been accepted almost unanimously by marine geologists and geophysicists, it will be used here as a framework upon which to base descriptions of the ridges.

According to the theory of plate tectonics, the outer 50 kilometres (30 miles) of the Earth constitutes a brittle shell, or lithosphere, that is broken into six large and perhaps a dozen smaller plates. Convection currents, or upwellings from the deep interior, cause these plates to move slowly about relative to one another and to the interior, and these motions generate the ridges. A typical large plate includes either one or two continents and the surrounding ocean floor.

The midocean ridge system and its branches mark boundaries along which upwelling is splitting the crest and creating new ocean floor along the trailing edges of both plates. This growth, which occurs equally on both sides, causes the plates to move apart. Particularly active upwellings at some places under the midocean ridge are marked by active volcanoes, which form such islands as Iceland.

Lateral ridges are thought to have formed where this localized activity has been of long duration. They have been formed by the outpouring of excess lava throughout the time of spreading of an ocean basin and thus mark the locus of movement of the two plates away from the hot spot.

Linear ridges are considered to have a similar origin, except that in their case the source of the lava does not lie on the axis of a spreading ridge. Instead, if one plate is driven over a hot spot from which lavas can penetrate to the surface, then those lavas generate a single chain of progressively older volcanoes, which mark the direction of past motion of the plate over that hot spot.

Boundary ridges are believed to have formed where an excessive upwelling of lavas occurred where an old ocean floor was split apart by the creation of a new section of midocean ridge crossing it.

Island arcs, young mountains and their accompanying trenches, mark subduction zones—zones where two lithospheric plates have been forced together so that one has overridden the other and has pushed it down to be reabsorbed into the mantle.

The concept is now widely accepted that some ocean basins, such as the Atlantic, grow by the spreading of the midocean ridges, whereas others, such as the Pacific, shrink by the overlap and absorption of one plate by another. Many authorities incline to the view that a system of convection currents rising under the midocean ridge forms the driving mechanism. Although the concept is clear enough, great difficulties have been encountered by those who have attempted, by either theory or experiment, to find precise models of rotating systems of currents.

Role of upwelling plumes

As a simpler alternative system of flow, U.S. geologist W. Jason Morgan proposed in 1971 that upwellings such as those under Iceland and Hawaii are the tops of plumes of hot material rising from deep within the mantle and that these are the currents that drive the plates. He noted that the plumes lift up the lithosphere above them in broad domes (as much as 1,000 kilometres [600 miles] across and two or three kilometres high) that are capped with volcanoes generated by the rising hot material. Where several domes lift the surface, the lithosphere may break between them to form plates that slide off the sides under the influence of gravity. The lavas that rise from the breaks in the lithosphere linking the domes come from much shallower depths than the lava in the plumes; this could explain the difference in composition between the axial islands and the rest of the ridge and the ocean floors generated by the ridge.

At the present time the plumes of hot matter rising under seven islands along the Mid-Atlantic Ridge appear to be spreading the floor of the Atlantic Ocean. Four other plumes, rising beneath islands on the crest of the East Pacific Rise, also appear to be actively driving that ridge apart. These two systems can both operate independently because the subduction zones around the rim of the Pacific separate them. Some other plumes, in particular those beneath islands in the Indian Ocean, are only partly successful. They have broken the lithosphere into plates and caused that ocean to open, but, because they are also being overridden, the sections of midocean ridge between them have to change position from time to time, which has complicated the pattern in that ocean. The active islands, including Kerguelen and Réunion, no longer lie on the crest.

Other plumes, such as those beneath Hawaii, have not yet joined with others to break the lithosphere and only leave trails of islands.

OCCURRENCE AND DISTRIBUTION

Ridges of the Atlantic Ocean. The Mid-Atlantic Ridge lies down the axis of the Atlantic Ocean. Topographically it occupies the central third of the basin between a series of flat abyssal plains, but structurally it continues beneath these to the continental coasts. Along the crest are seven groups of islands, of which Jan Mayen, Iceland, the Azores, Tristan da Cunha, and Bouvet are volcanoes that have been active in historical times. Ascension Island is also a recent volcano, but St. Peter and St. Paul Rocks are built of ultrabasic rocks (rich in iron and magnesium) believed to be uplifted mantle, although basalt lava has been dredged from the sea floor nearby. It is considered that rising plumes beneath these islands are widening the Atlantic Ocean by spreading the continents that border it apart.

Movements of the African and American plates

In the south the African and American plates are sliding off the ridge by rotation about a pole near Iceland. In the north the Eurasian and American plates are sliding off the ridge by rotation about a pole near the New Siberian Islands. An active ridge that links the Azores to Gibraltar marks the junction of the Eurasian and African plates. From the four axial islands in the South Atlantic the Sierra Leone Rise, the Guinea Rise, the Walvis Ridge, and the Cape Rise are lateral ridges parallel to one another that join these islands to the African coast. Although it has been suggested that the Walvis Ridge is a microcontinent or a block of upfaulted ocean floor, the Cape Rise has been mapped as a chain of volcanic seamounts, and many believe that all these lateral ridges are trails of former volcanoes left by hot spots. On the west side, with the exception of the well-marked Rio Grande Rise from Tristan, the lateral ridges are less clear, but there are some indications of them in islands and seamounts off Brazil. This herringbone, or chevron-shaped, pattern in the South Atlantic contrasts with the orthogonal (right-angle) pattern of the ridges that extend away from Iceland in directly opposite directions to either coast. This difference is believed to have arisen because the southern continents have been moving northward as well as east and west over the mantle since the breakup of Gondwana (a protocontinent), whereas the northern continents have not.

A remarkable feature of the equatorial Atlantic is the series of great fracture zones that offset the ridge to accommodate it to the bend marked by the Gulf of Guinea and the corresponding angle in the northeast coast of Brazil. These are all transform faults formed as the two plates were torn apart, and they do not extend into the continents of Africa and South America.

To the north the Atlantic structure gets progressively more complicated. This may be due to a shift in the position of the Mid-Atlantic Ridge, and it has been postulated that a predecessor of the present ridge lay up Baffin Bay and across the Arctic Basin, where the Alpha Ridge may be its inactive remnant. If so, the Lomonosov Ridge formed as a boundary ridge when the Mid-Atlantic Ridge jumped to the position in which it is now active. The exact nature of the Lomonosov Ridge has been debated, but it is generally believed that it is a sliver of continental shelf separated from the adjacent coast of Siberia, which has the same shape.

In the Norwegian Sea and Northern Atlantic off the British Isles are several other small, irregular ridges. Immediately south of Iceland the actively spreading Reykjanes Ridge is not in the centre of the ocean but halfway between Greenland and the Rockall Bank, which lies from 200 to 400 kilometres (125 to 250 miles) off the British coast and is separated from it by deep water. The nature of the volcanic rocks constituting the islet and bank of Rockall and the results of deep-sea drilling have confirmed that the bank is a sunken continental block, or microcontinent. It remains to be explained why it should have sunk. It is believed that until a few tens of millions of years ago the active ridge lay between Great Britain and Rockall Bank and separated them by spreading. This section of midocean ridge then jumped to its present location.

North of Iceland the active ridge again does not lie along the axis of the Norwegian Sea. It is much closer to Greenland and midway between that island and the submerged Voring Ridge, which is again separated from Norway by deep water. Voring Ridge is therefore regarded as another sunken microcontinent like Rockall Bank and Lomonosov Ridge. Between Norway and the Voring Ridge a minor ridge regarded as the former spreading crest has been identified. It is now inactive.

Ridge movements in the Arctic

This contrast between the regular pattern of steady spreading that has proceeded without interruption in the South Atlantic for over 80,000,000 years is in striking contrast with the behaviour in the Arctic regions, where the location of the midocean ridge has jumped to three locations in the past 60,000,000 years. Yet this difference is believed to be a natural consequence if the plates are driven by random, long-lived plumes rising at fixed locations in the mantle. If by some chance one group of plumes has become dominant—for example, those in the South Atlantic—then the growth and interaction of rigid lithosphere plates are such that other spreading ridges cannot also remain fixed but must change their positions from time to time.

In considering these rather complex interactions, the details of which have not yet been fully worked out, it is essential to distinguish between different kinds of poles of rotation. Any pair of plates have one pole about which they mutually rotate, but it is important to appreciate that the pole of rotation between two plates may itself be moving over the mantle. If so, there exist two other poles, about one of which each of the plates rotates relative to the mantle. To state that the spreading of the South Atlantic is a dominant motion means that all three of these poles between the African and American plates and the mantle are coincident and near Iceland.

The Eurasian plate is moving relative to both of these plates and therefore has different sets of poles with them. Thus, the mutual pole between the American and Eurasian plates is near the New Siberian islands, but, because the pole of the American and African plates is fixed in the mantle near Iceland, the pole of the American and Eurasian plates near the New Siberian Islands cannot also be fixed in the mantle. The Arctic section of the midocean ridge is therefore also moving over the mantle and hence across its driving plumes. When a section of ridge is displaced too far from its driving plumes it is liable to become abandoned, and a new section is created over the plumes again. This could explain the ridges of the Arctic.

Ridges of the Pacific Ocean. The dominant feature of the Pacific Ocean Basin is the East Pacific Rise, which is that part of the midocean ridge system that extends from south of New Zealand to the mouth of the Gulf of California. It is broad and much smoother than the Atlantic section. It also lacks a crestal rift. Several great fracture zones cross it, notably at 55° south latitude and near Easter Island.

Off the west coast of North America, north of Mexico, the presence of several inactive fracture zones and the pattern of magnetic anomalies and short isolated sections of midocean ridge seem to represent the western half of a continuation of the East Pacific Rise and suggest that it once extended farther north until it was overridden by North America.

Several great fracture zones, including the Mendocino, off California, cross this part of the ocean floor. Two active branches of the Rise join Easter Island to the coast of Southern Chile and cross the Panama Basin from near Galápagos Islands to the coast of Columbia.

Spreading of the East Pacific Rise

Any chart of the Pacific shows a striking difference between the southeastern half of the Pacific Basin, which is underlain by the East Pacific Rise, and the northwestern part, which contains many more islands. The topographical boundary of the rise has been placed close to latitude 150° west, except in the extreme south, but many consider that the whole Pacific Basin is progressively older from the rise to the trenches off Japan, and that it is all part of the same system. Others, noting the change in the abundance of islands, consider that a boundary ridge extends down the Pacific from Kamchatka to the Campbell Plateau. Chief elements are the Emperor Seamount Chain and the great ridge of the Line Islands.

It has been suggested that the driving force that is spreading the East Pacific Rise is the upwelling of a series of plumes. The tops of some of these form the Islas de Revillagigedo, off Mexico, the Galápagos Islands, Easter Island, and Macquarie Island, south of New Zealand. It has been suggested that several other plumes that do not lie on the crest have been overridden to form linear chains of islands.

The most conspicuous group of parallel linear chains form the Hawaiian, Marquesas, Tuamotu, Society, and Tubuai islands. Two other parallel lines of seamounts cross the Gulf of Alaska. Where evidence exists, as it does for the Hawaiian and Tubuai islands, it shows that the active and younger islands are to the southeast and the islands get progressively older to the northwest, which suggests that the Pacific plate is moving northwesterly, as confirmed by other evidence. Some authors have regarded the Emperor Seamount Chain, Line Islands, and Cook Islands not as a boundary ridge, but as older continuations of the Hawaiian, Tuamotu, and Tubuai islands. They consider that the angle between the two sets marks a change in direction of motion of the Pacific plate.

Another interesting observation is that the Nazca Ridge and another smaller, parallel ridge of seamounts off the coast of Peru and northern Chile are in a mirror-image position across the East Pacific Rise relative to the Tuamotu and Tubuai islands.

The full significance of these observations is not yet clear. There are not enough geophysical data from the vast Pacific Basin, and only a few drill holes have been obtained by oceanographic vessels. Observation is handicapped because the ridges are largely submarine, and most islands in the tropics are mantled by young coral. Further, only high volcanic islands, of which there are few, can be radiometrically dated.

Between Australia and New Zealand, several submarine ridges, including Lord Howe Rise and Norfolk Ridge, are generally regarded as sunken microcontinents because they are connected with New Zealand and New Caledonia and have continental geophysical properties. If this is so, the ocean floor has spread between them, and sections of the midocean ridge have jumped about, probably for the same reason as that given for the Arctic regions. It is not known why such continental ridges would have sunk, but the same phenomena have also been observed in the Rockall Bank and Agulhas Plateau, both of which have continental properties.

Ridges of the Indian Ocean. The Indian Ocean Basin is the most complex, and its ridges are the least understood. As elsewhere, the ridges may first be divided into active and aseismic varieties. The active midocean ridge system has here been divided into five segments, each with local names. Along the whole length of the Gulf of Aden an active median ridge called the Sheba Ridge can be traced.

Occurrence of fracture zones

It has a median rift and is much offset by fracture zones trending northeast–southwest that displace it by as much as 180 kilometres (110 miles). It shows all the characteristic features of high heat flow, magnetic lineations, low gravity, and a spreading motion indicated by recent earthquakes along the axis.

At the entrance to the gulf, the Owen Fracture Zone displaces the axis 300 kilometres (200 miles) to the southwest and marks the beginnings of the Carlsberg Ridge, which lies halfway between the west coast of India and the Seychelles portion of the Mascarene Plateau (Seychelles-Mauritius Plateau), which is presumably a boundary ridge. Spreading of the Carlsberg Ridge, which is still active, is assumed by authorities to be connected with the rapid northward movement of India during the last 65,000,000 years, but the details of this occurrence have yet to be established.

The Mid-Indian Ridge, which extends south for 25° of latitude, is connected to the Carlsberg Ridge at the Equator. It is broken and offset by many large fracture zones trending northeast–southwest. Recent work suggests that the Mid-Indian Ridge was opened by the spreading of an earlier fracture zone with a north–south strike and whose remnants are the Chagos-Laccadive Plateau, off the coast of India, and the central part of the Mascarene Plateau. The Rodriguez Seamount Chain projects east as a spur from the plateau and appears to be a later addition.

The southern end of the Mid-Indian Ridge is at a triple point and junction with the Southwest Indian Ridge and Southeast Indian Rise. The former passes south of Africa to join the Mid-Atlantic Ridge near Bouvet Island. It differs considerably from most other segments for reasons that are imperfectly understood but are generally attributed to a very slow spreading rate. This is indicated by lack of a well-defined magnetic pattern and the narrow crestal zone free of sediments. Most authorities also consider that it has been cut by many north–south fracture zones.

The Southeast Indian Rise is a normal one. It is offset 1,100 kilometres (700 miles) to the south by a fracture zone through Amsterdam Island and by others south of Australia and New Zealand, where it joins the East Pacific Rise. In its northwestern part its features are similar to those of the Mid-Atlantic Ridge, while in the portion south of Australia they are like those of the East Pacific Ocean in such aspects as a fast spreading rate, the absence of a median rift, and relatively smooth topography. The properties of such active ridges are thus compatible with the view that the principal motion at the present time is a rotation of the northeastern part of the Indian Ocean Basin away from the southwestern part about a pole in the vicinity of Arabia. It is also clear, however, that other motions of unknown nature operated in the past.

The Indian Ocean is also marked by a large number of aseismic ridges of a considerable variety. One striking group is elongated in a north–south direction, and it seems probable that at least some groups originated as large fracture zones or linear chains during the northward movement of India. Of these, the Chagos-Laccadive Plateau has already been mentioned. Three groups of atolls rise from a narrow ridge 2,700 kilometres (1,700 miles) long that apparently terminates to the north in the Deccan basalts near Bombay. The Ninety East Ridge is 4,800 kilometres (3,000 miles) long and about 200 kilometres (125 miles) wide. Its top lies at depths of 1,800 to 3,000 metres (5,900 to 10,000 feet), and its relief is up to 3,500 metres (11,500 feet). It is apparently composed of basalt and has also been held to be an upthrust horst, or a large block bounded by normal faults.

The Mascarene Plateau is a curved ridge 2,300 kilometres (1,400 miles) long. Its northern end, the Seychelles Bank, is of a composite nature and is a true microcontinent of Late Precambrian (older than 570,000,000 years) granite-gneiss. The southern end is the Tertiary volcanic island of Mauritius. In between lie a series of coral banks resting upon basalt foundations. Separated from Mauritius by a small gap is the active volcanic island of Réunion.

The Madagascar and Mozambique plateaus are other elongated ridges extending south from Madagascar and the coast of Africa. They are believed to be associated with fracture zones, but little is known about them. Off the southern tip of Africa the submarine Agulhas Plateau has been shown to be continental, whereas the Crozet Plateau is of unknown origin and is capped with the extinct basaltic volcanoes of the Îles Crozet.

In the southeastern part of the Indian Ocean Basin several ridges are arranged in a mirror-image fashion. These include the Broken Ridge and Naturaliste Plateau, extending west from Australia, and the Kerguelen Plateau, off Antarctica. Before the Southeast Indian Rise opened they would have been together and are thus considered to be boundary ridges.

Since 1956 the principal ridges of the Indian Ocean have been located and named, but they are so large and complex that they are still incompletely known.

Oceans, Development of

Man's knowledge of the origin and evolution of the oceans has expanded greatly within the last two decades. To provide a unique explanation of the history of seawater requires answers to many other problems of earth history. Although some of these problems are at the forefront of scientific investigation in the earth sciences today and are far from being solved, it is possible to present a model for the development of the oceans that is reasonably consistent with available data and present concepts of earth history. It is, however, likely that the model will be revised and parts of it rejected as knowledge of the earth increases.

The concept of the oceans as a chemical system has changed from one in which the oceans have been thought of as a continuous accumulator of the salts brought down by rivers to a view in which the oceans are chiefly a mechanism of transfer of material from the continents to the sea floor. Today it is generally agreed that the ocean is a steady-state system, in which the continuous influx of dissolved species (material in solution) approximately equals their efflux. Current controversy concerns the degree to which seawater composition can vary through time, as a result of changing rates of influx or efflux or changing chemical composition.

Information about material being added to the oceans is fairly good as to both the minerals in the detrital (solid particles) load and the concentrations of species in the dissolved load of streams. Similar information, except for carbonate minerals (*q.v.*), is not available for the substances that are lost, however. Although estimates of the minerals formed and their relative amounts have been made, these have been neither proved nor disproved by observation.

The chemical history of the oceans has been divided into three stages. The first is an early stage in which the earth's crust was cooling and reacting with volatile or highly reactive gases of an acid, reducing nature to produce the oceans and an initial sedimentary rock mass. This stage lasted until about 3,500,000,000 years ago. The second stage was a period of transition from the first to essentially modern conditions, and it is estimated to have ended 1,500,000,000 to 2,000,000,000 years ago. Since that time it is likely that there has been little change in ocean-water composition.

THE EARLY OCEANS

The initial accretion of the earth by agglomeration of solid particles occurred about 5,000,000,000 years ago. Heating of this initially cool, unsorted conglomerate by the decay of radioactive elements and the conversion of kinetic and potential energy to heat resulted in the development of a liquid iron core and the gross internal zonation of the earth (see EARTH, STRUCTURE AND COMPOSITION OF). It has been concluded that formation of the earth's core took about 500,000,000 years. It is likely that core formation resulted in the escape of an original primitive atmosphere and its replacement by one derived from loss of volatile substances from the earth's interior (see ATMOSPHERE, DEVELOPMENT OF). Whether most of this degassing took place during core formation or soon afterward or whether there has been significant degassing of the earth's interior throughout geologic time is uncertain. Recent models of earth formation, however, suggest early differentiation of the earth into three major zones (core, mantle, and crust) and attendant early loss of volatile substances from the interior. It is also likely that the earth, after initial cold agglomeration, reached temperatures such that the whole earth approached the molten state. As the initial crust of the earth solidified, volatile gases would be released to form an atmosphere that would contain water (H_2O), later to become the hydrosphere; carbon gases, such as carbon dioxide (CO_2), methane (CH_4), and carbon monoxide (CO); sulfur gases, mostly hydrogen sulfide (H_2S); and halogen compounds, such as hydrochloric acid (HCl). Nitrogen also may have been present plus minor amounts of other gases. Gases of low atomic number, such as hydrogen and helium, would escape the earth's gravitational field. Substances degassed from the earth's interior have been called excess volatiles because their masses cannot be accounted for simply by rock weathering. An estimate of the masses of the various volatiles degassed throughout geologic time is given in Table 1.

Earth formation and gases released

Table 1: Estimate of "Excess Volatiles"
(units of 10^{20} grams)

Water	16,600
Total carbon as carbon dioxide	910
Sulfur	22
Nitrogen	42
Chlorine	300
Hydrogen	10
Boron, bromine, argon, fluorine, etc.	4

Source: W.W. Rubey (1951).

At an initial crustal temperature of about 600° C (1,100° F), almost all of these compounds, including H_2O, would be in the atmosphere. The sequence of events that occurred as the crust cooled is difficult to construct. Below 100° C (212° F) all of the H_2O would have condensed, and the acid gases would have reacted with the original igneous crustal minerals to form sediments and an initial ocean. There are at least two possible pathways by which these initial steps could have been accomplished.

One pathway assumes that the 600° C (1,100° F) atmosphere contains, together with other compounds, H_2O, CO_2, and HCl in the ratio of 20:3:1 and would cool to the critical temperature of H_2O. The H_2O therefore would have condensed into an early hot ocean. At this stage, the hydrochloric acid would be dissolved in the ocean ($\sim$ 1 mole per litre), but most of the CO_2 would still be in the atmosphere with about 0.5 mole per litre in the ocean water. This early acid ocean would react vigorously with crustal minerals, dissolving out silica and cations and creating a residue that consisted principally of aluminous clay minerals (*q.v.*) that would form the sediments of the early ocean basins. This pathway of reaction assumes that reaction rates are slow relative to cooling. A second pathway of reaction, which assumes that cooling is slow, is also possible. In this case, at a temperature of about 400° C most of the H_2O would be removed from the atmosphere by hydration reactions with pyroxenes and olivines (*q.v.*). Under these conditions H_2O would not condense until some unknown temperature was reached, and the earth might have had at an early stage in its history an atmosphere rich in CO_2 and no ocean: the surface would have been much like that of Venus today.

The pathways described are two of several possibilities for the early surface environment of the earth. In either case, after the earth's surface had cooled to 100° C (212° F), it would have taken only a short time geologically for the acid gases to be used up in reactions involving igneous rock minerals. The presence of bacteria and possibly algae in the fossil record (*q.v.*) of rocks greater than 3,000,000,000 years old attests to the fact that the earth's

surface had cooled to temperatures lower than 100° C (212° F) by this time and that the neutralization of the original acid gases had taken place. If most of the degassing of primary volatile substances from the earth's interior occurred early, the chloride released by reaction of HCl with rock minerals would be found in the oceans and seas or in evaporite deposits, and the oceans would have a salinity and volume comparable to those that they have today.

Early salinity and volume

This conclusion is based on the assumption that there has been no drastic change in the ratios of volatiles released through geologic time. The overall generalized reaction indicative of the chemistry leading to formation of the early oceans can be written in the form: Primary igneous rock minerals + acid volatiles + H_2O → sedimentary rocks + oceans + atmosphere. Notice from this equation that if all the acid volatiles and H_2O were released early in the history of the earth and in the proportions found today, then the total original sedimentary rock mass produced would be equal to that of today, and ocean salinity and volume would be near that of today. If, on the other hand, degassing were linear with time, then the sedimentary rock mass would have accumulated at a linear rate, as would oceanic volume. However, the salinity of the oceans would remain nearly the same if the ratios of volatiles degassed did not change with time. The most likely situation is that presented here, namely, that major degassing occurred early in earth's history, after which minor amounts of volatiles were released episodically or continuously for the remainder of geologic time. The salt content of the oceans based on the constant proportions of volatiles released would depend primarily on the ratio of sodium chloride (NaCl) locked up in evaporites to that dissolved in the oceans. If all the NaCl in evaporites were added to the oceans today, the salinity would be approximately doubled. This value gives a sense of the maximum salinity the oceans could have attained throughout geologic time.

Production of oxygen

One component missing from the early earth's surface was free oxygen, because it would not have been a constituent released from the cooling crust. Early production of oxygen was by photodissociation (separation due to the energy of light) of water in the earth's atmosphere as a result of adsorption of ultraviolet light. The reaction is $2H_2O + h\nu \rightarrow O_2 + 2H_2$ in which $h\nu$ represents photon of ultraviolet light. The hydrogen produced would escape into space, and the O_2 would react with the early reduced gases by reactions such as $2H_2S + 3O_2 \rightarrow 2SO_2 + 2H_2O$. Oxygen production by photodissociation gave the early reduced atmosphere a start toward present-day conditions, but it was not until the appearance of photosynthetic organisms approximately 3,000,000,000 years ago that it was possible for the accumulation of oxygen in the earth's atmosphere to proceed at a rate sufficient to lead to today's oxygenated environment. The photosynthetic reaction leading to oxygen production may be written $6CO_2 + 6H_2O + h\nu \rightarrow C_6H_{12}O_6 + 6O_2$, in which $C_6H_{12}O_6$ represents sugar.

THE TRANSITION STAGE: 3,500,000,000–1,500,000,000 YEARS AGO

The nature of the rock record from the time of the first sedimentary rocks (~3,500,000,000 years ago) to about 1,500,000,000 to 2,000,000,000 years ago suggests that the amount of oxygen in the earth's atmosphere was significantly lower than today and that there were continuous chemical trends in the sedimentary rocks formed and, more subtly, in oceanic composition. The source rocks of sediments during this time were likely to be more basaltic than would later ones; sedimentary detritus was formed by the alteration of these rocks in an oxygen-deficient atmosphere and accumulated primarily under anaerobic marine conditions. The chief difference between reactions involving mineral-ocean equilibria at this time and today was the role played by ferrous iron. The concentration of dissolved iron in today's oceans is low because of the insolubility of oxidized iron oxides. During the period 1,500,000,000–3,500,000,000 years ago, oxygen-deficient environments were prevalent; these favoured the formation of minerals containing ferrous iron (reduced state of iron) from the alteration of basaltic rocks. Indeed, the iron carbonate siderite and the iron silicate greenalite, in close association with chert and the iron sulfide pyrite, are characteristic minerals that occur in middle Precambrian iron formations. The chert originally was deposited as amorphous silica; equilibrium between amorphous silica, siderite, and greenalite at 25° C (77° F) and one atmosphere total pressure requires a CO_2 pressure of about $10^{-2.5}$ atmospheres, or ten times today's value.

The oceans at this time can be thought of as the solution resulting from an acid leach of basaltic rocks, and because the neutralization of the volatile acid gases was not restricted primarily to land areas as it is today, much of this alteration may have occurred by submarine processes. The atmosphere at the time was oxygen deficient; anaerobic depositional environments with internal CO_2 pressures of about $10^{-2.5}$ atmospheres were prevalent, and the atmosphere itself may have had a CO_2 pressure near $10^{-2.5}$ atmospheres. If so, the pH of early ocean water was lower than that of modern seawater, the calcium concentration was higher, and the early ocean water was probably saturated with respect to amorphous silica (~ 120 parts per million [ppm]).

The pH of seawater

To simulate what might have occurred, it is helpful to imagine emptying the Pacific Basin, throwing in great masses of broken basaltic material, filling it with HCl so that the acid becomes neutralized, and then carbonating the solution by bubbling CO_2 through it. Oxygen would not be permitted into the system. The HCl would leach the rocks, resulting in the release and precipitation of silica and the production of a chloride ocean containing sodium (Na), potassium (K), calcium (Ca), magnesium (Mg), aluminum (Al), iron (Fe), and reduced sulfur species in the proportions present in the rocks. As complete neutralization was approached, Al could begin to precipitate as hydroxides and then combine with precipitated silica to form cation-deficient aluminosilicates. The aluminosilicates, as the end of the neutralization process was reached, would combine with more silica and with cations to form minerals like chlorite, and ferrous iron would combine with silica and sulfur to make greenalite and pyrite. In the final solution, chlorine (Cl) would be balanced by Na and Ca in roughly equal proportions, with subordinate K and Mg; Al would be quantitatively removed, and silicon (Si) would be at saturation with amorphous silica. If this solution were then carbonated, Ca would be removed as calcium carbonate ($CaCO_3$), and the Cl balance would be maintained by abstraction of more Na from the primary rock. The sediments produced in this system would contain chiefly silica, ferrous iron silicates, chloritic minerals, calcium carbonate, calcium-magnesium carbonates, and minor pyrite.

If the HCl added were in excess of the CO_2, the resultant ocean would have a high content of calcium chloride ($CaCl_2$); but the pH would still be near neutrality. If the CO_2 added were in excess of the Cl, Ca would be precipitated as the carbonate until it reached a level approximately that of the oceans today, namely, a few hundred parts per million.

If this newly created ocean were left undisturbed for a few hundred million years, its waters would evaporate and be transported onto the continents (in the form of precipitation); streams would transport their loads into it. The sediment created in this ocean would be uplifted and incorporated into the continents. Gradually, the influence of the continental debris would be felt and the pH might shift a little. Iron would be oxidized out of the ferrous silicates to make iron oxides, but the water composition would not vary a great deal.

The primary minerals of igneous rocks are all mildly basic compounds. When they react in excess with acids such as HCl and CO_2, they produce neutral or mildly alkaline solutions plus a set of altered aluminosilicate and carbonate reaction products. It is improbable that ocean water has changed through time from a solution approximately in equilibrium with these reaction products, which are clay minerals and carbonates.

CHEMICAL VIEW OF MODERN OCEANS

It is likely that the oceans achieved their modern characteristics 1,500,000,000 to 2,000,000,000 years ago. The chemical and mineralogical compositions and the relative proportions of sedimentary rocks of this age differ little from their Paleozoic counterparts. Calcium sulfate deposits of late Precambrian age testify to the fact that the acid sulfur gases had been neutralized to sulfate by this time. Chemically precipitated ferric oxides in late Precambrian sedimentary rocks indicate available free oxygen, whatever its percentage. The chemistry and mineralogy of middle and late Precambrian shales is similar to that of Paleozoic shales. Thus, it appears that continuous cycling of sediments like those of today has occurred for 1,500,000,000 to 2,000,000,000 years and that these sediments have controlled oceanic composition.

Salt content of the oceans

It was once thought that the saltiness of the modern oceans simply represents the storage of salts derived from rock weathering and transported to the oceans by fluvial processes. With increasing knowledge of the age of the earth, however, it was soon realized that, at today's rate of delivery of salts to the ocean or even at much reduced rates, the total salt content and the mass of individual salts in the oceans could be attained in geologically short-time intervals compared to earth's age. The total mass of salt in the ocean can be accounted for at today's rates of stream delivery in about 12,000,000 years. The mass of dissolved silica in ocean water can be doubled in only 20,000 years by addition of stream-derived silica; to double sodium would take 70,000,000 years. It then became apparent that the oceans were not simply an accumulator of salts, but as water evaporated from the oceans, along with some salt, the introduced salts must be removed in the form of minerals. Thus, the concept of the oceans as a chemical system changed from that of a simple accumulator to that of a steady-state system, in which rates of inflow of materials into the oceans equal rates of outflow. The steady-state concept permits influx to vary with time, but it would be matched by nearly simultaneous and equal variation of efflux. Calculations of rates of addition of elements to the oceanic system and removal from the system show that for at least 100,000,000 years the oceanic system has been in a steady state with approximately fixed rates of major element inflow and outflow and, thus, fixed chemical composition.

Mineral–seawater equilibria. In recent years it has been shown that not only is the oceanic system steady state but that its composition is probably controlled by chemical equilibria involving seawater and minerals found in marine sediments. In 1961, L.G. Sillén published a paper on *The Physical Chemistry of Sea Water*, in which he showed that the chemical composition of seawater is approximately that of a theoretical solution brought to chemical equilibrium with the minerals quartz, illite, montmorillonite, chlorite, kaolinite, calcite, and phillipsite, and the atmosphere. He pointed out that in his model the ratios of the major chemical species would be fixed but that their absolute concentrations could increase or decrease with changes in the concentration of NaCl. Sillén's model further implies that even if the rates of addition of feed material to the oceanic system are changed or the proportions of minerals in the feed, the chemical composition of seawater will be invariant.

Equilibrium with silicate minerals

If seawater maintains near equilibrium with the detrital silicates that have been falling through it for billions of years, its composition should correspond to that predicted by thermodynamic calculations of the composition of an aqueous solution in equilibrium with those phases. It is impossible, of course, for ocean water to have one equilibrium composition, a balance that depends upon temperature and pressure, among other factors, because its temperature ranges from 0° to 35° C (32° to 95° F) and its pressure from 1 to 1,000 atmospheres. Moreover, it cannot be in equilibrium simultaneously with all the minerals being delivered. Gibbsite and feldspar, for example, are incompatible because if placed together in a solution they would react: one would disappear and the other would be left with the final solution and an intermediate phase.

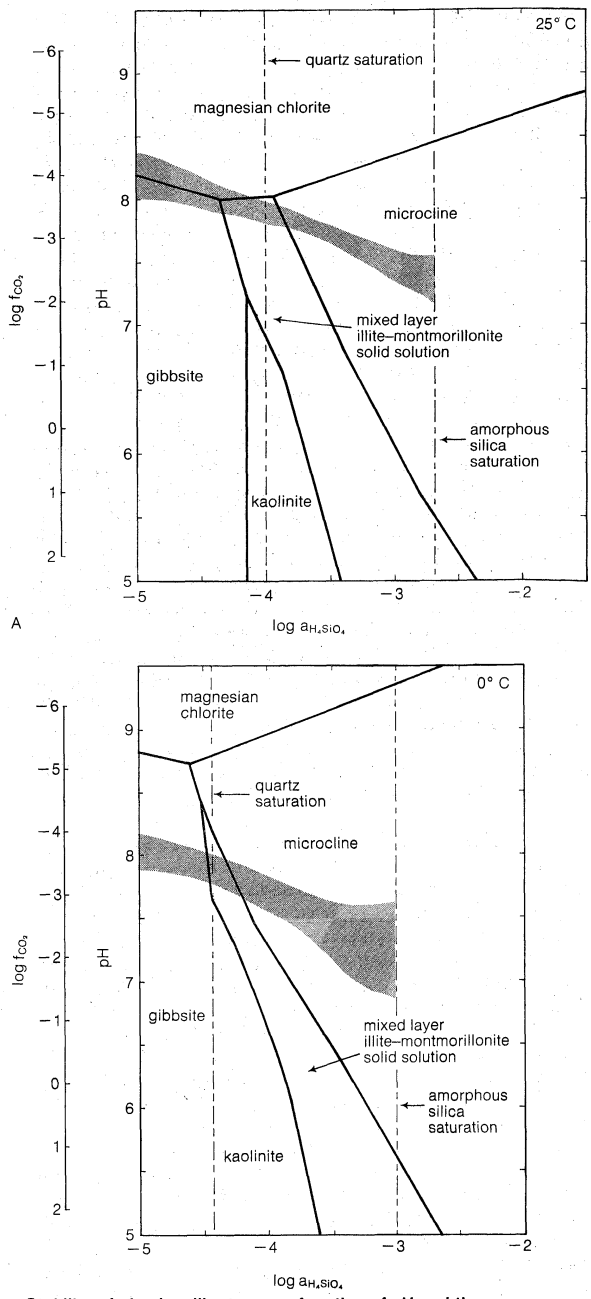
The Figure shows the phases that would be in equilibrium with present-day seawater at 25° C and 0° C (77° F and 32° F), respectively. The stability fields of the phases are shown as functions of pH and dissolved silicon dioxide (SiO_2). The shaded areas denote the range of seawater compositions. Gibbsite, kaolinite, montmorillonite, K-feldspar, and illite all can be stable species within the commonly observed range of seawater composition. At a P_{CO_2} near that of today's atmosphere, calcite is also a stable phase. This relation does not prove that these minerals are the cause of seawater composition, but it does show that if a mixture of these minerals were placed in a NaCl solution with the same Cl as seawater, maintained in equilibrium with the atmosphere, and allowed to come to equilibrium with the final solution, no matter which of the various coexisting mineral assemblages remained, it would fall within the typical range of composition of seawater.

The chemical equilibrium relations predict that present-day seawater has a chemical composition that is compatible with that expected for a solution continuously reacting with the great variety of minerals being added to it. Of these minerals, it is nearly in equilibrium with the typically detrital clay minerals and is out of equilibrium with most of the primary igneous rock minerals such as plagioclase feldspar, pyroxenes, and olivines. This situation may be transient and but an instant in a long-term chemical trend. On the other hand, it is compatible with continuous control of seawater by the synthesis and dissolution of a few silicate phases, resulting in seawater that never deviates far from saturation.

Mass balance of the oceans. The various equilibrium models of the oceanic system imply that the major chemical components of seawater are held near saturation values (value at which addition of the component will result in precipitation); oversaturation may occur, but the departure from saturation should not be great. For calcium carbonate, this situation has been shown to be a distinct possibility within the limits of measurement; the influx of calcium carbonate is equal to its efflux, and ocean water is slightly oversaturated with respect to calcium carbonate ($CaCO_3$) in the upper few hundred metres and slightly undersaturated at depth. For the other dissolved constituents brought to the oceans by streams, the mechanisms of removal are not well known. Furthermore, if these constituents do enter newly formed minerals, the question remains whether the formation of the minerals can hold their chemical components near saturation values in seawater.

Calcium carbonate equilibrium

Current models of seawater composition imply that stream-derived dissolved species must precipitate from ocean water or be cycled back through the atmosphere to fall on the continents. Balance sheets have been drawn up to account for the removal of these constituents. The most complete balance to date provides for removal of the various constituents of stream water in minerals commonly found in modern and ancient sediments and sedimentary rocks. In this balance, it was found necessary to remove part of the stream-derived Na, Mg, K, and dissolved silica by reaction with poorly crystalline, alumina- and silica-rich solids of the suspended load of streams, when these materials reach the oceans. The minerals chosen as the most likely candidates for removal of constituents consisted of 28 percent evaporite minerals (salt and gypsum), 26 percent carbonate rock minerals (calcite, dolomite, etc.), 41 percent clay minerals (kaolinite, montmorillonite, illite, and chlorite), and minor percentages of pyrite and silica. Several of the proposed mineral species have not been conclusively demonstrated as forming in seawater. The amounts of new minerals formed each year that are necessary to remove dissolved constituents and maintain a steady-state oceanic system are very small. In this balance the point was made that to maintain a constant composition ocean requires reverse weathering. If the CO_2 consumed in the weathering process by reaction with carbonate and silicate rock minerals is not returned to the atmosphere by depositional processes, decrease in the CO_2 content of the atmosphere will result; and ocean water, because of the accumulation of bicarbonate ion, will tend to become alkaline. Because the weathering of



Stability of aluminosilicates as a function of pH and the activity of dissolved silica drawn for seawater of present composition, one atmosphere total pressure, unit activity of H_2O, at (A) 25° C and (B) 0° C (see text).

calcium carbonate is known to be balanced by an equal rate of calcium carbonate deposition in the oceans, any net drain on the CO_2 of the atmosphere will come from failure of reversal of silicate weathering reactions. About 20 percent of the bicarbonate ion (HCO_3^-) in stream waters is derived from the neutralization of CO_2 involved in silicate weathering; the reaction is siliceous silicate + CO_2 + H_2O = less siliceous silicate + cations + dissolved silica + HCO_3^-. The mass of CO_2 in the present atmosphere is about 1.6×10^{18} grams, that neutralized by weathering of rock minerals on the continents is 1.3×10^{14} grams per year. Therefore, removal of all CO_2 by weathering of carbonate and silicate minerals at the present rate of consumption would require only about 12,000 years. This value provides an estimate of the rate required for restorative processes of CO_2 addition to the atmosphere if the atmospheric CO_2 content is to remain at today's level and the approximate time scale on which the atmosphere might change if the restorative processes failed to operate. No reversal of silicate weathering in the oceanic system during deposition or on a time scale of a few tens of thousands of years of burial would mean that the atmosphere could be nearly completely drained of CO_2; this situation is not likely to have obtained during much of geologic time.

Experimental evidence. Another approach to the question of what mechanisms remove dissolved materials added to the oceans is laboratory investigation of the reactions between clay minerals and aqueous solutions containing cations and dissolved silica. If it can be demonstrated that clay minerals react rapidly when the new phases formed are like those found in marine deposits and if the resultant solution has a chemical composition like that of seawater, then the feasibility of the maintenance of a steady-state oceanic system with a small range of composition will have been shown.

Clay minerals and silica equilibrium

Clay minerals have been added to seawater solutions initially containing little dissolved silica (~0.03 ppm) or an excess of silica (~25 ppm). In both cases the pH and silica concentration of the solutions were monitored with time; constant values of pH and silica concentration were reached in short time intervals compared to the time of exposure to seawater of clay minerals deposited in the marine environment. In the silica-deficient experiments, dissolved silica was added to the seawater by reaction with the clay minerals; constant values of 2–6 ppm were reached. For the silica-enriched solutions, dissolved silica was removed by reaction with clay minerals; the constant concentration values obtained were higher and more variable, ranging from 6 to 18 ppm. Release of silica from the minerals into silica-deficient seawater was accompanied by formation of a second compound, less siliceous than the parent clay, whereas uptake of silica from the enriched solutions took place by adsorption of molecular silica or by the formation of a new phase more siliceous than the one that was reacted. Further experimental work has shown that the new phases produced are probably not simple nonaluminous silicates, whereas theoretical thermodynamic calculations are consistent with the phases, being similar in composition to hydrated aluminum oxides and aluminosilicates (clay minerals).

The experiments show that the clay minerals of the detrital load of streams, when they enter the oceans, should be able to influence the dissolved silica content of the oceans, and they can influence the cation concentrations and the pH if the new phases formed are aluminosilicates. Unfortunately, the silica-uptake experiments did not demonstrate that a new phase is formed in accord with the reverse weathering reaction; if silica uptake were by adsorption of molecular silica, there would be no effect on the bicarbonate balance and the return of CO_2 to the atmosphere. Field tests of the reversible nature of silicate weathering today may serve to demonstrate the validity of the reversal of the reaction by finding an appropriate amount of silicate regeneration taking place in the marine environment. Alternatively, such tests may show that the dissolved silica brought to the oceans is precipitated in molecular form as the tests of siliceous organisms, thus proving indirectly that silicate synthesis over a short period of time does not take place. The results of attempts to apply both tests are inconclusive to date. No clear-cut examples of regeneration reactions of the magnitude required have been discovered, and a controversy rages over the rate at which siliceous organisms are abstracting silica from seawater and accumulating in marine sediments (*q.v.*). Furthermore, because the silicate reverse weathering reactions can involve intervals of time of a few tens of thousands of years before the CO_2 content of the atmosphere is affected, it is possible that these reactions take place as the sediment is being buried and involve the return of materials through the sediment column to the hydrosphere–atmosphere. Our knowledge of the quantitative importance of this path is even less than that of the significance of early reverse weathering reactions.

