Tolman called himself a behaviourist and ostensibly was bound by Watson's insistence on objectivity. But he also was interested in thinking, expectancy, and consciousness. Tolman found his solution to this problem of incompatible theories after his association with the Vienna Circle of Logical Positivists, whose deterministic teachings he brought to the attention of U.S. psychologists about 1920. He maintained that learning is inexorably produced (determined) by such independent (directly manipulable) variables as the organism's previous training and physiological condition and by the response the environment requires. According to Tolman, the development of learning is revealed through the changing probability that given behaviour (the dependent variable) will result. He held that learning itself is not directly observable; it is an intervening variable, one that is inferred as a connecting process between antecedent (independent) variables and consequent (dependent) behaviour.

An attractive possibility is that intervening variables may have discoverable physiological bases. Psychologists Paul E. Meehl and Kenneth MacCorquodale proposed a distinction between the abstractions advocated by some and the physiological mechanisms sought by others. Meehl and MacCorquodale recommended using the term intervening variable for the abstraction and hypothetical construct for the physiological foundation. To illustrate: Hull treated habit strength as an intervening variable, defining it as an abstract mathematical function of the number of times a given response is rewarded. By contrast, Edward L. Thorndike (1874–1949) handled learning as a hypothetical construct, positing a physiological mechanism: improved conduction of nerve impulses.

Intervening variables and hypothetical constructs need not be incompatible; Thorndike's hypothetical neural process could empirically be found to be the mechanism through which Hull's abstraction operates.

Miniature theories. With growing realization of the complexity of learning, the grand theories of Guthrie, Hull, and Tolman generally have been abandoned except as historic landmarks. Hope for any impending, comprehensive theory was almost dead in the 1970s. More modest miniature theories remain, many likely to be of temporary value. An account of their major themes and issues, however, should have more enduring interest.

MAJOR THEMES AND ISSUES

Association. A dominant ancient theme in theories of learning has been that of association. Although the concept was accepted by Aristotle, it was brought into the developing psychology of learning by British empiricist philosophers (Locke, Berkeley, Hume, the Mills, and Hartley) during the 17th, 18th, and 19th centuries. Popular acceptability of the notion of association was related to progress in the physical sciences. The physical universe had been shown to consist of a limited number of chemical elements that can combine in innumerable ways. By analogy, a science of "mental chemistry" seemed appealing. The theorized elements in this new "science" were called ideas, said to be based on what were named sensations. The synthesizing principles by which these posited ideas combined in conscious experience were expressed as so-called laws of association. It was suggested that such conditions as temporal and spatial contiguity, repetition, similarity, and vividness favoured the formation of associations, and each was called a law of association. Thus, there were "laws" of repetition, of similarity, and so on.

At the end of the 19th century the notion of association was widely accepted among psychologists. German psychologist Wilhelm Wundt (1832–1920) took a position nearly identical with that of the British empiricist philosophers. Also in Germany, Hermann Ebbinghaus (1850–1909) began to study rote learning of lists of nonsense verbal items (*e.g.,* XOQ, ZUN, ZIB). He maintained that the association of each word with every succeeding word was the primary mechanism in learning these lists. Pavlov in Russia offered temporary associative connections in the nervous system as a hypothetical basis for conditioned reflexes.

Rote learning

These European influences coalesced in North America. Wundt's notions were introduced there when a student of his from England, Edward Bradford Titchener (1867–1927), came to teach at Cornell University in Ithaca, New York. Ebbinghaus' method and theory became standard in Canadian and U.S. studies of verbal learning; Watson and other behaviourists applied Pavlov's conceptions to their learning experiments. Experimental psychology in the Western Hemisphere came to be dominated by what seemed to be a search for laws of