SEDIMENTARY ROCK MASS AND COMPOSITION

Sufficient data now have accumulated to predict to a first approximation the total mass of sedimentary rocks (*q.v.*)

that has accumulated throughout geologic time and the distribution of the mass as a function of time. The actual distribution and mass of the various rock types also can be estimated. Because of the chemistry and mineralogy of the sedimentary rocks that have been used to determine the nature of the hydrosphere–atmosphere through time, however, it is worthwhile at this point to evaluate what information can be gained from these rocks and the concepts of differential sedimentary cycling and chemical uniformitarianism, that is, that present chemical processes are similar in kind to those which were operative in the past.

Cycling of sedimentary rocks through time

A major problem faced by students of sedimentary rocks is whether the compositions of these rocks and the distribution of rock types through time are representative of the compositions and ratios at the time of deposition or whether they have been modified by processes that were operative after burial. If the features are primary, then they can be used directly to evaluate the history of the atmosphere–hydrosphere; if they are secondary, then conclusions need to be tempered by inclusion of the processes that modify the compositions and ratios through time. For example, the relatively high proportion of iron formations in the sedimentary rock mass of middle Precambrian age previously was taken as representative of a primary feature of the rocks accumulated during this time. Thus, the iron formations are indicative of a hydrosphere–atmosphere different from today. Also, the appearance of calcium sulfate deposits in rocks of late Precambrian age has been used as evidence to suggest that by this time most of the reduced sulfur gases degassed from the earth's interior had been oxidized to sulfate. However, there is evidence that suggests that some features of the sedimentary rock mass are secondary.

Recent analysis of the mass and distribution of sedimentary rock types as a function of time has shown that the mass of sedimentary rocks remaining is about $32{,}000 \times 10^{20}$ grams and that this mass is distributed in such a way that 56 percent of it consists of rocks accumulated during the last 600,000,000 years of geologic time whereas the remainder is of Precambrian age. The centre of mass is at 500,000,000 to 600,000,000 years. Simple mathematical models of this distribution show that the best fit is obtained if five times as much sediment has been deposited during geologic time as accumulated; that is, the whole sedimentary mass has been turned over five times. These models also demonstrate that limestones cycle at a rate equal to two times the sedimentary rock mass as a whole, and evaporites three times. Thus the centres of mass of limestones and evaporites are at about 300,000,000 and 200,000,000 years, respectively. One of the important points of these models is that, because of differential cycling rates of the various sedimentary rock types, the limestones and evaporites form a progressively larger proportion of sedimentary rocks accumulated per unit time with decreasing rock age. This relationship is a secondary feature of the sedimentary rock mass and is a result of the selective, more rapid destruction by erosion of carbonates and evaporites than shales and sandstones and redeposition of these types farther ahead in time. Thus, the ratios of sedimentary rock types of a particular age that remain today do not necessarily represent the ratios of the same types at the time of deposition. Furthermore, the use of these ratios to explain hydrosphere–atmosphere evolution must be considered in light of differential sedimentary cycling.

Two further aspects of modelling of the sedimentary rock mass that are of importance in considering the development of the oceans are: (1) The proportions of rock types deposited at any particular time since 1,500,000,000–2,000,000,000 years ago have been nearly constant; that is, as a first approximation, the types and quantities of sedimentary materials passing through the oceans have been nearly the same for this interval of time. As a consequence the oceanic system has been in a steady state, with a nearly fixed seawater composition governed by reactions between the materials entering the oceans and the water. (2) The nature of the detrital and dissolved materials entering the oceans throughout this time interval has not changed significantly. These materials represent a slow, selective, postdepositional water leaching of substances such as $CaCO_3$ in shales and selective, more rapid destruction of easily eroded materials such as limestones and evaporites. The predominance of the clay mineral illite with minor chlorite in pre-Mesozoic/Cenozoic shales and the abundance of the clay minerals montmorillonite and kaolinite in younger shales is thought to be a postdepositional feature resulting from the reaction: (high silica) montmorillonite + (low silica) kaolinite + potassium → (intermediate silica) illite + SiO_2, Na, Mg (lost from rock).

The materials lost from shales through time by the above process, plus materials gained by leaching and selective destruction of $CaCO_3$ and evaporite minerals enter streams and are redeposited in the oceans. The rock mass remaining is changed through time in mineralogy and chemistry and in proportions of rock types, but the materials brought to the oceans in the last 1,500,000,000 to 2,000,000,000 years to a first approximation have remained nearly the same, a statement of the concept of chemical uniformitarianism. Differential sedimentary cycling creates problems in the interpretation of hydrosphere–atmosphere evolution because the rock ratios of a particular age may not represent the ratios at the time of deposition; however, chemical uniformitarianism implies that the nature of the materials transported to the oceans since 1,500,000,000 to 2,000,000,000 years ago has been nearly constant. This constancy of composition of materials passing through the oceans suggests that the oceanic system, when viewed over time intervals of 200,000,000 or 300,000,000 years, is in a steady state and that seawater has had a composition since middle Precambrian time much like that existing today.

PERIODIC COMPOSITIONAL EXCURSIONS

Alterations of the model

It is premature to try to evaluate the fluctuations in seawater composition that would have resulted from time to time, as coincidences of various sets of physical and biological conditions changed the composition of the material going into or coming out of the oceans. If there were times when almost no erosion of the land was occurring, then seawater might have had a chance to react more completely with detrital primary rock materials, as opposed to being continuously exposed to the altered products of weathering. At best a few limits that have been established can be cited. In general, they constitute negative evidence, and the arguments are based on the absence of a mineral that would form if seawater composition were changed in a given way. Knowledge of such limitations is scant; little experimentation on changing the composition of seawater (with the exception of evaporating it) has been done.

The silica content of seawater cannot increase above 25 ppm at a pH of eight without precipitating a magnesium silicate such as sepiolite ($Mg_2Si_3O_6[OH]_4$). Sepiolite is found as a mineral in oceanic sediments, but its occurrences are rare. It is common in the deposits of saline lakes but relatively unimportant in sedimentary rocks.

If the pH of seawater is increased to about ten, brucite ($Mg[OH]_2$) would precipitate. Brucite, like sepiolite, occurs in sedimentary rocks, but it does not exhibit the extensive distribution that would result from precipitation throughout the whole mass of seawater.

It can be calculated that instantaneous addition and dissolution of about 7 percent of the evaporite deposits into the oceans would saturate them with respect to gypsum. On the other hand, the total salinity would be increased only a few parts per thousand. There is no record of gypsum in sedimentary rocks interpreted as open-ocean deposits; all the evaporites have formed in restricted portions of the sea. Gypsum seems to be a mineral whose component concentrations in the open oceans always have been less than the saturation value. Furthermore, the absence of evidence in the rocks for open-ocean gypsum requires the continuous storage of most of the sulfate in evaporites and, hence, uniformitarianism.

These are a few of the kinds of restrictions that can now be suggested for the limits of seawater chemical

variation; eventually a much greater number will be investigated by experimentation.

THE PRESENT HYDROSPHERE

Ocean waters and sediment pore waters form most of the present hydrosphere (Table 2). About 80 percent of the water in the hydrosphere is contained in the oceans and seas. The pores of sediments and sedimentary rocks hold nearly all the rest: about 24 percent of that in the oceans or 20 percent of the total. Ice now locks up a little more than 1 percent of the total and may have accounted for 3 percent or so during the peak of the last Ice Age, but water storage in rivers, lakes, or the atmosphere represents a trivial percentage of the total.

Table 2: Mass of the Present Hydrosphere

	total mass (units of 10^{20} grams)	percentage of total hydrosphere
Oceans	13,700	80.0
Pore waters in sediments	3,300	18.8
Ice	200	1.2
Rivers, lakes	0.3	0.002
Atmosphere	0.13	0.0008
Total hydrosphere	17,200	100.0

Relationship of freshwater to seawater

On the other hand, the rate of water circulation through the rain–river–ocean–atmosphere system or hydrologic cycle (*q.v.*) is relatively fast; the amount of water discharged into the oceans each year from the land is 0.32×10^{20} grams and is approximately equal to the total mass of water stored at any instant in rivers and lakes. The average dissolved solid concentration of stream water is 130 ppm; thus about 42×10^{14} grams of dissolved constituents are carried to the oceans yearly by streams, the main source of materials for the ocean.

Seawater has an average salinity of about 35,000 ppm; the proportions of the various dissolved solids in seawater and river water are markedly different. River water is a bicarbonate solution containing significant proportions of calcium, dissolved silica, and sulfate, whereas seawater is a sodium chloride solution (Table 3).

Table 3: Major Constituents of River Water and Seawater

The mass balance between streams and oceans previously discussed indicated an attempt to demonstrate how seawater composition could not result from simple evaporation and concentration of river-derived dissolved constituents but involves processes of chemical differentiation and evaporation of river water that affect each element differently and thereby result in waters of different compositions.

The oceans were once commonly thought of as a huge storage tank of water and dissolved solids; however, some comparisons of masses of material and rates of material transfer in the crust–ocean system are of use in negating this idea in favour of the steady-state concept. The mass of the oceans is only about 20 to 30 percent of the mass of sedimentary rocks now in existence and about 5 percent of the earth's crust. The mass of materials brought to the oceans by streams, small as they seem on a yearly basis, over geologic time would overwhelm the ocean basins. It would take only 12,000,000 years to account for the mass of dissolved constituents in the oceans at today's rate of stream delivery. Enormous tonnages of materials have passed through the oceans throughout geologic time, perhaps more than a million trillion metric tons. Dissolved solids constitute only 3.5 percent of the oceanic mass; thus storage by the oceans accounts for roughly 1 percent of the materials currently involved in the sedimentary cycle. Little wonder that the idea of the oceans as a simple accumulator of materials has given way to the steady-state concept.

The dissolved materials transported by streams to the oceans remain as dissolved constituents in the oceans or interstitial waters of marine sediments and are chemically or biochemically precipitated or are released into the atmosphere as sea-spray particles generated at the ocean–atmosphere interface. These tiny salt particles fall back on the sea surface or are transported over the continents by winds and fall as rain or dry fallout on the land surface. Thus recycled salts are added to the stream-borne dissolved constituents derived from rock weathering. About 50 percent of the sodium and chloride in stream waters is derived from the atmosphere. For other constituents, the percentages are less.

More than 99 percent of the dissolved solids in river water can be accounted for by the constituents chloride, sodium, sulfate, magnesium, calcium, potassium, bicar-

*Residence time is expressible in terms of the same variables as storage time; however, residence time calculations may or may not contain corrections for atmospherically and rock-derived cyclic materials and for eolian particulate matter. Also, the amount of the constituent in suspension in the ocean or streams may enter the residence time calculation.

bonate, and silica; the same constituents make up more than 99 percent of the dissolved materials in ocean water. A feeling for the huge amount of H_2O and dissolved solids carried to the oceans by streams can be attained simply by calculating the time it would take for river fluxes alone to attain oceanic amounts. Table 4 shows that these times vary considerably but that only chloride should require more than 100,000,000 years. A correction for atmospherically cycled marine salts can be applied to river fluxes, and the same calculation made. The time necessary to attain oceanic amounts for river-derived sodium and chloride is about doubled when the corrections for cyclic sodium and chloride are made. This further illustrates the large amount of sodium and chloride that is cycled through the atmosphere. The other major constituents are predominantly derived from the weathering of rocks, and the correction for atmospherically cycled salts affects only slightly the time required for them to reach oceanic amounts.

These times, uncorrected for cyclic salts, may be called storage times; storage time can be expressed by the equation:

$$\lambda = \frac{A}{dA/dt}$$

in which A is the total amount of the constituent in the ocean, and dA/dt is the amount in solution introduced by streams per unit time. The storage time of a particular constituent in the ocean, if it is considered that the ocean is a well-mixed, steady-state system, is indirectly a measure of the rate at which stream-derived dissolved constituents leave the ocean.

Oceans and Seas

The oceans and seas cover about 71 percent of the Earth's surface and constitute its most conspicuous feature. These waters, together with the relatively small amount that occurs in the form of rivers, lakes, ice, and groundwater, are called the Earth's hydrosphere. The other physical spheres of the Earth are the atmosphere and the lithosphere (the rock sphere of the Earth).

The oceans and seas form an integrated unit and together may properly be called the World Ocean. The Caspian Sea and the Dead Sea, however, are generally considered to be salty lakes. The exact boundaries between the various seas and oceans are arbitrarily defined and have been fixed by convention (see Figure 1).

For many years, five oceans were accepted, namely the Atlantic, Pacific, Indian, Arctic, and Antarctic oceans. After the work of Otto Krümmel (*Handbuch der Ozeanographie* 1897), however, it became common practice to recognize only three oceans, the Atlantic, Pacific, and Indian. The Arctic Ocean is now regarded as belonging to the Atlantic Ocean; this is a not unreasonable view, because it is a marginal sea of the Atlantic. The Bering Strait, which divides the Arctic from the Pacific Ocean, is only 58 kilometres (36 miles) wide and 58 metres (190 feet) deep.

The great Southern Ocean, as it is sometimes called, is one continuous stretch of water encircling the Antarctic continent. By convention, it has been divided into three portions, one for each of the three principal oceans. The dividing line between the Atlantic and the Indian oceans is the meridian through Cape Agulhas, South Africa (20° E). The Atlantic is divided from the Pacific Ocean by a line extending from Cape Horn at the southern tip of South America to the South Shetland Islands, off the tip of the Antarctic continent, in the Falkland Islands dependency; in the north, the separation consists of the narrowest part of the Bering Strait, separating Alaska and western Siberia. The dividing line between the Indian Ocean and the Pacific extends from the Malay Peninsula through Sumatra, Java, Timor, and Cape Londonderry in Australia to Tasmania and thence continuing along the meridian of 147° E, directly south to Antarctica. Notwithstanding these conventional divisions, the great marine area in the far south, the Southern Ocean, exhibits global continuity and marked oceanographic and meteorological features that distinguish it as a physical entity. One outstanding feature is the predominance of west winds, which give rise to the powerful West Wind Drift, a broad, closed west–east current in the upper water layers.

The oceans predominate over land areas in the Southern Hemisphere far more than they do in the Northern Hemisphere; the ratio of water to land area is roughly 4:1, 81:19 in the Southern Hemisphere and roughly 3:2, 61:39 in the Northern. Considering zones, or belts, on the earth's surface at intervals of five degrees latitude, land predominates only between 45° and 70° N, where the Eurasian continent lies, and between 70° and 90° S, which is the location of Antarctica. Everywhere else the oceans predominate; indeed, between about 84° and 90° N there is no known land at all, and from 45° to 66° S only a very small fraction of the surface is land. The areas of the Atlantic, the Indian, and the Pacific oceans, including their marginal seas, are roughly in the proportion of 10:7:17, respectively. More accurate figures are given in Table 1, which also shows the areas of various marginal seas.

In shape, the Atlantic Ocean is distinctly oblong in a north–south direction and is much more irregular than the other two oceans. It narrows between the eastern tip of Brazil and the western bulge of Africa, and this aspect of its shape is striking. On both sides of the North Atlantic but especially on the eastern side, large marginal seas and bays occur; the Mediterranean and Black Sea, the Bay of Biscay, the North Sea, the Baltic Sea, all on the eastern side, Baffin Bay, Hudson Bay, the Gulf of Mexico, and the Carribbean Sea on the western side are examples (see GULFS AND BAYS). By contrast, the configuration of the South Atlantic is much smoother, as is the eastern littoral (coastal region) of the Pacific Ocean from north to south. The western border of the Pacific, however, is indented considerably by adjacent seas such as the Sea of Okhotsk, the Sea of Japan, the East China Sea, the Yellow Sea, the South China Sea, and the seas of the Indonesian archipelago. Finally, in the Indian Ocean, only a few seas of significance occur along its northern margin, namely the Red Sea, the Persian Gulf, the Arabian Sea, and the Bay of Bengal.

The Atlantic Ocean has the greatest length of coastline because of its irregular shape; the length is greater than that of the Indian and Pacific oceans combined. Another distinctive feature of the Atlantic Ocean is that the majority of major continental rivers discharge into it. Because navigation has played an important part in the history of civilization, the presence of irregular coastlines with many marginal seas, shielded bays, and river mouths, which provide excellent natural harbours, has contributed to the development and spread of culture. The lands bordering the Mediterranean Sea and western Europe and the coastal regions of India, China, and Japan have been so favoured.

Depths of water

Table 1 shows the horizontal dimensions of the oceans and seas and, in addition, gives their average depths and volumes.

The average depth of all the seas has been estimated at 3,790 metres (12,430 feet), a figure considerably larger than that of the average elevation of the land above the sea level, which is 840 metres (2,760 feet). If the average depth is multiplied by its respective surface area, the volume of the World Ocean is 11 times the volume of the

land above sea level. The maximum depth of the ocean, 10,850 metres (35,597 feet), occurs in the Mariana Trench, halfway between the islands of Guam and Yap in the Pacific Ocean. This depth exceeds the height of Mt. Everest, which is 8,848 metres (29,028 feet).

Table 2 shows the areas that are occupied by various ocean depth zones in relation to total area of the sea surface, as a percentage. Because the 0–200-metre (660-foot) depth zone corresponds to the continental shelf, it covers almost as large an area as the zone with depths of 200–2,000 metres, which is the region of occurrence of the far steeper continental slope; on the other hand, depths of more than 6,000 metres cover only a very small part of the ocean bottom, in contrast to 3,000–6,000-metre depths. The proportions of the various depth zones are shown in Figure 2, along with the names given to the various depth regimes that constitute marine environments.

The relatively shallow, submerged platform bordering the continents, called the continental shelf, slopes gently seaward to the shelf break, where an increase in gradient leads to the continental slope. Conventionally, the edge of the shelf has been placed at the 100-fathom (180-metre; about 600-foot) depth line, although the water depth at the shelf break is more nearly 85 fathoms. The width of the continental shelf varies enormously, from nearly zero along parts of the west coast of North and South America to more than 1,000 kilometres (620 miles) off the north coast of Siberia. The average width is 75 kilometres (47 miles), and the average slope is 1.7 metres per kilometre (0.1°). The continental slope extends downward to a depth of about 4,000 metres (13,000 feet). Its average slope near the shelf is some 70 metres per kilometre (4°) over a width of 20–100 kilometres, and farther out to sea it gradually becomes gentler. The third zone, which may vary in width from 0 to 600 kilometres (400 miles), is called the continental rise. It merges with the deep-sea abyssal plain at an average depth of about 4,000 metres (13,100 feet).

Features of the sea floor

An extraordinary feature of the continental slope is that at many places it is intersected by chasms with steep irregular sides, called submarine canyons, which extend from the continental margin to the ocean floors. Certain other sea-bottom forms shown by bathymetric (depth) charts of the oceans are referred to in established terms.

A rise is a long, broad elevation coming gently and smoothly from the sea floor. A ridge is a long, narrow elevation of the sea floor with steep sides and topography more irregular than that of a rise. Sometimes, the highest parts of a ridge project as islands above the sea, as is the case with the Azores, on the Mid-Atlantic Ridge. A sill is a ridge or rise separating a partially closed basin, trough, or trench from another basin or from the adjacent sea floor. The greatest water depth over a sill is called the sill depth. A plateau is the upper surface of a comparatively flat-topped, extensive elevation of the sea floor, normally rising more than 100 fathoms on all sides. A bank is an elevation of the sea floor that is located on a continental shelf or an island shelf and over which the

depth of water is relatively shallow but sufficient for surface navigation. A basin is a large depression of the sea floor that is more or less equidimensional in form. When the length of a depression is considerably greater than the width, and the slope of the sides is fairly gentle, the feature is called a trough. A trench is a long, narrow depression of the deep-sea floor having relatively steep sides and generally greater depths than those occurring in troughs.

Table 2: Depth Zones of the World Ocean and Their Extent

depth of zones		extent of zones		percentage of total surface of the sea
m	ft	000,000 sq km	000,000 sq mi	
0–200	660	2.74	1.06	7.6
200–1,000	660–3,300	15.5	6.0	4.3
1,000–2,000	3,300–6,600	15.2	5.9	4.2

Dealt with in this article are the physical and chemical properties of seawater, the general interaction of the atmosphere and the oceans that produces oceanic circulation and other water motions, and the life and economic potential of oceans and seas. For further information on the configuration of the ocean basins and their development through time, see OCEAN BASINS; CONTINENTAL SHELF AND SLOPE; OCEANIC RIDGES; and SEA-FLOOR SPREADING. See also MARINE SEDIMENTS; OCEANS, DEVELOPMENT OF for discussions of oceanic deposits and the evolution of the oceans, respectively, and WATER WAVES; TIDES; and OCEAN CURRENTS for additional details on water motions. The nature, scope, and methods of oceanography are found in HYDROLOGIC SCIENCES; methods of bathymetry are in HYDROGRAPHIC CHARTING.

This article is divided into the following sections:

I. Physical and chemical properties

COMPOSITION OF SEAWATER

The constituents of seawater include dissolved inorganic substances (such as salts), dissolved gases, and dissolved organic substances. Apart from these dissolved substances, seawater contains widely varying concentrations of particulate matter in suspension. This particulate matter, nonliving and living (such as plankton, floating forms of marine organisms), can influence certain properties of seawater, but the discussion at this point will be confined primarily to inorganic components. See below *Life in the open sea* for a discussion of the role of organisms; and see below *Dissolved organic substances* for a discussion of organic constituents.

Dissolved inorganic substances. Table 3 shows the principal inorganic constituents of seawater other than gases. Excluding water, the constituents are listed not as chemical compounds but rather as ions, the electrically charged parts of compound molecules that dissociate because of the electrolytic action of the water in which they are dissolved. The last column, in addition, gives the percentage occurrence of constituents relative to their total mass.

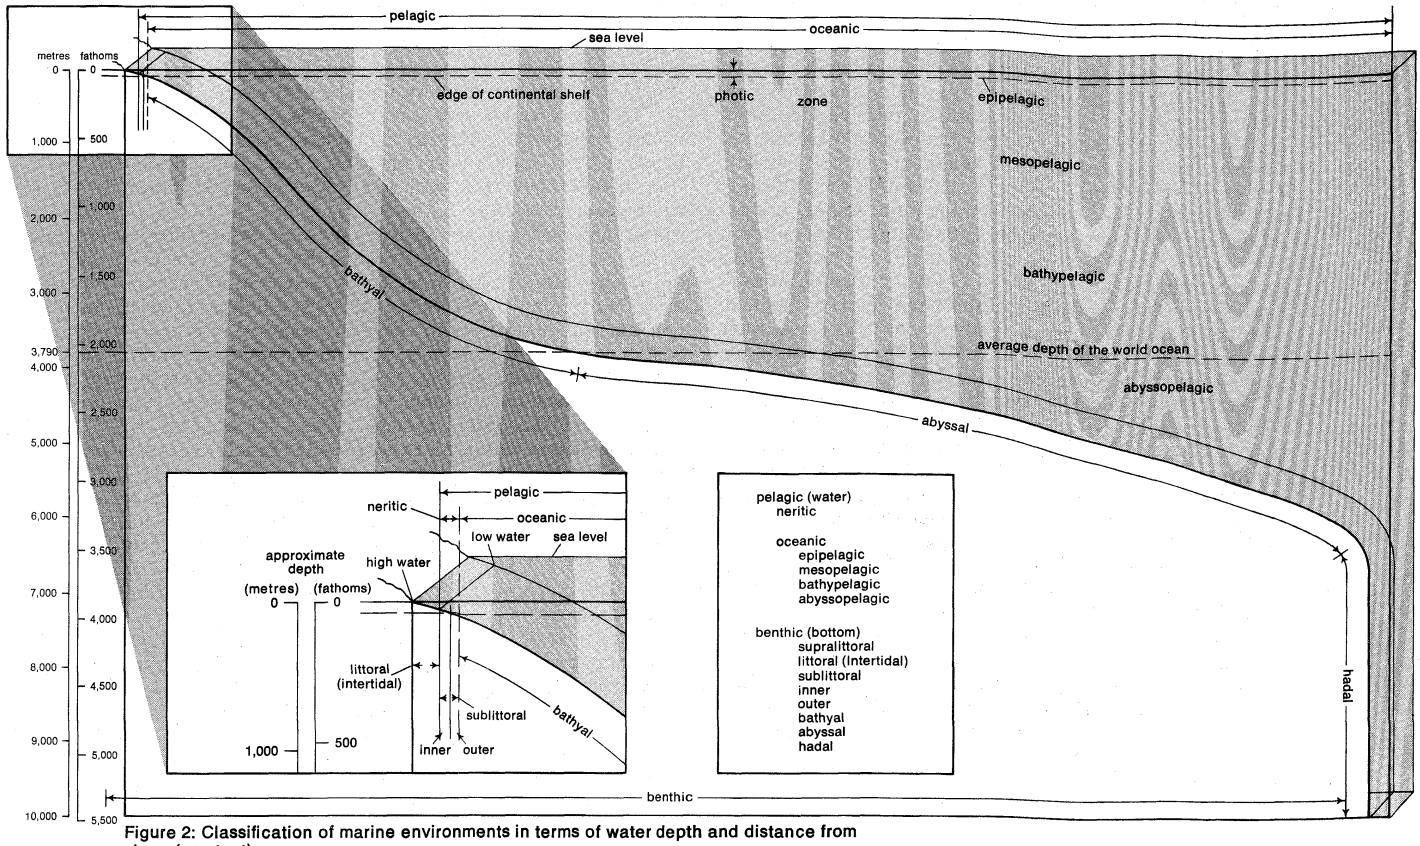

Figure 2: Classification of marine environments in terms of water depth and distance from shore (see text).
From J.W. Hedgpeth (ed.), *Treatise on Marine Ecology and Paleoecology* (1967); The Geological Society of America

Sodium and chloride ions predominate in seawater; together they form more than 85 percent by weight of the total amount of dissolved salts. The last column of the table indicates that, although the total amount of these dissolved substances may vary from place to place and from time to time, the relative proportions of the components are remarkably constant. The total salt content may vary, because seawater can be diluted by additions of precipitation in the form of rain or snow, fresh river water, or meltwater from icebergs. At other times or places, seawater may become more saline because of evaporation of water. In both cases, the proportions of the salt constituents remain the same. The middle column of Table 3 shows the amounts of the various components relative to the amount of seawater, as parts per thousand by weight, or pro mille (grams per kilogram of seawater). These figures are only illustrative, because the total salt content may vary.

Table 3: Principal Constituents of Seawater
(of 19 parts per thousand chlorinity)

constituent	g/kg of seawater	proportion of total salt content (percent)
Chloride (Cl^-)	18.980	55.044
Sulfate (SO_4^{2-})	2.649	7.682
Bicarbonate (HCO_3^-)	0.140	0.406
Bromide (Br^-)	0.065	0.189
Fluoride (F^-)	0.001	0.003
Boric Acid (H_3BO_3)	0.026	0.075
Sodium (Na^+)	10.556	30.613
Magnesium (Mg^{2+})	1.272	3,689
Calcium (Ca^{2+})	0.400	1.160
Potassium (K^+)	0.380	1.102
Strontium (Sr^{2+})	0.013	0.038
Total	34.482	100.000
Water (with traces of other substances)	965.518	
Total	1,000.000	

Because the total volume of the oceans and seas is 1,370,000,000 cubic kilometres (329,000,000 cubic miles), and the average total concentration of salt in the seawater amounts to about 3.6 kilograms per litre, the total amount of salt in the sea may be computed to be roughly 5×10^{18} kilograms, or 5,000,000,000,000 tons. Dried and spread over the whole Earth, this would produce a layer 45 metres (150 feet) thick.

The list of components given here is not complete. Although they account for virtually the entire weight of the dissolved substances, there are other trace elements (minute quantities of matter) in seawater that may be of essential importance to the economy of the sea and to life for certain organisms. Chemical analyses of seawater have revealed traces of iodine, which is an important constituent of some seaweeds, and of copper, which occurs in the blood of crabs. Several chemical elements were found in marine organisms before their identification in seawater. Because rivers continuously carry products of the Earth's crust from the land to the sea, the sea should contain all the elements that are found on the lands. Radioactive matter also occurs naturally in the sea, albeit in exceedingly minute concentrations. Uranium, in concentrations of about three milligrams per cubic metre, and radium, in concentrations of 0.03–0.15 milligram per 1,000,000 cubic metres, generally increase in concentration with water depth. In addition, there are such isotopic constituents as the radioactive isotope of potassium (potassium-40), which has an abundance of 0.0118 percent of the total potassium content and which constitutes by far the largest single source of radioactivity in the ocean. The radioactive isotopes of carbon (carbon-14) and hydrogen (tritium, hydrogen-3) play an important role in estimating the "age" of deep-water masses in the oceans (*i.e.*, the time elapsed since these waters were in contact with the atmosphere).

Salinity and chlorinity of seawater

Salinity is used by oceanographers to characterize the total salt content of a sample of seawater. It is defined as the total amount of solid material (in grams) that is in solution in one kilogram of seawater, when the bromine and iodine content have been replaced theoretically

by an equivalent amount of chlorine, when all the carbonate has been converted to oxide, and when all the organic matter has been completely oxidized. This definition arises partly from certain considerations in analytical chemistry. With respect to the major dissolved constituents, seawater has a composition relatively constant enough so that any single major element can be selected for use as a measure of other elements and of salinity. The standard method of analysis determines the chlorinity of the sample; in effect, bromine and iodine present in the seawater are replaced by an equivalent amount of chlorine, because those two elements are precipitated by silver nitrate as well as the chlorine. The chlorinity, expressed in grams per kilogram of seawater, is identical with the number of grams of silver that is just necessary to precipitate the halogens in 0.3285233 kilogram of the seawater sample. The empirical relation between salinity (S) and chlorinity (Cl), which has been used since the standardization of the method of chlorinity determination, is that salinity equals 0.03 more than 1.805 times the chlorinity, written $S = 1.805\ \mathrm{Cl} + 0.03$. Most salinity determinations currently are made from measurements of electrical conductivity. The conductivity–chlorinity relationship has been internationally established on the basis of analyses of samples from all the seas of the world, and the chlorinity–salinity relation adopted is written $S = 1.80655\ \mathrm{Cl}$.

Both salinity and chlorinity are written as pro mille; that is, as parts per thousand (‰, or grams per kilogram).

In the vast majority of places in the oceans, the salinity lies between 34 and 37 parts per thousand. The horizontal and vertical distribution of salinity will be discussed later (see below *Physical properties of seawater: Salinity distribution*).

Dissolved gases

Because the sea is continually in contact with the atmosphere, the gases that occur in the atmosphere are also found in seawater, in concentrations depending upon their solubilities and on the chemical and biochemical reactions in which they are involved.

The solubilities of nitrogen (N_2), oxygen (O_2), and carbon dioxide (CO_2) differ greatly. They are present in air in proportions of 78 percent, 21 percent, and 0.03 percent by volume, respectively, but their saturation concentrations in seawater of 19 parts per thousand chlorinity at a temperature of 12° C (54° F), in contact with air of one atmosphere pressure, are 11.1, 6.2, and 0.3 millilitres of gas per litre of seawater. The solubility of oxygen considerably exceeds that of nitrogen, and carbon dioxide is much more soluble than either of these gases. The value given for carbon dioxide here includes carbonic acid, the compound formed by reaction of carbon dioxide with water. The solubility of gases decreases with increasing temperature.

Nitrogen is of little importance to life in seawater, with the exception of certain bacteria living on or near the bottom that manufacture ammonium salts and nitrates from nitrogen.

Oxygen is derived from the atmosphere and from marine plants that use sunlight to manufacture carbohydrates from water and carbon dioxide by photosynthesis, by which process oxygen is released. Both sources exist near the surface of the sea; at greater depth it is too dark for photosynthesis by green plants to take place. On the other hand, oxygen is consumed everywhere, even at the greatest depths, because organisms that use oxygen live there. Moreover, oxygen is consumed by combination with organic waste products when the dead remains of organisms sink to the bottom and decompose. Hence, near the surface there is overproduction of oxygen, and at greater depths there is overconsumption. In between there is a level at which production and consumption are just balanced (called the compensation depth), which may vary between one metre and 100 metres (about three to 330 feet), depending on the amount of sunlight available at the sea surface, the transparency of the water, and the abundance of plant life—which in its turn depends on available nutrients. Because oxygen is subject to consumption at all depths, it might be thought that no oxygen exists at great depths, where the production of oxygen is essentially zero, but water refreshment is brought about by the slow, continual, large-scale, water circulation within the World Ocean. At high latitudes the very heavy cold-water masses sink toward the bottom and spread to lower latitudes through the entire deep-sea layers. In the area between the upper layers of the sea, where oxygen is naturally abundant, and the deep layers, where oxygen is supplied by the oceanic circulation, a layer having a minimum oxygen concentration often occurs.

Oxygen-deficient environments

In some seas that are nearly enclosed, ventilation is lacking, and oxygen is completely absent in the stagnating deep water. Part of the Black Sea bottom waters, some Norwegian fjords with high sills (shallow inlets), and the Kau Bay of Halmahera (Indonesia) are examples. In such cases, there is a lack of horizontal communication with outside deep waters, but, in addition, stable water stratification prevents mixing of the upper and lower layers. Anaerobic bacteria (those in reducing, or oxygen-deficient, environments) produce much hydrogen sulfide (H_2S) in such water.

Apart from the fact that carbon dioxide (CO_2) is highly soluble in seawater and combines with water to give carbonic acid, the latter dissociates partly to give bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}) ions, and it also reacts with calcium and magnesium to form calcium and magnesium carbonate and bicarbonate. All these reactions are reversible and may proceed in either direction, depending on the amount of carbon dioxide that is available. Because of this reversibility, the sea has a large buffering capacity (storing and regulating capacity) with respect to processes involving carbon dioxide in the atmosphere and in the sea, including those pertinent to plant life and photosynthesis. The whole system of reactions in which carbon dioxide is involved, however, is extremely complex.

Dissolved organic substances. Seawater contains a diversity of dissolved organic compounds that originate from the decomposition of organisms after their death. The amount of total dissolved organic carbon in the open ocean varies from 0.2 to 2.5 milligrams per litre. Higher values are found in landlocked areas, such as the Black Sea and the Baltic; the shallow water of the Dutch Waddenzee may contain as much as eight milligrams per litre. The highest organic-carbon concentrations are in waters of high phytoplankton (floating forms of small marine plants) productivity. In deeper water, the products of decomposition of organisms that sink toward the bottom tend to be released in the lower layers, beneath the zone where they might serve as nutrients for phytoplankton. From those depths, they may again be brought up by the water-circulation systems and by upwelling along certain coastal regions.

CHEMICAL EVOLUTION

The early hydrosphere may have formed in part by condensation from the early atmosphere, and speculations about the early history of seawater therefore centre on the history of the early atmosphere. Only a very small fraction (less than 1 percent) of the water now present in the oceans may have been derived from the Earth's crust by rock decomposition or weathering; the major part is assumed to have had its source in the release of gases (degassing) from the Earth's core and mantle. Volcanic vents or hot springs often serve as channels for this degassing. A number of other volatile constituents, such as carbon (including carbon dioxide), chlorine, sulfur, and nitrogen, are thought to have arisen from this source because of their abundances. Early accumulations by condensation probably took place in a number of isolated, closed basins. Because of the large amount of carbon dioxide present in the atmosphere at that time, these original oceans, or proto-oceans, must have been quite acid. Exposed rocks would be subject to rapid weathering, and large amounts of dissolved material would be carried into the basins in a short time. Negatively charged ions in the early ocean were probably carbonate and bicarbonate ions predominantly, rather than chloride ions. Sedimentary deposits that are 1,800,000,000 years old suggest that

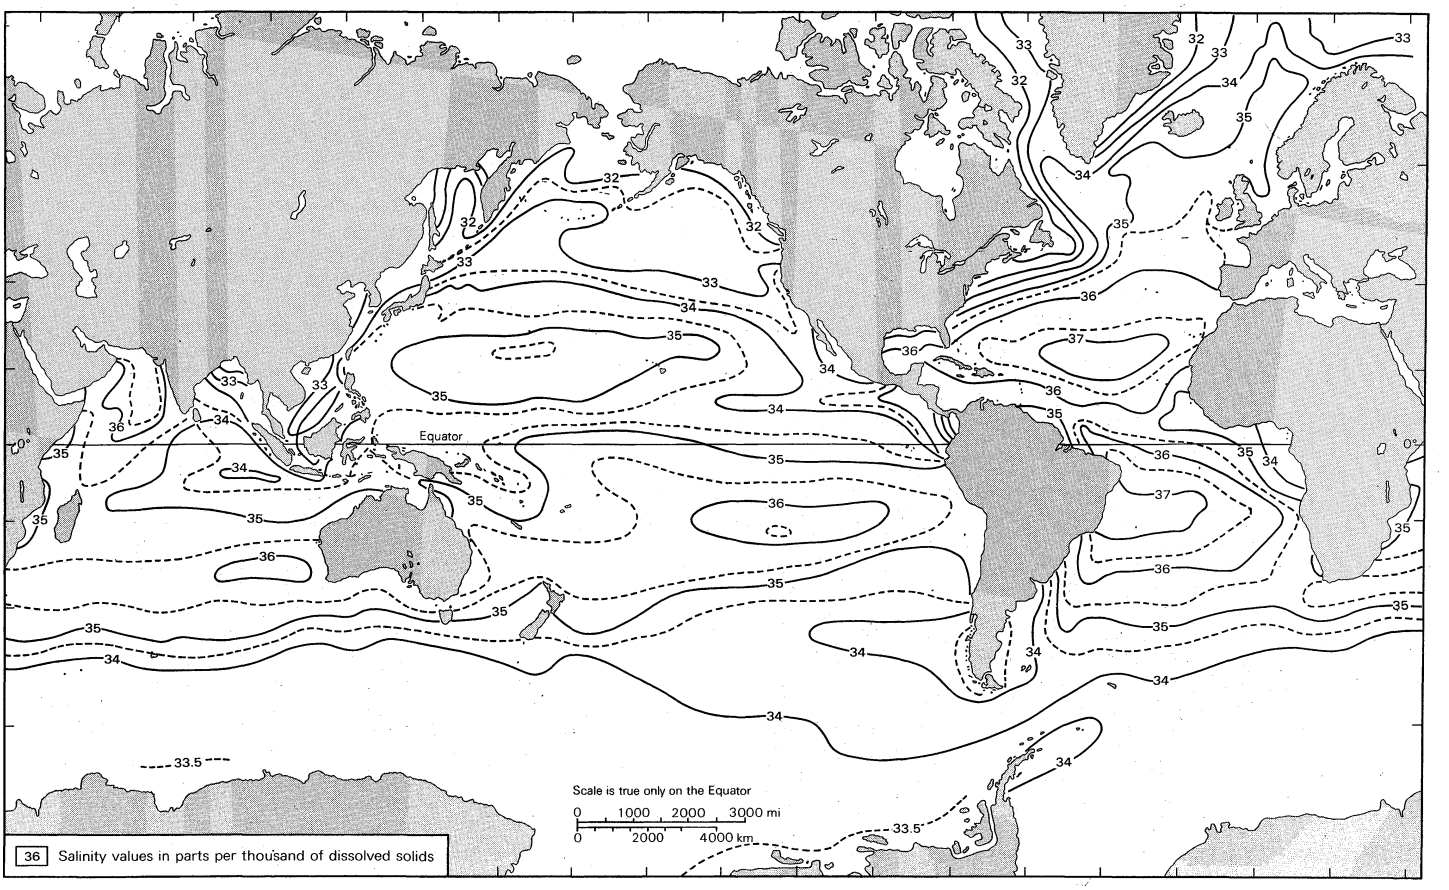

Figure 3: Salinity distribution in surface waters of the World Ocean.

Characteristics of the initial ocean

the oxygen content of the atmosphere at that time was still very low. Photodissociation (breakdown involving the energy of light) of water (H_2O) into hydrogen (H_2) and oxygen (O_2) was responsible for an increase of oxygen; hydrogen escaped from the gravitational field, but much of the oxygen initially was consumed in the oxidation of such reducing constituents of the primeval atmosphere as methane (CH_4), ammonia (NH_3), graphite, and iron. In the time interval between 2,500,000,000 and 1,000,000,000 years ago, however, the atmospheric oxygen pressure must have risen sufficiently to permit the beginning of life. As biological activity expanded, carbon dioxide was consumed, and oxygen was produced much more rapidly. Throughout this time, condensation of water continued, and the proto-oceans merged to become larger oceans. As the carbon dioxide content of air and seawater decreased, saturation of the seawater with respect to calcium carbonate ($CaCO_3$) required much lower concentrations of calcium than were originally present, and large-scale precipitation of limestones (rocks consisting principally of calcium carbonate) was initiated, aided by biological processes. From that time on, a considerable portion of the Precambrian sediments (older than 570,000,000 years) consists of carbonate rocks. Partly as a consequence of this development, chlorine became the dominant negative ion, and the composition of seawater probably had attained a composition very near that of today's oceans and seas. For further details of the several lines of evidence and of the chemical models involved, see ATMOSPHERE, DEVELOPMENT OF; and OCEANS, DEVELOPMENT OF.

PHYSICAL PROPERTIES OF SEAWATER

Salinity distribution. In the example given in Table 3, the calculated salinity is 34.48 parts per thousand. The salinity generally varies in open seas within rather narrow limits; it is between 34 and 37 parts per thousand in most places (Figure 3). It is lowest wherever there is much rainfall or where there is an influx of freshwater from many large rivers that empty into the sea. In regions receiving much freshwater in this way, particularly if they are somewhat divorced from the open ocean, salinities may be less than 34 parts per thousand as in coastal lagoons and shallow isolated areas, such as the Waddenzee behind the Frisian Islands. The salinity also is less than 34 parts per thousand in the vicinity of Newfoundland, not only because freshwater is discharged to the sea by the St. Lawrence River and the rivers of Labrador but also because pack ice and icebergs float down from the north and release their meltwater. Meltwater generally contains less salt than ocean water, and in the case of icebergs it contains no salt at all. Another example is the Baltic, where the salinity is as low as 10 parts per thousand or less in many places; in the Gulf of Bothnia and the Gulf of Finland, it is as low as 5 parts per thousand. This low salinity is caused by the great freshwater discharge of many rivers in the area and by the fact that saline ocean water can enter only in very restricted measure through the narrows connecting the Baltic with the Atlantic Ocean. The surface salinity of the Arctic Ocean is also comparatively low, especially opposite the coast of northern Siberia, where many great rivers have their outlets. Because this freshwater is less dense, it remains on the surface; the salinity at greater depth in the Arctic Ocean is normal for seawater.

In the open oceans, the general salinity distribution is governed by the exchange of water with the atmosphere, that is, by the difference between precipitation and evaporation. Lower salinities occur in moderate and high latitudes and in the equatorial zone, where precipitation exceeds evaporation, and higher salinities prevail in the subtropical zones, where evaporation dominates. This general trend is depicted in Figure 4. In the Sargasso Sea, for instance, in the middle of the Atlantic Ocean at about latitude 25° N, the salinity in summer is more than 37 parts per thousand. Salinity is still higher in the Mediterranean (38 parts per thousand) and the Red Sea (41 parts per thousand). These high salinities are the result of

the small amounts of freshwater received by such seas and the high prevailing evaporation rates. Furthermore, because the water bodies are almost enclosed, they have poor communication with the open ocean. Communication of the Mediterranean Sea with the Atlantic Ocean, for example, is maintained through the narrow Strait of Gibraltar. There, water flows in from the Atlantic Ocean, notably in the upper layers, and at greater depths a countercurrent carries more saline water of the Mediterranean Sea over the sill of the strait into the Atlantic (see also DENSITY CURRENTS).

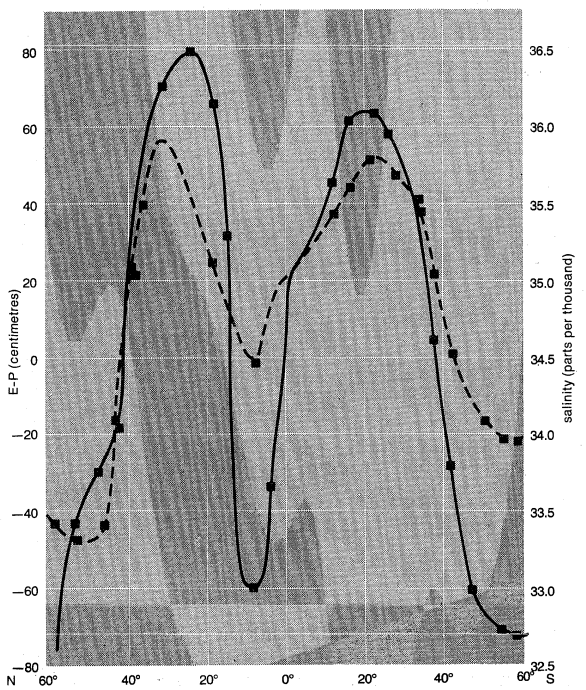

Figure 4: Mean meridional distribution of evaporation precipitation (E-P; solid line) and surface salinity (dashed line) for the entire ocean.

Differences in salinity in the deep sea are smaller than those at the surface, ranging from 34.5 to 35.0 parts per thousand. Very exceptional conditions have been found in a few places on the floor of the Red Sea, where salinities in small bottom depressions are as high as 256 parts per thousand. These values are accompanied by temperatures as high as 60°C (140° F). It is believed that mineral salts have been extracted directly from the underlying crust in these restricted pockets.

Surface temperatures

Temperature distribution. The temperature of the surface waters of the oceans and seas varies greatly in different parts of the world. It may be −1.9° C (29° F) in the polar seas and may rise to as much as 30° C (86° F) in such subtropical waters as the South China Sea and the Gulf of Mexico; temperatures may be higher still in such restricted marginal seas as the Persian Gulf, where 33° C (91° F) is not exceptional. Figure 5 shows mean annual temperatures of the ocean surface waters for the several latitudes, averaged along circles of latitude, together with the approximate annual temperature range. For the sea, the coldest and warmest months are usually February and August in the Northern Hemisphere, outside the equatorial belt, and the reverse in the Southern Hemisphere. In tropical seas and in the polar regions, the annual range is small, about 1° to 2° C (1.8 to 3.6° F). It is largest, as far as the open ocean is concerned, between latitudes 40° and 45° N in the North Atlantic Ocean, where it is roughly 8° to 9° C (about 14° to 16° F), and in the North Pacific, where it is about 9° to 10° C (16° to 18° F). In these regions, especially on the western sides of oceans, the annual range is increased by cold offshore winds in winter that lower the winter temperatures of the sea. There is scarcely anything of this kind in the Southern Hemisphere, where the largest annual temperature range, roughly 5° to 6° C (about 9° to 11° F), occurs between latitudes 30° and 40° S. In shallow marginal seas, the annual range will generally be greater than it is in the open ocean because of the influence of neighbouring land areas.

With increasing depth beneath the surface, the annual temperature variations become smaller. In general, they may be perceptible down to 300 metres (1,000 feet), but often these temperature variations extend downward no farther than about 100 metres (330 feet).

There are certain zones of significant temperature changes over a short distance in the general pattern of horizontal temperature distribution at the ocean surface, giving the appearance of a front. Such is the case on the left-hand side of the Gulf Stream, east of the northern United States and Newfoundland, where cold waters from the north meet the warm Gulf Stream waters and partly dive under it. The boundary here is called the Arctic Polar Front, or Arctic Convergence. In the Pacific, a similar phenomenon occurs to the northeast of Japan, where the cold waters of the Oyashio meet the warm Kuroshio, or Japan Current. In the Southern Hemisphere, there is the Antarctic Convergence, winding as a closed line around the globe between latitudes 50° and 60° S, along which cool waters from higher latitudes meet warmer waters from mid-latitudes; this meeting causes the surface temperature to jump two or three degrees within a short distance.

Subsurface temperatures

Temperatures generally decrease with increasing depth, except in the polar water masses, where temperatures are low from the surface to the bottom. The vertical temperature decrease often shows a jump, above which the water often is more or less isothermal; that is, it has the same temperature at different depths. This phenomenon may be caused by wind mixing or, in the cold season, by cooling from above, which induces vertical circulation (convection), or by both. These factors tend to make the mixed layer attain its greatest depth (to 100 metres or 330 feet) in winter and in spring. The jump also may be absent, particularly after a period of heating from above, or may be broken into sublayers. The drop in temperature found beneath the mixed layer is called the thermocline.

Beneath this thermocline, the decrease in temperature is more gradual, down to very low temperatures; even in tropical regions, temperatures of less than 1° C (34° F) have been found at depths of 5,000 metres (16,400 feet) or more, and the temperature already is 3.5° C (38.3° F) or less in most places at depths of 2,000 metres (6,600 feet). The cause of these low temperatures is the slow

From "Treatise on Marine Ecology and Paleoecology," vol. 1 (1967)

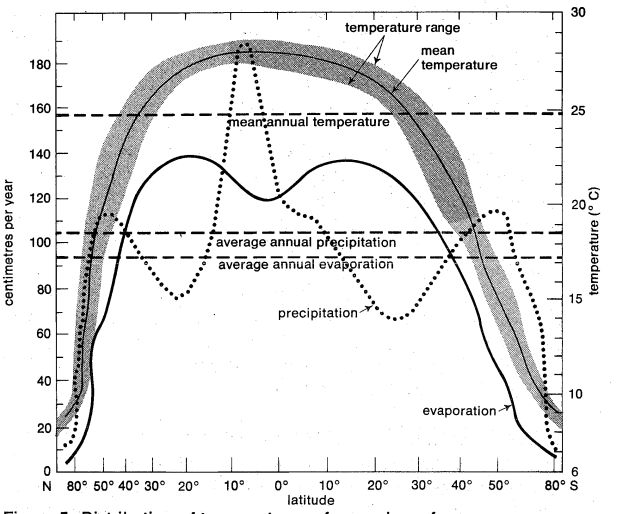

Figure 5: Distribution of temperatures of oceanic surface waters and variation of water gains (precipitation) and losses (evaporation) with respect to latitude. The latitude scale has been adjusted for ocean area to reflect the greater water expanse in the Southern Hemisphere.

deep-sea circulation, referred to earlier in connection with the oxygen content of these deep waters. These cold-water masses are of polar or subpolar origin, and the very coldest have come from the Antarctic. In order to have a true circulation, the water must, of course, eventually come up again from these great depths. This rise does occur, but it takes place in a diffuse manner and is extremely slow everywhere in the World Ocean. This deep-sea circulation, fed by cold polar and subpolar water masses, has its place mainly within the deep part of the body of the World Ocean. It is the colder part, the other part being the warm and moderately warm upper waters of tropical and subtropical regions. These warm waters form a layer several hundred metres thick, situated roughly between latitudes 45° S and 45° to 55° N; the boundary at the surface is not sharply defined, certainly not in the eastern part of the North Atlantic Ocean, which receives the Gulf Stream waters. The lower boundary of the warm layer also is not well defined. It is usually placed at the isothermal level of approximately 10° C (50° F). The two layers may be called the thermosphere (warm sphere) and the cryosphere (cold sphere), but the important point is that the thermosphere has a circulation of its own; the two circulations are associated, however, and water may pass sometimes from one layer into the other.

There are places in the deep sea where at some depth the temperature stops falling and then rises slightly at greater depth. Such temperature inversions occur in certain deep basins and troughs, particularly in the Moluccan seas, where the bottom water enters across a shallow sill and then flows downward for a considerable vertical distance. In flowing down, it is subjected to compression, which increases with depth, and this causes adiabatic heating—heating without any heat exchange with surrounding water.

Thermal properties. The adiabatic temperature change just mentioned is a consequence of the fact that water is compressible. An increase in pressure causes the volume to decrease slightly so that work is performed on the water, and, if this takes place adiabatically, then the energy gained causes a rise in temperature. For example, if seawater of 35 parts per thousand salinity and a temperature of 18° C (64° F) is lowered adiabatically from the surface to 1,000 metres depth (3,300 feet), the temperature increases by 0.18° C (0.32° F); for seawater of 2° C (36° F), the rise in temperature would be 0.06° C (0.1° F); taken down to 10,000 metres depth, the water would undergo a temperature increase of 1.3° C (2.3° F). These effects depend on the compressibility and the thermal-expansion coefficient of seawater, which have different values at different temperatures and pressures. They also depend, of course, on the specific heat (heat capacity) of seawater. If water is raised from a lower to higher level, the adiabatic temperature change has the same numerical value but is negative, which means a temperature decrease. In this connection, the concept of potential temperature must be mentioned. This is the calculated temperature that a quantity of water would assume if it were brought to a certain standard level of pressure adiabatically—for instance, to the sea surface. If water is actually lowered or raised, the actual temperature will change, but the potential temperature will not. The latter, called a conservative property, can therefore be used to trace water masses in the deep sea.

The specific heat of seawater is the amount of heat required to raise the temperature of one kilogram (2.2 pounds) of seawater by 1° C (1.8° F) under constant pressure or with constant volume. It is somewhat smaller in value than the specific heat of pure water at the same temperature. At a temperature of 17.5° C (63.5° F), it is 1,000 calories per kilogram for pure water (under constant pressure of one atmosphere), whereas it is 932 calories per kilogram for seawater of 35 parts per thousand salinity. Specific heat decreases slightly with increasing temperature and with increasing pressure.

The freezing point of saltwater is lower than that of freshwater. For various salinity values the freezing point is as follows:

salinity (parts per thousand)	0	10	20	30	35
freezing point	0.00	−0.53	−1.08	−1.63	−1.91° C

Water density. The density of seawater is the mass per unit volume, expressed in kilograms per cubic metre. It increases with increasing salinity and pressure and decreases with increasing temperature.

The dependency on salinity is exemplified by the following figures: at a temperature of 0° C (32° F), under atmospheric pressure, pure water has a density of 999.9 kilograms per cubic metre. Seawater of 20 parts per thousand and 35 parts per thousand salinity has a density of 1,016.1 and 1,028.1 kilograms per cubic metre, respectively. The effect of pressure becomes apparent from the following figures for seawater of 0° C and 35 parts per thousand salinity at various depths:

depth (metres)	0	1,000	2,000	10,000
density (kg/m^3)	1,028	1,033	1,037.5	1,071

The dependence of density on temperature deserves some special attention. Unlike freshwater, seawater attains its maximum density not at 4° C (39° F) but at a lower temperature. The higher its salinity, the lower the temperature at which its density is a maximum; and, if its salinity is 24.7 pro mille or more, seawater continues getting heavier with decreasing temperature until the freezing point is reached. This fact is of special importance in connection with the freezing over of seawater. If the sea is cooled from above, and the surface water thus becomes colder than the water underneath, it will sink downward, and water from below will take its place. For this reason, the surface water cannot drop to freezing temperature as long as the water beneath is not almost equally cold. This phenomenon explains why, apart from the lower freezing temperature, the sea does not freeze over as readily as freshwater, which remains at the surface when cooled below 4°C. The fact that the coldest seawater is the heaviest, provided its salinity is not less than 24.7 parts per thousand, also has an important bearing on global deep-sea circulation, which is driven by the sinking of ice-cold polar water masses.

The figures below give some values of the density of seawater of 35 parts per thousand salinity, for various temperatures, at atmospheric pressure (in oceanographic literature it is customary to use a quantity called sigma [σ], which is equal to density in kilograms per cubic metre minus 1,000; for the density as a function of temperature at atmospheric pressure, the symbol sigma-t [σ_t] is in use):

temperature	0	10	20	25	30° C
density (kg/m^3)	1,028.1	1,027.0	1,024.8	1,023.4	1,021.75
σ_t	28.1	27.0	24.8	23.4	21.75

Pressure. The pressure on water in the sea is expressed in a unit called the bar, which is equal to 10^5 newton per square metre, the newton being the physical unit of force according to the international system of units. The practical unit is the decibar, which equals 0.1 bar. One decibar corresponds approximately to the pressure of one metre of seawater of normal salinity. The exact pressure exerted by a column of seawater depends on its density. If it is in equilibrium with the force of gravity, the pressure difference between the top and the bottom of a column of seawater is equal to density times acceleration of gravity times the height of the column. Because density varies with salinity, temperature, and pressure, an exact computation of pressures in the sea requires the summation of partial pressures corresponding to portions of the whole water column involved, for which the values of salinity and temperature at various depths are known from observation. Calculation of pressures in the sea is of special importance with respect to the dynamics of ocean currents.

Optical properties. The interaction of light with seawater has two principal effects, namely, absorption and scattering. Absorption is defined as the conversion of

Absorption and scattering of light

radiant energy to other forms of energy (mostly heat) and scattering as the irregular deviation of light from straight-line propagation. A parallel beam of light that is propagated through seawater suffers attenuation by the combined action of these two processes; the relative loss of light intensity per metre of path length is called attenuance, which is absorptance plus scatterance. Sometimes the term absorption coefficient or extinction coefficient is used.

The absorption and scattering of light in seawater are caused by four constituents, namely, water, dissolved salts, dissolved organic substances, and suspended particles. Sea salts have negligible effect on attenuation. For pure seawater, Table 4 shows values of attenuance,

Table 4: Light Attenuance in Pure Seawater

wavelength (micron)	attenuance (percent per m)	scatterance (percent per m)	absorptance (percent per m)
0.375	4.4	0.7	3.7
0.400	4.2	0.5	3.7
0.450	1.9	0.3	1.6
0.500	3.5	0.2	3.3
0.550	6.7	0.1	6.6
0.600	16.7	0.1	16.6
0.650	25.0	0.1	24.9
0.700	39.3	0.0	39.3

scatterance, and absorptance for various wavelengths. Seawater is most transparent to blue light, and red light is strongly absorbed (infrared even more). The scattering produced by the water molecules is inversely proportional to the fourth power of the wavelength. Of the organic substances dissolved in seawater, a yellow substance, mainly carbohydrate-humic acids, especially adds significantly to the absorption of light, particularly in the shorter wavelengths. The substance is formed by decomposition of organic particulate matter and is especially abundant in northern coastal waters.

Suspended particles in the sea are responsible for absorption as well as scattering. The absorption is generally stronger for short wavelengths of light than for longer waves. Scattering, on the other hand, is virtually independent of wavelength. Table 5 shows some values of the attenuance for various wavelengths in different types of seawater.

Table 5: Loss of Light (Percent) in One Metre of Seawater*

	violet		blue		green	yellow	orange	red
Wave length (micron)	0.30	0.40	0.46	0.50	0.54	0.58	0.64	0.70
Oceanic water, most transparent	16%	4%	2%	3%	5%	9%	29%	42%
Oceanic water, least transparent	57%	16%	11%	10%	13%	19%	36%	55%
Coastal water, average		63%	37%	29%	28%	30%	45%	74%

*According to Jerlov.

Colour and transparency of seawater

The colour of seawater depends on the spectral distribution of attenuance. It is blue for clear ocean water and shifts toward greater wavelengths for less transparent (more turbid) waters, in accordance with the shift of the spectral-attenuation minimum.

The intensity of underwater light derived from the sunlight falling on the sea surface depends on the amount of reflection at the sea surface and on the depth and transparency of the intervening layer of water. The reflection from a smooth sea surface with the Sun at various elevations in a clear sky varies from 3 percent for a high Sun to very high values for a low Sun, as is shown by the following data:

Sun's elevation (degrees)	90	50	40	30	20	10	5
reflectance (percent)	3	3	4	6	12	27	42

If the sea surface is rough because of wave action, the reflectance is decreased at low elevations and increased at higher elevations of the Sun. Also, with an overcast sky, the differences of reflectance for different elevations of the Sun become smaller.

The transparency of the sea for daylight is usually smallest in the topmost few metres of water, because of the presence of small-sized drifting material and air bubbles (foam). The amount of light reaching various depths is, of course, different for different wavelengths. For average ocean water, the following values provide an example of the relative downward light intensities, expressed in percentage of the light intensity immediately below the sea surface:

depth (m)	0	10	20	50	130	200
relative intensity (percent)	100	9.5	3.7	0.31	5×10^{-4}	2×10^{-6}

Various instruments are used to measure optical properties of the sea, the most common being the transparency meter and the Secchi disk. The principal parts of the former, also called the turbidity meter, are a light source that emits a directed beam of light and a photoelectric cell placed at some fixed distance. The cell measures the intensity of the light transmitted through the intervening column of water. The Secchi disk, about 30 centimetres (12 inches) in diameter, painted white or yellow, is lowered into the sea, and the depth at which it vanishes from sight is taken as a measure of the transparency of the water.

Velocity of sound

Acoustical properties. The velocity of sound in seawater varies from about 1,450 metres per second to about 1,570 metres per second (about 4,760 to 5,150 feet per second); it increases with temperature at a rate of about 4.5 metres per second per degree C (8.2 feet per second per degree F), and it increases with salinity at a rate of 1.3 metres per second per part per thousand of salinity. The increase with depth (pressure) is at a rate of 1.70 metres per second per 100 metres (330 feet). At the sea surface, in water of 35 parts per thousand salinity and a temperature of 10° C (50° F), the velocity is 1,501 metres per second (4,923 feet per second). A typical sound-velocity profile along a vertical in the ocean generally shows a decrease of velocity with increasing depth down to about 1,500 metres, caused by the dominating effect of the temperature decrease, which is followed by a steady increase of velocity with greater depths. This velocity increase results from the effect of increasing pressure.

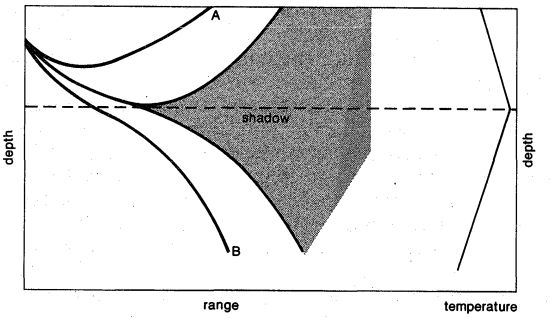

Figure 6: Acoustical properties of seawater: shadow zone formation that occurs when a positive temperature gradient lies above a negative temperature gradient. The sound projector is located within the positive gradient, and AB indicates boundaries of the sound channel (see text).

In the topmost ten to 100 metres of the sea, a slight increase of sound velocity with depth may occur because of the pressure effect if this top layer is a mixed layer with constant temperature and salinity.

The differences in sound velocity at different depths give rise to refraction, or bending, of the sound rays. When velocity decreases with increasing depth, a downward bending occurs; when it increases with depth, there is an upward bending of the sound rays. Refraction of sound gives rise to such phenomena as shadow zones and sound channels. A shadow zone is produced when a layer with downward increase of sound velocity occurs above a lay-

er with downward decrease of sound velocity. If a sound projector, as used in underwater acoustic detection, is in the upper layer, one gets a shadow zone as depicted in Figure 6.

A sound channel is caused by a sound-velocity minimum in the velocity profile, such as that mentioned above. Along the axis of the velocity minimum, sound rays are refracted successively upward and downward and essentially are trapped. The sound is focussed in the channel, and loss of intensity is minimized. Small charges exploded at the right depth (about 1,500 metres, or 5,000 feet) produce sounds that may be detected by hydrophones placed in the channel many thousands of miles from the source. This phenomenon is the principle of the SOFAR, sound fixing and ranging system used to locate positions at sea.

ICE IN THE SEA

There are two types of ice in the seas: sea ice, which is ice formed by the freezing of seawater, and ice that has come from land, such as icebergs and ice islands.

Sea ice. From an initial stage of so-called frazil crystals (floating needles and platelets) and sludge composed of them, sea ice grows to a compact aggregate of crystals of pure ice with pockets of seawater entrapped between them. Because of this composition, the salinity of sea ice is lower than that of the seawater from which it has grown. The initial sea-ice salinity may vary between 20 and two parts per thousand; the more rapid the freezing, the saltier the ice. After sea ice has formed, a process of salt removal by drainage of part of the enclosed brine sets in, because the cells in which it is contained are not completely isolated. Old ice has very low salinity, less than one part per thousand.

The growth rate of sea ice depends on surface temperature, the depth of snow cover, and the heat flux in the underlying water. In the central Arctic, the thickness of an ice cover formed in one growing season is about two metres (six and one-half feet). If the ice is not broken up, it finally reaches an equilibrium thickness of about three to four metres (10 to 13 feet) in five to eight years, when the annual ablation (loss by any means) at the top and the bottom equals the annual growth. In the Antarctic, perennial sea ice is found only in the Weddell Sea and a narrow strip around the continent. Most of the Antarctic sea ice is seasonal and reaches a thickness of about 1.5 metres (five feet) by the end of October.

The drastic change of reflectivity that occurs when the sea freezes over (from 5 to 10 percent to 80 percent) makes sea ice an important factor in the heat budget of the ocean. The boundaries of the sea ice are highly variable. In the Norwegian and Greenland seas, deviations of 300 kilometres (200 miles) north or south of the average position are not uncommon. The estimated mean areas of sea ice at the end of the summer and at the end of the winter in the Arctic are 9,000,000 square kilometres (3,500,000 square miles) and 12,000,000 square kilometres (4,600,000 square miles), respectively. In the Antarctic, the corresponding values are 4,000,000 square kilometres (1,500,000 square miles) and 20,000,000 square kilometres (8,000,000 square miles). The mean total volume of sea ice on Earth is 40,000 to 50,000 cubic kilometres (9,600 to 12,000 cubic miles), and the total amount of freezing and melting that occurs each year has been estimated at 30,000 cubic kilometres (7,200 cubic miles).

In the Arctic, it is possible to distinguish three regimes of sea ice: the great inner core, the permanent polar cap of sea ice (the Arctic pack), which covers about 6,000,000 square kilometres (2,300,000 square miles); around this the true drift ice or pack ice; and the landfast ice, which is present during nine months of the year, when it fringes the shores of the Arctic Sea out to the 22-metre (72-foot) depth line, approximately. Large amounts of pack ice drift southward each year. The ice discharge through the gap between Greenland and Spitsbergen is estimated to be 3,000 cubic kilometres (720 cubic miles) per year. On the west side of the North Atlantic, the pack ice reaches approximately latitude 45° N in winter and spring. On the east side, along the Norwegian coast, the sea remains open up to 73° N.

Ice islands and icebergs. Ice islands, of which a number have been found drifting in the Arctic Sea, are heavy sheets of ice that are far thicker than sea ice. Their thickness easily may amount to 50 metres (160 feet), five metres (16 feet) of which project above water. The surface area of the largest known ice island is approximately 1,000 square kilometres (400 square miles), but others are far smaller. Ice islands consist of a kind of glacier-like snow ice. The majority of them probably have been formed by the breaking of the shelf ice that borders the north coast of Ellesmere Island. The first ice island reported has undergone little change in configuration since its detection in 1946.

Icebergs and their distribution

Icebergs are formed by the calving (detaching of parts) of glaciers or of inland ice that reaches the sea. The main sources of icebergs in the northern seas are the valley glaciers of Greenland, which produce some 12,000 to 15,000 sizable icebergs annually. Almost as many are calved by the glaciers reaching the sea on the eastern seaboard as by those on the west coast, but the icebergs deriving from the east side do not travel much farther south than Kap Farvel, the southern tip of Greenland. The icebergs of the west coast, on the other hand, after travelling northward and across to the other side of Baffin Bay, are carried far south, along Baffin Island and Labrador, by the Labrador Current. It is estimated that about one in every 20 icebergs derived from west Greenland ends up south of Newfoundland (48° N), the greatest numbers arriving there in April, May, and June.

The icebergs of the Antarctic derive from an ice barrier, or shelf ice, a layer of ice that stretches out from the inland ice into the sea. It rests on the bottom near shore, but farther out to sea it floats on the water. Because of their origin, the Antarctic icebergs are very much longer than they are high, occasionally measuring some tens of kilometres in length. For this reason they are called table bergs.

The frequency with which icebergs occur in the Southern Ocean does not vary much with the season, in contrast to the North Atlantic occurrences. Generally speaking, October and November are the months in which they are most numerous in the south because of the release of the bergs from the pack ice in the southern spring. They reach farthest north from November to February. The average northern boundary for icebergs is about 40° S in the Atlantic Ocean, between 40° and 50° S in the Indian Ocean, and about 50° S in the Pacific. At least several thousands of them are adrift every year in the southern seas (see also ICEBERGS AND PACK ICE).

II. Dynamics and motions of the sea

OCEAN–ATMOSPHERE INTERACTION

Radiation and heat budget. Incoming sunlight is the primary source of energy for the atmosphere, the oceans, and the land. The heat flow from the interior of the Earth through the sea bottom is approximately 0.1 watt per square metre (see EARTH, HEAT FLOW IN). The supply of energy to the oceans by direct and scattered solar radiation, averaged over all seas and for the entire year, has been estimated at 150 watts per square metre, or 3.5 kilowatt hours per day per square metre, less than half of the incoming solar radiation at the top of the atmosphere, which averages 350 watts per square metre. The loss is due to backscattering and absorption by the air, reflection by clouds, and reflection by the surface of the sea. Besides this shortwave primary radiation, there is a considerable supply of infrared heat radiation from the atmosphere, derived from the clouds, the water vapour, and, to a small extent, from carbon dioxide. This radiation from the atmosphere is quite variable, depending on the water-vapour content, the temperatures in the lower layers of the atmosphere, and, particularly, on the cloud cover. Averaged over the whole World Ocean, it amounts to some 235 watts per square metre. On the other hand, the Earth's surface loses heat by radiation, by evaporation, and by direct conduction through contact with the atmosphere. The loss by radiation at any place is propor-

Energy gains and losses

tional to the fourth power of the absolute temperature of the Earth's surface at that place. For the whole World Ocean, the average outgoing radiation is estimated at 300 watts per square metre. The average heat loss by evaporation is estimated at 75 watts per square metre, and the average heat conduction to the overlying air is about ten watts per square metre. Thus, the total heat gains and heat losses both amount to 385 watts per square metre. The considerable effect of the atmospheric down radiation upon the temperatures of the Earth's surface is called the greenhouse effect of the atmosphere.

Heat losses by evaporation and by conduction vary greatly from place to place and from time to time. They may even be negative, because there may be a gain of heat by condensation on the sea surface instead of evaporation at certain places. Often there is conduction of heat from the air to the seawater if the seawater is colder, as is usually the case in summer and in regions of cold ocean currents. In general, evaporation is greatest in winter, when the seawater is usually warmer than the overlying air.

Although taken as a whole there is a balance between the thermal gains and losses of the oceans of the world, this need not be the case for any particular area, because transport of heat within the oceans occurs by current action. In the northeastern part of the Atlantic Ocean to the west of Norway, expenditure in the form of heat transfer to the atmosphere and upward radiation exceeds the incoming radiation. This deficit is balanced, however, by the internal transfer of heat carried through the ocean by the Gulf Stream system. The reverse occurs in the northwestern part of the Atlantic, where cold water carried down by the Labrador Current with its burden of ice fields balances out the surplus of heat received from above.

Water budget. The annual water budgets of the oceans and the lands are approximately as follows:

	oceans	lands
evaporation km³/year	360,000	70,000
precipitation km³/year	330,000	100,000
runoff km³/year	30,000	−30,000

Stated differently, the values are

	oceans	lands
evaporation m³/sec	11.4×10^6	2.2×10^6
precipitation m³/sec	10.4×10^6	3.2×10^6
runoff m³/sec	1.0×10^6	-1.0×10^6

The annual precipitation averaged over all the oceans and seas and expressed as the height of a water column amounts to 91 centimetres (36 inches). All these figures are estimates and incorporate a considerable degree of uncertainty, but they reflect one important aspect of atmosphere–ocean interaction (see also HYDROLOGIC CYCLE).

Air–sea transfer processes. The upward or downward transport of water vapour and heat from or toward the sea surface was referred to above in relation to the energy exchange of the sea with the air. This transport is performed by fluctuating vertical motions of the air immediately above the water surface. Except within about one millimetre (0.04 inch) of the interface, where molecular processes are of importance, turbulence is responsible for the vertical transport of matter and heat. Another property that is important in connection with transport is horizontal momentum. Momentum per unit mass is velocity, the rate of supply of momentum is force, and the rate of transfer of horizontal momentum per unit area of the surface is force per unit area, which is a stress exerted through the surface. A downward transfer of horizontal momentum across the sea surface means that a wind stress is exerted on the water.

Horizontal and vertical transport

The rate of turbulent transfer of any property depends on spatial differences of that property—that is, on its gradient (difference per unit distance)—and on the magnitude of the turbulent velocities. The definition and significance of turbulent velocity will be considered later in connection with turbulence in the sea. If in the lowest layers of air there is an upward gradient of horizontally averaged value of any mass property (Q)—*e.g.*, heat content, water-vapour content, or momentum per unit volume—a parcel of air moving downward at a certain level is liable to carry a higher value of Q with it than does an upward moving parcel of air at the same level; statistically, then, there will be a net downward flux of the corresponding quantity (heat, water vapour, momentum). Thus, the direction of flux is opposite to the direction of the gradient of Q and this is also the case with ordinary molecular diffusion. The relationship between flux and gradient is often written as

$$\text{flux} = -A \times \text{gradient of } Q,$$

in which A is the turbulent exchange (or Austausch) coefficient. Instead of A, it is customary to write $A = \text{K} \times$ density (of air), in which K is the turbulent, or eddy, diffusivity for the property concerned. In contrast to molecular diffusivity, K is not a constant characteristic of the air but is dependent upon the intensity of the turbulence and on the distance from the boundary surface. In the case of air over water, for example, it depends on the height above the water surface. In general, it will also depend on the property concerned; that is, it may be different for the exchange of water vapour, heat, and momentum. In the case of momentum transfer, K is called the eddy viscosity.

For practical purposes, instead of using the local gradient Q for determining the corresponding flux, the difference of Q between two levels is often used. For instance, the difference between the value at the sea surface and the value at some standard level, usually chosen to be ten metres (33 feet) above sea level, can substitute for the gradient of Q. The relationship used is then: upward flux $= -D\ (Q_1 - Q_0)$, in which D is the eddy diffusion factor for the property concerned. Empirically, this factor has been shown to be roughly proportional to the wind velocity (U_1) at standard height, at least if the air is not too unstable or too stably stratified. The formula for the flux then becomes: upward flux $= -CU_1\ (Q_1 - Q_0)$, in which the factor C represents a nondimensional quantity (a pure number), which depends on what meaning has been assigned to Q.

In the case of wind stress, which is a downward transfer of momentum, Q means density times wind velocity, so that, if the wind velocity at the very sea surface is supposed to be zero, the above formula becomes:

$$\text{wind stress} = C_1 \rho U_1^2,$$

in which rho (ρ) equals air density. C_1, called the drag coefficient, depends on the height of the standard level chosen and on the roughness of the sea surface or the small corrugations of that surface and consequently is not a true constant. Empirically, it has been shown to have values of about 0.001 to 0.002 for wind velocities of at least seven metres per second. It increases somewhat with increasing wind velocity. Also, it tends to be greater for pronounced instability of the air and to be smaller for pronounced stability.

Three movements of seawater

Three types of movements of seawater may be distinguished, namely, oscillating and rotating movements, as in water waves and tides; regular, or direct, currents; and irregular eddying movements, or turbulence that is superposed on waves or ocean currents as a form of "noise" (secondary or background disturbance).

Turbulence in the sea. The distinction between regular currents and turbulence is not absolute, because a varying current system of restricted dimensions within the framework of a larger current system may be looked upon as an element of turbulence with respect to that larger system. It may also be considered as a regular, though not constant, current system of its own with respect to still smaller eddies, with its own field of superposed turbulence. If, then, the turbulent velocity is defined as the momentary velocity at a certain point minus the average velocity of the current (the average being taken over a certain area), the outcome of this definition depends on the scale of averaging.

The effect of turbulent motions is to bring about an exchange of mass, heat, and momentum in much the same way as molecular motions bring about molecular diffu-

sion, heat conduction, and viscosity. The flux, or the net amount of substance, heat, or momentum that passes per unit time through a surface of unit area by turbulence, is proportional to the gradient of mean mass of the substance concerned per unit volume. The coefficient of proportionality, called eddy diffusivity, eddy conductivity, or eddy viscosity, respectively, is not a physical constant (as is molecular diffusivity, conductivity, or viscosity) but depends on the nature of the turbulent motion and on the scale of averaging. It depends on the scale of the phenomenon under consideration, and, consequently, it may have much larger values for horizontal than for vertical exchange. On the whole, it may vary from 0.1 to 10^9 square centimetres per second, increasing with increasing scale of the phenomenon. It has the same order of magnitude for the exchange of mass, heat, and momentum. Vertically, it also depends on the stability of the stratification; pronounced stability tends to counteract the development of turbulence. In the ideal case of statistical equilibrium between the eddies of different sizes, eddy diffusivity has been shown to be proportional to the 4/3rd power of the scale involved. As a consequence, the horizontal spreading of a patch of matter (suspended particulate matter or a dissolved substance) goes on at a rate that increases in time with the dimensions of the patch; indeed, as the patch becomes larger, ever larger eddies participate in spreading it; as long as the patch is of a smaller size, a larger eddy only displaces it, the spreading being left to the smaller eddies.

Eddy viscosity, concerned with momentum, is of paramount importance for the dynamics of currents in the sea, particularly for wind-driven currents. In the neighbourhood of boundaries, its value decreases with decreasing distance to the boundary (*e.g.*, bottom or sea surface) and depends on its roughness.

WAVES OF THE SEA

Waves of the sea are of many different kinds, and only gravity waves, of which gravity is the stabilizing factor, will be considered here. Gravity waves may be surface waves or internal waves; and, in either case, a further distinction can be made between running waves and standing waves.

The tides are essentially gravity waves that are running, standing, or in an intermediate state. The tides may be termed forced waves, because they have fixed, prescribed periods that are strictly determined by the relative movements of moon, Earth, and Sun. Sometimes the word tide is used in a wider, somewhat loose sense, including such phenomena as surges, which are called storm tides, or meteorological tides. Also, the term tidal wave is sometimes used in a general sense to denote very long gravity waves; that is, waves whose wavelength is very much greater than the depth of the sea. In the following discussion the use of the words tide and tidal will be restricted to the tides of astronomic origin and the forces and phenomena connected with them.

Surface waves. Of the nontidal kinds of running surface waves, three types may be distinguished, namely, wind waves and swell, wind surges, and sea waves of seismic origin (tsunamis).

Wind waves and swell. Wind waves are the wind-generated waves that are controlled and strengthened by the wind or wind field that made them. Afterward, when the wind has abated or shifted or when the waves have left the wind field, they run on independently as swell.

The dependence of the sizes of the waves on the wind field is a complicated one. A general impression of this dependence is given by the descriptions of the various states of the sea corresponding to the scale of wind strengths known as the Beaufort scale (Table 6), after the British admiral Sir Francis Beaufort, who drafted it in 1808, using as his yardstick the surface of sail that a fully rigged warship of those days could carry in the various wind forces. In the list given in Table 6, each Beaufort number is accompanied by a brief description of the appearance of the sea, on the lines adopted by the German sailing-ship captain Peterson. These descriptions were approved by the World Meteorological Organization for use at sea to determine the force of the wind. The Beaufort wind force is followed by the name given to such a wind at sea, and the next column gives the range of wind speeds.

Table 6: The Beaufort Scale

Beaufort number	name of wind	wind speed		description of sea surface
		knots	km/hr	
0	calm	<1	<1	like a mirror
1	light air	1–3	1–5	ripples with the appearance of scales are formed, but without foam crests
2	light breeze	4–6	6–11	small wavelets, still short but more pronounced; crests have a glassy appearance and do not break
3	gentle breeze	7–10	12–19	large wavelets; crests begin to break; foam of glassy appearance, perhaps scattered white horses
4	moderate breeze	11–16	20–28	small waves, becoming longer; fairly frequent white horses
5	fresh breeze	17–21	29–38	moderate waves, taking a more pronounced long form; many white horses are formed (chance of some spray)
6	strong breeze	22–27	39–49	large waves begin to form; the white foam crests are more extensive everywhere (probably some spray)
7	moderate gale	28–33	50–61	sea heaps up and white foam from breaking waves begins to be blown in streaks along the direction of the wind
8	fresh gale	34–40	62–74	moderately high waves of greater length; edges of crests begin to break into spindrift; the foam is blown in well-marked streaks along the direction of the wind
9	strong gale	41–47	75–88	high waves; dense streaks of foam along the direction of the wind; crests of waves begin to topple, tumble and roll over; spray may affect visibility
10	whole gale	48–55	89–102	very high waves with overhanging crests; the resulting foam, in great patches, is blown in dense white streaks along the direction of the wind; on the whole the surface of the sea takes a white appearance; the tumbling of the sea becomes heavy and shock-like; visibility affected
11	storm	56–65	103–117	exceptionally high waves (small and medium-sized ships might be for a time lost to view behind the waves); the sea is completely covered with long white patches of foam lying along the direction of the wind; everywhere the edges of the wave crests are blown into froth; visibility affected
12–17	hurricane	above 65	above 117	the air is filled with foam and spray; sea completely white with driving spray; visibility very seriously affected

When considering the descriptions, it must be remembered that the size of the waves depends not only on the strength of the wind but also on its duration and its fetch; that is, the length of its path over the sea. Moreover, the waves are liable to be modified considerably by tidal currents; the sea is affected by precipitation (rainfall, snow, hail); and at moderate and high latitudes, at the same wind speed at observation level, the motion of the sea is higher in an air mass colder than the water than it is in one that is warmer.

Wave characteristics and motion

The theory of waves starts with the concept of simple waves, those forming a strictly periodic pattern with one wavelength and one wave period and propagating in one direction; but real waves always have a more irregular appearance. They may theoretically be described as composite waves, in which a whole spectrum of wavelengths, or periods, is present and which have more or less diverging directions of propagation. In reporting observed wave heights and periods (or lengths) or in forecasting them, one height or one period is mentioned as the height or period, however, and some agreement is needed in order to guarantee uniformity of meaning. The height of simple waves means the elevation difference between the top of a crest and the bottom of a trough. The significant height, a

characteristic height of irregular waves, is by convention the average of the highest one-third of the observed wave heights. Period, or wavelength, can be determined from the average of a number of observed time intervals between the passing of successive well-developed wave crests over a certain point, or of observed distances between them.

Wave period and wavelength are coupled by a simple relationship: wavelength equals wave period times wave speed, or $L = TC$, when L is wavelength, T is wave period, and C is wave speed.

The wave speed of surface gravity waves depends on the depth of water and on the wavelength, or period; the speed increases with increasing depth and increasing wavelength, or period. If the water is sufficiently deep, then the wave speed equals the wave period times the acceleration caused by gravity, divided by two pi, or the square of the wave speed equals the wavelength times the acceleration caused by gravity, divided by two pi; these relations may be expressed as:

$$C = gT/2\pi \text{ or } C^2 = gL/2\pi,$$

in which C is wave speed, g is the acceleration caused by gravity (9.8 square metres per second), and T and L are again wave period and length. In this case, the depth does not appear explicitly in the formula. Here, deep and shallow have only a relative meaning, denoting the ratio of depth to wavelength. In practice, for the water to be called deep and the above formula applied, it is sufficient if the depth is more than half the wavelength. A few examples are listed below, giving the period in seconds, the wavelength in metres, and wave speed in metres per second:

period T (seconds)	1	2	4	8	16
wavelength L (m)	1.56	6.2	25.0	100	400
wave speed in deep water (m/sec)	1.56	3.1	6.2	12.5	25.0

For waves in very shallow water, another simple formula holds, one in which wavelength and period do not appear explicitly. It is: wave speed squared equals the depth times the acceleration caused by gravity, or:

$$C^2 = gD,$$

in which D means depth. In practice, this formula may be applied if the depth is less than $\frac{1}{25}$ of the wavelength or if L is more than 25 times the depth. Instead of denoting this expression as one for waves in very shallow water, it often is considered to be for long waves, both expressions meaning the same thing.

Wave trains and group velocity

Waves often appear in groups as the result of interference of wave trains of slightly differing wavelengths. A wave group as a whole has a group speed that generally is less than the speed of propagation of the individual waves; the two speeds are equal only when the waves are in very shallow water. For deep-water waves, the group velocity (V) is half the wave speed (C). In intermediate cases, V has a value from 0.5 C to C. In the physical sense, group velocity is the velocity of propagation of wave energy. From the dynamics of the waves, it follows that the wave energy per unit area of the sea surface is proportional to the square of the wave height, except for the very last stage of waves running into shallow water, shortly before they become breakers.

The height of wind waves increases with increasing wind speed and with increasing duration and fetch of the wind. Together with height, the dominant wavelength also increases. Finally, however, the waves reach a state of saturation, because they attain the maximum significant height to which the wind can raise them, even if duration and fetch are unlimited. For instance, winds of five metres (16 feet) per second, 15 metres (50 feet) per second, and 25 metres (80 feet) per second may raise waves with significant heights up to 0.5 metre (1.6 feet), 4.5 metres (15 feet), and 12.5 metres (41 feet), respectively, with corresponding wavelengths of 16 metres (53 feet), 140 metres (460 feet), and 400 metres (1,300 feet), respectively.

After becoming swell, the waves may travel thousands of miles over the ocean, particularly if the swell is from the great storms of moderate and high latitudes, whence it easily may travel into the subtropical and equatorial zones, and the swell of the trade winds, which runs into the equatorial calms. In travelling, the swell waves gradually become lower; energy is lost by internal friction and air resistance and by energy dissipation because of some divergence of the directions of propagation (fanning out). With respect to the energy loss, there is a selective damping of the composite waves, the shorter waves of the wave mixture suffering a stronger damping over a given distance than the longer ones. As a consequence, the dominant wavelength of the spectrum shifts toward the greater wavelengths. Therefore, an old swell must always be a long swell.

When waves run into shallow water, their speed of propagation and wavelength decrease, but the period remains the same. Eventually, the group velocity, the velocity of energy propagation, also decreases, and this decrease causes the height to increase. The latter effect may, however, be affected by refraction of the waves, a swerving of the wave crests toward the depth lines and a corresponding deviation of the direction of propagation. Refraction may cause a convergence or divergence of the energy stream and result in a raising or lowering of the waves, especially over nearshore elevations or depressions of the sea bottom.

In the final stage, the shape of the waves changes, and the crests become narrower and steeper until, finally, the waves become breakers (surf). Generally, this occurs where the depth is 1.3 times the wave height.

Wind surges. Running wind surges are long waves caused by a piling up of the water over a large area through the action of a travelling wind or pressure field. Examples include the surge in front of a travelling storm cyclone, particularly the devastating hurricane surge caused by a tropical cyclone, and the surge occasionally caused by a wind convergence line such as a travelling front with a sharp wind shift.

Generation of tsunamis

Waves of seismic origin. A tsunami (Japanese *tsu*, "harbour," and *nami*, "sea") is a very long wave of seismic origin that is caused by a submarine or coastal earthquake, landslide, or volcanic eruption. Such a wave may have a length of hundreds of miles and a period of the order of a quarter of an hour. It travels across the ocean at a tremendous speed; to a depth of 4,000 metres (13,000 feet), for instance, the corresponding wave speed is about 200 metres per second, or 720 kilometres per hour (450 miles per hour). Tsunamis have caused enormous destruction of life and property, because they ultimately pile up in coastal waters at places thousands of miles away from their point of origin, particularly in the Pacific Ocean.

A freestanding wave may arise in an enclosed or nearly enclosed basin as a free swinging of the whole water mass. Such a standing wave is also called a seiche, after the name given to the oscillating movements of the water of Lake Geneva, where this phenomenon first was studied seriously. The period of oscillation is independent of the force that first brought the water mass out of equilibrium (and that is supposed to have ceased after that) but depends only on the dimensions of the enclosing basin and on the direction in which the water mass is swinging. Assuming a simple rectangular basin of constant depth and supposing the most simple lengthwise oscillation, the period of oscillation (T) is equal to two times the length of the basin divided by the wave speed computed from the shallow-water formula above. This relationship may be written: $T = L/C$, in which L equals two times the length of the basin and C is the wavespeed found from the formula, using the known depth of the basin. Besides this fundamental tone (or response to stimuli), the water mass may also swing according to an overtone, showing one or more nodal lines across the basin.

The water in an open bay or marginal sea may also perform such a free oscillation as a standing wave, the difference being that in an open bay the greatest horizontal displacements are not in the middle of the bay but at the mouth. For the fundamental period of oscillation, the

formula given above is used with a wavelength equal to four times the length (from the mouth to the closed end) of the bay. In practice, of course, it is more difficult than that, because the form of a bay or marginal sea is irregular, and the depth differs from place to place. The North Sea has a period of lengthwise swinging of about 36 hours. The cause of such free oscillations may be a temporary wind or pressure field, which brought the sea surface out of its horizontal position and which afterward ceased to act more or less abruptly, leaving the water mass out of equilibrium.

Internal waves. Waves that have their maximum energy at some depth rather than at the surface are called internal waves. They are carried by an interface, or layer, separating lighter water above from heavier water below; the difference in density is caused either by a difference in salinity or by a difference in temperature. Internal waves manifest themselves by a regular rising and sinking of the water layers around which they centre, whereas the height of the sea surface is hardly affected at all. Because the restoring force, excited by the internal deformation of the water layers of equal density, is much smaller than in the case of surface waves, internal waves are much slower than the latter. Given the same wavelength, the period is much longer (the movements of the water particles being much more sluggish), and the speed of propagation is much smaller; the formulas for the speed of surface waves include the acceleration of gravity (g), but those for internal waves include the gravity factor times the difference between the densities of the upper and the lower water layer divided by their sum.

Role of density differences

The cause of internal waves may lie in the action of tidal forces (the period then equalling the tidal period) or in the action of a wind or pressure fluctuation. Sometimes, a ship may cause internal waves (dead water) if there is a shallow, brackish upper layer.

Tides of the sea. The tides may be considered as a kind of forced waves, partially running waves, partially standing waves. They are manifested by vertical movements of the sea surface (the height maximum and minimum are called high water [HW] and low water [LW]) and in alternating or rotating horizontal movements of the water, the tidal currents. The words ebb and flow or flood are used to designate the falling tide and the rising tide or the tidal currents accompanying the falling tide and the rising tide, respectively.

The forces that cause the tides are called the tide-generating forces. A tide-generating force is the resultant force of the attracting force of the moon or the Sun and the force of inertia (centrifugal force) that results from the orbital movement of the Earth around the common centre of gravity of the Earth–moon or Earth–Sun system. Details of this mechanism are treated in the article TIDES.

Tide-generating forces

Considering the Earth–moon system, at any time the tide-generating force is directed vertically upward at the two places on the Earth where the moon is in the vertical (on the same and on the opposite side of the Earth); it is directed vertically downward at all places (forming a circle) where the moon is in the horizon at that moment; at all other places, the tide-generating force also has a horizontal component. Because this pattern of forces is coupled to the position of the moon with respect to the Earth and because for any place on the Earth's surface the relative position of the moon with respect to that place has, on the average, a periodicity of 24 hours 50 minutes, the tide-generating force felt at any place has that same periodicity. When the moon is in the plane of the Equator, this force runs through two identical cycles within this time interval, because of the symmetry of the global pattern of forces described above. Consequently, the tidal period is 12 hours 25 minutes in this case; it is the period of the semidiurnal lunar tide. The fact that the moon is alternately to the north and to the south of the Equator causes an inequality of the two successive cycles within the time interval of 24 hours 50 minutes. The effect of this inequality is formally described as the superposition of a partial tide called the diurnal lunar tide, with the period of 24 hours 50 minutes, on the semidiurnal lunar tide.

In the same manner, the Sun causes a semidiurnal solar tide, with a 12-hour period, and a diurnal solar tide, with a 24-hour period. In a complete description of the local variations of the tidal forces, still other partial tides play a role, because of further inequalities in the orbital motions of the moon and the Earth.

The interference of the solar-tidal forces with the lunar-tidal forces (the lunar forces are about 2.2 times as strong) causes the regular variation of the tidal range between spring tide, when it has its maximum, and neap tide, when it has its minimum.

Although the tide-generating forces are very small in comparison with the force of gravity of the Earth (the lunar tidal force at its maximum being only 1.14×10^{-7} times the force of gravity), their effects upon the sea are considerable, especially because of their horizontal component. Because the Earth is not surrounded by an uninterrupted envelope of water but shows a very irregular alternation of sea and land, the mechanism of the response of the oceans and seas to the tidal forces is extremely complex, a further complication being brought about by the deflecting force of the Earth's rotation (Coriolis force).

In the Southern Ocean, the tide is propagated east–west around the world as a running wave, but it manifests itself between the continents—for instance, in the Atlantic Ocean—partly as a north-going running wave and partly as an east–west swinging standing wave; both wave movements are modified by the action of the Coriolis force. In gulfs and bays, the tide is generated by the tide of the open ocean as a forced standing wave to which the Coriolis force adds a swinging cross component, and both oscillations together result in a rotating tide. In such nearly enclosed seas as the Mediterranean, the Black, and the Baltic, a standing wave is generated by the direct action of the local tidal forces.

In these seas, the tidal range of sea level is only on the order of centimetres (one inch equals 2.5 centimetres). In the open ocean, it generally is on the order of tens of centimetres. In bays and adjacent seas, however, the tidal range may be much greater, because the shape of a bay or adjacent sea may favour the development of the tide inside; in particular, there may be a resonance (large co-oscillation) of the basin concerned with the tide. The largest known tides occur in the Bay of Fundy, where spring tidal ranges up to 15 metres (50 feet) have been measured.

OCEAN CURRENTS

Causes of ocean currents

Two primary causes of regular, nontidal currents in the sea may be distinguished, namely, wind and gravity. Winds act externally at the surface, and gravity acts internally, through pressure differences.

In the case of a wind-driven current system, the current may be the direct result of the wind locally, or it may be controlled by the wind elsewhere. The latter, for instance, may occur if the current is the returning part of a closed circulation of which one part only is directly driven by the wind. Examples are the North Equatorial Current and the South Equatorial Current, which flow east–west and are directly driven by the trade winds (on the north and south sides of the Equator), and the Equatorial Countercurrent, which runs from west to east and brings part of the water of those currents back though the belt of equatorial calms.

For the generation of gravity currents, pressure differences in a horizontal plane in the sea may be brought about by a slope of the sea surface, by juxtaposition of waters of different specific gravity, or, more often, by both. Combined forces operate in the Strait of Gibraltar, where the saltier (heavier) water of the Mediterranean Sea flows out in the lower layers, and the somewhat less saline (lighter) water of the Atlantic Ocean flows in in the upper layer. The same occurs at the mouth of the Red Sea, where it communicates with the Indian Ocean. Similar currents, called density currents (*q.v.*), flow through the entrances of the Baltic Sea and the Black Sea. There, however, the outgoing current is the upper one, because the waters of these seas have low salinities and are there-

fore lighter than the waters flowing in from the outside, which form the undercurrent.

Wind-driven-current patterns. In each of the three oceans, the general pattern of the great ocean currents is controlled largely by the systems of prevailing winds and is broadly as follows: to both sides of the Equator flow the North and South Equatorial currents, driven by the trade winds, an Equatorial Countercurrent flowing between them. On the west side of the ocean, the two equatorial currents bend poleward (except in the North Indian Ocean) and merge into currents that feed the broad west–east travelling currents in moderate and higher latitudes under the westerly winds prevailing there, and these eastbound currents, in their turn, feed currents that on the east side of the ocean flow toward the Equator and in low latitudes merge into the equatorial currents, thus closing the circuit.

In the North Atlantic Ocean, the northerly current on the west side is the Gulf Stream, coming from the Gulf of Mexico, into which part of the water of the North Equatorial Current has flowed. Much of the water carried by the Gulf Stream does not join the corresponding eastgoing current but flows in a northeasterly direction toward the coasts of northwestern Europe, finally entering into the Arctic Sea to the north of Norway and near Spitsbergen. As compensating currents, on the west side of the northern part of the Atlantic Ocean, the East Greenland Current and the Baffin Island-Labrador current carry polar waters to the south.

In the Pacific Ocean, a warm current, analogous to the Gulf Stream, is called Kuro-shio, or Japan Current. The cold countercurrent on the northwest side of it is called Oya-shio.

In the North Indian Ocean, the North Equatorial Current is present only during part of the year. In summer it is replaced by the Monsoon Current, driven by the southwest monsoons (*q.v.*).

A peculiar phenomenon in the equatorial belts of the oceans is the Equatorial Undercurrent, a subsurface current running at some depth, down to about 300 metres (1,000 feet) below the surface, from west to east.

In the Southern Ocean, the easterly currents of the three oceans merge into one broad current, encircling the whole of the Southern Hemisphere, the great West Wind Drift. Lastly, there is a narrow stream from east to west along the edges of Antarctica.

Current-generating forces. The dynamics of the currents of the sea are governed by the following forces: the pressure-gradient forces (vertical and horizontal), frictional forces, gravity, and the Coriolis force. The force of gravity is, on the average, balanced by the vertical pressure-gradient force. Thus, the three remaining forces, acting horizontally, are: the horizontal pressure-gradient force (G), the frictional force (F), and the horizontal Coriolis force (C). In general, dynamic systems in the ocean tend toward an approximate equilibrium of forces. In steady water movements, therefore, the three forces, G, F, and C, may be supposed to balance each other. Of these forces, the Coriolis force is always present wherever there is a current, because C is proportional to the velocity. Moreover, because it is proportional to the sine of the geographic latitude, it vanishes only at the Equator. In latitudes of about 45° N or S, for a velocity of one metre per second, the Coriolis force amounts to 0.0001 square metre per second per unit mass. It acts at right angles with the direction of motion, pointing to the right on the Northern Hemisphere and to the left on the Southern Hemisphere.

Effect of the Coriolis force

With respect to the other two forces, two special cases deserve attention: first, that in which C and G balance, friction being negligible; and, second, that in which C and F balance, pressure gradients being negligible.

In the first case, the current is called a gradient, or geostrophic, current, which results from a balance between the horizontal Coriolis and pressure-gradient forces; it is comparable to the geostrophic wind in meteorology. Because of the supposed equilibrium of forces, it runs at right angles with the horizontal pressure gradient —the higher pressures are on the right-hand side of the current if it is on the Northern Hemisphere and on the left-hand side if it is on the Southern Hemisphere. Near the surface, a horizontal pressure gradient in the water means a tilt of the sea surface; the surface slopes up to the right of the current in the Northern Hemisphere. At about 45° N or S, for a velocity of one metre per second, this slope amounts to 1:100,000; that is, one metre per hundred kilometres. In deeper layers, the horizontal pressure gradient corresponds in the same way with the slope of an isobaric surface (surface of equal pressure). A simple formula makes it possible to calculate the gradient current at any depth from the slope of the isobaric surface at that level. Assuming that the water at very great depths is nearly at rest, so that the isobaric surfaces there are about horizontal, it is possible to calculate the slopes of isobaric surfaces at higher levels from known values of the density and thus to calculate the gradient current. This method assumes that the current is, on the average, influenced to only a minor extent by the action of the wind or bottom friction, because wind and bottom friction are the main causes of internal friction between water layers.

In the second special case, drift current, wind stress is the main acting force: horizontal pressure gradients are supposed to be negligible, and the Coriolis force is balanced by the force of internal friction that accompanies the wind-made drift of the water. Because of the Coriolis force, the direction of the current deviates to the right of the wind direction in the Northern Hemisphere. At the surface, the angle of deviation is about 40°, but it increases with increasing depth, and the current velocity becomes smaller and smaller, virtually vanishing at some depth that is roughly proportional to the wind velocity. With a wind of ten metres per second, at moderate latitudes, this depth—called depth of friction—is about 90 metres (300 feet). The velocity at the surface amounts to about 1.5 percent of the wind velocity, at moderate latitudes, because depth of friction and surface velocity both decrease with increasing latitude.

This case of a pure drift current is rather theoretical. In reality, wind-driven currents usually are accompanied by a slope of the sea surface. This condition obtains for a wind blowing parallel to a coast. The Coriolis force causes the water to tend to move away from or toward the coast, thus creating a slope of the sea surface that may partly balance the Coriolis force. This condition is of particular importance in subtropical latitudes on the west side of the continents, where an upwelling of water from deeper layers is brought about in this way. The upwelling compensates for the surface water that flows away from the coast. Such upwelling of rather cold water has a profound influence on the climate of these coastal areas. Moreover, the upwelling water is rich in nutrients, so that there is abundant life in the zones in which upwelling occurs. Of course, upwelling is not confined to the regions just mentioned.

Deep-sea circulation. Water movements in the cold realms at great depths form part of a global deep-sea circulation, treated earlier in the sections on chemical and physical properties of seawater, particularly with respect to oxygen content and temperature. The water masses involved in this deep circulation come from source regions where waters sink from the surface because of their excessive density. The two prominent source regions of the deep-sea water masses are: (1) The Weddell Sea bordering the Antarctic continent, where the heaviest kind of seawater of all the oceans flows down to form the Antarctic Bottom Water and spreads northward over the beds of the three oceans, well into the Northern Hemisphere; and (2) the Irminger Sea between Iceland and Greenland and the area between south Greenland and Labrador, where cold and heavy water masses sink in winter to form the Atlantic Deep Water, which presses on southward, filling a large portion of the Atlantic deep sea (where it is joined by highly saline Mediterranean water), far into the Southern Hemisphere on top of the Antarctic Bottom Water.

Flow of water from the Arctic and Antarctic

These two water masses together form most of the deep-sea water of all the oceans, spreading eastward from

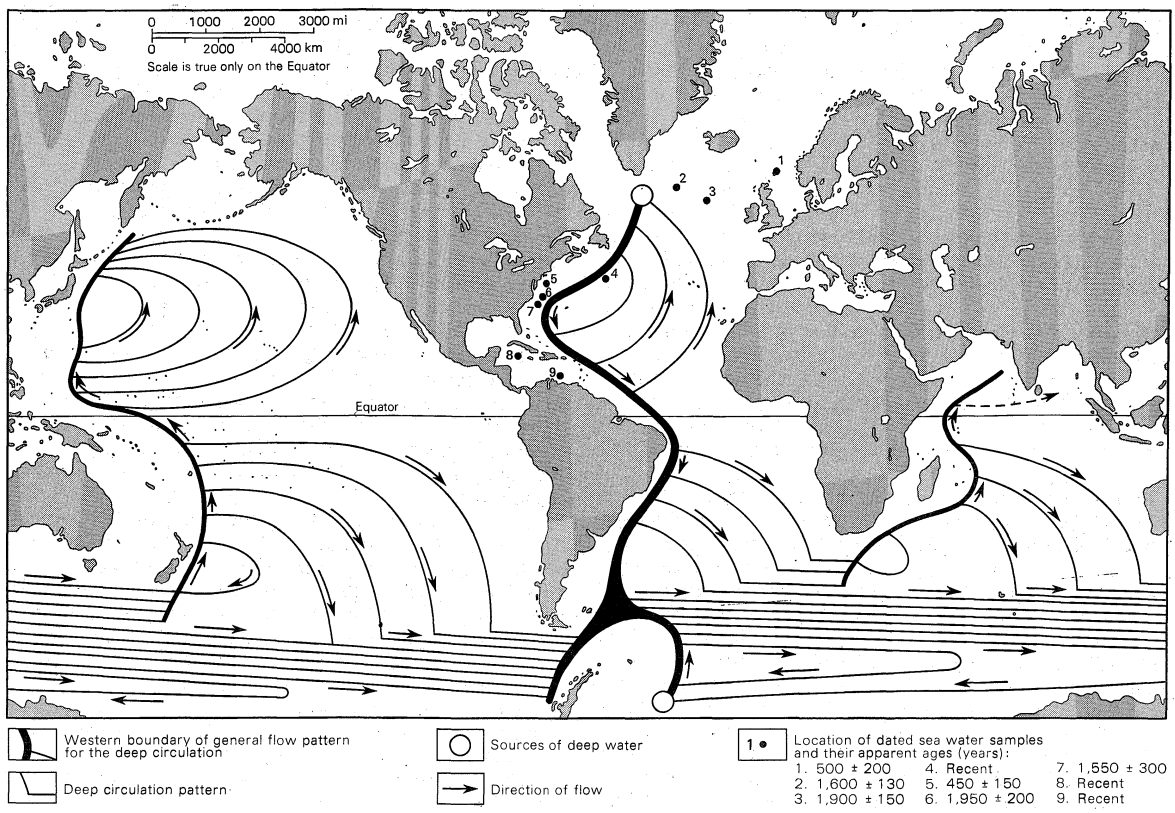

Figure 7: Deep-sea circulation pattern of the world's oceans.

the South Atlantic into the Indian Ocean and further on into the Pacific Ocean. Figure 7 illustrates this horizontal spreading. (P.Gr.)

III. Life in the open sea

THE SEA AS A BIOLOGICAL ENVIRONMENT

Despite its many moods and its ceaseless activity, the sea is the most constant environment of earth. This most equable habitat for living things is characterized by very narrow ranges of change in chemical and physical properties, in seasonal and horizontal fluctuations, in temperature (from about 0° to 30° C; 32° to 86° F), and in salinity. Although vertical pressure differences are significant, they are relatively constant at any particular depth.

Because of mixing processes, the relatively unstratified, upper lighted (euphotic) zone is one of vertical and horizontal constancy. The relative constancy of the euphotic zone is due to surface mixing processes that favour oxygenation of the water, maximum levels of photosynthesis, and thereby utilization of the existing nutrients. It is this zone of active plant–animal growth that determines oceanic productivity. From it, by a downward rain of organic material, arises the enormous stores of nutrients in the deep, dark layers of the open ocean.

In the deep strata, with high concentrations of carbon dioxide and relatively low concentrations of oxygen, vertical stratification occurs, but horizontal constancy remains unbroken. In the lighted strata, plants are responsible for seasonal variations in concentrations of inorganic salts, some of which, such as phosphorus, are physiologically important, and even slight departures from constancy are significant.

The open ocean possesses relative uniformity of kinds and numbers of planktonic organisms, especially of the smallest planktonic forms, nannoplankton, which do not vary appreciably, because they utilize dissolved organic substances available uniformly in the euphotic layer. The tendency toward biological constancy lessens for larger organisms that undergo periodic vertical or horizontal migrations in response to light and current.

It is reasonable to speculate that during early geologic time the lifeless waters encompassing the continents fluctuated in mineral content, augmented by periodic runoff from land areas, and eventually the salt content and surrounding physical factors reached levels favourable to the development of life. The first photosynthetic organisms were probably bacteria that could oxidize sulfides anaerobically (in the absence of free oxygen) without the production of free oxygen. (The ability to use hydrogen sulfide as a hydrogen donor permits photosynthesis with 1/10 the light energy required by oxygen-producing photosynthesis.) This circumstance seemingly had the advantage of increasing the depth zone for primitive life in the early ocean environment. The presence of blue-green algae, for example, in Precambrian sediments indicates that microscopic algae were well developed in relatively deep, upper strata.

First organisms

For higher marine animals, a water environment containing salts in such concentration that no effective movement of water (*i.e.*, no osmosis) takes place between it and the organism is the most favourable medium. This similarity has led to the supposition that the sea was already saline when life arose in the sea. Evidence that the sea is the original environment of animal life is based on the general composition of present-day faunas, similarity in chemical composition of body fluids and seawater, life histories, and paleontological relationships. Considering all animals, marine groups predominate. The role of the marine environment was to develop and maintain a wide diversity of lower forms of life. In contrast, the terrestrial environment, with more rigorous habitats, has produced less diversity of forms but a higher type of complexity.

During geological time, the runoff from land areas gradually produced increasing salt concentrations until the present levels of salinity were reached. It is not surprising then that as animal life developed in great structural complexity during geological time, providing the oceans with jellyfish and whales at opposite extremes of size, the fluid volume and fluid content of ocean life should show corresponding variability. The water content of animals varies generally between 70 percent and 85 percent —in jellyfish it is as high as 96 percent. Because their cell membranes are selectively permeable, marine animals are

able to tolerate varying changes in salinity encountered in changing environments. Most marine invertebrates are as "salty" as their sea environment. The plasma membrane of marine protozoa is permeable to water, but, in higher forms, the membrane possesses varying tolerances to salt concentration. The ability to control their fluid volume is possessed in varying degrees by marine animals such as worms. Some marine vertebrates, such as hagfish, alter the concentration of their body fluids toward that of their surroundings by adjusting their blood chloride. Teleost fish regulate the salt concentration of their blood by eliminating excess salt through the gills or by resisting water loss through the kidneys. The salt content (and osmotic pressure) of marine mammals is slightly higher than that of terrestrial mammals but still well below that of seawater. In general, the body fluid of marine forms such as seals and killer whales has a relatively low salt content (about 1 percent sodium chloride), whereas that of marine invertebrates is practically equivalent to that of seawater.

Habitat zonation

Life in the open sea occupies the vast extent of the sea bottom (benthic zone) and overlying water (pelagic zone). Assuming that 200 metres (660 feet) below the surface is the upper limit of the habitat of the deep-sea fauna, the surface of the deep-sea region lies under about 92 percent of the total surface of the sea, equivalent to about two-thirds of the total surface of the globe. This three-dimensional region of faint light or complete darkness, with its strange creatures, possesses monotonous uniformity and stands apart from other biological realms on earth.

The lighted, shallow, populated pelagic zone extends upward and oceanward from the upper boundary of the continental slope. The dark, deep, sparsely populated pelagic zone extends outward and upward from the continental slope and the deep-sea floor and abyssal region (see Figure 2). The corresponding zones of bottom-dwelling, or benthic, organisms are the archibenthic (800–1,100 metres; 2,600–3,600 feet) and abyssobenthic (below 1,100 metres) zones. The latter zone is sparsely populated and contains some of the most unusual animals known.

CHARACTER OF OCEANIC POPULATIONS

Organisms of upper layers of the open sea (Figure 8) are exposed to the full daylight spectrum. Relatively small numbers of organisms inhabit the offshore oceanic waters. The more conspicuous components of the surface population are the Portuguese man-of-war (*Physalia*), the by-the-wind sailor (*Velella*), the purple storm snail (*Janthina*), and a nudibranch mollusk, *Gaucus*.

The transient animal life of the surface layers includes many fishes. The relatively permanent surface fauna, apart from such large forms as cetaceans (whales), turtles, and sea snakes, are of two main types: animals adapted entirely to a surface existence partly in air and partly in water and animals that inhabit the immediately subsurface layers. The strictly surface forms usually have floats of various types; some are definite organs of buoyancy, while others are formed of bubbles or trapped air. The only known open-ocean insects are water striders that live on the surface film, buoyed by air trapped in the hairs on the body.

The subsurface layers of the lighted open sea contain a great variety of the free-floating, or planktonic, forms, including many kinds of animal larvae. Apart from the blue coloration that is a most striking characteristic of plankton of the open ocean, there are few signs of adaptive characteristics special to this environment. The minute copepods of the family Pontellidae are capable of jumping out of the water to distances of about six inches (15.25 centimetres). The paper nautilus (*Argonauta*) is able to ride on the upper surface of the bells of certain jellyfish.

Seaweed buoyed by bladders is widespread in the oceans of the world and carries with it many associated animals that show adaptations of colour and form suitable to the habitat (interestingly, most of these animals are from near the shore, not oceanic).

Plankters such as diatoms and copepods migrate up and down in response to light. Illumination in the upper few metres is too bright for survival of most phytoplankton and zooplankton; hence, this vertical zone of distribution is sparsely populated. The zooplankton of the deeper but still lighted zone in which photosynthesis is active undergo diurnal migrations determined by food and light intensity. Vertical movements of plankton diatoms are related to variations in structure. Increase in spination (the distribution and arrangement of spines) increases the relative surface area and so retards sinking or flotation of the organism when its specific gravity differs from that of the water. Special types of plants adapted to a floating existence have evolved.

In the open sea, the chief grazers are the copepod crustaceans, semimicroscopic in size, that feed mainly on diatoms, dinoflagellates, and other micro-organisms. Protozoans and the larval stages of larger invertebrates also graze upon the phytoplankton. Some fish, such as herring and menhaden, feed on phytoplankton but are mainly coastal forms.

Life in dark open water

Bathypelagic animals inhabit the deep, dark waters of the ocean above the bottom (Figure 8). The deep-sea plankton contains no algae except for a few so-called olive-green cells. At 50 metres (160 feet) or less, from 3,000 to 100,000 plankton forms occur per litre. The number of species in the plankton does not decline with depth as strikingly as its number of individuals. Unusual size characterizes some of the deep-sea plankton forms. Microscopic swimming forms such as crustaceans differ significantly from their relatives of shallow seas in usually being luminous and sometimes blind. Other forms have enlarged eyes and very long appendages that assist in floating.

There is a great diversity of features and forms among the deep-sea fishes. Many of them are quite blind and small, from about 10 to 30 centimetres (four to 12 inches) in length. One of the chief characteristics of this deep zone is food scarcity. Another is the size and extension of locomotory appendages of crustaceans as well as fish. The scarcity of food near the sea bottom results in considerable modification of feeding structures: the great teeth, the enormous jaws, and the uncannily extensible stomachs characteristic of these deep-sea forms.

Organic material in various states of decomposition rains down from above and is consumed by middepth and abyssal detritus feeders. In fact, plant material as such probably never reaches the bottom but goes into solution to be reclaimed by bacteria and other consuming forms. The previously mentioned olive-green cells have maximum distribution below the euphotic zone and are believed to reclaim significant amounts of dissolved organic matter.

Deep-sea benthic animal life shows special features. The abyssal region extends from 100 to 1,500 metres to the lowest depths. It is a zone of muddy bottom characterized by low temperatures (usually between 1° and 2.5° C; 34° and 37° F) and by food scarcity. The population is sparse. Sessile animals (those that tend to remain in a given locale but that are not necessarily fixed) are characteristic and include sponges, stalked polyps, sea anemones, sea lilies, and rhizopod protozoans. Characteristic forms are the echinoderms, such as the sea urchins, some of which have abnormal body forms. There are giant isopods, 15 to 20 centimetres (six to eight inches) long, with large eyes. Some blind isopods have very long legs and tactile feelers that enable them to move over the muddy ooze and feel for their prey. Deep-sea crabs often have long, slender extremities, sometimes armed with great spikes that keep them from sinking into the ooze.

ADAPTATIONS TO MARINE CONDITIONS

Structural adaptations. Structural adaptations pertain to the rigid conditions of existence at great depths. They relate to acquisition of food, absence of light, stillness of waters, low temperature, and great pressure. The uniformity of these factors is more marked in the deeps than elsewhere in the ocean. The enormous pressure experi-

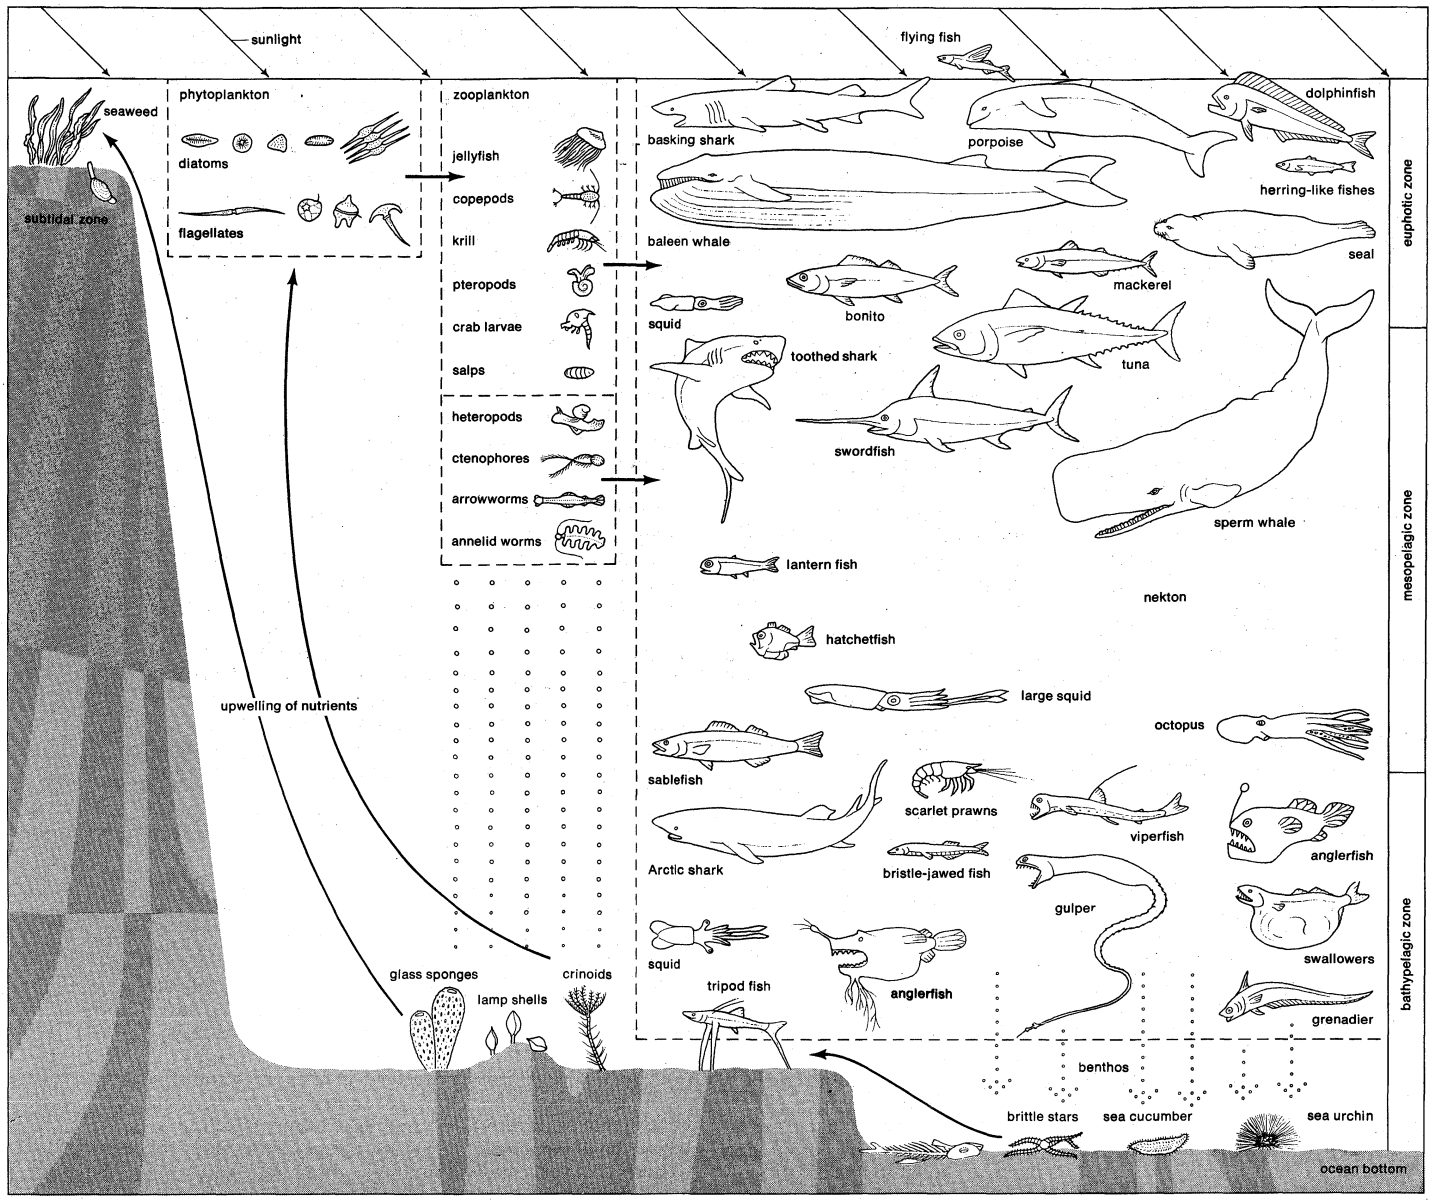

Figure 8: *The food chain in the marine environment.*
All life in the sea is dependent upon sunlight, which is directly converted into food by microscopic plantlike floating organisms (phytoplankton). Phytoplankton in turn is eaten by animal-like plankton (zooplankton). The plankton supports a succession of actively swimming predators (nekton). Organic debris rains down (dots) and provides food for animals at lower depths. Near-shore organisms are supported by land drainage. Coastal upwelling (upward arrows) provides the phytoplankton with nutrients released by decomposition of organic matter on the bottom. (Organisms not drawn to scale.)

enced by deep-sea organisms is not countered by any special development. Because of the balancing of external and internal pressures, water pressure is apparently not felt. Pressure changes can be endured if they are gradual enough to permit adjustment. A swim bladder, the hydrostatic apparatus so widespread in surface-living fishes, enables them to float or, by varying the gas content, to rise or sink in the water. A number of deep-sea fishes possess swim bladders. At a depth of 1,000 metres (3,300 feet), with a pressure of 100 atmospheres, the gas content of the swim bladder is compressed to 1/15 of the volume it would have at a ten-metre (33-foot) depth.

Aids to buoyancy

The most widespread means of reducing specific gravity among pelagic forms is through the absorption of large amounts of water in, for example, connective tissue, thus producing transparent gellike tissue found in cnidarians (coelenterates) snails, annelid worms, and pelagic cephalopods. Certain decapods are so transparent because of such tissue that print may be read through their bodies. Plankton fishes and eel larvae are also watery and transparent.

More effective than the absorption of water is the storage of lighter materials, such as low-salinity water, fat, or even air. The fluid of vacuoles of radiolarians and certain ctenophores has a lower specific gravity than seawater. The accumulation of fat is widely distributed among pelagic animals, thus lowering the general specific gravity. It is present in protozoans, such as radiolarians that contain oil drops, in crustaceans such as cladocerans and copepods, in some mollusks, and in many fishes that store food in the form of fat in their livers and that have oil drops in their eggs.

The most effective buoyancy means is the inclusion of air or other gases in the body. Jellyfish have air sacs filled with gas from a gas-producing gland. Certain cephalopods, such as *Nautilus*, have a shell containing air in chambers. The air sacs of fishes have already been discussed.

The relative immobility of deep water favours special animal developments. Fragility of the skeleton and other structural elements of the body is an example. Occasional development of giant forms—sponges and coelenterates

more than two metres high and sessile tunicates one metre high—are a product of perpetually still water. The deep-sea environment also produces the largest of the sea urchins, crabs, ostracods, isopods, and sea spiders. This unique environment also permits the degeneration of all supporting and strengthening elements of the body. Thus, the shells of unicellular radiolarians, skeletal spicules of sponges and echinoderms, shells of sea urchins, mussels, and snails, and bones of fish are often so thin and scarce that they could not provide support or protection in disturbed waters. Below 2,500 metres, the water is so deficient in calcium that that element dissolves readily in it; hence, it is difficult for animals to build up and maintain calcareous supporting structures.

The common factor of all pelagic animals is their independence of the bottom. They have obvious means, already discussed, for maintaining themselves in open water without sinking. In addition, shelled pelagic protozoans have thinner shells than bottom species. The calcium carbonate content of the shells is higher and the size of the pores is larger in the pelagic forms, thus favouring suspension. The shells of pelagic crustaceans are less calcified than those of their benthic relatives; they also have a higher fat content. Pelagic snails have delicate shells or none at all. The pelagic bivalve mollusk *Planktomya* has uncalcified shells. The skeleton of many pelagic fishes is weak, little calcified, or significantly reduced. Reduction of weight in pelagic copepods is achieved by depositing their eggs singly instead of carrying the egg sacs with them.

Effects of light and oxygen content. Lack of light in oceanic depths has important implications for physiological vitamin balance. For example, vitamin D, needed for building bones of vertebrates, can form and function only in the presence of light. Perhaps the lack of this vitamin accounts for the slightness and delicacies of bones of deep-sea fishes and for the markedly distorted forms of many bottom-living fishes.

Pelagic forms of the deep usually have an adequate supply of oxygen. Because of the low temperatures, these animals have low oxygen requirements. But the benthic occupants of the deep-water sediments require adaptations to meet the problem of low oxygen content. Some bottom dwellers can survive for relatively long periods without oxygen in the liquid environment. Respiratory pigments may provide an oxygen reserve during short periods in oxygen-deficient depths. The shipworm (*Teredo*), which may be found at great depths, makes use of glycogen as an oxygen supply, the glycogen comprising half the dry weight of its tissues. The biology and physiology of inhabitants of such anaerobic sediments are specially adapted to their environment. Besides a biochemical adaptation through the breakdown of glycogen, some animals cease to move. Others have morphological features that enable them to supply aerated water to vital respiratory organs.

Luminescence of fishes

Bioluminescence, or the production of light by organisms, is especially characteristic of the deep-sea population. The bottom of the abyssal swarms with light producers, including coelenterates, echinoderms, and annelid worms. As many as 44 percent of the fishes of depths below 900 metres (3,000 feet) are light producers. The light organs of deep-sea fishes vary in size and form. Their source is functionally metamorphosed skin glands or trapped luminous bacteria. Bioluminescence serves to lure prey, to frighten enemies, to enable the sexes to find each other, and to enable species that move in schools to keep together (see BIOLUMINESCENCE).

Maximum diatom abundance in the open sea is at around 30 metres (100 feet) depth. The daytime concentration of upper zooplankton is at about 125 metres (410 feet), the level varying with location and light intensity. Most of the zooplankton ascend to the surface at night. The echo phenomenon known as the scattering layer is caused by plankton or nekton or both throughout the oceans of the world at from about 400 to 800 metres (1,300 to 2,600 feet). Some of the animal components of this layer undergo diurnal migration of 400 metres or more.

The distribution of euphausid crustaceans has been explained in terms of temperature and salinity. In the Antarctic, there appears to be a regular cycle in which the immatures and adults are carried into lower latitudes by shallow water movements, and the eggs are returned to high latitudes by deeper, southward flowing water movements.

Associations. Mutualism is illustrated by the widespread cleaning of fish surfaces of undesirable parasites by associated organisms in search of food. Many species of fish and shrimps, as well as other organisms, clean parasites from other animals. The host is relieved of irritation while the cleaning species gains food. An example is the Spanish hogfish (*Bodianus rufus*), which swims into the mouth of the barracuda and forages among its teeth for food.

The advantage derived by a commensal (species associated with the host) may be the provision of a resting place, shelter, or transport and often of food. Commensals in somewhat permanent contact with their hosts include a great variety of animals and plants that simply require physical support. Certain barnacles are found only on the backs of whales, where they benefit by being transported great distances. Pilot fish eat leftovers from the sharks, to which they attach by means of a suction disk. Whiting and man-of-war fish shelter among the tentacles of jellyfish. Tiny gobies hide under the gill covers of larger fish.

Fish serve as hosts to a large number of parasites, including protozoans and many kinds of worms. They are also plagued by fish lice or copepods. In many deep-sea angler fish, the male lives as a tiny permanent parasite upon the body of the female and obtains his entire nourishment from her blood supply. These species have solved the problem of finding mates in the inky blackness of the deep sea.

PRODUCTIVITY OF MARINE COMMUNITIES

The productivity of the oceans may be judged by the biological oxygen consumption of the water or by nutrient concentration, including soluble inorganic phosphates, nitrates, nitrites, ammonium salts, and silicates. These minerals are consumed in the upper lighted layers, the inorganic phosphorus and nitrogen are regenerated by bacterial decomposition or by dissolved organic debris, and silicates are reformed by the dissolution of planktonic tests. The return of nutrients to the upper photosynthetic layers is accomplished by upwelling and the action of currents.

Nutrient layers

There are vertical-distributional strata that may differ markedly in nutrient concentrations in any one ocean. Four layers are recognized: (1) the surface, well-mixed, euphotic layer of relatively low concentration that varies little with depth; (2) the layer in which the concentrations increase significantly with depth; (3) the layer of maximum concentration, which has a range of between about 500 and 1,600 metres; and (4) the thick bottom layers of relatively uniform phosphate and nitrate concentrations and in which silicate content increases significantly with depth.

Differences in the nutrient concentrations of the oceans depend largely on the composition of the deep water masses at their origin and upon subsequent changes induced by circulation and biological processes. Meaningful comparisons of oceans are thus difficult to make. Available data for the Indian Ocean suggest annual biological oxygen-consumption levels of around 0.45 millilitre of oxygen per litre of seawater in the upper 400 metres (1,300 feet) in the Antarctic shelf area and corresponding levels in the equatorial region of about 1.5 millilitres per litre. The North Indian bottom water levels below 2,000 metres (6,600 feet) average about 0.04 millilitre per litre, and at depths between 600 and 1,200 metres (2,000 and 4,000 feet) biological oxygen consumption levels have been found to range from 1.5 to 2.0 millilitres per litre.

The standing crop, or abundance, of zooplankton in the Antarctic waters in summer has been found to be about ten times greater than that in the tropical Atlantic waters.

At low temperatures, a larger total number of organisms can be supported on the same amount of food; and, in colder waters, nutrients may be supplied more rapidly in relation to their use. In tropical waters with great upwelling of nutrients from the bottom layers, a large standing crop of plankton exists and can support a productive food chain.

Probably the total marine biomass is far greater than the combined biomass of land and freshwater. Standing-crop data are commonly reported as milligrams of carbon (C) per cubic millimetre (or other unit of volume). The range is commonly ten to 1,000 milligrams of carbon per cubic metre. Values are usually derived from measurement of phytoplankton pigments, especially chlorophyll *a*. Values for open-ocean areas may range around five to 150 milligrams of carbon per cubic metre.

Distribution of the yield

The entire oceanic productivity falls in the range 1.6 to 15.5×10^{10} tons of carbon per year, compared to 1.9×10^{10} tons for the land. About 58×10^6 tons of fish and shellfish are produced annually by the oceans, an amount believed to represent only about 0.03 percent of the total amount of organic material estimated to be produced annually in the sea. Most of the fishery yield comes from waters over the continental shelves and within the 200-metre depth range where nutrient concentrations are high.

This productive area represents only about 3 percent of the total ocean surface. The deep, open-ocean areas are comparable to continental deserts. The reduction in biomass from shallow coastal waters to oceanic depths is about 10^6 for a benthos (organism living on or near the bottom); and for the plankton it approaches 10^4. Undoubtedly, this very low rate is associated with and indeed reflects the very small amount of detritus and other food material reaching the bottom at great depths. The low temperatures of the ocean deeps reduces respiratory rates and growth rates. Maintenance demands in terms of food supply are correspondingly low. In summary, the pelagic and benthic zones of the deep open ocean are sparsely populated and the least productive of all oceanic areas.

Instances of productivity variations among the Atlantic, Pacific, Indian, and Arctic oceans are associated with latitudinal temperature differences and upwelling of deep water rich in nutrients. The maximum–minimum variations in standing crop of zooplankton during the year at a particular station in the open ocean may amount to a factor of 2 or 3. With approach to continental regions, the productivity of the water is greater, and the seasonal variations in volume of dominant zooplankton forms is much greater, perhaps seven or eight times richer. Temperate areas of the Atlantic are much richer in macroplankton numbers than the sparsely populated waters of the Sargasso Sea, which are about four times less populated than continental-slope areas. The standing crop of zooplankton in cold northern waters is sometimes over eight times that of tropical waters, and there is believed to be a possible tenfold to twentyfold increase in zooplankton from the winter minimum to the late summer maximum. (C.N.)

IV. Economic aspects of oceans and seas

The sea is generally accepted by scientists as the place where life began on earth. Without the sea, life as it is known today could not exist. Among other functions, it acts as a great heat reservoir, levelling the temperature extremes that would otherwise prevail over the earth and expand the desert areas. The oceans provide the least expensive form of transportation known to man, and the margins of the sea serve as one of his major sites of recreation. The sea is a major source of food and a dumping ground for many wastes. And the sea is a major potential source of protein, minerals, and power, all of which are required in ever-increasing quantities by all industrialized societies.

In this section, the principal economic aspects of the sea —both realized and potential—in the general areas of transport and communications, food and water, energy resources, and waste disposal are dealt with.

TRANSPORT AND COMMUNICATIONS

From the beginning of recorded history, man has used the sea as a means of transport, first for himself, and then as a means of distributing products throughout the world. The bulk of the tonnage of products transported throughout the world today is moved in ocean vessels. The size of these vessels ranges from small boats capable of carrying a few tons to bulk carriers capable of transporting almost 500,000 tons of oil. The cost of transporting goods on the ocean depends on the product, the form of shipment, and the type of vessel. Probably the cheapest form of transportation known to man is that of the great oil carriers in which a ton of oil may be shipped for an average cost of hundredths of a cent per ton mile. This cost is about 100 times cheaper than shipping such material on land, if the use of pipelines is excluded. As the per capita consumption of materials increases, the outlook for marine transportation is one of ever-increasing tonnages and size of carrying vessels, not only in conventional vessels but also in ground-effect vessels (already in commercial operation in Europe) and in bulk-carrying submarines to pass beneath the polar ice cap.

Since the laying of the trans-Atlantic cable in the 19th century, the oceans have served as a major means of communication between continents and islands. Hundreds of sea-floor cables connect all major centres of world population. With the development of satellite communications, ocean-floor cables as a means of communication may tend to decrease in importance, but they will continue to carry information for many decades to come.

In addition to communications, cable and pipes laid on the ocean floor carry electrical energy, oil, and other commodities in many parts of the world.

FOOD AND WATER

Fishing. Man extracts about 60,000,000 tons of food from the ocean annually by fishing. The food-producing potential of the sea, however, is several hundreds of times the present rate of production. The methods by which man takes food from the sea are inefficient, and the fact that he takes only certain choice species of fish makes fishing in the ocean doubly inefficient. The development of a process to extract protein concentrates from all types of fish might rectify this shortcoming. This protein concentrate could be stored, transported, and utilized very efficiently. It has been estimated that the daily protein requirements for a human being can be produced from fish for less than a penny. It is estimated that, by efficient harvesting of all the fish of the sea, the ocean could produce a sustained yield of about 2,000,000,000 tons of food annually, but it must be noted that such utilization requires, in many instances, a change in human attitudes. In many parts of the world, wheat has proved to be an unacceptable substitute for rice where rice is a customary, integral part of the diet of the inhabitants.

Fish-farming

The Japanese have instituted a substantial program of continental-shelf-development studies to develop the eventual farming of adequate supplies of fish and edible plants there. While Japan has farmed oysters in its oceanic bays for many years, its fishermen have been active around the world's oceans in the manner of those from other countries. With that activity seemingly at a point of diminishing returns, Japan has thus turned to home waters.

Fish need not be fenced in to be farmed. They will stay where the food supply is. By creating an artificial food supply in a given location, fish can be kept where they are wanted. Creating a food supply for the fish need not mean the adding of fish nutrients to the sea but the development of some means of mixing the nutrient-rich bottom layers of water in the ocean with the life-rich upper layers of water. Wherever a natural upwelling of the bottom layers of water occurs, such as off Peru, a tremendous fish population also is found. By encouraging such an upwelling artificially, the fish population could be greatly increased at some more convenient point rather than at the location nature has provided. Developing this technique could probably increase the potential yield of the ocean by ten times or so over the present potential

productive capacity of the ocean. The energy for sustaining this upwelling in the ocean can be produced by several sources; for example, by nuclear reactors on the bottom of the ocean. The development of this or any other means of producing upwelling, however, will probably await economic necessity, if not actual crisis; reactors on the sea floor do not appear to be likely in the immediate future.

Desalination. Although springs of freshwater issuing on the ocean floor are known to occur in water depths as great as 1,000 metres (3,300 feet), these springs never will prove to be a major source of freshwater for the world. Of greater interest is the prospect of desalting seawater itself. Throughout the world, hundreds of desalination units, producing from a few thousand to 10,000,000 or more gallons per day, already are in operation. In general, the desalination plants in production are in areas where the population has outstripped the onshore water supply and where high-cost desalinated water can be afforded. This situation tends to arise in coastal-desert areas, or on densely populated islands because the costs of pumping water through pipelines to interior areas would add prohibitively to the basic cost—at the sites of desalination.

A population usually can afford to pay about ten times as much for water for domestic purposes as it does for agricultural water. Proposals for large-scale nuclear desalination facilities, when constructed, promise to lower the cost of desalinated water to 10 cents to 30 cents per 1,000 gallons—at the desalination sites—a price that all domestic users, most industries, and a few agricultural enterprises can afford.

The bulk of the water produced from seawater is produced by some form of evaporation and condensation. Although the principle of this technique is quite simple, the mechanics of achieving high efficiencies can become quite complicated. Superheated water and multiple evaporation and condensation units, operating at varying temperatures and pressures, are employed in a number of these facilities. The choice of construction materials is quite important, because the brines produced in extracting pure water can be corrosive.

Other processes under consideration as potential economic methods of desalting seawater are freezing, reverse osmosis, ionic processes, electrodialysis, and techniques that change the physical or chemical properties of water itself so that it can be separated from the salts in seawater. In the future, it can be expected that the ocean will become an increasingly important source of freshwater. If production and transportation costs can be lowered sufficiently, it may be possible to produce freshwater to irrigate large areas that border the oceans in many parts of the world.

ENERGY RESOURCES

There are a number of recognized techniques by which energy can be extracted from the sea. The major problem in taking energy resources from the sea is that they tend to be diffused over a large lateral area. A point-concentration energy source is necessary if it is to be exploited economically.

Power generation. Although energy presently is extracted from the tides (*q.v.*) of the ocean, it is unlikely that man will develop a technique for extracting efficiently large amounts of energy from such sources as the waves of the sea. Another potential power source in the ocean, however, is the temperature differential between the surface layers and the lower layers of water; it can be as large as 50 degrees over vertical distances of as little as 300 feet (90 metres) in some areas of the ocean. For many years, the French have experimented with techniques of using this temperature differential to generate electricity. The processes they used were a technical success; but they were not economic, mainly because the plant was located on land, and most of the energy obtained from this system was used in pumping the seawater into and out of the plant.

Utilization of temperature differentials

A group in the United States has developed a system whereby the energy can be extracted by a floating power plant that eliminates the pumping problem. Propane or some similar fluid that will boil at the temperature of the surface layer of water is used, the gaseous phase then being released to a turbogenerator to manufacture the power. After the gas is condensed to a liquid in the cooler, lower layers of water, it is pumped to a surface boiler to be recycled. To be economically practical, the temperature differential should be several tens of degrees, and major markets for the energy created should not be more than a few hundred miles from the power plant. The areas of the ocean in which it would be most efficient to operate such a plant, normally in the tropics, are not near major markets.

Some techniques have been developed in the 1970s for handling liquid hydrogen and liquid oxygen on a large scale. If power generated in remote areas of the ocean were used to reduce seawater to hydrogen and oxygen, these gases might be utilized economically in shoreside thermal power plants. This procedure is, admittedly hypothetical. Followed to its logical though futuristic conclusion, it suggests that oceanic thermal power plants may someday be used to power the artificial upwelling previously mentioned.

A conservative estimate of the energy resources presently available in the ocean is several thousands of years, at present rates of world energy consumption. Even more significant, however, is the fact, that because this thermal differential is generated by the sun, it is renewing itself about 100 times as fast as it could be used to provide the whole world with its present total energy consumption. Man could take from the sea about 200,000,000 megawatt hours of energy each day. The United States presently consumes about 1,000,000 megawatt hours of power each day; thus, the sea can produce power at a rate of about 200 times present consumption rate of the United States. There are, of course, no fuel costs involved in generating power in the sea, and the estimated plant operational and capital costs indicate an overall power-production cost substantially lower than that of power generated from conventional sources.

Petroleum. In the mid-1950s, the production of oil and gas from oceanic areas was negligible. By the 1970s, about 6,000,000 barrels per day, or about 16 percent of the world's production, came from ocean wells; it is predicted that by 1980 the offshore areas will yield about 23,000,000 barrels per day, or about 35 percent of the 1980 world production. About 300 offshore drilling and production rigs were at work in the early 1970s, at more than 60 offshore locations throughout the world drilling, completing, and maintaining offshore oil wells (see PETROLEUM; NATURAL GAS). Estimates have placed the potential offshore oil resources at about 2,000,000,000,000 barrels, or about half of the presently known onshore potential oil sources.

It was once thought that only the continental-shelf areas contained potential petroleum resources, but discoveries of oil deposits in deeper waters of the Gulf of Mexico (about 3,000 to 4,000 metres [10,000 to 13,000 feet]) have led to a revision of this idea. It is now believed that the continental slopes and neighbouring ocean-floor areas will contain large oil deposits, thus enhancing potential petroleum reserves of the ocean bottom.

Minerals. The rivers of the world dump billions of tons of material into the sea each year. Sea-floor springs and volcanic eruptions also add many millions of tons of elements. Even the winds contribute solid materials to the sea in appreciable quantities. Most of these sediments rapidly settle to the sea floor in nearshore areas, in some cases forming potentially valuable placer mineral deposits. The dissolved load of the rivers, however, mixes with seawater and is gradually dispersed over the total oceanic envelope of the earth. Because of the nature of the minerals and their mode of formation, it is convenient to consider the occurrence of sea deposits in several environments, namely marine beaches, seawater, continental shelves, sub-sea-floor consolidated rocks, and the marine sediments (*q.v.*) of the deep-sea floor. Minerals are mined from all of these environments except for the deep-sea-floor area, which was only in the 1970s recog-

nized as a repository for mineral deposits of unbelievable extent and significant economic value.

Placer and nearshore deposits

Minerals that resist the chemical and mechanical processes of erosion in nature and that possess a density greater than that of the earth's common minerals have a tendency to concentrate in gravity deposits known as placers. During the ice ages (about 10,000 to 2,500,000 years ago), sea level was appreciably lowered as the ocean water was transferred to the continental glaciers. Because of the cyclical nature of the ice ages and the intervening warm periods, series of beaches were formed in nearshore areas both above and below present sea level. Also, when sea level was lowered in past ages, the streams that now flow into the sea coursed much further seaward, carrying placer minerals to be deposited in channels that are now submerged. With geophysical-exploration techniques, these channels and beaches can be easily delineated, even though these features are totally covered by Recent or Holocene sediments; that is, those deposited during the last 10,000 years.

Sand and gravel, mined from a number of offshore locations around the world, generally with hydraulic dredges, are used mainly for construction purposes or for beach replenishment or nearshore fills.

Sulfur, which is taken from salt domes in the Gulf of Mexico, is mined by a process in which pressurized hot water is pumped into the sulfur-containing cap of the dome, melting the sulfur and forcing it to the surface. Compressed air is also used to pump sulfur to the surface; the still-molten sulfur is then pumped ashore through insulated pipelines.

Of considerable interest are the sea-floor phosphorite deposits on the coastal shelves of many nations. The phosphorite off California occurs as nodules that vary in shape from flat slabs, several feet across, to small spherical forms termed oölites. The nodules commonly are found as a single layer at the surface of coarse-grained sediments. Phosphorite composition from the California offshore area is surprisingly uniform and contains potentially economically attractive amounts of phosphorus.

Another type of phosphate deposit has been found off the west coast of Mexico, namely, a fine-grained, unconsolidated deposit in about 50 metres (160 feet) of water. It contains as much as 40 percent apatite (common phosphate mineral), and it is speculated that there is as much as 20,000,000,000 tons of recoverable phosphate rock in this deposit.

Deep-sea deposits

Mineral deposits of monumental size and potential economic significance are found in the deep-sea areas of the ocean. Minerals formed in the deep sea are frequently found in high concentrations, because there is relatively little clastic material generated in these areas to dilute the chemical precipitates.

An estimated 10^{16} tons of calcareous oozes, formed by the deposition of calcareous shells and skeletons of planktonic (floating) organisms, cover some 130,000,000 square kilometres (50,000,000 square miles) of the ocean floor. In a few instances, these oozes, which occur within a few hundred miles of most nations bordering the sea, are almost pure calcium carbonate; but they often show a composition similar to that of the limestones used in the manufacture of portland cement.

Covering about 39,000,000 square kilometres (15,000,000 square miles) of the ocean floor in great bands across the northern and southern ends of the Pacific Ocean and across the southern ends of the Indian and Atlantic oceans are other oozes, consisting of the siliceous shells and skeletons of plankton animals and plants. Normally these oozes could serve in most of the applications for which diatomaceous earth is used, for fire and sound insulation, for lightweight concrete formulations, as filters, and as soil conditioners.

An estimated 10^{16} tons of red clay covers about 104,000,000 square kilometres (40,000,000 square miles) of the ocean floor. Although compositional analyses are not particularly exciting, red clay may possess some value as a raw material in the clay-products industries, or it may serve as a source of metals in the future. The average assay for alumina is about 15 percent, but red clays from specific locations have assayed as high as 25 percent alumina; copper contents as high as 0.20 percent also have been found. A few hundredths of a percent of such metals as nickel and cobalt and a percent or so of manganese also are generally present in a micronodular fraction of the clays and probably can be separated and concentrated from the other materials by screening or by some other physical method.

Underlying the hot brines in the Red Sea are basins containing metal-rich sediments that potentially may prove to be one of the great metal-deposit discoveries of all time. It has been estimated that the largest of several such pools, the Atlantis II Deep, contains over $2,000,000,000 worth of copper, zinc, silver, and gold values in relatively high grades. These pools lie in about 2,000 metres (6,600 feet) of water, midway between The Sudan and the Arabian Peninsula. Because of their gel-like nature, pumping these sediments to the surface should prove relatively uncomplicated. These deposits are forming today under present geochemical conditions, and they are similar in character to certain major ore deposits on land.

Manganese nodules

From an economic standpoint, the most interesting oceanic sediments are manganese nodules—small, black to brown, friable lumps found to be widely distributed throughout the three major oceans in the late 19th century by the famous "Challenger" and "Albatross" expeditions.

Many theories have been proposed to account for the formation of manganese nodules, the best probably being that the ocean is saturated at its present state of acidity–alkalinity in iron and manganese. For this reason, these elements precipitate as colloidal particles that gradually increase in size and filter down to the sea floor. Colloids of manganese and iron oxides collect many metals and bear an electrical charge; they tend to agglomerate as nodules at the sea floor rather than settle as particles in the general sediments.

An estimated 1,500,000,000,000 tons of manganese nodules are on the Pacific Ocean floor alone, and they are estimated to be forming at an annual rate of about 10,000,000 tons. Averaging about four centimetres (slightly less than two inches) in diameter (Figure 4) and found in concentrations as high as 100,000 tons per square mile, these manganese nodules contain as much as 2.5 percent copper, 2.0 percent nickel, 0.2 percent cobalt, and 35 percent manganese. In some deposits, the content of cobalt and manganese is as high as 2.5 percent and 50 percent, respectively. Such concentrations would be considered high-grade ores if found on land, and, because of the large horizontal extent of the deposit, they are a potential source of many important industrial metals. Table 7 lists some statistics concerning the amount of reserves and rate of accumulation of various metals in the nodules.

Relatively simple mechanical cable bucket or hydraulic dredges with submerged motors and pumps can effect the mining of the nodules at rates as high as 10,000 to 15,000 tons per day, from depths as great as 6,000 metres (20,000 feet). The estimated costs to mine and process the nodules indicate that copper, nickel, cobalt, and other metals can be economically produced from this source.

WASTE DISPOSAL

One of the least known but most important uses of the sea is as a garbage dump. In the past, the ocean was capable of assimilating the wastes of societies without noticeable pollution effects. Because society is becoming increasingly affluent, however, the dumping of wastes into the ocean is overwhelming the ocean's capacity to digest them. Great marginal areas of the world's oceans have been heavily polluted by many forms of man's wastes, the most obvious of which is sewage. Less apparent forms of pollution are atomic wastes, chemical wastes, trash and oil spills from vessels, oil spills from offshore wells, and heat. Great power plants are generally located along coastlines to reduce the costs involved in cooling their condensers by water-circulation systems. Although the

whole of the ocean never will be affected by the waste heat dissipated by these plants, great environmental effects can be caused in the immediate area of the power-plant outfall. Crude oil from leaking offshore oil wells, from sinking tankers, and from bilges pumped by practically all vessels using oil for power have polluted countless beaches throughout the world. Lead, which is highly toxic to life, is being added to the ocean in great quantities by fallout from internal-combustion exhausts, which enters the earth's atmosphere and ultimately precipitates and reaches the seas. Pollution by mercury, another highly toxic substance, became of great concern around 1970 after analyses revealed its presence in marine and freshwater fish. The effects of dumping these wastes into the ocean are becoming great enough to pollute the entire ocean in some manner. Man can continue to use the ocean as a dumping ground for his wastes, but he must control the form and point of dumping into the ocean so that the pollution effects are reduced to an acceptable level. (J.L.M.)

BIBLIOGRAPHY

Physical and chemical aspects of oceans and seas: There are many works that provide general coverage of oceanography but the interested reader should not fail to consult the classics by M.F. MAURY, *The Physical Geography of the Sea* (1855, reprinted 1963); J. MURRAY and J. HJORT, *The Depths of the Ocean* (1912); and O. KRUMMEL, *Handbuch der Ozeanographie*, 2 vol. (1907–11). Recent texts on oceanography that are both readable and comprehensive include W.S. VON ARX, *An Introduction to Physical Oceanography* (1962); G.L. PICKARD, *Descriptive Physical Oceanography*, 2nd ed. (1966); G. NEUMANN and W.J. PIERSON, JR., *Principles of Physical Oceanography* (1966); P. GROEN, *De wateren der wereldzee*, 2nd ed. (1961; Eng. trans., *The Waters of the Sea*, 1967); and P.K. WEYL, *Oceanography: An Introduction to the Marine Environment* (1970). In this same vein, no list of general texts would be complete without citing H.U. SVERDRUP, M.W. JOHNSON, and R.H. FLEMING, *The Oceans* (1942), which was in many ways the forerunner of all modern general texts; it covers biological aspects as well as the physics and chemistry of the oceans. More mathematical treatment of oceanography is provided by J. PROUDMAN, *Dynamical Oceanography* (1953); A. DEFANT, *Physical Oceanography*, 2 vol. (1961); and the collection of papers on selected topics edited by M.N. HILL, *The Sea: Ideas and Observations on Progress in the Study of the Seas*, 3 vol. (1962–63). Also worthy of mention here is the Soviet oceanographic atlas, Mopckon atrac, 3 vol. (1950–58); and *the Encyclopedia of Oceanography*, ed. by R.W. FAIRBRIDGE (1966), which contains many readable articles on specific water bodies as well as on general oceanographic topics.

Life in the open sea: W.V. CROMBIE, *The Living World of the Sea* (1967), a popular book on marine subjects of wide general interest; K. GUNTHER and K. DECKERT, *Wunderwelt der Tiefsee* (1950; Eng. trans., *Creatures of the Deep Sea*, 1956), a classic work on deep, underwater animals; B.E. and N. MACGINITIE, *Natural History of Marine Animals*, 2nd ed. (1968), an excellent, generalized treatment of the ecology of widely representative marine animals stressing those from the Pacific Coast of North America; R.C. MILLER, *The Sea* (1966), a fascinating book on marine life, habitats, and phenomena written in an exceptional style with a unique format; H.B. MOORE, *Marine Ecology* (1958), authoritative book on marine ecology suitable for use as a college text; J.A. COLIN NICOL, *The Biology of Marine Animals*, 2nd ed. (1967), a scholarly exhaustive treatment of physiological topics and mechanisms pertaining to marine organisms; F.S. RUSSELL and C.M. YONGE, *The Seas*, 3rd ed. (1963), a well-written popular account of life and habitats in the seas of the world, their importance and use to man.

Economic aspects of oceans and seas: J.H. and J.H. ANDERSON, "Power from the Sun by Way of the Sea?" *Power* 109:64–65 (1965), the original paper describing a method of extracting power from the thermal differential of the ocean using a floating power plant; J.E. BARDACH, "Aquaculture," *Science*, 161:1098–1106 (1968), a comprehensive review on growing food in bodies of water; J.L. BISCHOFF and F.T. MANHEIM, "Economic Potential of the Red Sea Heavy Metal Deposits," in E.T. DEGANS and D.A. ROSS (eds.), *Hot Brines and Recent Heavy Metal Deposits in the Red Sea*, pp. 535–541 (1969), a paper dealing with the economic potential of the heavy metal deposits underlying the Red Sea brines; R.H. CHARLIER, "Harvesting the Energies of the Ocean," *MTS Journal*, 3:13–32 (1969), a comprehensive paper dealing with the techniques of extracting power from the tides and waves of the ocean; J.L. MERO, *The Mineral Resources of the Sea* (1965); J. MURRAY and A.F. RENARD, *Report on Deep-Sea Deposits Based on the Specimens Collected During the Voyage of H.M.S. Challenger* (1891), two classic references on the mineralogy of deep-sea deposits; D.F. OTHMER, "Desalination of Seawater," in F.C. FIRTH (ed.), *The Encyclopedia of Marine Resources*, pp. 162–169 (1969), a review article on the techniques of desalting seawater; L.A. WALFORD, *Living Resources of the Sea* (1958), a classic; L.G. WEEKS, "The Ocean's Resources," *Offshore*, 28:39–48, 87–88 (1968), a comprehensive review of the petroleum resources of the sea.

Ockham, William of

William of Ockham, the most influential philosopher of the 14th century and a controversial figure because of a bitter dispute with the Pope, was a late Scholastic thinker who is regarded as the founder of Nominalism—the school of thought that denies that universal concepts such as "father" have any reality apart from the individual things signified by the universal or general term. He is considered by some, though not all, historians as a forerunner of Martin Luther, the great 16th-century Reformer.

Early life

Ockham was an Englishman, born probably in Surrey about 1285. It seems that he was still a youngster when he entered the Franciscan order. At that time a central issue of concern in the order and a main topic of debate in the church was the interpretation of the rule of life composed by St. Francis of Assisi concerning the strictness of the poverty that should be practiced within the order. Ockham's early schooling in a Franciscan convent concentrated on the study of logic; throughout his career, his

interest in logic never waned, because he regarded the science of terms as fundamental and indispensable for practicing all the sciences of things, including God, the world, and ecclesiastical or civil institutions; in all his disputes logic was destined to serve as his chief weapon against adversaries. After his early training, Ockham took the traditional course of theological studies at Oxford University and apparently between 1317 and 1319 lectured on the *Sentences* of Peter Lombard—a 12th-century theologian whose work was the official textbook of theology in the universities until the 16th century. His lectures were also set down in written commentaries, of which the commentary on Book I of the *Sentences* (a commentary known as *Ordinatio*) was actually written by Ockham himself. His opinions aroused strong opposition from members of the theological faculty, and he left the university without obtaining his master's degree in theology; he thus remained, academically speaking, an undergraduate—known as an *inceptor* ("beginner") in Oxonian language or, to use a Parisian equivalent, a *baccalaureus formatus.* Ockham continued his academic career, apparently in English convents, simultaneously studying points of logic in natural philosophy and participating in theological debates. When he left his country for Avignon, France, in the autumn of 1324 at the Pope's request, he was acquainted with a university environment shaken not only by disputes but also by the challenging of authority: that of the bishops in doctrinal matters and that of the chancellor of the university, John Lutterell, who was dismissed from his post in 1322 at the demand of the teaching staff.

However abstract and impersonal the style of Ockham's writings may be, they reveal at least two aspects of Ockham's intellectual and spiritual attitude: he was a theologian-logician (*theologicus logicus* is Luther's term). On the one hand, with his passion for logic he insisted on evaluations that are severely rational, on distinctions between the necessary and the incidental and differentiation between evidence and degrees of probability—an insistence that places great trust in man's natural reason and his human nature. On the other hand, as a theologian he referred to the primary importance of the God of the creed whose omnipotence determines the gratuitous salvation of men; God's saving action consists of giving without any obligation and is already profusely demonstrated in the creation of nature. The medieval rule of economy, that "plurality should not be assumed without necessity," has come to be known as "Ockham's razor"; the principle was used by Ockham to eliminate many entities that had been devised, especially by the Scholastic philosophers, to explain reality.

Treatise to John XXII

Ockham met John Lutterell again at Avignon; in a treatise addressed to Pope John XXII, the former chancellor of Oxford denounced Ockham's teaching on the *Sentences,* extracting from it 56 propositions that he showed to be in serious error. Lutterell then became a member of a committee of six theologians that produced two successive reports based on extracts from Ockham's commentary, of which the second was more severely critical. Ockham, however, presented to the Pope another copy of the *Ordinatio* in which he had made some corrections. It appeared that he would be condemned for his teaching, but the condemnation never came.

At the convent where he resided in Avignon, Ockham met Bonagratia of Bergamo, a doctor of civil and canon law who was being persecuted for his opposition to John XXII on the problem of Franciscan poverty. On December 1, 1327, the Franciscan general Michael of Cesena arrived in Avignon and stayed at the same convent; he had been summoned by the Pope in connection with the dispute over property. They were at odds over the theoretical problem of whether Christ and his Apostles had owned the goods they used; that is, whether they had renounced all ownership (both private and corporate), the right of property and the right to the use of property. Michael maintained that because Christ and his Apostles had renounced all ownership and all rights to property, the Franciscans were justified in attempting to do the same thing. The relations between John and Michael grew steadily worse, to such an extent that, on May 26, 1328, Michael fled from Avignon accompanied by Bonagratia and William. Ockham, who was already a witness in an appeal secretly drafted by Michael on April 13, publicly endorsed the appeal in September at Pisa, where the three Franciscans were staying under the protection of Emperor Louis IV the Bavarian, who had been excommunicated in 1324 and proclaimed by John XXII to have forfeited all rights to the empire. They followed him to Munich in 1330, and thereafter Ockham wrote fervently against the papacy in defense of both the strict Franciscan notion of poverty and the empire.

Instructed by his superior general in 1328 to study three papal bulls on poverty, Ockham found that they contained many errors that showed John XXII to be a heretic who had forfeited his mandate by reason of his heresy. His status of pseudo-pope was confirmed in Ockham's view in 1330–31 by his sermons proposing that the souls of the saved did not enjoy the vision of God immediately after death but only after they were rejoined with the body at the Last Judgment, an opinion that contradicted tradition and was ultimately rejected. Nevertheless, his principal dispute remained the question of poverty, which he believed was so important for religious perfection that it required the discipline of a theory: whoever chooses to live under the evangelical rule of St. Francis follows in the footsteps of Christ who is God and therefore king of the universe but who appeared as a poor man, renouncing the right of ownership, submitting to the temporal power, and desiring to reign on this earth only through the faith vested in him. This reign expresses itself in the form of a church that is organized but has no infallible authority—either on the part of a pope or a council—and is essentially a community of the faithful that has lasted over the centuries and is sure to last for more, even though temporarily reduced to a few, or even to one; everyone, regardless of status or sex, has to defend in the church the faith that is common to all. For Ockham the power of the pope is limited by the freedom of Christians that is established by the gospel and the natural law. It is therefore legitimate and in keeping with the gospel to side with the empire against the papacy or to defend, as Ockham did in 1339, the right of the king of England to tax church property. From 1330 to 1338, in the heat of this dispute, Ockham wrote 15 or 16 more or less political works; some of them were written in collaboration, but *Opus nonaginta dierum* ("Work of 90 Days"), the most voluminous, was written alone.

Excommunication

Excommunicated after his flight from Avignon, Ockham maintained the same basic position after the death of John XXII in 1334, during the reign of Benedict XII (1334–42), after the election of Clement VI, and even after the death of Louis the Bavarian in 1347. In these final years he found time to write two treatises on logic, which bear witness to the leading role that he consistently assigned to that discipline, and he discussed the submission procedures proposed to him by Pope Clement. Ockham died at a convent in Munich, probably in 1349, apparently of the Black Death.

BIBLIOGRAPHY. A critical edition of Ockham's political works (*Guillelmi de Ockham Opera Politica*) is in preparation by the University of Manchester (already published are: vol. 1, 1940; vol. 2, 1963; vol. 3, 1956); and of the nonpolitical works in 25 vol. by the Franciscan Institute, St. Bonaventure, N.Y., vol. 1 (1956). LEON BAUDRY, *Guillaume d'Occam: sa vie, ses oeuvres, ses idées sociales et politiques,* vol. 1 (1949), is an authoritative study of Ockham's life and works, with emphasis on a discussion of the problems of authenticity and chronology. A fairly complete bibliography of editions, manuscripts, and studies to date of publication is included. JURGEN MIETHKE, *Ockhams Weg zur Sozialphilosophie* (1969), also an authoritative work, studies Ockham's career through his writings, showing the development of his political theory, including his doctrine of the church.

(P.D.V.)

Oda Nobunaga

Oda Nobunaga was a 16th-century Japanese general who, after a century of feudal wars had engulfed Japan in seemingly never-ending anarchy, made himself virtual

dictator of the country. Aided by Toyotomi Hideyoshi and by Tokugawa Ieyasu, the first of the Tokugawa shoguns, he succeeded in restoring a stable government and in unifying the country.

Nobunaga was born in 1534, in the province of Owari, the son of a government official who had amassed wealth and a respectable force of military retainers. In

Oda Nobunaga, portrait by Kano Munehide, 1583. In the collection of Choko-ji, Aichi Prefecture.

1549 Nobunaga succeeded to his father's estate and soon overpowered his relatives and the principal family of the province. By 1560 he had proved his brilliant strategic gifts by bringing all of Owari under his sway; and in the same year he astonished all of Japan by defeating the huge forces of Imagawa Yoshimoto, one of the overlords of his neighbourhood provinces, his first step toward unification of the country.

Stout-hearted, audacious, and autocratic, Nobunaga was quick to seize on any promising new invention. Ahead of other feudal barons, or daimyo, he organized units equipped with muskets. He also brought under his control the agricultural production of the fertile Owari plain, as well as the rising merchant class of the city of Nagoya in the centre of the plain. With an economic base thus assured, he planned to advance on the Kinki district, the prosperous area surrounding Kyōto, long the centre of Japanese power.

Rise to power

In 1562 he entered into an alliance with Tokugawa Ieyasu, a capable feudal lord of the neighbouring province of Mikawa; and in 1567 Nobunaga, feeling that he had secured his rear flank, moved his base of operations north to the city of Gifu. In the following year, he supported Ashikaga Yoshiaki, who escaped from the rebel band, hoping to become shogun after the assassination of his elder brother, the former shogun Ashikaga Yoshiteru. Nobunaga marched on Kyōto, the capital, and made Yoshiaki shogun. Soon, however, he fell out with Yoshiaki, and at last in 1573 he deposed him, thus ending the Ashikaga shogunate, even though it nominally lasted until Ashikaga Yoshiaki's death. In 1576, in order to consolidate his hold on the area, Nobunaga built for his headquarters a magnificent castle at Azuchi on the shore of Lake Biwa in the neighbourhood of the capital.

Meanwhile, he promoted a new economic policy by abolishing the checkpoints for collecting tolls on the roads as well as from the guilds, both of which had been privileged sources of income for the local daimyo (lords of manors). He also strengthened his military forces; and in 1571 he destroyed the Enryaku-ji monasteries, which had maintained their traditional power in politics and religion ever since the beginning of the Heian period in the 8th century. In the meantime, the fanatically religious Buddhist Ikkō sect held out against Nobunaga's attempts to unify the country by retaining the loyalty of minor local lords, extending its secular power, aiding Yoshiaki, and allying its members with the powerful daimyo of many provinces. In fact, Nobunaga had fought the Buddhist Ikkō sect directly and indirectly for more than ten years. It was only through the mediation of the Imperial court that Nobunaga in 1580 finally achieved the surrender of the fortress-monastery of Hongan-ji at Ōsaka, the most important political and military centre of the Ikkō. After capturing a great number of manors and temple estates, Nobunaga established his hold on the samurai and the wealthier farmers by investing them with the newly won estates. He thus gained a firm political and economic basis, which he strengthened by reducing even further the traditional influence of the Buddhist temples.

Elimination of Buddhist influence

Once established in Kyōto, he extended his protection to the Jesuit missionaries and assisted them in building a church in the capital and a seminary in Azuchi. He did so not only because of his interest in European culture but because he regarded the encouragement of Christianity as a further means of restraining the influence of the Buddhist temples. Nobunaga was a non-believer; his attitude toward Christianity was frankly political.

In 1582 he conquered central Japan and then made an attempt to conquer western Japan. In June of that year, however, he was killed during the rebellion of a discontented vassal. By the time of his death, Nobunaga had succeeded in bringing nearly half of the provinces of Japan under his control. He had overthrown the *ancien régime* and old order of fractionized power held by the daimyo and had paved the way for the political and economic unification of the country.

BIBLIOGRAPHY. TADACHIKA KUWATA, *Oda Nobunaga* (1964); and RYOICHI SUZUKI, *Oda Nobunaga* (1967), are the standard biographies (both in Japanese). GEORGE B. SANSOM, *The Western World and Japan* (1950) and *A History of Japan, 1334–1615*, 3 vol. (1961); and MICHAEL COOPER (ed.), *The Southern Barbarians: The First Europeans in Japan* (1971), provide useful information on Nobunaga's period.

(A.Eb.)

Oder River

The Oder River, a vital economic artery in eastern Europe, runs through the western portions of Poland and has considerable contemporary regional significance. It is one of the largest rivers in the catchment basin of the Baltic Sea, second only to the Vistula in size. For the first 83 miles from its source, it passes through Czechoslovakia. For a distance of 100 miles in its middle reach, it constitutes the boundary between the Polish People's Republic and the German Democratic Republic, before reaching the Baltic Sea via a lagoon north of the Polish city of Szczecin. Called the Odra in Polish and Czech and the Oder in German, the river is an important waterway, kept in good operating condition. It forms a link, by way of the Gliwice Canal, between the great industrialized areas of Śląsk (Silesia), in southwestern Poland, and the trade routes of the Baltic Sea and beyond. The Oder is connected with the Vistula, Poland's largest river, by means of a water route utilizing the Warta and Noteć rivers, together with the Bydgoszcz Canal, and is tied in with the waterway system of western Europe by way of the Oder-Spree and Oder-Havel canals in the German Democratic Republic.

The total length of the Oder River is 550 miles (886 kilometres), 464 miles of which lie in Poland. The total watershed area has been calculated at 46,000 square miles (119,150 square kilometres), of which close on 90 percent is in Polish territory. The mean elevation of the Oder Basin above sea level is 535 feet. From the river's source and over the greater part of its course, the Oder flows in a generally southeast to northwest direction; only from the junction with the Neisse (Nysa łużycka) River does the northward trend toward the Baltic commence. The principal left-bank tributaries are the Opava of Czechoslovakia, and the Osobłoga, Nysa Kłodzka, Oława, Ślęza, Bystrzyca, Kaczawa, Bóbr, and Neisse; while from the east the Oder receives the following tributaries: Olše, Kłodnica, Mała Panew, Strobrawa, Widawa, Barycz, Obrzyca, Warta, Mysła, and Ina. From the junction with Opava, the Oder is navigable for a distance of 472 miles for 220 to 230 days of the year. Towns of

particular importance along the Oder are Ostrava in Czechoslovakia; Frankfurt in East Germany; and Racibórz, Opole, Brzeg, Wrocław, Nowa Sól, and Szczecin in Poland.

The course. The Oder starts its course in Czechoslovakia, at an altitude of 2,080 feet in the Oder Mountains of the Hrubý Jeseník Range. Initially it runs as a mountain stream with a steep gradient that progressively lessens until the river reaches the floor of the structural depression called the Moravian Gate; from here on, the Oder continues its course in a wide valley. After receiving the Olše River, a tributary, the Oder enters Poland, and makes its way as a lowland river that in a characteristic manner alternates between following ancient east–west stream valleys of glacial origin and crossing gaps cut in the intervening uplands. Where the Oder takes advantage of these pre-existing valleys, it reaches widths as large as six miles or more, while in gaps it narrows down to about a mile. Near Koźle, the Gliwice Canal enters the Oder; and from here as far as Brzeg Dolny, the river has a navigable channel 116 miles long, controlled by 23 locks. From Brzeg Dolny downstream until the final outflow into the Szczecin Lagoon, the river channel is fully improved. Beginning with the mouth of the Neisse River, the Oder becomes the borderline between Poland and East Germany. In this part of the valley, there branch off the Oder-Spree and the Oder-Haval canals. Farther downstream, the Oder Valley shows numerous cross branches and parallel channels. Fifty-two miles from its outflow into the Baltic, the Oder splits into two main branches; the left canalized branch, called the Western Oder, passes through the city of Szczecin and enters the Szczecin Lagoon directly, while the right branch, the Eastern Oder (in its final section known as Regalica) passes east of Szczecin via the large Lake Dąbie and then also enters the Szczecin Lagoon.

Origin

Hydrology. The Oder has a limited flow volume. During low-water periods, in summer and autumn, the river is fed from storage reservoirs built in the upper tributaries. The mean water depth in the Oder channel is three feet, and the mean rate of flow is three feet per second. In summer the upper reaches of the Oder system are flooded by heavy precipitation, while in spring the middle and lower reaches suffer from meltwater floods. Flow volume varies from as low as 530 cubic feet per second in the upper reaches to up to 50,000 cubic feet per second in the lower. Annually the Oder delivers into the Baltic an average volume of no less than 3.8 cubic miles of water. The ice cover on the river lasts up to 40 days per year. As is the case with many of the world's great rivers flowing through heavily industrialized regions, the Oder's waters are, unfortunately, heavily polluted; of the fish that are still found in the river, the most common are bream and eel.

Improvements

The first hydraulic works—embankments and other methods of flood prevention—were started in the Oder Valley as early as the 12th century; spillway dams built in the 13th century were in operation until the 18th century, when work was initiated on channel straightening by means of excavated cuts. Improvement of the straightened part of the Oder channel was for the most part completed around 1900 (although final improvements were not made until after World War II), while control works in the middle and lower reaches were carried out in the interwar period.

Historical background. Due to its geographic situation, the Oder was, in ancient times, of major importance as the zone where people inhabiting southern and northern Europe came into contact with each other and exchanged cultural values. The first agricultural population arrived from the south after passing the Moravian Gate, which separates the Sudety from the Carpathian mountains. Along the middle reach of the Oder there developed the pre-Lusatian and the Lusatian cultures (of the Bronze Age), which greatly affected the later evolution of the Slav population. In the area surrounding the Oder estuary, there was a mutual interpenetration by Scandinavian, Germanic, and Slav cultures. Finally, in the 9th and 10th centuries, the Polish state developed between the Oder and the Vistula. In the 13th century, the German expansion dislodged Poland eastward, away from the Oder Basin. But on the basis of the 1945 Potsdam Conference between the Soviet Union, the United States, and Great Britain, the Polish nation returned to its former lands bordering the Oder River.

Regional significance. The Oder River is an important element in the Polish economy, serving as a supplement to the heavily overburdened railway and highway systems linking the highly industrialized regions of the south with the largest Polish seaport, Szczecin, at the Oder's Baltic mouth. The river carries about 10 percent of the total tonnage handled by the port. The Oder is also used by the barges of the German Democratic Republic, which travel over a system of navigable canals that connect the Oder with the Central European waterway network.

A system of navigable canals connects the Oder with the Vistula, Poland's largest river, and also with the rivers of the eastern portion of the country and the waterway system of the Soviet Union. This creates the possibility that the entire system may evolve into an all-water commercial route, transporting commodities from west to east and from east to west. Before full advantage of this situation can be taken, however, further investments, notably the construction of river port and embankment facilities, appear indispensable. (W.Pa./Je.P.)

Odonata

Large, active by day, and often strikingly coloured, dragonflies (order Odonata) are among the few insects that have secured a major place in folklore and art. Though they cannot inflict injury to man, longstanding vernacular names such as "horse stinger" and "devil's darning needle" testify to their formidable appearance. In Japan, where a journal (*Tombo*) is devoted solely to reports of their biology, dragonflies traditionally have been held in high regard.

Dragonfly is the common name for large, winged, sun-seeking insects comprising the order Odonata. Adult dragonflies have two pairs of narrow transparent wings, a long slender abdomen, and prominent eyes; they can be recognized by the skewed thorax, forwardly directed legs, and small inconspicuous antennae. Typically they fly near ponds and rivers in which their larvae develop. Dragonflies are predatory insects; the adults catch small flying insects on the wing. Although they consume mosquitoes and other insects troublesome to man, they are catholic feeders and not considered of appreciable value in controlling specific pests.

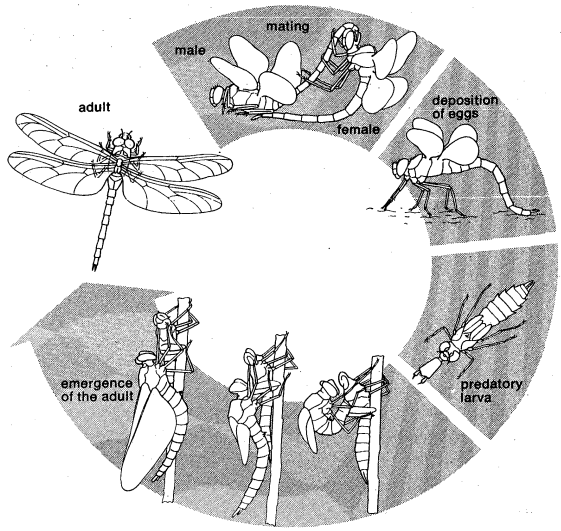
Distribution and size range

The order Odonata is small, well known, and widely distributed. The world fauna probably does not greatly exceed the 5,000 species now known. Dragonflies occur from the tropics, where they are most numerous and varied, to the latitudinal limit of trees. At a medium-sized pond, populations seldom exceed a few hundred adults of each species. Though the structure of adults is uniform, there is a wide range of sizes, and the wingspans of the smallest and largest species are about 1.8 and 19.3 centimetres, respectively.

Natural history. Since it is fully aquatic, the larva (or nymph) differs markedly in structure and behaviour from the flight-oriented adult. During development the larva molts approximately 8 to 15 times and passes through a corresponding number of stages or instars; the number of stages varies within and between species. There is no pupal stage.

A few minutes after hatching from an egg, the sheathlike cuticle of the first instar larva (prolarva) splits and releases the spider-like second instar. The early instar larvae feed actively on various small water animals including minute Crustacea and Protozoa; during later instars, the larva feeds on midge larvae, aquatic beetles and snails, and even small fishes. Wing pads appear at an early stage and grow larger with subsequent molts. Toward the end of the last instar, the organs become adult inside the larval skin. A few days later the larva climbs out of the water and molts to disclose the adult, a process known as emer-

gence. The largest dragonflies usually leave the water after sunset and take to flight just before sunrise; therefore, their emergence is seldom witnessed. Smaller species may emerge during the daytime.



Life cycle of the dragonfly.

The newly emerged adult dragonfly is soft, reproductively immature, and lacks full coloration. One of its first actions is to fly away from water. Adult life consists of two stages, a prereproductive (or maturation) period that lasts two days to two weeks (depending on the species and weather) and a reproductive period that lasts one to six weeks.

Mating behaviour

During the first stage the adult feeds actively, away from water. The second stage begins when, as a sexually mature adult, the dragonfly flies to the mating rendezvous, usually a pond or river where the eggs will be laid. Males assemble there slightly earlier than females and space themselves along the shore or over the water. Each male, once established, defends an area of characteristic extent, much as birds defend territories. When a male adult approaches or enters a "territory" occupied by another individual of the same species, the occupant acts aggressively and a contest often ensues; thus, territories are held by the most vigorous males. If a female adult approaches or enters a territory the resident male tries to mate with her. In some species mating is preceded by a courtship display during which, by her responses, the female accepts or rejects the male. Usually, however, there is no evident prelude, and copulation occurs immediately.

The mating posture is unique among insects. With the claspers at the end of his abdomen, the male grasps the top of the female's head or prothorax; then, by his movements he induces her to bring the tip of her abdomen forward so that it meets the intromittent organ at the base of his abdomen; in this way the female receives a sperm capsule. This "copulation wheel" can be formed in flight, though mated adults usually alight promptly. Copulation lasts between a few seconds and several hours, depending on the species. After mating, the female may lay eggs immediately or after a delay of hours or days. If she lays immediately, she may do so alone, with her partner still attached in tandem, or with him hovering nearby darting at other males that approach. In this way females lay eggs with little interference.

Eggs are laid in one of two ways. Species with a well-formed ovipositor place them within or on plant tissue, above or in the water. Some climb beneath the water surface to lay and remain submerged for an hour or more. Species without an ovipositor wash the eggs off the end of the abdomen or drop them onto the water surface. Eggs of some species are laid in running water and usually possess adhesive or tangling devices that prevent their being swept downstream.

In order to reproduce, the adult dragonfly requires warm weather, food, and water in which to lay its eggs. In equatorial waters reproduction occurs throughout the year; elsewhere, however, the life cycle is modified so that the reproductive stage coincides with the appropriate season. Where rainfall is a seasonal constraint, as in the tropics, the adult survives dry periods in one of two ways, either by retiring to humid woodlands (*Lestes, Gynacantha*) or by becoming nomadic and following the moving rainbelt, laying eggs in temporary pools that appear in its path (*Pantala, Tramea*). In both cases the larval stage is brief (one to three months), and the adult stage relatively long. Outside the tropics, where the seasonal constraint is imposed by low temperatures rather than drought, winter is passed in a resistant stage. In a few species the resistant stage is the immature adult and sexual activity is postponed until spring (*Aciagrion, Indolestes, Sympecma*); in other species it is the egg (*Lestes, Aeshna*); but most often the resistant stage is the larva, which, depending on the species and location, may require one to five years to complete development. Thus the larval stage lasts considerably longer than the adult one, which may last only a few weeks. In temperate regions, each species flies at a characteristic time of year, as determined by larval responses to climatic variables such as temperature and day length.

Requirements for reproduction

Dragonfly larvae are eaten by fishes, birds, and each other; predators at the time of emergence include birds and small crocodiles. Once they have left the emergence site, the adult insects have few regular enemies. In flight they are able to evade almost all predators by their agility. Larvae and adults are parasitized by flukes (Trematoda) and water mites (Hydracarina), and eggs by minute wasps.

Form and function. *Adult structure.* The principal structural features of adult dragonflies reflect adaptations to flight. The large wings are strengthened with a network of veins, and each has a thickened patch (the pterostigma) on the anterior edge near the tip. In certain migratory Anisoptera (*Libellula, Pantala, Tramea*), the expanded hindwing permits gliding flight. The sloping thorax accommodates large wing muscles and sets the legs forward where they can grasp prey. Where the head joins the thorax, a delicate orientation organ maintains equilibrium during flight. The large compound eyes, acutely responsive to movement and form, play an important role when adults capture food or interact with other dragonflies. In most Anisoptera the compound eyes meet dorsally, and in certain Aeshnidae that fly only in subdued light (*e.g., Gynacantha*) the eyes occupy almost the entire surface of the head.

Adaptations to flight

The unique method of copulation exhibited by Odonata can be regarded as a special way of transferring a sperm capsule. Instead of placing the capsule on the ground or a leaf for the female to pick up (as certain primitive insects do), the male puts it on his own body, where accessory genitalia at the base of the abdomen are especially constructed to receive it and transmit it to the female during flight. Interlocking structures on the male claspers and female head or prothorax make the copulation wheel secure.

Larval structure. Larval structure, though broadly similar to that of the adult, reflects demands of the aquatic environment, particularly with respect to respiration, locomotion, feeding, and concealment. Oxygen is replenished by diffusion through gills; in most Zygoptera these are three leaflike plates at the tip of the abdomen, while in most Anisoptera they are outgrowths of the hindgut wall, ventilated as water is pumped in and out of the anus. Both respiratory systems are used in emergencies as methods for locomotion; the jet propulsion employed by Anisoptera is particularly effective. Unlike the adult, the larva exhibits wide variation in form. Species living within fine sediment are cylindrical, with a terminal siphon that maintains respiratory contact with the water above (*Aphylla*); those residing on the surface of mud or sand often are flattened, with lateral spines (*Ictinogomphus*); those living among plants near the surface are streamlined and very active (*Anax, Lestes*).

Adaptations to aquatic environment

The larva captures prey in an unusual way. Typically it remains motionless until it detects a victim by sight or

touch. When the prey comes within range, the larva shoots out a prehensile organ (the labium) that grasps the prey and draws it back to the mandibles. In the resting position the labium lies beneath the head and thorax, sometimes obscuring the front of the head like a mask. It can be extended almost instantaneously by a localized increase in blood pressure that is controlled by a muscular diaphragm in the abdomen.

Evolution, paleontology, and classification. The extinct Protodonata possessed a complete series of alternate convex and concave wing veins; the two suborders, Palaeodonata and Archodonata, are known from the Upper Permian and Upper Carboniferous, respectively. The Odonata, in which the series of wing veins lacks the posterior media and anterior cubital, contain four extinct and three living suborders. The extinct ones are Meganisoptera (Upper Carboniferous and Upper Permian), which included the gigantic *Meganeura monyi* with a wing-span of 70 centimetres; Protanisoptera (Lower and Upper Permian); Protozygoptera (Lower Permian); and Archizygoptera (Triassic and Jurassic). Living suborders are listed below.

Distinguishing taxonomic features. Features used by taxonomists in classifying members of the order Odonata are, for adults, the shape and venation of the wings, distance between the compound eyes, form and development of caudal appendages, and presence of an ovipositor. Larvae are classified according to the type and form of respiratory organ, shape and armature of labium, number and arrangement of body spines, and shape of abdomen.

Annotated classification. The classification given here is that of F.C. Fraser (1957); it takes account of the fossil record of this group, which is unusually long and rich. In this scheme the superorder Odonatoidea (Odonatoptera of Lameere) comprises two orders: the Protodonata and Odonata.

ORDER ODONATA

Carnivorous insects with aquatic larvae (except *Megalagrion*), terrestrial and winged adults; adults with two pairs of similar richly veined wings and a pterostigma, small movable prothorax, large obliquely set thorax with forwardly placed legs, intricate accessory genitalia on second and third sternites in the male; larvae with labium modified to seize prey, gills in hindgut or as caudal or lateral abdominal structures; about 5,000 known species, of which all but two are Zygoptera or Anisoptera.

Suborder Zygoptera (damselflies)

Upper Permian to present; both pairs of wings similar, petiolate at the base; eyes more than one diameter apart; male adult with four caudal appendages, two superior and two inferior, female with ovipositor well developed; larva with caudal or lateral gills, gizzard with 8–16 radially symmetrical fields; one extinct, 17 living families; small, delicate, weakly flying insects; long slender abdomen attains greatest development in *Mecistogaster; Megalagrion oahuense*, small forest dweller in Hawaii, only known member of the Odonata with a terrestrial larva; size: body length about 1.9–15.0 cm, wingspan about 1.9–19.3 cm.

Suborder Anisoptera

Jurassic to present; well represented in Tertiary; hindwings broader at base than forewings; wings not petiolate at base; eyes less than one diameter apart or touching; male adult with three caudal appendages, two superior and one inferior, female with ovipositor well developed (Aeshnidae, Petaluridae) or reduced; larva characterized by rectal gills, anus closed by three robust spines, gizzard with four to eight dental folds; eight living families; robust, strongly flying, agile insects; some accomplished migrants; size: body length about 1.8–11.9 cm, wingspan about 2.4–15.7 cm.

Suborder Anisozygoptera

Mainly Mesozoic; adults intermediate in structure and appearance between the other two living suborders; larvae resembling Anisoptera; 11 families, all extinct except one (Epiophlebiidae), known from two similar species inhabiting highland streams in Japan and Nepal; size: body length about 5.1 cm, wingspan about 6.5 cm.

Critical appraisal. The Odonata, as the only living descendants of the Odonatoidea, occupy a uniquely isolated position in the phylogeny of insects, having separated from all other winged groups at a very early stage of evolution. There is general agreement among specialists regarding the status and affinities of living families and genera and, with few exceptions, classifications based on the adult and larva correspond. The evolution of the two major suborders has, however, been a matter for continuing debate. Some authorities consider that the Zygoptera and Anisoptera arose independently from the Protodonata. According to Fraser (1957), the Anisoptera, in their descent from the Protodonata, passed through a zygopterous stage. This view of the genealogy of the order Odonata has gained wide acceptance.

Office Machines

For a variety of reasons the work load of business offices has increased rapidly during the 20th century, and, because much of the work is repetitive and routine, many kinds of office machines and appliances have been developed to handle it efficiently and accurately. The manufacture of such machines and appliances has become a major world industry in which new products are constantly under development.

Most office machines fall into either of two broad categories, writing and reproducing machines and computing and accounting machines. Among the former are typewriters, dictating machines, and the various types of duplicating and copying machines, In the second group are calculating machines, cash registers, accounting machines, and classifying and tabulating machines. In addition, there are several miscellaneous types of office machinery such as coin sorters, mail handlers, electronic paging devices, and others.

History. While the origins of modern office machinery may be said to date back to ancient times and the invention of the abacus, the major developments occurred in the late 19th and 20th centuries. This is attributable in part to the multiplication of office tasks with the growth of large-scale enterprise, and in part to certain basic advances in technology. The machine-tool industry, which developed in the United Kingdom in the mid-19th century, made possible the mass production of precision components, a prerequisite to such devices as the typewriter, which appeared in the U.S. in the 1870s. Important problems in a totally different field, sound recording, had to be solved before the typewriter's companion, the dictating machine, could come into being. Although Thomas Edison patented his original phonograph in 1877, it was a

dozen years before he produced a modification suitable for office usage.

Similarly, the original invention of photography in the mid-19th century required considerable refinement before an economically practical office photocopying process could be developed.

The most important advance in basic technology came with the birth of electronics in the early years of the 20th century. Most modern office equipment, of which the computer is the outstanding example, has been based first on the utilization of the electron tube and, more recently, on the transistor.

With the increasing sophistication of office machinery, and the consequent increasing capital investment represented by it, considerable study has been given to the rationale of using such equipment. This may be briefly summarized as depending on the economy of labour effected by the greater speed and volume of output, the value of possible improvements in accuracy, and the effects on office personnel, such as retraining problems.

WRITING AND REPRODUCING MACHINES

Typewriters. The typewriter, the most common office machine, came into use in the 1870s and has virtually eliminated handwritten business letters and reports. The many improvements made in the typewriter since its invention have culminated in electric and automatic electric typewriters. The automatic typewriter produces typewritten copies of form letters or other documents in any number desired. The copy for such applications is first typed in the form of coded perforations on a roll of paper tape or in the form of impulses on magnetic tape. The tape activates the type bars on the typewriter. Automatic typing may be stopped to enable an operator to insert particular amounts, names, dates, and other information. In the late 1960s the automatic typewriter was connected to a computer, which can be programmed to enter names and other individualized information on the forms being produced (for a detailed discussion of this equipment see TYPEWRITERS).

Automatic typewriters

Dictating and transcribing machines. Dictating and transcribing machines provide for the storage and later reproduction of spoken messages. Dictating machines normally employ a magnetic process, recording the voice on plastic disks or belts, wire, or coated tape, which can be removed from the machine after dictation and forwarded to the point of transcription. The transcribing machine reproduces the dictated message so that it can be typed. By the use of these machines, stenographic transcription can be carried out while additional dictation progresses.

The dictation and transcription units are often portable and can be housed in a single unit. Recent developments include centralized systems in which individual desk controls with microphone or telephone are connected to a central bank of dictating–transcribing machines. Fewer machines are thus necessary and there is less manual handling of the message media. A highly sophisticated arrangement requires no handling of discs, tapes, or related supplies. Instead, an automatic handset smaller than a telephone permits the person dictating to record the message, correct errors or modify his statements, and review one word or the entire dictation, merely by operating a switch on the handset. The message is recorded in a transcription unit that lights up for the secretary when a message is to be typed. This signal goes off when there are no more messages in line. The system also allows for dictation from regular and out-of-plant telephones at any time.

Duplicating machines. Around 1000 BC a cylinder mounted on a frame and rolled by hand over a slab of clay became an early duplicating process. Later, damp tissue applied against a gum-base ink served the same function. Many new and sophisticated kinds of duplicating machines have since been developed. Yet some modern machines still use variations of these early techniques. The major classifications of duplicating machines are stencil, hectograph, multilith (or offset), and imprinting, all of which will be discussed later. Regardless of variations in these processes, all duplicating machines require the preparation of a master from which copies are made by a machine. Duplicating machines in this sense are thus differentiated from copying machines (discussed later), in which copies are made from an existing original in an exposure–image-forming process. It should also be noted that on the basis of this distinction the typewriter is not a duplicating machine even when carbon paper inserts are used, because the copies are prepared simultaneously with the original rather than printed from a master.

Early duplicating process

Stencil. The stencil method of duplicating involves the use of a coated fibre sheet for a stencil. Using a typewriter with the ribbon shifted out of the way so that the keys do not strike it, the operator types the material to be duplicated on the stencil, cutting the coating on the stencil and exposing the fibre base so that ink can pass through to it. Corrections are made by a special sealing fluid that permits retyping over the patched-error position. Signatures or drawings may be placed on the stencil with a hand stylus.

Two machines are widely used to produce copies from stencils. In one the stencil is fastened to the ink-saturated surface of a hollow, rotating cylinder. As the cylinder rotates, the ink flows through the cuts in the stencil to the sheets of paper fed under the cylinder. The other machine has two cylinders around which a silk-screen belt rotates. The stencil is attached to the screen, and the ink is distributed to the surface of the rotating cylinders by two rollers. The ink is thus pressed through the small openings in the screen and through the stencil openings, or image areas. Paper is fed between the stencil, and an impression roller to create the copy. Up to 5,000 copies can be made in either process from a single stencil, and stencils can be stored for considerable periods of time for re-use.

Hectograph. There are two types of hectograph or direct-process duplicators: gelatin and spirit.

Gelatin and spirit processes

The gelatin process, now rarely used, requires the preparation of a special master paper upon which the copy to be duplicated is typed, written, or drawn with a special ink or ribbon. This sheet is then pressed face down against a moist gelatin surface, to which the image is transferred in reverse form. Sheets of paper pressed against this impregnated gelatin receive an image impression. Either a flatbed or rotary machine, similar to that used in the stencil method, can make the duplicate copies. The master copy can be prepared in a variety of colours by using ink and carbon sheets of different shades. Multicoloured copies may thus be produced in one operation. The practical limit on copies produced by the gelatin process is about 200.

The spirit method is also referred to as the direct, or fluid, process. The master copy is prepared by typewriter, handwriting, punched card, or computer-printing devices. Master copies can also be prepared by copying machines and microfilm reader-printers. The master sheet is then fastened to a rotating drum. As copy sheets, slightly moistened by a special liquid, are brought into direct contact with the master sheet, a minute amount of the carbon is transferred to them, resulting in finished copies. Multicolour duplication in one operation is possible, as it is with the gelatin process. A further advantage of the spirit process is that information can be added to or deleted from the master. Up to 300 copies can be made from one master sheet. Special hectographic masters can be produced directly from an original or from certain reproductions by using the thermocopier, which employs a facsimile-like process.

Offset. Offset duplicating processes, also known as multilith or lithograph, require either chemically fixing copy on a metal sheet or preparing a paperlike master copy by typing, printing, or drawing, or by an electrostatic or xerographic copying process. This master impression is inked and brought against an intermediate composition agent, usually rubber, to which the image is transferred. The image is immediately transferred (offset) again to a copy sheet. The process operates on the principle that grease will not mix with water. Since a special grease-base ink forms the image on a moisture-retaining

surface, the moisture remains in blank areas, repelling the ink to the image area. Thousands of copies can be produced, and masters can be stored for indefinite periods and re-used. In photo offset the material is prepared on a layout sheet and photographed on an offset plate or master. After the completed master is attached to the drum of a duplicator, copies are prepared as explained in the offset process.

Imprinting. There are three basic methods of imprinting: (1) spirit hectograph master cards, (2) stencil cards, and (3) metal or plastic plates. Hectograph master cards are made with the aid of hectograph carbon. The imprint on the card is transferred by means of a chemical solution to envelopes or other forms. Up to 250 imprints may be made from a single master card. Stencil cards consist of small pieces of stencil tissue mounted in a cardboard frame. The copy to be imprinted is typed or written on the stencil tissue. When a drawer of stencil cards is attached to the addressing machine, the machine automatically brings together the cards and the envelopes or other forms to be imprinted, performs the imprinting, places the stencil cards in a tray, and stacks the imprinted forms. Metal or plastic plates of various sizes may be embossed, with the text standing out in relief, on a special machine. Forms or envelopes are imprinted through an inked ribbon as the raised-image plates are fed through another machine, which operates automatically at high speed. The plates are practically indestructible.

The most common office machine for this kind of imprinting is the addressing machine, which addresses postcards, envelopes, shipping labels, or tags. It is also used widely for imprinting checks, production orders, schedules, requisitions, time tickets, routing slips, tax bills, and similar forms.

The mailing selector

Attachments for these machines are designed for special services. A selector, for example, permits certain plates to pass through the machine without imprinting, thus directing mailings only to selected groups. A cutoff device permits the printing of selected data only. A repeating device prints the data several times before the plate is ejected, thus permitting names and addresses to be entered on envelopes and invoices in one operation. A dating device that enters the date on forms along with the other data embossed on the plates is used frequently in entering names and addresses on letters and statements. It is also possible to use these machines for distribution and addition of figure information. Holes punched in plates at predetermined points activate a sensing mechanism that translates desired information and lists it on forms. The preparation of billing records and payrolls is an example of ways in which this device may be used.

Copying machines. There are several major types of copying processes, including photocopy, thermography, electrostatic copy, and facsimile transmission, all of which are now discussed. In none of these is a master copy needed as an intermediary step, as in the case of duplicating machines. Some copying machines are fully automatic, compact, and capable of making copies at very high speeds. Such machines, especially electrostatic copiers, are beginning to compete favourably with stencil and hectographic processes in speed and on a cost-per-copy basis, so that the distinctions between duplicating and copying are becoming less clear.

Photocopy. One of the oldest processes involves photographing a negative in the making of a positive image. Although other light-utilizing processes and some sophisticated variations have evolved, the most commonly used photographic processes are diffusion transfer, dye transfer, and diazo, which are contact processes, and microfilm, which utilizes a camera.

In the diffusion-transfer process the original copy is made by typing, drawing, or printing on a translucent paper or cloth sheet, which is placed, image side up, on light-sensitized paper. Both sheets are exposed to light, which passes through the translucent sheet and deactivates the nonimage areas. Since the printed areas absorb light and thus do not permit it to pass through to the sensitized sheet, these image areas remain activated. Another variation employs a two-step process in which a light-sensitized negative sheet is placed on top of the original, sensitized side down. The light source passes through the negative sheet to the original, which absorbs the light in the image areas. The nonimage areas reflect the light to the sensitized side of the negative paper, turning these areas black. The negative is developed in contact with positive transfer paper in a chemical solution. The two sheets are then squeezed and peeled apart.

In the dye-transfer process, the original is placed against the sensitized paper as in two-step diffusion transfer and then exposed to light. The image is formed in a solution in which areas not exposed to light are transformed into a dyelike substance that, when placed against nonsensitized paper, transfers to it and forms the copy. Dye-transfer machines can also produce masters for offset duplicating machines.

In the diazo process, an improved form of blueprinting, a translucent original and a sheet of copy paper treated with azo dye are used. With the original and copy paper placed together as in the one-step diffusion-transfer process, an ultraviolet light source is used. The copy paper is developed by passing it either between two rollers moistened with developer or, in the case of dry diazo, through ammonia vapours.

In contrast with the contact processes are the photographic processes in which cameras are used to take pictures of the material to be reproduced. Most processes produce a negative from which positive copies in various sizes may be made.

Small strips of film carrying information and attached to carrier pigeons were used for communications as far back as 1870 during the Franco-Prussian War. Today microfilm is widely used in office files. The capacity of the microfilm camera for information miniaturization is such that it can transform 100 file drawers of original documents into as few as two drawers of filmed records. Records-retention management can often be facilitated in this way, with the added advantage that the film can be noncombustible.

Origins of microfilm

Microfilm information can be stored in any of a number of forms. Rolls and cartridges of film necessitate sequential access to given records, while jackets or card-held microfilm frames are unit records with sequential storing within each unit. Variations of this latter form have led to microfiche, which consists of rows of frames placed directly on films, and aperture cards, which are regular punch cards with film inserts for computerized storage and retrieval of visual and punched information. The film may be studied through a viewer, which shows the image in its original size, or, if duplicate sets are needed, it may be used to make reproductions of the original copy, either on paper or on microfilm.

Innovations provide for high-speed filming and reduction–expansion of computer output data as well as fast copy generating units. Much greater reduction capacities are also available for specialized storage needs, as is the case with libraries; a whole book can easily be printed on a single file card.

Thermography. The commercial application of heat or infrared copying methods—sometimes called thermography—is relatively new. Special copy paper and the original copy are placed in contact with each other and run through a machine in which they are exposed to infrared, or heat, rays. The original copy absorbs the rays in areas darkened by print, line drawings, or other illustrations, making the same impressions on the heat-sensitive surface of the copy paper. The original with the new copy paper attached may be put through the machine repeatedly to produce the number of copies desired.

Electrostatic copy. Exceptionally flexible, electrostatic copying processes can copy anything that is written, printed, typed, or drawn. They will reproduce halftones (photographs) and will enlarge or reduce copy.

Xerography: "dry writing"

In the transfer electrostatic process, or xerography (from the Greek "dry writing"), the original document is scanned by a mirror that reflects the image onto a drum coated with amorphous selenium, a nonmetallic element that is able to hold an electrostatic charge in the dark while allowing it to dissipate when exposed to light. From

here the process operates on the principle of opposite charges attracting and like charges repelling one another. The selenium on the drum is given a positive electrostatic charge that is held in the dark areas of the reflected image but dissipates in the light, nonimage areas. The coating is then treated with negatively charged powder, or toner, which adheres to the positive image area. The darker the image, the more toner adheres. This reverse image is transferred to positively charged ordinary paper after it has passed over the drum, drawing the powder onto itself. The toner is fused by infrared heat to form a permanent copy.

A direct electrostatic process differs from xerography in that the image is shown directly on specially coated paper with no intermediate transfer needed.

Facsimile. In facsimile reproducing processes, a transmitter scans the original material, converting the image into electrical signals that are sent over telephone lines or by other means of communication, such as radio or microwave. A receiver reconverts the signals into the original image on paper, the clarity of the copy depending on the number of scanning lines per inch utilized in the process. The combination transmitter receiver is normally housed in one unit small enough for use on an office desk. Printed, written, graphic, and photographic material can thus be copied at great distances from the original documents. Some units transmit the image over telephone lines and then allow for normal voice transmission over the same lines.

COMPUTING AND ACCOUNTING MACHINES

Calculating machines. The earliest and most long-lasting calculating device ever devised is the abacus. Various versions of this instrument were extensively used in ancient and medieval Europe and Asia. The abacus probably grew out of a more primitive instrument, a board sprinkled with sand, on which tallies were marked. When lines were drawn in the sand dividing the board into columns, to represent tens, hundreds, and thousands, the calculating board, or abacus, was born, with pebbles or bones used as counters. The abacus continues to be widely used in much of Asia today. Because a skilled operator can perform a variety of calculations with great speed and accuracy, the simple and economical abacus retains its popularity even in industrially advanced Japan.

The rise of interest in natural philosophy in western Europe in the 17th century spurred the development of mechanical calculating instruments. John Napier, a Scottish mathematician, in 1614 discovered the logarithm, which made the task of multiplying very much easier. The mechanization of the logarithm led to the development of a whole class of calculating machines called analog, or measurement, devices.

Pascal's digital calculator

In 1642 a French scientist, Blaise Pascal, invented an adding machine that in a sense represents the first digital calculator. It is called digital since it performs its operations by the counting of digits, the numbers 1 through 9, and 0. In 1671 a German mathematician, Gottfried Wilhelm Leibniz, invented a machine that performed the multiplication process by repetitive adding. His stepped gear wheel, a gear wheel with two or more complete circular sets of teeth arranged adjacently on the same rim so that corresponding teeth form a series of steps, still appears in a few 20th-century devices.

During the last quarter of the 19th century, inventors developed machines that were more compact and made possible modern desk calculators, which can perform the processes of addition, subtraction, multiplication and division, and, by shifting numbers left or right, the operations of multiplying or dividing by powers of 10. They can store the result of an operation on counter wheels visible to the operator, and data can be introduced by means of keys on a board. In all these machines, however, it is necessary for the operator to intervene at each step of a calculation. The time required for the calculation thus depends on the speed of the user.

In carrying out a mathematical calculation, man performs three distinct functions that must be incorporated into any calculating machine: first, the basic arithmetic operation of adding, subtracting, multiplying, or dividing; second, the decision on what to do next (*e.g.*, take the number in column one, multiply it by the quantity just produced); and third, storage of the initial, intermediate, and printing of final results on sheets of paper or other media.

Many attempts were made to make this entire process automatic. Technical difficulties, however, stood in the way of the goal until an American scientist, Vannevar Bush, and associates at the Massachusetts Institute of Technology developed and placed in operation the first differential analyzer in 1930. It was a fully automatic calculating instrument that could be programmed to do different types of problems. In addition to the three basic steps of computation, the analyzer had an input–output device that permitted communication between the mechanism and the user. Since 1930 the developments in this field have been extraordinarily rapid. (For a detailed discussion see COMPUTERS.)

Basic types of calculators. Modern calculating machines fall into one of three basic types: adding–listing, key-driven, and rotary. The first and third type are either ten-key or full keyboard machines. Ten-key machines are designed for one-hand touch operation. Numbers are entered by depressing one key at a time, beginning with the left-most digit and proceeding to the right until all digits, including zeros, have been recorded. Full keyboard machines provide a vertical column of keys for each digit position from one to nine. The machines vary in capacity of digits, depending upon the number of columns of keys included.

Adding–listing machines

Adding–listing machines, either ten-key or full-keyboard, are capable of adding, subtracting, dividing, and multiplying. Because multiplying and dividing operations are slow, they are generally used for adding and subtracting. The individual amounts entered as well as the totals are listed on a paper tape.

In key-driven machines, which are full-keyboard, calculations are performed directly by depressing the keys. The results of the calculations appear on a dial. Some machines of this type have two dials, one indicating individual calculations and the other registering grand totals and net results. Although key-driven machines can perform all four arithmetic functions, they are especially suitable for problems that require rapid addition and multiplication.

Rotary calculators need the additional operation of a lever or motor bar to record a number in the register. Although they are capable of performing the four arithmetic functions, they are used primarily for division and multiplication problems. Both listing and nonlisting and either ten-key or full keyboard models are available. Calculators of this type vary in the number of answer registers available. Some have only one; others may have as many as five. A register holds a figure or amount until it can be used with amounts in other registers to perform additional calculations.

Some rotary calculators have split registers, enabling the operator to add individual items in one half while accumulating them in the other half of the register. A variety of special features are available, including automatic squaring, decimal placement, and high-speed, short-cut multiplication. In fully automatic machines of this type, complex problems can be solved by recording the factors and depressing the multiply or divide key. The machine performs the calculation, repositions the carriage, and then stops.

Modern electronic calculators. The electronic desk calculator, though fully developed only in the 1960s, has a long engineering design history. The first electronic calculators were slow and cumbersome. When solid-state devices were introduced in the 1950s, calculator size was reduced by the miniaturized transistor and diode.

Use of integrated circuits

When a special photo-reduction process made it possible to miniaturize these solid-state circuits the integrated-circuit generation of electronic calculators came of age. Solid-state circuits were reduced to an eighth of an inch square on a silicon wafer known as a metal oxide silicon chip. Each chip, the size of a half dollar, houses an entire

circuit capable of performing the same functions of their solid-state ancestors. The entire chip, produced under dust-free conditions to prevent imperfections in manufacture, is embedded in special plastic with gold leads connecting the outside to the integrated circuit (see also INTEGRATED CIRCUITRY).

The latest generation of circuitry involves the further integration of a number of metal oxide silicon chips in forming a large-scale integrated circuit. Such circuits, which require fewer connections in the machine, become less costly as their size increases. As manufacturing techniques improve, costs may be expected to decline and increasing numbers of electronic calculators will doubtless appear for nonbusiness and home use.

Developments in electronic calculating machines include such sophisticated capabilities as display screens to show the results of operations. The electronic display characters are created in various ways, including cathode-ray–tube projection, neon lumination, or luminated vacuum-tube processes. Usually from two to five display registers are available, affording visual access to operational results as well as to variables of the operation. Some units feature instead a listing or printing device housed within the regular package. These are electromechanical in design and are the source of noise and heat. While fast, they are much slower than the electronic operations of the major unit, which performs in milliseconds. The calculator unit itself has no internal moving parts and is therefore noiseless.

The modern electronic calculator is simple to operate. Besides the basic processes of addition, subtraction, multiplication, and division, most units handle square roots, squaring, percentages, and logarithms with the pressing of an appropriate key. The machine can also often handle several operations automatically. Decimal placement is easily accomplished, with as many as 15 or more significant places possible in many machines. In addition to the several display registers for results and variables, registers are also available for the storage of constants and intermediate results.

Exponential and trigonometric operations

Very sophisticated machines handle exponential and trigonometric operations through the use of special keys that utilize core memories much like those in modern computers. Accessory card programmers that accept punch cards, magnetic tape cassettes, and other input devices provide some units with computer-like capabilities, all in a desk-size machine. The keying in of the necessary data for the calculation is still necessary. These machines go through programmed routines processing numeric data on command. Graphic output has also been achieved with the use of a special accessory printer, and some machines signal the operator if an impossible task is included in the problem.

It should be noted that electronic calculators perform operations once thought to be possible only in computers. Meanwhile, computer sophistication has resulted in smaller units, some of which are beginning to resemble electronic desk calculators. The two may be distinguished by the abilities of the computer to handle alphabetic and symbolic information and to "branch"—*i.e.*, decide which sequences or subsequences of instructions to follow when certain conditions arise in the data. Perhaps even these differences will be less distinct with future developments in the two lines of machines.

Specialized calculating and accounting machines. *Cash registers.* Cash registers are recording and adding machines that help a merchant control his business and assist salespeople in serving customers. Cash registers make records of each transaction for the customer and the merchant. There are many different types, some extremely simple and others highly complex. Most cash registers have certain fundamental features and functions. The typical machine indicates the amount of a transaction at the top of the register so that it can be seen by both customer and salesman. It keeps separate totals of sales by various classifications. It prints and issues a receipt on cash sales or overprints a record of the transaction on a sales docket on charge sales. It keeps within the register an audit strip, which is a complete printed record of every transaction that has been made. It has special counters to show the number of customers handled and the number of each kind of transaction. In a recent development, a clerk records on a preprinted card the number of each of several items sold. The card is inserted into an electronic calculator, which calculates and enters on the card the cost of each item and the total. The price of each item is stored in advance in the calculator. These prices may be changed by merely running a revised price card through the calculator. Information on the items sold and cash received is simultaneously transmitted to a central computer, which provides inventory and cash-on-hand data to management on a minute-by-minute basis. This application is especially useful in branch office and franchising operations.

Accounting machines. Accounting machines are complex devices that combine features of the computing machines already described with some provision for writing. They have taken over much of the labour of bookkeeping. Billing machines, for example, are designed to type names, addresses, and descriptions, to multiply, to figure discounts, and to add net total. A simple accounting machine generally has only one or two registers and no typewriter facility. Abbreviated description keys are used to denote the type of transaction, and the carriage is designed to hold a number of forms at once, a capability that enables the operator to post associated documents, such as ledger card and daybook, simultaneously. More elaborate accounting machines have many registers, often have a typewriter built in, and can carry out a number of operations automatically. Accounting machines post to one account at a time and frequently accumulate in the manner of cash registers to permit summarizing and distributing accounts. The window-posting accounting machine, in common use in banks, hotels, and retail stores, prints the transaction on the customer's statement or passbook as well as on an audit sheet and automatically calculates new balances.

Billing machines

Classifying and tabulating machines. These machines use cards on which coded data are recorded. Their function is to facilitate the sorting and tabulation of diverse data. The simplest card systems function by notching the perforated perimeter of the card according to codes. These systems are limited to the performance of sorting tasks. They are operated by a simple machine or device, frequently merely a metal rod, which is inserted in a specific perimeter location of a stack of cards. It will thus penetrate both notched and unnotched holes. When the rod is lifted, those cards that have notched holes will drop out.

The first modern device of this type was designed for the automatic tallying or tabulating of statistics. Following extensive development, however, modern tabulating machines can now automatically figure and print a report based on the information given to it in the form of perforations in cards or tape. Between 1834 and 1854, Charles Babbage in England designed and partly built an "analytic engine" in which both the amount to be operated upon and the nature of the operation were entered by perforated cards. His machine was never completed, largely because modern precision techniques of fabricating metal parts to close tolerances were not yet developed. The modern tabulating machine was finally produced by a U.S. statistician, Herman Hollerith.

Census tabulation

Hollerith tallied census returns by an electrical reading of the data punched into cards (which provided coded information on each individual in the census) and accumulated the totals in separate registers. The system was successfully used in the U.S. census of 1890 and the British census of 1911. During the next decade notable improvements were made, including provisions for automatically feeding cards under brushes for reading and a machine for sorting the cards rapidly into desired groupings. The U.S. census in 1900 furnished particularly good evidence of the possibilities of the system. The population volume was ready one year and seven months from the start of enumeration. It was estimated that hand tabulation of only three factors—sex, nativity, and occupation—would have required the services of 100 clerks for 7

years and 11 months. Since 1901 the commercial utility of a punch-card system has been greatly increased. The tabulating or unit record method is now to be found in general use throughout the world.

Whenever a transaction involves a number of amounts that are later to be used as units two or more times in compiling various totals, it is generally economical to translate it onto a perforated card. If, for instance, the data connected with the cost of production of a certain part are recorded on a card, this card can be used in computing totals of individual wages, departmental costs, machine costs, and productive hours.

The card upon which the data are recorded in the form of perforations has a column for each number or symbol to be entered. The digits 0 to 9 are denoted by holes punched proportionate distances from the bottom edge of the card, starting with the 9 position. Above the 0 position is space for two additional perforations used principally for actuating certain control operations of the machine. These additional positions may also be used for special classification numbers or in combination with perforations in the regular digit position to denote alphabetic characters. The card is divided vertically into fields, each of which denotes a particular fact of the total information recorded. Some of the information is descriptive and some of it is quantitative. The former controls sorting and indicating; the latter represents amounts to be totalled. Sorting and totalling are accomplished by different machines. Three separate mechanical devices are necessary in the system: a perforating machine or punch, a sorter, and a tabulator. The ordinary form of perforating machine has a set of 12 punches under which the card is advanced a column at a time. By means of a drum card or skip bar and stops, certain fields can be skipped where no punching is to be done. More complex types of perforating machines are arranged to permit the automatic duplication of information already on one card, or other cards, to punch any predetermined number of cards with identical data, and to number cards consecutively as they are punched. The speed with which trained operators can perforate the cards depends on the nature of the information being recorded as well as its extent.

Sorting devices

The sorter arranges cards in numeric or alphabetic sequence or sorts them into related groups for tabulation. A sort brush electrically reads the punches in a card, one column at a time, at the rate of from 400 to 2,000 cards per column per minute. One well-known type of sorting machine has 13 pockets, one for each possible columnar perforation and one for rejects. As the perforations are sensed by the sorting brush, the cards are dropped into appropriate pockets, depending upon the information punched into the column being processed. Newer sorters are capable of sensing perforations in cards by photoelectric cells instead of by brushes and are thus faster. Some are equipped with special devices which are capable of providing certain types of computational and statistical information.

The tabulator, or accounting machine, reads data from perforated cards by means of reading brushes and processes the data in accordance with instructions it receives from a control panel or wired unit. The control panel, which is similar to a telephone switchboard, determines which card columns are to be read, what is to be done with the data in these columns, and where to print the processed information. The tabulator can either calculate amounts punched in cards—about 150 per minute—and print only the total, or list each amount individually, followed by a total for the group. Generally, tabulators contain several counters, making it possible to take totals of several card fields simultaneously and store the amounts for grand totals. Subtraction is also possible, and devices can be added to the printing mechanism for handling report and bill forms. As a result, tabulating machines have become automatic accounting and billing machines.

MISCELLANEOUS OFFICE MACHINES

In offices where quantities of coins must be handled, machines are used to sort, count, wrap, or dispense coins. Sorting is accomplished simply by sifting the various sizes. Trip counters count the coins, and wrapping machines wrap a standard number in paper. The coin-dispensing machine releases a specific sum when an appropriate key on a keyboard similar to that on an adding machine is depressed.

Mail-handling machines

Mail-handling machines are designed to expedite handling of large quantities of incoming and outgoing mail. Since outgoing mail requires the most work, machines are designed to aid in this task. The main types are folding machines, inserting machines, and envelope sealers. Stamp-affixing machines mechanically separate stamps from a roll, moisten them, and apply them to envelopes. Postage meters print stamp charges directly on envelopes or on adhesive strips to be affixed to envelopes. The machines are set by postal employees to print postage equal to the amount of deposit paid. An automatic postage meter and mail-scale machine feeds, stamps, seals, and stacks letters at high speed. It also automatically weighs and computes the postage on parcel-post packages.

The modern office is frequently of such size that efficient communication becomes a factor in maintaining the flow of work. Two-way voice systems operate on the telephone principle to permit communication between specific areas. In a commonly used version, the individual may call any one or any combination of a limited number of stations by depressing appropriate keys on the receiver–transmitter box. When he speaks into the box, his voice, amplified electrically, is broadcast from similar boxes at the various stations. Others may then reply in similar fashion from their stations.

Paging systems utilizing either the telephone switchboard operator or private internal telephone systems are very popular. Flashing lights, bells, and similar signals locate persons by a code or speakers call out their names. Those paged then call the operator or designated persons to receive the message. This process frees individuals from a fixed position in the office or plant because the signalling devices can be spread throughout the building and grounds.

Teletype systems provide typed communications between two or more points. Messages are received and recorded even though no person is in attendance at the receiving machine. These systems are especially valuable for rapid intercommunication among a number of widely separated offices and frequently span an entire country or link offices in different countries. Telegraph services are also available to subscribers on a basis much like that of telephone service.

Recording units mounted on regular telephones also receive spoken messages after first announcing to the caller why his call is being answered by machine. One of these has become popular because of its ability to use regular telephone lines with special transmitter and receiver handling computer data from cards by converting them into appropriate tones. Machines can thereby "talk together" for the price of a regular phone call.

Dataphone

Closed-circuit television installations permit viewers to see documents and hear explanations transmitted from distant locations. Rapid transmission of recorded information is thus possible for verification, identification, or computation. Signatures or account balances may be transmitted for verification from a central office to many points instantaneously, eliminating the need for large numbers of duplicate records. Monitoring of operations is also a key application. Closed-circuit television holds much promise in its capacity to handle visual and animated information.

Paper cutters, punches, binding equipment, and folding equipment are available in a wide range of sizes for office use. Document-destroying equipment disposes of outdated paper documents by shredding or chopping. Collating equipment assembles pages of printed matter in a specific order.

Time-recording machines combine a clock mechanism with a recording device to provide a quick, correct recording of the time of occurrence of certain routine events. Time-stamping machines are manually actuated to stamp the time upon letters and documents. Time-re-

cording clocks record the times of arrival and departure of employees. The employee inserts a time card into the machine when he arrives and again when he departs. Job-recording clocks function in identical fashion to record time of beginning and finishing particular tasks.

Check-writing machines that print amounts on checks so that they cannot be altered; check-signing machines; and numbering, dating, and receipting machines are examples of other office devices.

Ogata Kōrin

One of the most typically Japanese artists of the Tokugawa or Edo era (1603–1867), Ogata Kōrin was a versatile painter and designer whose work and life were a perfect expression of the luxury-loving Genroku period (1688–1703), during which the well-to-do merchant class of Kyōto became the patrons of an elegant art that reflected their wealth and social position. Much admired during his lifetime, Kōrin's fame and influence have continued unabated since his death, and today he is regarded as one of the two great masters of the school of decorative painting known as the Sōtatsu-Kōrin school. In addition to the splendid, colourful screen paintings for which he is primarily famous, he was an expert lacquer artist whose work has had a tremendous influence on craftsmen working in this field. He is also famous for his textile designs and the pictorial decorations that he supplied for the ceramics of his brother, Ogata Kenzan, who is regarded by many critics as Japan's greatest potter.

Family and youth

Coming from an old and distinguished Kyōto family, Kōrin was descended from a samurai (warrior aristocrat) who had served under the Ashikaga rulers and was related to a famous calligrapher and swordsmith, Kōetsu. Kōrin's grandfather and father were owners of Karigane-ya, a prosperous store dealing in fabrics for kimonos that was patronized by some of the most powerful ladies of the capital. Members of his family were also keenly interested in the arts. Kōrin's grandfather, Sōhaku, spent the later years of his life in Takagamine, an art colony established at the outskirts of Kyōto by Kōetsu; and Kōrin's father, Sōken, was an accomplished calligrapher of the Kōetsu school, as well as a lover of Nō drama.

Born in 1658 in Kyōto, the ancient capital of Japan, Kōrin grew up in an environment of luxury and aesthetic refinement. His original name was Ichinojō, but when he was 34 or 35 years old, he changed it to Kōrin. Having received a considerable inheritance from his father, the artist spent his youth leading a carefree life filled with the pursuit of pleasures and amorous adventures. He was not married until 1697, when he was almost 40. The extravagance of Kōrin's life-style is best illustrated by a story of a lavish picnic party that Kōrin and his friends gave at Arashiyama outside of Kyōto. As each of the participants showed off his splendid dishes, Kōrin provided the climax by producing his food wrapped in bamboo leaves decorated with gold. When the meal was over, the artist tossed the leaves into the river, an action for which he was banished from Kyōto because it violated the law forbidding the use of gold and silver among the common people. Because of such extravagances, Kōrin lost the fortune he had inherited and had to turn to art for a living. Earlier in his life, he had studied painting for many years, at first probably under the tutelage of his father, who was an accomplished painter, and later under Yamamoto Sōken, a member of the officially recognized Kanō school. Sōken, who was skillful in both Chinese-style ink painting and the traditional Tosa school painting, which employed Japanese subject matter and a colourful decorative style, instructed his pupil in both these manners. Other influences on his early work were paintings of Kanō Yasunobu and especially the work of Sōtatsu, who were the two most outstanding decorative painters of the early 17th century. Very few of Kōrin's early paintings have been identified, and those works that can be attributed to this phase of his career appear to have been painted in ink in the traditional Kanō style.

Kōrin's artistic maturity began in 1697, when he established himself as a professional painter. In 1701, at the age of 44, he was given the rank of Hokkyō, indicating that he was an accomplished artist, and after that virtually all his work bears the signature Hokkyō Kōrin. Because almost none of his paintings bear dates, it is difficult to determine the chronology of his artistic output, but it appears that all his important work was produced in the 20-year period after 1697. These years may be divided into three parts: the formative Kyōto period, from 1697 to 1703, when he gained recognition as an art-

Artistic maturity

ist; the period from 1704 to 1710, when he lived in Edo (present-day Tokyo); and the years 1711 to 1716, when he reached his artistic climax. His first masterpiece was a screen representing autumn grasses and flowers (now in a private Japanese collection), which combined his two most outstanding characteristics: a fine sense of abstract decorative design and a close study of nature. The culmination of this phase was in the famous iris screen, a work that is believed to date from 1701. After moving to Edo in 1704, he enjoyed the patronage of rich merchants and some of the great lords of feudal Japan. Among the works attributed to this period are a hand scroll depicting the flowers of the four seasons that has been handed down in the Tsugaru family of Tokyo; a charming hanging scroll of red and white azaleas (Hatakayama Museum, Tokyo); and a twofold screen representing waves. After his return to Kyōto in 1711, the work of Sōtatsu became the overwhelming influence on his art. In fact he based the compositions of two of his most famous screens on the painting of this master. These are the two sixfold screens depicting the waves at Matsushima and the twofold screen "God of Thunder and God of Wind" (Tokyo National Museum). The work that is usually regarded as the supreme achievement of this period is the screen "Red and White Plum Trees," now in the Atami Museum (see illustration). In this work, Kōrin's sense of flat, decorative design and his feeling for nature combined with an emphasis on an abstract colour pattern are seen at their very best. Although he died at the age of 59 in 1716, he left many pupils and followers. The most outstanding of these was Sakai Hōitsu, who was active during the early years of the 19th century.

MAJOR WORKS

Kōrin was the originator of the style named after him; below are a few works attributed to Kōrin (active late 17th–early 18th century): "Irises" (Nezu Art Museum, Tokyo); "Red and White Plum Trees" (Atami Art Museum, Shizuoka, Japan); "Narihira at Yatsuhashi" (Tokyo National Museum); "Narihira Going Eastward" (S. Hisamatsu Collection, Matsuyama, Japan); "Waves at Matsushima" (Museum of Fine Arts, Boston); "Waves" (Metropolitan Museum of Art, New York).

O'Higgins, Bernardo

Bernardo O'Higgins, the revolutionary leader and first Chilean head of state, was a key figure, as both a political and a military leader, in the winning of Chile's independence from Spain. After Chilean independence was established, he led the nation for six years, maintaining its security through the first critical years, and built the administrative foundation of the republic.

O'Higgins, oil painting by Jose Gil. In a private collection.

Bernardo O'Higgins was probably born on August 20, 1778, in Chillán, a town in southern Chile, then a colony of Spain. As noted in his certificate of Baptism, he was the illegitimate son of Ambrosio O'Higgins, a Spanish officer of Irish origin, who became governor of Chile and later viceroy of Peru; his mother was Isabel Riquelme, a prominent lady of Chillán.

Education and early influences

Bernardo's father had only indirect contact with his son, who used his maternal surname until his father's death. At 12, Bernardo was sent to Lima, Peru, for his secondary education. Four years later he went to Spain. At 17 he was sent to England for further education. In London he became imbued with a sense of nationalist pride in Chile, a pride largely fostered by his contact with several political activists, of whom Francisco Miranda, the Venezuelan champion of Latin-American independence, exerted the greatest influence on him. Along with several other future revolutionary leaders, he belonged to a secret Masonic lodge, established in London by Miranda, the members of which were dedicated to the independence of Latin America. In 1799 he left England for Spain, where he came into contact with Latin-American clerics who also favoured independence and doubtless further strengthened his views. His political position was remarkable in view of the fact that his father was viceroy of Peru.

Bernardo's father died in 1801, leaving him a large hacienda near Chillán; by 1803 he was working the estate. This interlude may have been the most satisfying period of his life. The hacienda began to prosper almost immediately and Bernardo was soon maintaining a house in Chillán. In 1806 he became a member of the local town council.

Before O'Higgins had time to settle into his agrarian way of life, however, the foundations of Chilean society were threatened. In 1808 Napoleon I invaded Spain, which, occupied with its own defense, left its colonies, including Chile, largely uncontrolled; the first steps toward national independence began to be taken throughout Spanish America. On September 18, 1810, a national junta, composed of local leaders who replaced the governor general, was established in Santiago, and by 1811 Chile had its own congress. O'Higgins was a member, and during the next two years he played a key role in the country's turbulent political affairs.

By early 1813 Chile had a constitution and a junta that seemed able to control the country and to avert the threat of civil war. In 1814, however, the Viceroy of Peru sponsored an invasion to re-establish royal authority. Within a few months, O'Higgins rose from the rank of colonel of militia to general in chief of the defensive forces. Soon, he was also appointed governor of the province of Concepción, in which the fighting took place. But the war went badly and O'Higgins was superseded in command. In October 1814, at Rancagua, the Chilean patriots lost decisively to the Peruvian-led forces. For the next three years the country was occupied by the royalists.

Several thousand Chileans, including O'Higgins, crossed the Andes into Argentina in flight from the royalists. O'Higgins spent the next three years preparing for the reconquest of Chile. In January 1817, O'Higgins returned to Chile with the Argentine general José de San Martín and a combined army of the Andes consisting of Argentine troops and Chilean exiles. At Chacabuco, on February 12, 1817, they decisively defeated the Spanish, and with Chile largely reconquered, O'Higgins was elected interim supreme director.

Supreme director

For the next six years, as supreme director, O'Higgins maintained, on balance, a successful administration. He created a working governmental organization and provided the essentials of the new nation—peace and order. Under adverse circumstances he succeeded in building a national navy and in mounting a major military expedition against Peru to fight the royalists.

O'Higgins, however, was not politically astute: by 1820 he had antagonized the conservative church and the aristocracy with his reforms. Later he alienated the business community. He did not perceive the importance of a solid

political base, and, because his support was based on his prestige as a war leader in a threatened country, his fall was assured once the danger of war had disappeared. O'Higgins was associated with a grand scheme of continental independence that was essentially Argentine in its conception; by the time of his resignation—under pressure—in January 1823, a growing Chilean nationalism had rendered him and his Argentine colleagues much less attractive than they had been in 1817.

In 1809, at the age of 31, O'Higgins had observed: "The career to which I seem inclined by instinct and character, is that of laborer"; in rural life, he would have come to be "a good *campesino* and a useful citizen." As supreme director, O'Higgins had the positive attributes of solid moral principles, an eagerness to work hard, and singular honesty. In the countryside, as he himself understood, these virtues would have been ample, but in public administration they were not enough.

Last years

From 1823 until his death in October 1842, O'Higgins lived in exile in Peru, dividing his time between his hacienda and Lima. His last years were poignantly similar to his first: in his youth circumstances required that he live away from home; now in maturity circumstances again conspired to keep him abroad. In both periods he longed to return home.

Little is known of O'Higgins' personal life. Though he never married, he managed to acquire a family, in the same manner as his father had. His natural son Pedro Demetrio O'Higgins was his companion in exile.

O'Higgins was a liberal in the 19th-century sense of the term and an admirer of the British constitutional system. Although not as conservative as some contemporary Chilean leaders, he was not a democrat either. While his reputation since his death has fluctuated with the political predilections of governments and historians, his leading role in establishing Chile as a republic remains unquestioned.

Ohio

The first state to be carved from the Northwest Territory when it became the 17th member of the Union in 1803, Ohio, in the 20th century, reflects the urbanized, industrialized, and ethnically mixed United States that developed from an earlier agrarian period. The pattern of its life is so representative of the nation as a whole that it is often used to test attitudes, ideas, and programs in education, politics, and industry. Significantly, Ohio has supplied by birth or residence more than one-fifth of the presidents of the United States—William H. Harrison, Ulysses S. Grant, Rutherford B. Hayes, James A. Garfield, Benjamin Harrison, William McKinley, William H. Taft, and Warren G. Harding.

Overview of the state

The state's accessibility has been perhaps the key factor in its growth. Its location between the populous states of the Eastern seaboard and the growing Middle West and its lack of natural barriers to movement made it a corridor for east–west travel, whether by riverboat down the Ohio River, packet across Lake Erie, or wagon, railroad, or automobile and truck across its land. With Pennsylvania on the east, West Virginia and Kentucky on the southeast and south, Indiana on the west, Michigan on the northwest, and Lake Erie on the north, Ohio lies in the heart of the United States' most industrialized area, close to major resources of raw material and manpower and to the markets of the East, Middle West, and South.

Ohio's area of 41,222 square miles (106,764 square kilometres), excluding 3,457 in Lake Erie, ranks only 35th in size among the states; it is the smallest, after Hawaii and Indiana, west of the Appalachian Mountains. The more than 10,500,000 Ohioans counted in the 1970 census, however, made it sixth in population, with a density of about 260 persons per square mile, compared with the national average of just over 50. The state capital, after being located in Chillicothe and Zanesville during the early years of statehood, was finally settled in newly founded and centrally located Columbus in 1816. (For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; NORTH AMERICA; and GREAT LAKES.)

THE HISTORY OF OHIO

Prehistory and settlement. Remains of archaic civilizations dating from 5,000 to 7,000 years ago have been found in Ohio. Among later cultures, the Hopewell peoples, who disappeared about 1500, represented the highest prehistoric development; their burial mounds contained exquisitely crafted artifacts. The earliest white explorers in the 17th and 18th centuries found the region occupied largely by Miami, Shawnee, Wyandot, and Delaware Indians, as well as a host of smaller tribes.

Indian cultures

The region between the Appalachians and the Mississippi River was in nearly constant contention between France and Britain until 1763. Ordinances of 1785 and 1787 by the new United States government set the pattern for settlement and for government, though the Virginia Military District in southern Ohio and the Western Reserve (*i.e.*, of the state of Connecticut in 1786) in northern Ohio were set aside for veterans of the Revolution.

Statehood. In the decades after Ohio attained statehood in 1803, the foundations for future social and economic diversification were laid. Threats of Indian warfare were halted, and in 1813 the naval battle on Lake Erie played a major role in the War of 1812 with Britain. In spite of several economic panics, a program of internal improvements created a network of land, water, and rail transportation. By 1850 Ohio was the third most populous state in the nation, with nearly 2,000,000 inhabitants, and the leader in diversified agriculture, but it was still an essentially rural, agricultural state.

Economic growth. The basis of Ohio's industrial structure was built between 1850 and 1880, when the value of its manufacturing grew to more than twice that of agriculture. A great stimulus was provided by the Civil War (1861–65), in which Ohio supported the North, though strong antiwar sentiment existed. After the war, the growth continued, notably in the northeast and around Lake Erie. This growth led to considerable economic and social dislocation. After 1900 considerable attention was given to municipal reforms in Cleveland, Toledo, and other cities and to statewide programs of social legislation that attempted to alleviate problems caused by industrialization. In 1920 two Ohioans, Warren G. Harding and James M. Cox, faced one another for the presidency, and, in following decades, Ohio continued to play a pivotal role in national political life. Ohio reflected the racial strife that was widespread in the United States in the summer of 1966, when disorders in the predominantly black Hough district of Cleveland cost four lives. In 1968 Carl B. Stokes became the first Negro ever elected mayor of a U.S. city as large as Cleveland, though in 1967 and 1968, respectively, Springfield and Dayton also came under the administration of Negro mayors. The state became the focus of national attention in May 1970, when four students were killed by national guardsmen, who had been called out as a result of demonstrations at Kent State University, near Akron. Tragically, Ohio had again proved itself the mirror of the troubled nation as a whole.

THE NATURAL LANDSCAPE

The topography, river systems and groundwater, and soils in most of Ohio are the product of past glacial activity. These factors have strongly influenced the patterns of human settlement and land use.

Physiographic provinces. Three larger physiographic provinces extend into Ohio. The Allegheny Plateau reaches westward from Pennsylvania and West Virginia into the counties along Ohio's eastern border, from near Lake Erie to the Ohio River. The northeast is only partially glaciated, while the unglaciated terrain in the south-

east has made it the one region in the state that has showed declining population and economic power for decades. Throughout the plateau, the land is dissected by rivers winding among steep hills, and many elevations reach 1,400 feet (425 metres).

The Lake Plains stretch along Lake Erie to the northwestern counties and the Michigan boundary, then irregularly to the south. These level to slightly rolling lands were once underwater, and the swampiness of the northwest, around Toledo, presented obstacles to settlement before drainage made it more arable. The Central Plains, which extend westward beyond the Mississippi, take in western and southwestern Ohio and provide a deep soil. Curiously, the state's highest and lowest points are found here: the former, at 1,550 feet, is near Bellefontaine; the latter, at 425 feet, lies at the confluence of the Miami and Ohio rivers, near Cincinnati.

Waters. The principal water sources are the rain-fed streams, lakes, and reservoirs. Floods, which were once prevalent, have been controlled by numerous state and federal dams and other conservation measures throughout the state. Groundwater is used widely for public supplies, though the major industrial and population centres have limited resources. Huge stores are buried in preglacial valleys in central and south central Ohio; cities, which require millions of gallons daily for industrial use alone, are contemplating the use of these sources.

Lake Erie and the river systems

Lake Erie has an average depth of only 62 feet, which makes it the shallowest of the Great Lakes. It is also the most tempestuous, with frontal storms often roaring across it from Canada, and the most liable to shoreline erosion, harbour silting, and filling of its bed. Its shallowness, coupled with the concentration of population and industrial plants in its watersheds, led to a pollution that drew wide attention beginning in the 1960s. Programs in various areas were begun to deal with the environmental problems of the lake, which continues to be the principal source of water for many lakeside cities.

A low watershed separates the 30 percent of Ohio drained by the Maumee, Cuyahoga, and other rivers into Lake Erie from the 70 percent drained by the Miami, Scioto, Muskingum, and others into the Ohio–Mississippi system. The Ohio, no part of which is under state jurisdiction, is canalized and channelled for its entire length, as is the Muskingum from Zanesville to Marietta. Of the 110 lakes in Ohio, 83 have been built for industrial, supply, recreational, and other purposes.

Soils. Most of Ohio's soils are well suited to agriculture. The Great Plains soils are mainly rich glacial limestones, but the Lake Plains are the most productive. The sandstone soils of central and northeastern Ohio are best adapted to pasturelands, while the thin and heavily eroded hilly areas of the southeast provide little basis for productive farming. State and federal conservation and reforestation programs are under way in that area.

Climate. Temperatures in Ohio are similar to those across the north central and eastern United States, with summer highs and winter lows only infrequently reaching 100° F (38° C) and −20° F (−29° C), respectively. It is open both to cold, dry fronts from Canada and to warm, moist fronts from the Gulf of Mexico. The frequent meeting of such fronts causes much of the precipitation, which totals about 38 inches (965 millimetres) a year, including an average annual snowfall of about 28 inches, which is about one-seventh of the total precipitation.

Vegetation and animal life. The great hardwood forests that covered 95 percent of Ohio prior to white settlement have been reduced to less than 20 percent. The forests in the glaciated areas have less forest but better stands of timber, which include oak, ash, maple, walnut, basswood, hickory, and beech. Both wild and domestic flowers abound, though the clover, wild rye, and bluegrass of early Ohio are gone.

About 350 bird species are found in Ohio, at least 180 of them native. Among the 170 fish species are bass, trout, and perch, while the 60 or so species of wild animals include deer, opossum, fox, skunk, groundhog, and rabbit.

THE PEOPLE OF OHIO

The urban areas of Ohio first exceeded the rural in population by 1910 and by 1970 included more than 75 percent of all Ohioans. Five counties surrounding the major cities contained 43 percent of the people. Nonetheless, Ohio's large cities are following the national pattern of losing population to surrounding suburban areas. The growth of Columbus proper is largely attributable to municipal annexation of the suburbs.

The early settlers. The people who laid the foundations of Ohio, most of them of English ancestry, came from the older seaboard states. The first permanent American settlement in Ohio and the Northwest Territory was at Marietta in 1788 by a company of New Englanders who had fought in the Revolution. In the same year a group from New Jersey established a settlement near Cincinnati, and in the next few years other villages sprang up. In the south, particularly in the Virginia Military District between the Scioto and Miami rivers, many of the settlers came from Virginia and Kentucky. In 1796 the Western Reserve in northern Ohio was first settled, mainly by New Englanders from Connecticut.

The northern European stock

Pioneers from other European nations appeared in the years before 1830. Germans and Swiss came from Pennsylvania into the east central area. Many settlers of Ulster Protestant background also came in from the Middle Atlantic and Southern states. After 1830, settlers came directly from Germany and Ireland. Many Irishmen came from the Erie Canal to work on the Ohio canals and stayed on, and, when the railroads were built, Irish and German workers remained as permanent settlers. Germans who drained the Black Swamp country of the northwest stayed on to develop the farmlands around such centres as New Bremen, New Bavaria, and Minster.

After 1830 immigrants from southern Ireland settled in such cities as Cleveland, Defiance, and Cincinnati, where by 1850 they were second to the Germans among the foreign-born. In the 1830s Columbus also became an important centre of German population, as did Lancaster, where immigrants from Württemberg joined the Pennsylvania Germans who had founded the city.

In northeast Ohio, such towns as Massillon, Alliance, and Canton were established at an early date by Pennsylvania Germans, as was Steubenville, farther to the east. German settlers were also attracted to the rolling surface and fertile soil of Wayne County, which became one of the top agricultural counties in the nation. German-speaking Moravian missionaries came to Christianize the Indians in the early 1760s under the leadership of John Heckewelder, David Zeisberger, and Frederick Post. In 1817 Joseph Bimeler founded an experimental communistic settlement in Zoar that lasted until 1898. The Swiss settled around Dover and Sugar Creek in Tuscarawas County, as well as in Monroe County. This general area is sometimes referred to as the "Little Switzerland of Ohio." In Holmes County, Amish immigrants from Germany and Switzerland established settlements that remain. Today there are more Mennonites in Ohio than in Switzerland.

The Welsh arrived in the early 19th century to develop the mineral resources in Jackson County, and, for a long period, Welsh was the only language spoken. The Eisteddfodd, a festival of Welsh bards, and other elements of Welsh culture and music flourished. The language persisted to the third generation in many communities, with old Welsh songs passed on from father to son.

Later waves of immigration. In 1850 the principal racial stock was Scotch–Irish, although the Germans and the English also were important elements. In 1870 nearly 14 percent of Ohio's and 40 percent of Cleveland's population were foreign-born. The New England character of northern Ohio's beginnings was changing. Each new group established its own newspapers, clubs, social life, and churches, as the state became increasingly industrialized and urbanized between 1870 and 1900.

Increasing numbers of immigrants from eastern and southern Europe came into Ohio after 1880. By 1920 great numbers of Italians, Poles, Hungarians, Russians, and others had come to Cleveland, Toledo, Youngstown,

Akron, Dayton, Middleton, and other industrial communities. No other Ohio city, however, acquired such a polyglot population as Cleveland. Cleveland's foreign-born population was supplemented between 1880 and 1890 by new arrivals from Austria, The Netherlands, Russia, Hungary, Portugal, Greece, China, Japan, Turkey, and Mexico. Eventually, the city's culture was enriched by over 48 groups with different languages and backgrounds. There were many new Roman Catholic and Eastern Orthodox churches, as well as synagogues. The Greeks brought their coffeehouses, and the Slovenes and Poles brought their social halls. By the 1970s, through the action of the "melting pot" character of Ohio, the descendants of these many ethnic groups had firmly established themselves in the social, economic, and political life of the state.

The diversity of Cleveland's population

The changing ethnic character of the state is shown as well in the growth of the black population. In 1843, when the Wyandot Indians left Ohio for new lands west of the Mississippi, the Negro population of Ohio numbered about 25,000. By 1870 it had risen to more than 62,000, most of which was in southern Ohio, where Wilberforce University, one of the first permanent Negro educational institutions, was established. By 1970 the black population had risen to about 970,000, most of it in the cities.

THE STATE'S ECONOMY

A good physical location, a rich store of natural resources, productive soils, and ample transportation facilities made Ohio one of the first great industrial states in the nation. Over one-half of the nation's population is within 500 miles of its borders; and coal, iron, water, salt, limestone, ferroalloys, chemicals, clays, and plastics are close at hand. In all, two-thirds of the raw materials processed in Ohio's factories come from its mineral, agricultural, and forest resources. Although well over one-third of its labour force is employed in manufacturing, its continuing activity in agriculture and mineral production provides economic balance and diversity.

Economic resources. *Agriculture.* In 1850 Ohio ranked first among the states in agricultural production, and in the 1970s it continued to rank near the top. Although its farming acreage and the number of farms and farmers had decreased, more than 60 percent of Ohio was still farmland. Ohio farms have become larger, supplying more food with fewer man-hours of work through the application of science and technology. In 1900 the farm was an almost self-sustaining unit, providing its own food, fertilizers, and fuel; today, however, it requires machinery, motor power, electricity, and tractors, as well as a substantial investment of money and skill.

One of the leading states in the production of corn, oats, and hay, Ohio maintains large marketing inventories of fruit, feed, and vegetables, as well as livestock and poultry.

Mineral production. Ohio's mineral resources include stones and clays for manufacturing and construction and such mineral fuels as coal, petroleum, and natural gas for heat, power, and transportation. In recent years the value of Ohio's mineral production has reached new highs. Coal production accounted for the highest return, followed by industrial minerals, oil, and gas.

Coal was discovered in Ohio as early as 1808. It was adapted for use with iron and limestone in the pioneer iron-making enterprises that sprang up in the eastern and southwestern parts of the state. Later, the discovery of deposits of iron ore in the upper Midwest gave rise to great iron and steel centres of northern Ohio. Today, good-quality coal is found in 32 eastern and southeastern counties. Remaining supplies are estimated at approximately 42,000,000,000 tons. More than half the coal is produced by strip-mining procedures, which have left a scarred landscape, polluted water supplies, and a generally damaged environment. Although Ohio has laws regulating strip mining and requiring restoration, the results were not satisfactory. Citizen groups led the battle for stronger safeguards.

Limestone is used in many construction and manufacturing processes. Ohio is first among the states in sandstone production, accounting for about two-thirds of the nation's building sandstone, and it is third in sand and gravel production. The abundance and quality of surface clays, plastic fireclays, shales, and some gypsum and peat have made Ohio a leader in the manufacture of ceramic products. Almost one-half of its extensive salt production comes from natural brine, the remainder from large rock-salt mines. Important industrial consumers of salt in Ohio are the soda-ash and chlorine industries. Geologists estimate that the state's salt deposits could supply the nation's need for centuries to come.

Petroleum and natural-gas production

Ohio has been a producer of oil and natural gas since 1860, but, by 1900, billions of barrels of crude oil had been taken, and production in the state declined. In the early 1960s, however, new oil and gas deposits were discovered, and the industry experienced a revival. In 1970 there were more than 21,000 producing gas and oil wells.

Other natural resources of importance to Ohio's economy are its forest products and water supplies. Climate and soil are conducive to the production of fine hardwood. Ohio leads the nation in the industrial use of water, with countless industries depending upon the groundwater supply.

Manufacturing. Ohio's manufacturing is its most important economic activity and represents the largest single segment of Ohio's employment. Measured by employment, the most important manufacturing enterprises are the nonelectrical-machinery industry and the automobile and aircraft industries. In spite of increased activity in other parts of the nation, the northeast-to-Middle West manufacturing belt that stretches through Ohio still constitutes the chief industrial strength of the country. The state leads all others in such diversified manufactures as rubber products and porcelain ware, electrical machinery and apparatus, pumps and plumbing equipment, steam shovels, and coffins, and it is listed among the leaders in almost all industrial classifications.

Economic regions. Governmental planners have identified eight regions throughout Ohio that possess distinctive economic characteristics in terms of their human and physical resources, landforms, transportation, communications, and other attributes.

The northern strip. The Maumee Valley region, comprising ten counties in the northwest, is primarily agricultural, though it lies in the path of industrial expansion from east and west. Corn and wheat, as well as hogs and dairy and poultry products, are important. Its largest city, Lima, has a growing manufacturing base. The Lake Plains region, comprising ten counties on the southwestern shores of Lake Erie, also have flat, fertile plains with highly productive soils. Toledo, the major city, is an important centre in the Great Lakes industrial belt and the leading coal-handling port in the United States. It supplies glass and transportation equipment to nearby Detroit, Michigan, and processes the farm products of the region.

Economic diversity

The Lakeshore and Uplands region comprises 16 counties in the north and northeast. This area contains Ohio's largest industrial concentration and, on 18 percent of the state's land, holds 42 percent of its people. Cleveland is the industrial, financial, and cultural centre. Akron is the rubber capital of the world, a trucking centre, and a large cereal producer. Youngstown, in the United States "Ruhr Valley," is a major metal producer and fabricator, and Canton specializes in roller bearings, bank vaults, and vacuum cleaners.

Central and southern regions. The Miami Valley region, with some 2,300,000 inhabitants in southwestern Ohio, centres on Cincinnati and Dayton. Cincinnati leads the world in the manufacture of machine tools, soaps and detergents, and playing cards. Dayton is the world's largest producer of cash registers and magazines and the nation's largest producer of putty and plastics; it is the home, as well, of Wright-Patterson Air Force Base, a major flight-testing and research centre. The Sandusky Valley, seven counties with fewer than 250,000 people, is basically agricultural, though the small cities of Marion, Galion, and Bucyrus have manufacturing.

The Scioto Valley region of rolling plains in central

Ohio has a diversified economic base. Columbus, its central city, is the home of state government and numerous educational institutions, including the Ohio State University. Two-thirds of the working force is in government, education, finance, and other service occupations. The sparse populations of the Tuscarawas Valley region of eastern Ohio, and of the Ohio valley region in the southern and southeastern portion of the state, are predominantly rural. Terrain limits the agricultural productivity of both regions. In the southwestern Ohio Valley, mining and lumbering are major activities. Stone, clay, glass, chemicals, and metal fabrication are major industries.

Transportation. Ohio's chief transportation system in the first years of statehood, as in the territorial period, was its water routes. Lake Erie and the Ohio River provided east–west passage for the Indian trader, pioneer, and settler, and many rivers provided access into the interior. Shortly after statehood, the development of land transportation facilities was begun, when, in 1811, the federal government began to build a major portion of the National Road running from Cumberland, Maryland, to Vandalia, Illinois. In the same year the first steamboats appeared on the Ohio River, and in the 1820s the era of canal building began and lasted for some 30 years. The first railroad was constructed in 1832, and in the 1850s the first great east–west rail lines were constructed across Ohio as the shortest and easiest route to the Western cities, prairies, and beyond.

Ohio's transportation facilities of the 1970s play a major role in moving the nation's people and goods from east to west and from north to south, by highway, railroad, river and lake, and air. The shipping to and from its lake ports is worldwide, and the Ohio River carries twice the tonnage of the Panama Canal. The railroad mileage is the nation's sixth largest, though Cleveland and other major cities lost interstate passenger service when the semipublic Amtrak system went into operation in 1971. The pioneer experiments of Dayton's Wright brothers, Orville and Wilbur, led to man's first successful powered flight, at Kitty Hawk, North Carolina, in 1903, and Ohio today is both a testing centre and a focus of commercial aviation. Among the many research and development facilities contributing to Ohio's economic life is a huge Transportation Research Center administered by the Ohio State University.

ADMINISTRATION AND SOCIAL CONDITIONS

Governmental structure. Ohio's government, which is more extensive than that of many small nations, is a multibillion-dollar enterprise. The state and local governments are similar to those in other states.

State level. The executive branch, which is headed by the governor and other elected officials, includes the heads of 22 agencies serving as an executive cabinet. The General Assembly comprises a Senate and a House of Representatives. It has broad powers in policy formulation and monetary appropriation. The judiciary, which interprets and applies the law in cases before it, comprises a Supreme Court, ten courts of appeals, courts of common pleas and of probate in each of the 88 counties, and such other inferior courts as the legislature may establish. All judges are elected for six-year terms.

Executive, legislature, and judiciary

Local government. Each county exists as a quasi-municipal corporation, an arm of state government, but without general authority of self-government in the legislative field. Various optional forms are available, and the increasing social and economic problems of the multicounty metropolitan areas may lead to newer forms. Most larger cities operate under home-rule charters that permit them to choose the form most suitable to their needs. The mayor–council type is most common, though Cincinnati operates under a city-manager–council plan. The township, Ohio's oldest form of government, remains a viable form, though the number is diminishing as they are annexed into municipalities or as newly incorporated villages assume their functions.

Political life. State laws carefully prescribe the rules for forming and running political parties, conducting elections, and balloting. The two-party system has prevailed generally, but Ohio has produced such minor-party leaders as Norman Thomas, many times a presidential candidate on the Socialist Party ticket; Victoria Claflin Woodhull, the first woman to run for president, with the Equal Rights Party; and such leaders of fringe political groups as Jacob Coxey, who led the march of "Coxey's Army" from Massillon, Ohio, to Washington, D.C., in 1894 to demand various economic reforms.

Since its inception the Republican Party has been slightly more successful than the Democratic in statewide elections. In national politics, the parties are evenly matched, making Ohio a focus of national electioneering. In addition to eight presidents, Ohio has supplied three vice presidents, three chief justices and eight associate justices of the U.S. Supreme Court, and 35 federal Cabinet officers. One of these chief justices was William Howard Taft, who also served as president. Although political dynasties have been rare in Ohio political life, Taft's father had been secretary of war and attorney general under Grant and was later U.S. minister to Russia and Austria-Hungary. His son, Robert A. Taft, served in the United States Senate from 1939 to 1953, and his grandson, Robert A. Taft, Jr., was elected to the U.S. Senate in 1970.

Social conditions. The major expenditures of state government are for education, health, welfare, and highways. A number of state executive agencies administer the programs in these areas, often in conjunction with federal bodies.

Education. More than 50 percent of the Ohioan's state-tax dollar is channelled into education. More than 3,000,000 students are accommodated at schools of all levels, which include 12 public and 65 private institutions of higher learning. Several municipal universities also receive state aid. A nine-member Board of Regents is responsible for the development of higher education in Ohio.

Higher education

Called a "land of schools and colleges" from its beginning, contemporary Ohio ranks about seventh in the United States in the number of accredited colleges it contains. Ohio University was established by Ohio's first legislature in 1804 as the first state institution of higher education west of the Alleghenies. In 1809 Miami University became the second state university. Both these institutions conduct important programs of work, have large enrollments, and maintain numerous branches. Ohio State University, which was founded in 1870, is the largest contemporary state-assisted university. It is also a land-grant college. A major graduate and professional centre, it also has one of the largest undergraduate enrollments in the nation. It maintains several regional campuses and a graduate program at Dayton. Many of Ohio's small independent colleges have made distinguished contributions to the state and have served as pioneers in education in various ways. Thus Oberlin College, founded 1833, became the first coeducational college in the United States and one of the first to admit Negroes. Antioch College, which was founded in 1852, is one of the nation's oldest experimental liberal arts colleges. Like several other institutions in the state, it has implemented innovative programs for advancing students from minority group backgrounds. The University of Cincinnati, established as Cincinnati College in 1819, is the nation's oldest municipal university.

Welfare and social services. The aged and poor, the blind and disabled, and crippled and dependent children are among the groups benefitting from the welfare activities of several state agencies. Other state bodies oversee programs in the prevention and cure of illness. A youth commission operates diagnostic and training centres, youth corps, and schools. State activities with labour and industry include programs in employment and unemployment services, industrial safety, and job-connected-injury compensation.

The development and use of natural resources fall under the jurisdiction of the Department of Natural Resources, which handles forestry, reclamation, parks, wildlife, and similar environmental concerns. The Department of Agriculture's responsibilities include economic and health problems of farm life and the regulation of foods through

pure-food-and-drug laws. Organized research is carried out at the Ohio State University and at the Ohio Agricultural Experiment Station in Wooster. A department of urban affairs cooperates with local and regional bodies and coordinates state programs bearing on community problems.

CULTURAL LIFE AND INSTITUTIONS

Early settlers of Ohio put the stamp of their former homes—New England, the Middle Atlantic states, Virginia, and Kentucky—upon certain sections of the state. Situated at the crossroads of the nation with an ever-changing society, Ohio never developed a distinctive state culture.

The arts. There has never been a clearly identifiable Ohio school in any of the arts, though there has been great activity in all of them. Such diverse Ohio writers as William Dean Howells, Ambrose Bierce, Paul Laurence Dunbar, Brand Whitlock, Charles F. Brown ("Artemus Ward"), David R. Locke ("Petroleum V. Nasby"), Sherwood Anderson, Louis Bromfield, and James Thurber drew upon their Ohio background. None of them, however, attempted to develop a distinctive regional character in his work.

When the log-cabin phase of early Ohio was ended, the settler was likely to follow the building styles he had known in his former home. In the Virginia Military District, where Southern influence was marked, the red-brick and stone houses were built in the Southern Federal architectural style. In the Western Reserve and the Marietta area, the New England influence was manifested in the austere lines of the Early American style and the later modified Georgian style. Later developments tended to follow the fashions of American architecture in general, most of them revivals of earlier European modes such as Greek, Gothic, and Romanesque. In recent years, in line with international trends, the emphasis has been on simplification and functionalism.

The performing arts: music and the theatre

The thousands of musical organizations in Ohio range from symphony orchestras to local choral societies. The symphony orchestra of Cleveland is among the finest in the world, and that of Cincinnati (which was considered the musical centre of the inland United States in the early days) is also renowned. Programs in music, theatre, dance, and the visual arts abound in Ohio's colleges and universities. With community theatres and arts centres, they serve as the cultural centres for many cities and towns. The Cleveland Play House (1915–16) and the Karamu Theatre (1915), an organization predominantly of black performers, also in Cleveland, have long enjoyed a national reputation. Cincinnati's Playhouse-in-the-Park (1960), noted for its experimentation, has become one of the United States' major regional professional theatres. The Ohio Arts Council, established in 1965 by the legislature, aids communities and arts organizations in stimulating greater interest as well as participation.

Libraries. Ohio has several hundred public libraries in addition to college and university facilities containing over 14,000,000 volumes and about 100 specialized libraries in many fields. The Ohio State Library, in Columbus, provides service to every Ohioan. Bookmobile service is a feature of rural areas.

Folk and popular culture. Reflecting Old World origins are the Welsh Eistedfodd festivities in Cleveland, Steubenville, Lima, Columbus, and Jackson and a German Saengerfest (Song Festival). More than 40 other nationality groups—including Hungarians, Bohemians, Swiss, Scandinavians, and Irish—present folk music and dances at festivals throughout the state. Other gatherings, in addition to the annual state and county fairs, include the Apple Festival in Jackson, the "River Days" Festival in Portsmouth, the Ohio Hills Folk Festival in Quaker City, and the Pumpkin Show in Circleville.

Sites of public interest. In the early 1970s Ohio had more than 100 museums of art, science, and history. The Cleveland Museum of Art ranked among the foremost art galleries in the nation, and those in Cincinnati, Toledo, Youngstown, and Columbus also held major art collections. In addition, many historical sites are maintained by state and local societies, including Indian mounds, old forts and battle sites, reconstructions of early settlements, and graves, homesteads, and similar memorials to Ohio's presidents and other leading citizens.

Recreational facilities include more than 125,000 acres of state park facilities, at 50 locations, for water sports, hiking and camping, or picnicking—in addition to numerous municipal recreational areas. Numerous public gardens, zoos, caves and caverns, and privately run amusement parks add to Ohio's recreational repertory.

Newspapers, broadcasting, and publishing

Communications. Ohio's newspapers have experienced numerous mergers and consolidations in recent decades, though some 450 of varying political views remain. They are more likely to carry syndicated columns expressing a spectrum of opinion than to be the organ of one party. Some newspapers have attempted to meet the competition of the broadcasting media by acquisition of stations. All of Ohio is well served by both commercial and noncommercial radio and television stations. Cleveland is a centre of publishing, and several of Ohio's universities publish through their own presses.

Research and development. A top-ranking state in scientific manpower, Ohio has a great number of laboratories maintained by specialized institutes, industries, educational institutions, and national and state agencies. Reflecting industrial concentrations, Akron is the world centre for rubber research, Cleveland for research in lighting. Glass, steel, soap, and electronics are among the many other products undergoing constant testing and evaluation. Federal centres include ones devoted to aviation medicine, aeronautics and space, atomic energy, agriculture, and forestry.

PROSPECTS

Ohio continues to reflect trends in the rest of the United States in its increasing concentration of population, in its loss of population from farms that are at the same time becoming vastly more productive, in the growing problems of the inner cities, and in the concern for the quality of the environment everywhere. Northern Ohio is already being considered as part of an urban agglomeration stretching west to Chicago from Buffalo, New York, and Pittsburgh, Pennsylvania. Similar concentrations have begun to develop through central Ohio around Columbus, along the Ohio River, and in the Miami Valley from Dayton to Cincinnati.

This demographic growth compounds both environmental and urban problems. Public attention has turned increasingly to programs to conserve natural resources, to reverse the pollution of rivers and lakes, to reclaim land scarred by strip-mining, to ensure clean air and water, and to rehabilitate the inner cities. In the southeast, relief programs have been undertaken for the rural poor. The effective treatment of problems of this character continue to challenge the best efforts of the people of Ohio, and of the nation.

BIBLIOGRAPHY. CARL F. WITTKE (ed.), *The History of the State of Ohio*, 6 vol. (1941–44), is the definitive work on this subject. EUGENE H. ROSEBOOM and FRANCIS P. WEISENBURGER, *A History of Ohio*, 2nd ed. (1967), the most authoritative one-volume account, contains a valuable annotated bibliography on Ohio. The *Ohio Historical Quarterly*, originally the *Ohio Archaeological and Historical Quarterly* (1887–), presents articles on a variety of Ohio historical subjects. Highly readable accounts of various aspects of Ohio history may be found in HARLAN HATCHER, *Buckeye Country*, rev. ed. (1947) and *Western Reserve: The Story of New Connecticut in Ohio* (1949); as well as in WALTER HAVIGHURST, *The Heartlands: Ohio, Indiana, Illinois* (1962). Ohio's economic geography and governmental processes are examined at length in ALFRED J. WRIGHT, *Economic Geography of Ohio*, 2nd ed. (1957), and in FRANCIS R. AUMANN and HARVEY WALKER, *The Government and Administration of Ohio* (1956). Current data on Ohio's economy, vital statistics, housing, education, science, religion, welfare, and the like may be obtained from a number of publications prepared by the ECONOMIC RESEARCH DIVISION OF THE DEVELOPMENT DEPARTMENT OF THE STATE OF OHIO, such as *Ohio Manufacturing* (1965); *Ohio's Economic Regions* (1964); *Ohio Population* (1968); *Ohio Economic Outlook* (1969); and the *Statistical Abstract of Ohio*, 2nd ed. (1969).

(F.R.A.)

Oils, Fats, and Waxes

Oils and fats are substances of plant or animal origin. They are nonvolatile, insoluble in water, and oily or greasy to the touch; they constitute, along with proteins and carbohydrates, one of the main kinds of foodstuffs, and they are widely distributed in nature. Chemically (see below for details), fats and oils are compounds produced by reaction between an alcohol called glycerol and certain members of a group of compounds called fatty acids. Waxes are the esters that result from a reaction between fatty acids and certain alcohols other than glycerol, either of a group called sterols, such as cholesterol, or an alcohol that contains 12 or more even numbers of carbon atoms in a straight chain, such as cetyl alcohol. Essential oils are volatile materials isolated by a physical process from an odoriferous plant of a single botanical species, such as oil of cloves. The dominant chemical compounds are terpenes, organic compounds consisting of multiples of isopentane units (*i.e.*, containing five carbon atoms), but many other classes of chemical constituents have been observed in various essential, volatile, or ethereal oils.

The term oils is used in a generic sense to describe all substances that are greasy or oily fluids at ordinary temperatures. The term also can refer (1) to the individual fatty or fixed (*i.e.*, nonvolatile) oils, such as olive or soybean oils; (2) to the hydrocarbon or mineral oils and derivatives, such as petroleum, shale oils, oils from the low-temperature distillation of coal, fuel oils, and lubricating oils; (3) to the odoriferous and volatile essential oils; and (4) to synthetic materials that possess the characteristic of oiliness or lubricity; for example, silicone oils. The mineral or hydrocarbon oils and synthetic oils do not come within the scope of this article.

This article is divided into the following main sections and subsections:

I. Fats and oils

To understand reactions between organic compounds, a general knowledge of the nomenclature is necessary. Organic molecules consist of carbon atoms (each having four bonds) linked with single, double, or triple bonds to one another in straight chains, in various kinds of branching chains, and with the ends of the chain bonded together to form what are called cyclic compounds. The number of atoms in an organic molecule may reach tens of thousands and contain many kinds of atoms other than carbon. Organic compounds are classified by various criteria into families with similar structures and properties, the largest being the hydrocarbons, which contain only hydrogen and carbon, but each member of which has thousands of derivatives containing other kinds of atoms as well and each recognizable fragment of which—called a radical—participates in countless reactions. The carbohydrates, another large family, always contain oxygen as well as hydrogen, and they, too, have an enormous number of derivatives and participate, as free radicals in reactions with one another, with hydrocarbons, and other types of organic molecules. The vast majority of organic compounds have what are called functional groups; that is, groups of atoms that always react in the same way whatever radical they are bonded to. Some of the most important functional groups, when attached to a radical, form the subfamilies of compounds called alcohols, carboxylic acids, ketones, amines, ethers, and esters. All alcohols have a functional group consisting of an oxygen atom, one of whose two bonds is linked with a hydrogen atom, the other to a carbon atom in the chain. This is called the hydroxyl group and in formulas it is written R—OH, R being the radical to which it is attached. A molecule may have many such hydroxyl groups. The group forming carboxylic acids consists of a carbon atom double-bonded to an oxygen atom and single-bonded to a hydroxyl group, leaving the carbon with one bond free to attach to any other carbon (or a hydrogen, as in formic acid, the simplest carboxylic acid) in a molecule. The formula is written $R'-\overset{\overset{O}{\|}}{C}-OH$, R′ being the radical. In a great many chemical reactions, it is the functional groups that react. An important type of reaction is called esterification; it results when any alcohol group reacts with any carboxylic acid group to produce a characteristic compound called an ester, which consists of the radical (R′) of a carboxylic acid joined to the radical (R) of an alcohol through the functional group of the carboxylic acid, with the carbon atom double-bonded to one oxygen and single-bonded to the oxygen of the alcohol thus:

$$R'-\overset{\overset{O}{\|}}{C}-O-R.$$

Oil and fat compositions and properties

Oils and fats consist primarily of glycerides, which are esters formed by the reaction of three molecules of fatty acids with one molecule of glycerol to yield one molecule of triglyceride and three molecules of water. When the three fatty acids are the same, the product is a simple triglyceride; when there are at least two different acids, the product is a mixed triglyceride. Simple triglycerides rarely occur in nature.

Oils are usually liquids at ordinary temperatures, such as 25° C (77° F); fats are solid at this temperature. There is no basis, however, for chemical distinction between the two. The difference is only a physical one that can be removed by changing the environment.

Use of the word fat to include both fats and oils is becoming common, especially among chemists. Thus, both soybean oil and tallow would be considered fats. This terminology avoids confusion with nonfatty oils. No sharp distinction can be made between fats and oils, because at sufficiently low temperature all oils will solidify, and at even moderately elevated temperatures all fats will liquefy. Moreover, a fat is never entirely solid except under unique circumstances. Fats have been defined as plastic solids consisting of a mixture of crystalline particles and liquid oil.

Lipid (lipide) is a much broader term that may be used to include all of the ether-soluble, water-insoluble substances obtainable from plant and animal sources. An abbreviated definition is: (1) simple lipids are esters of fatty acids and various alcohols, classified as (a) fats and oils—*i.e.*, glycerides (fatty-acid esters of glycerol); and (b) waxes—*i.e.*, fatty-acid esters of alcohols other than glycerol. (2) Compound lipids are esters of fatty acids and alcohols containing additional groups, divided into (a) phospholipids (phosphatides)—*i.e.*, fatty-acid esters containing a phosphoric acid group (they also usually contain a nitrogenous group); (b) glycolipids—*i.e.*, compounds that consist of fatty acids, a carbohydrate, and a nitrogen-containing compound but no phosphoric acid group; and (c) others, such as sulfolipids and amino lipids. (3) Derived lipids are compounds derived from the preceding groups and having the general properties of the lipids; the derived compounds include (a) fatty acids; (b) alcohols, including glycerol, sterols, and the long-

chain alcohols from the waxes; and (c) others, including hydrocarbons such as squalene found in fish livers, and nitrogenous bases from the phospholipids (see also LIPID).

The fats comprise one of the three classes of food. Nearly all cells contain fat, protein, and carbohydrate. Fat is sometimes called nature's storehouse of energy because on a weight basis it contains more than twice as much energy as does carbohydrate or protein. It is probably as storehouses or depots of concentrated energy that fats appear in plant reproductive organs such as pollen grains and seeds. It is this fat that man recovers from plants for use as food or in industry. The fat content of the nonreproductive tissue of plants is usually so low that recovery is impracticable. Yet much of man's dietary fat comes from natural foodstuffs without being separated from the other plant materials with which it occurs. The proportion of fat in these foodstuffs varies from 0.1 percent in white potatoes to 70 percent in some nut kernels.

More than 90 percent of the fat recovered in the world is obtained from about 20 species of plants and animals. Most of this separated fat is used eventually as human food. Consequently, fat technology deals largely with the separation and processing of fats into forms acceptable to the various dietary customs in the countries in which they are to be used.

HISTORY OF USE

Early food and non-food uses

Man has used many natural fats for both food and nonfood purposes since prehistoric times. The Egyptians used olive oil as a lubricant in moving heavy building materials. They also made axle greases from fat and lime, mixed with other materials, as early as 1400 BC. Homer mentions oil as an aid to weaving and Pliny talks about hard and soft soaps. Candles and lamps using oil, tallow, or beeswax have been used for thousands of years.

Waxes and oils that had dried to hard films were used in protective or decorative coatings on walls and mummy cases, and as waterproofing agents for wooden ships. The form of painting known as encaustic employed a mixture of pigments in natural waxes. Tempera, another early form of painting, can be considered a forerunner of the modern emulsion paints. It was a water emulsion of wax or oil and pigments, stabilized with vegetable gums or egg yolk (see also PAINTS, VARNISHES, AND ALLIED PRODUCTS).

Apparently the first mention of the use of a drying oil as a protective coating was made in about the 6th century AD, after which the art grew rapidly. Transparent varnishes were made of linseed oil and natural resins. Chemical driers, however, were not used until much later.

The primary uses of fats for nonedible purposes are much the same as they were centuries ago, although the efficiencies of use have improved. The commercial uses of fats have increased in number as the understanding of the chemical nature of fats has expanded. C.W. Scheele, a Swedish chemist, discovered in 1779 that glycerol could be obtained from olive oil by heating it with litharge (lead monoxide), but it was not until about 1815 that the French chemist Michel-Eugène Chevreul (1786–1889) demonstrated the chemical nature of fats and oils. A few years later the separation of liquid acids from solid acids was accomplished. Margarine was invented by the French chemist Hippolyte Mège-Mouriès, who in 1869 won a prize offered by Napoleon III for a satisfactory butter substitute. The modern hydrogenation process had its origin in research in the late 19th century that led to the establishment of the vegetable-oil-shortening industry and a variety of industrial applications.

After World War I, organic chemists gained extensive knowledge first of fatty-acid compositions and then of glyceride compositions. Growth of the chemical industry stimulated a simultaneous expansion of the use of fats as raw materials and as intermediates for scores of new chemicals. The modern application of many organic chemical reactions to fats and fatty acids formed the foundation of a new and rapidly growing fatty-chemicals industry.

FUNCTIONS IN PLANTS AND ANIMALS

Fats as reserves and agents

The universal distribution of fats in plant and animal tissues suggests physiological roles that go beyond their function as a fuel supply for the cells. In animals the most evident function of fats is that of a food reserve to supply energy (through subsequent enzymatic oxidation—that is, combination with oxygen catalyzed by enzymes). The storage of fat in vegetable seeds can be explained similarly on the basis that it is a food reserve for the embryo. It is not so easy, however, to account for the presence of large quantities of fat in such fruits as olives, avocados, and palms; much of this fat is probably lost or destroyed before the seed germinates. Fats, and especially the waxes, fulfill other valuable functions in plants and animals. Subcutaneous deposits of fat insulate animals against cold because of the low rate of heat transfer in fat, a property especially important for animals living in cold waters or climates; *e.g.*, whales, walruses, and bears. Beeswax prevents dilution or contamination of concentrated sugar solutions in the comb. Waxes, and in some cases fats, secreted on the surface of plant leaves protect the underlying tissues against loss of water by transpiration. Apples, citrus fruits, and melons have natural protective wax coatings.

Fats that have been separated from tissues always contain small quantities of closely associated nonglyceride lipids such as phospholipids, sterols, vitamins A, D, and E, and various carotenoid pigments. Many of these substances are vital emulsifying agents or growth factors. Others function as agents that prevent deterioration of fats in plant tissues and seeds caused by destructive combination with oxygen. These minor constituents probably are present in the fats as a result of their physical solubility, and thus fats serve as carriers for these substances in animal diets.

Many animals require some fat containing one or more of the essential fatty acids (linoleic, arachidonic, and to a limited extent linolenic) to prevent the physical symptoms of essential-fatty-acid deficiency manifested by skin lesions, scaliness, poor hair growth, and low growth rates. These essential fatty acids must be supplied in the diet since they cannot be synthesized in the body.

The prostaglandins, discovered by the Nobel laureate U.S. von Euler of Sweden, are hormones derived from arachidonic acid. Despite intensive international research, in the early 1970s the functions of prostaglandins were understood only vaguely. These biologically active fatty acids, which are present in very minute quantities in animal tissues, apparently are involved in contraction of smooth muscles, enzyme activity in lipid metabolism, function of the central nervous system, regulation of pulse rate and blood pressure, function of steroid hormones, fat mobilization in adipose tissue, and a number of other vital functions. A prominent exploratory area is the study of prostaglandins as a means of once-a-month birth control.

SYNTHESIS AND METABOLISM IN LIVING ORGANISMS

Formation of fats in seeds and fruits occurs late in the ripening process. Sugars and starches predominate in fruits, seeds, and sap in the unripe condition. These apparently are converted by enzymes during the maturing process to fatty acids and glycerol, which then form glycerides. Studies with radioactive-tracer techniques confirm the synthesis of fats from carbohydrates in both plants and animals. In fact, it has been shown by the use of labelled acetic acid, or acetate, ions that any food source from which acetate ions may form as an intermediate metabolite can be converted to fatty acids in at least some animal tissues. It has been further demonstrated that acetate can be converted to cholesterol in animal tissue. It is noteworthy that, almost without exception, natural fats contain only fatty acids with an even number of carbon atoms. These acids apparently are built up of two-carbon units. Although the preponderance of fatty acids with 18 carbon atoms has suggested the hypothesis that fats are derived from three molecules of glucose (a carbohydrate with six carbon atoms), later discoveries through tracer studies have indicated the buildup from

Buildup of two-carbon units

Table 1: Common Fatty Acids

common name	systematic name	formula	carbon atoms	double bonds	melting point (°C)
Caprylic	octanoic	$C_7H_{15}COOH$	8	0	16.5
Capric	decanoic	$C_9H_{19}COOH$	10	0	31.5
Lauric	dodecanoic	$C_{11}H_{23}COOH$	12	0	44
Myristic	tetradecanoic	$C_{13}H_{27}COOH$	14	0	58
Palmitic	hexadecanoic	$C_{15}H_{31}COOH$	16	0	63
Stearic	octadecanoic	$C_{17}H_{35}COOH$	18	0	72
Arachidic	eicosanoic	$C_{19}H_{39}COOH$	20	0	77
Oleic	*cis*-9-octadecenoic	$C_{17}H_{33}COOH$	18	1	13.4
Linoleic	*cis*-9, *cis*-12-octadecadienoic	$C_{17}H_{31}COOH$	18	2	−5
Linolenic	*cis*-9, *cis*-12, *cis*-15-octadecatrienoic	$C_{17}H_{29}COOH$	18	3	−11.3
Eleostearic	*cis*-9, *cis*-11, *cis*-13-octadecatrienoic	$C_{17}H_{29}COOH$	18	3	49
Ricinoleic	12-hydroxy-*cis*-9-octadecenoic	$C_{17}H_{33}OCOOH$	18	1+OH	16
Arachidonic	5,8,11,14-eicosatetraenoic	$C_{19}H_{31}COOH$	20	4	−49.5
Erucic	*cis*-13-docosenoic	$C_{21}H_{41}COOH$	22	1	33.5

the two-carbon acetate units. Since acetate can be formed from fats, proteins, or carbohydrates by reaction with oxygen, it is thus possible for fats to be synthesized indirectly from any of these sources. The formation of multiple linkages between carbon atoms (double bonds) in the fats synthesized from acetate is accomplished (probably in the liver) by addition or removal of hydrogen atoms through the action of enzymes.

Utilization of stored fat by plant embryos has not been entirely explained, but it is known that in germinating embryos the glycerides are hydrolyzed—that is, decomposed to glycerol and fatty acids—by lipolytic (fat-splitting) enzymes. These may pass through oxidative processes to form intermediate metabolic products that can be oxidized further to carbon dioxide and water or can be converted to carbohydrates, which may then pass through the many steps of carbohydrate metabolism.

In animal digestive tracts, the fats in foods are emulsified with digestive secretions containing lipase, an enzyme that hydrolyzes at least part of the glycerides. The glycerol, partial glycerol esters, fatty acids, and some glycerides are then absorbed through the intestine and are at least partially recombined to form glycerides and phospholipids. The fat, in the form of microscopic droplets, is transported in the blood to points of use or storage. The fat of an individual animal may vary somewhat according to the composition of fats in the food. The body fat of swine that are fed cod-liver oil, for instance, is softer than normal and has some long-chain fatty acids containing more than 20 carbon atoms, characteristic of the dietary fat.

Fats used by or stored in animal tissues come from two sources—enzymatic synthesis and diet. The fat synthesized from carbohydrates or proteins is characteristic for each animal species. Most dietary fat is broken up by enzymes to small intermediates followed by enzymatic resynthesis to form the fat characteristic of the animal, but some dietary fatty acids are absorbed directly and recombined in the body fat. Mammary glands apparently have enzyme systems that can produce fats quite different from those stored in adipose tissue, but even so, milk fats still can reflect unusual components of ingested fats. It has also been found that the fatty-acid composition of milk fat can be altered substantially by feeding cows or goats fat-containing products that have been coated to prevent their combination with oxygen and resynthesis in the first rumen. Thus, the feeding of encapsulated polyunsaturated fats (fats containing two or more double carbon–carbon bonds in their molecular structure) such as corn oil or soybean oil to ruminants greatly increases the polyunsaturated-fatty-acid content of the milk fat.

The manner in which fat reserves are circulated to the organs where metabolism occurs is incompletely understood. Radioactive-tracer studies provide some insight into this complicated process. It has long been established that when mobilization of reserve fat takes place the stream is directed primarily to the liver, where fatty acids may be partially desaturated; *i.e.*, hydrogen is removed from the fatty-acid chains to produce unsaturated or double bonds between carbon atoms. This apparently facilitates subsequent oxidation in other tissues.

Oxidation of fatty acids

Fatty acids also may be oxidized directly in the various tissues as well as in the liver. Fatty-acid metabolism is presumed to be by oxidation in successive two- and four-carbon stages. Intermediate products could be acetoacetate and acetate groups. If the mechanism is faulty, acetone is formed and excreted (acetonuria). The final products of normal metabolism are carbon dioxide and water.

In certain genetic diseases that cause mental retardation and early death, there is an unusual accumulation of phospholipids in tissues, especially in the brain. In these diseases (Gaucher's, Tay-Sachs, Fabry's, and Niemann–Pick) there is an inherited lack of certain enzymes involved in lipid metabolism.

The relationship between dietary fats and the disease atherosclerosis, a form of arteriosclerosis, has been much studied but is little understood. It was observed empirically that there was a correlation between the content of cholesterol in blood serum and the incidence of atherosclerosis. Individuals with high blood-cholesterol levels (hypercholesterolemia) were frequently subject to atherosclerosis, a cardiovascular disease characterized by the accumulation of fatty material in the arterial system. In such cases partial replacement of solid animal fats in the diet by liquid fats resulted in a lowering of the serum cholesterol level in short-term feeding studies. Dietary interest was focussed on the polyunsaturated fatty acids —those with two or more double bonds in each molecule. The chief polyunsaturated acids considered in this connection were linoleic (two double bonds), linolenic (three), and arachidonic (four). The oils with the highest ratios of polyunsaturated to saturated acids (*P/S* ratio) are, in decreasing order: safflower, sunflower, corn, soybean, and cottonseed. Cholesterol, an alcohol, is rarely present in the free state but is combined with fatty acids. It was postulated that the higher melting cholesterol esters of solid fatty acids would be more difficult to transport and metabolize than the lower melting cholesterol esters of liquid fatty acids, and, as a result, a change in the dietary fat should reduce the cholesterol level. Results of incorporating polyunsaturated fats as partial replacements for animal fats in the diet have been inconclusive. Some tests indicate possible merit, but one large-scale study extending over a period of three years and completed in 1969 failed to confirm any significant value of polyunsaturated fats in reducing atherosclerosis (see also METABOLISM).

CHEMICAL COMPOSITION OF FATS

Although natural fats consist primarily of glycerides, they contain many other lipids in minor quantities. Corn oil, for example, may contain glycerides plus phospholipids, glycolipids, phosphoinositides (phospholipids containing inositol), many isomers of sitosterol and stigmasterol (plant steroids), several tocopherols (vitamin E), vitamin A, waxes, unsaturated hydrocarbons such as squalene, and dozens of carotenoids and chlorophyll compounds, as well as many products of decomposition, hydrolysis, oxidation, and polymerization of any of the natural constituents.

Fatty acids contribute from 94 to 96 percent of the total weight of various fats and oils. Because of their prepon-

Table 2: Saturation and Unsaturation in Fatty Acids

Lauric acid	$CH_3–CH_2–CH_2–CH_2–CH_2–CH_2–CH_2–CH_2–CH_2–CH_2–CH_2–COOH$	a saturated fatty acid with 12 carbon atoms
Oleic acid	$CH_3(CH_2)_7CH=CH(CH_2)_7COOH$	an unsaturated fatty acid with one double bond and 18 carbon atoms
Linoleic acid	$CH_3(CH_2)_4CH=CHCH_2CH=CH(CH_2)_7COOH$	an unsaturated fatty acid with two double bonds and 18 carbon atoms
Linolenic acid	$CH_3CH_2CH=CHCH_2CH=CHCH_2CH=CH(CH_2)_7COOH$	an unsaturated fatty acid with three double bonds and 18 carbon atoms
Arachidonic acid	$CH_3(CH_2)_4CH=CHCH_2CH=CHCH_2CH=CHCH_2CH=CH(CH_2)_3COOH$	an unsaturated fatty acid with four double bonds and 20 carbon atoms

Effect of fatty acids on properties

derant weight in the glyceride molecules and also because they comprise the reactive portion of the molecules, the fatty acids influence greatly both the physical and chemical character of glycerides. Fats vary widely in complexity; some contain only a few component acids, and at the other extreme more than 100 different fatty acids have been identified in butterfat, although many are present in only trace quantities. Most of the oils and fats are based on about a dozen fatty acids (see Table 1). In considering the composition of a glyceride it is particularly important to distinguish between the saturated acids (acids containing only single bonds between carbon atoms, such as palmitic or stearic), with relatively high melting temperatures, and the unsaturated acids (acids with one or more pairs of carbon atoms joined by double bonds, such as oleic or linoleic), which are low melting and chemically much more reactive.

In the series of saturated acids, the melting point increases progressively from below room temperature for the acids of lower molecular weight to high melting solids for the longer chain acids. Unsaturated acids may contain up to six double bonds, and as unsaturation increases the melting points become lower. Glycerides based predominantly on unsaturated acids, such as soybean oil, are liquids; and glycerides containing a high proportion of saturated acids, such as beef tallow, are solids. The carbon atoms in fatty acids are arranged in straight chains, and the first site of unsaturation (double bond) in most of the unsaturated acids appears between the ninth and tenth carbon atoms, starting the counting from the terminal carboxyl group (see Table 2). The specificity of location of unsaturation in fatty acids from both plant and animal sources suggests formation by a related enzymatic dehydrogenation mechanism.

During the 1960s, several revolutionary separation techniques, especially gas–liquid chromatography and thin-layer chromatography (methods used to separate and identify mixtures of chemical compounds), improved the precision of analysis and led to the discovery and characterization of a number of new and unusual fatty acids. Natural fatty acids were found with such structures as triple (acetylenic) bonds; hydroxyl and ketone groups (RC=O, where C is a carbon atom, O an oxygen atom, and R an alkyl group); and epoxy (a closed ring group consisting of two alkyl groups and an oxygen atom), cyclopropane, and cyclopentane rings. For years it was thought that fats contained only straight-chain fatty acids with an even number of carbon atoms, but it was demonstrated that butterfat and the depot fats of cattle and sheep contain small quantities (1.5 to 2 percent) of saturated and traces of unsaturated straight-chain acids with odd numbers (11, 13, 15, 17, 19) of carbon atoms. The same studies uncovered both odd- and even-numbered fatty acids containing 13, 14, 15, 16, and 17 carbon atoms and a methyl branch as minor components (0.5 to 1 percent) of these fats.

Since the glycerides, which make up 90 to 99 percent of most individual fats or oils of commerce, are esters formed by three fatty-acid molecules combining with one molecule of glycerol, they may differ not only in the fatty acids that they contain but also in the arrangement of the fatty-acid radicals on the glycerol portion. Simple triglycerides are those in which each molecule of glycerol is combined with three molecules of one acid; *e.g.*, tripalmitin, $C_3H_5(OCOC_{15}H_{31})_3$, the glyceryl ester of palmitic acid, $C_{15}H_{31}COOH$. Only a few of the glycerides occurring in nature are of the simple type; most are mixed triglycerides; *i.e.*, one molecule of glycerol is combined with two or three different fatty acids. Thus stearodipalmitin, $C_3H_5(OCOC_{15}H_{31})_2(OCOC_{17}H_{35})$, contains two palmitic acid radicals and one stearic acid radical. Similarly, oleopalmitostearin, $C_3H_5(OCOC_{15}H_{31})(OCOC_{17}H_{33})(OCOC_{17}H_{35})$, contains one radical each of oleic, palmitic, and stearic acids. Each mixed triglyceride containing three different acid radicals may exist in three different isomeric forms (molecules having the same composition but different structures), because any of the three can be linked with the centre carbon of the glycerol molecule. A mixed triglyceride containing two radicals of the same acid and one radical of another acid has only two isomeric forms.

Monoglycerides and diglycerides are partial esters of glycerol and have one or two fatty-acid radicals, respectively. They are seldom found in natural fats except as the products of partial hydrolysis of triglycerides. They are easily prepared synthetically, however, and have important applications mainly because of their ability to aid in the formation and stabilization of emulsions. As constituents of shortening in baked products they increase product volumes, improve tenderness, and retard staling. They also have technical importance as intermediates in the manufacture of coatings and resins.

Glyceride distribution in natural fats

The glyceride composition of natural fats tends to follow the rule of even distribution, which proposes that each of the individual fatty-acid radicals in a fat is apportioned evenly among the different glyceride molecules. Consequently, specific acids present in quantities less than one-third of the total acids are inclined to appear singly in the glycerides, and it is necessary to have an acid present in a quantity greater than two-thirds of the total acids before any simple triglycerides would be present. Vegetable-seed fats appear to follow this rule much more closely than do animal fats.

Some fats tend to follow the pattern of random, or statistical, distribution of fatty acids in their glycerides. In this pattern, the acids are distributed among the glycerides as if there were no directing influences and they had organized themselves by chance alone. In beef tallow, for example, which contains slightly more than 50 percent of saturated acids, the chance of a saturated acid appearing on any glyceryl group is ½, and the chance of three saturated acids combining with glycerol is $½ \times ½ \times ½ = ⅛$. The observed quantity of trisaturated glycerides is fairly close to the 12.5 percent level calculated for random distribution.

With the development of more sophisticated analytical tools, including specific enzymatic hydrolysis, it was found that fats deviate significantly from both even and random distribution patterns, and several "restricted random" theories have been proposed; these relate the fatty-acid distribution to enzyme-controlled biosynthesis.

Fats that are heated in the presence of certain alkaline catalysts, such as sodium methoxide, "rearrange" themselves to follow more closely the system of random distribution. Physical properties are often altered significantly. Some manufacturers in the United States, for example, rearrange the molecules in lard and other fats to make improved shortenings and margarines.

Table 3: Sources, Iodine Value, and Uses of Principal Oils and Fats

	principal sources of raw material	iodine value	principal uses
Vegetable oils			
Drying oils			
Parilla	China, Korea, Japan, India	193–208	paint, varnish
Linseed	U.S., Argentina, India, Canada, U.S.S.R.	175–205	paint, varnish, linoleum, printing ink
Tung	China, Japan, U.S.	160–175	paint, varnish
Oiticica	Brazil	139–155	paint, varnish
Semidrying oils			
Poppyseed	Levant, India	132–143	salad oil, artists' oil, soft soap
Safflower	U.S., India	130–150	salad oil, paints, resins
Soybean	U.S., China, Manchuria	125–140	food, paint, resins, chemicals
Corn (maize)	U.S., Argentina, Europe	115–130	food
Sunflower	U.S.S.R., South America, Eastern Europe	125–136	food, resins
Cottonseed	U.S., India, Egypt, Mexico, U.S.S.R.	103–116	food, soap
Sesame	India, Egypt, Levant	103–118	food, soap
Rape (colza)	India, Europe, Canada, Pakistan	94–105	food, lubricant
Nondrying oils			
Almond	southern Europe, North Africa	93–100	perfumery, pharmacy, food
Arachis (peanut, groundnut)	India, West Africa, China, U.S.	85–100	food
Olive	Mediterranean countries, U.S.	75–90	food, soap, lubricating, pharmacy
Castor	India, Mediterranean, Brazil, U.S.	80–90	medicine, lubricant, chemicals
Animal and marine oils			
Marine oils			
Anchovy	Peru	170–190	resins, leather currying, paints, food
Sardine	west coast of North America, Japan	160–190	resins, leather currying, paints, food
Menhaden	Atlantic coast of North America	150–180	resins, leather currying, paints, food
Herring	North Sea, Japan	120–145	leather currying, paints, food
Cod liver	North Sea, east coast of North America	120–180	vitamins, leather currying
Shark liver	coasts of North America	100–115	vitamins, leather currying
Seal	Arctic and Antarctic seas	130–150	food, leather currying, soap
Whale	Arctic and Antarctic seas	110–150	food, soap, fibre dressing, leather currying, greases
Sperm whale	west coast of South America	65–90	lubricating oil for delicate machinery
Terrestrial animal oils			
Neat's-foot	U.S., South America, Europe	67–75	lubricating, high-grade leather dressing
Vegetable fats			
Mahua (Illipe) butter	India, Malaysia	53–67	food, soap, candles
Shea butter	West Africa, The Sudan	53–65	food, soap, candles
Palm oil	West Africa, Indonesia, Malaysia, Brazil	50–60	soap, candles, tinplate industry
Cacao (cocoa) butter	Indonesia, Malaysia	32–42	chocolate, pharmacy, perfumery
Babassu oil	West Africa	12–16	food, soap
Coconut oil	Philippines, Indonesia, India, Sri Lanka, South American coasts	8–10	food, soap, chemicals
Japan wax	China, India, Japan	5–17	polishes
Animal fats			
Lard	U.S., central Europe	46–66	food, soap, pharmacy, chemicals
Bone	U.S., India, Europe	43–56	soap, candles
Tallow, beef	Argentina, U.S.	30–45	food, soap, candles, chemicals
Tallow, mutton	Australia	31–45	food, soap
Butter	U.S., Europe, Australia, Canada, U.S.S.R.	25–40	food

PHYSICAL AND CHEMICAL PROPERTIES

Fats and oils may be divided into animal and vegetable fats according to source. Further, they may be classified according to their degree of unsaturation as measured by their ability to absorb iodine at the double bonds. This degree of unsaturation determines to a large extent the ultimate use of the fat, as shown in Table 3. Oils having iodine values higher than about 150 (and therefore a high degree of unsaturation) are generally called drying oils and are used primarily in protective coatings. Those having iodine values of 100 to 150 are considered as semidrying and may be used either for food or in protective coatings. The nondrying oils, with the lowest amount of unsaturation, have iodine values generally below 100 and are used mainly in foods, soaps, chemicals, and specialty products.

Liquid fats (*i.e.*, vegetable and marine oils) have the highest degree of unsaturation, while solid fats (vegetable and animal fats) are highly saturated. Solid vegetable fats melting between 20° and 35° C (68° and 95° F) are found mainly in the kernels and seeds of tropical fruits. They have relatively low iodine values and consist of glycerides containing high percentages of such saturated acids as lauric, myristic, and palmitic. Fats from fruits of many members of the palm family, notably coconut and babassu oils, contain large amounts of combined lauric acid. Most animal fats are solid at ordinary temperatures; milk fats are usually characterized by the presence of short-chain carboxylic acids (butyric, caproic, and caprylic); and marine oils contain a large number of very long chain highly unsaturated acids containing up to six double bonds and up to 24 or even 26 carbon atoms.

Composition of vegetable oils

The fatty-acid composition of vegetable oils is strongly influenced by temperature during the period of seed maturation. Sunflower-seed oils from plants grown in the cool climate of the central Soviet Union or the plains area of the northern United States and southern Canada contain about 70 percent of linoleic acid, but oils from the same seed variety grown in the southern United States have half as much linoleic acid, with a corresponding increase in oleic acid. Even animals show effects of environmental temperature, and tallow from Indian cattle may have as much as 70 percent of saturated acids, compared with the normal 50 to 55 percent range for tallows from Europe, Argentina, and North America.

The plant breeder is beginning to play an important part in determining the chemical constitution of vegetable oils. Historically, the role of the plant breeder has been to improve resistance of plants to diseases and insect pests and to increase the yield of crops or of specific components of crops. As an outstanding example of this historical function, Soviet scientists, under the leadership of academician V.S. Pustovoyt, have increased the oil content of sunflower seed from 28 to 50 percent, a change that catapulted sunflower oil to second place behind soybean oil in worldwide importance. By genetic manipulation, breeders have created essentially new oilseed crops. Safflower contains about 11 percent of saturated acids, 12 percent oleic, and 77 percent linoleic. In the United States, a new crop, "high-oleic safflower," was developed; it has a composition of 80 percent oleic and 10 percent linoleic acids in the unsaturated fraction, a complete reversal of the normal pattern. Similarly, in Canada a new type of rapeseed, Canbra, was created in which oleic

acid replaces the 10 to 15 percent of eicosenoic acid and the 40 to 50 percent of erucic acid present in conventional rapeseed oil.

Specific gravities of oils and fats range from 0.913 (rapeseed oil) to 0.975 (Japan wax, myrtle wax); for most fats the value is 0.915 to 0.945.

Fats are practically insoluble in water and, with the exception of castor oil, are insoluble in cold alcohol and only sparingly soluble in hot alcohol. They are soluble in ether, carbon disulfide, chloroform, carbon tetrachloride, petroleum benzin, and benzene. Oils and fats have no distinct melting points or solidifying points because they are such complex mixtures of glycerides, each of which has a different melting point. Glycerides, further, have several polymorphic forms with different melting or transition points. The freezing points of the oils range from a few degrees above zero to about 30° C below zero (−22° F). At low temperatures (*e.g.*, 12° C, or 54° F, for cottonseed oil), solid portions, termed stearine, separate from many oils. Formerly, commercial separation was carried out simply by allowing oils such as cottonseed oil or fish oils to stand in outside storage tanks during the winter until higher melting components had settled out, leaving a clear supernatant layer of winter oil. Such oils remain limpid at low temperatures and are especially valued for use in salad dressings and mayonnaise. Mechanical refrigeration is now used in the preparation of winterized oils.

Effects of low temperatures

Fats can be heated to between 200° and 250° C (392° and 482° F) without undergoing significant changes provided contact with air or oxygen is avoided. On being heated above this temperature, the more unsaturated oils gradually polymerize and become considerably more viscous. When this is done commercially in the protective-coating industry, the process is called bodying. Castor oil, when heated to high temperature or under suitable conditions in the presence of catalysts, loses a molecule of water from each ricinoleic acid radical to form what is called dehydrated castor oil. This modified oil is used in the protective-coating industry for manufacture of light-coloured finishes that retain their colour during the service life of the coating. Above 300° C (572° F) fats may decompose, with the formation of acrolein (the decomposition product of glycerol), which has the pungent odour of burning fat. Hydrocarbons also may be formed at high temperatures.

On exposure to air, oils and fats gradually undergo certain changes. The drying oils absorb oxygen (dry) and polymerize readily; thin layers form a skin or protective film. The semidrying oils absorb oxygen more slowly and are less useful as paint oils. Still, sufficient oxygen is absorbed in time to produce distinct thickening and some film formation. Oxidation of the drying and semidrying oils is accelerated by spreading the oil over a large surface. On greasy cloths, for example, oxygen absorption may proceed so rapidly that spontaneous combustion ensues. The nondrying oils, of which olive oil is typical, do not oxidize readily on exposure to air, although changes do take place gradually, including slow hydrolysis (splitting to fatty acids and glycerol) and subsequent oxidation. This slow oxidation causes a disagreeable smell and taste described by the term rancidity.

The chemical reactions involved in oil oxidation have been studied widely. When oils and fats are exposed to air, little change takes place for a period of time that varies from oil to oil depending upon the amount and type of unsaturation and the content of natural antioxidants. During this so-called induction period, there is virtually no change in either odour or chemistry of the oil because of the protective effect of natural antioxidants, especially tocopherol. Gradually, the effectiveness of the antioxidant is overcome and there is an accelerating rate of oxidation of unsaturated acids, called autoxidation. Chemically, the first identifiable oxidation products are hydroperoxides. These break down into a large variety of low-molecular-weight aldehydes, esters, alcohols, ketones, acids, and hydrocarbons, some of which possess the pungent, disagreeable odours characteristic of rancid fats. In soybean oil exposed to air to the point of incipient rancidity, more than 100 different oxidation products have been identified. Natural oils such as coconut oil, with very low levels of unsaturation, are very stable to flavour deterioration, but the more highly unsaturated oils such as soybean oil or safflower oil lose their flavour more quickly. Sesame oil is unique in its flavour stability because of the presence of several natural antioxidants (sesamin, sesamolin, sesamol). Synthetic antioxidants such as propyl gallate, butylated hydroxyanisole (BHA), and butylated hydroxytoluene (BHT) have been used to retard the onset of rancidity and increase the storage life of edible fats.

When air is bubbled through heated drying or semidrying oils, oxygen is absorbed, and the oils polymerize to viscous products. These "blown oils" are used in various ways in the protective-coating industry. Oils blown at lower temperatures are used as plasticizers for nitrocellulose lacquers, and products of higher temperature processing are useful in caulks, putties, and paints.

Fats are hydrolyzed readily. This property is used extensively in the manufacture of soaps and in the preparation of fatty acids for industrial applications. Fats are hydrolyzed by treatment with water alone under high pressure (corresponding to a temperature of about 220° C [428° F]) or with water at lower pressures in the presence of caustic alkalies, alkaline-earth metal hydroxides, or basic metallic oxides that act as catalysts. Free fatty acids and glycerol are formed. If sufficient alkali is present to combine with the fatty acids, the corresponding salts (known popularly as soaps) of these acids are formed, such as the sodium salts (hard soap) or the potassium salts (soft soaps). Soaps of certain heavy metals, especially the lead, cobalt, and manganese salts, are called driers and are used to speed the rate of film formation of paints based on drying and semidrying oils.

Hydrolysis of fats

GENERAL METHODS OF EXTRACTION

The raw materials for the fat and oil industry are animal by-products from the slaughter of cattle, hogs, and sheep; fatty fish and marine mammals; a few fleshy fruits (palm and olive); and various oilseeds. Most oilseeds are grown specifically for processing to oils and protein meals, but several important vegetable oils are obtained from by-product raw materials. Cottonseed is a by-product of cotton grown for fibre, and corn oil is obtained from the corn germ that accumulates from the corn-milling industry, whose primary products are corn grits, starch, and syrup.

Fats may be recovered from oil-bearing tissues by three general methods, with varying degrees of mechanical simplicity: (1) rendering; (2) pressing with mechanical presses; and (3) extracting with volatile solvents.

Rendering. The crudest method of rendering oil from oleaginous fruits, still practiced in some countries, consists of heaping them in piles, exposing them to the sun, and collecting the oil that exudes. In a somewhat improved form, this process is used in the preparation of palm oil; the fresh palm fruits are boiled in water and the oil is skimmed from the surface. Such processes can be used only with seeds or fruits (such as olive and palm) that contain large quantities of easily released fatty matter. The rendering process is applied on a large scale to the production of animal fats such as tallow, lard, bone fat, and whale oil. It consists of cutting or chopping the fatty tissue into small pieces that are boiled in open vats or cooked in steam digesters. The fat, gradually liberated from the cells, floats to the surface of the water, where it is collected by skimming. The membranous matter (greaves) is separated from the aqueous (gluey) phase by pressing in hydraulic or screw presses; additional fat is thereby obtained. The residue is used for animal feed or fertilizer. Several centrifugal separation processes were developed in the 1960s. Cells of the fatty tissues are ruptured in special disintegrators under close temperature control. The protein tissue is separated from the liquid phase in a desludging type of centrifuge, following which a second centrifuge separates the fat from the aqueous protein layer. Compared with conventional rendering, the centrifugal methods provide a higher yield of better

quality fat, and the separated protein has potential as an edible meat product.

Tall-oil manufacture

In the manufacture of tall oil an unusual isolation technique is used that is somewhat related to rendering. In the sulfate pulping process for the manufacture of paper from pinewood, a dark-coloured, strong-odoured soap mass separates as a by-product. This separated soap is acidified with sulfuric acid, and crude tall oil, a mixture of about 60 percent of fatty acids and 40 percent of resin acids, separates and is skimmed off. Commonly, the crude product is distilled to yield the distilled tall oil of commerce, or it may be fractionally distilled, in which case two products are obtained. The fatty acids derived from tall oil consist of 55 to 60 percent of oleic acid, 35 to 40 percent linoleic acid, and from 1 to 3 percent of resin acids. The tall-oil rosin is a mixture of various cyclic resinous acids related to abietic acid. United States production of tall oil exceeds 1,200,000,000 pounds, and both the distilled product and the various fractionated grades find use in coatings manufacture, paper sizes, and miscellaneous industrial products.
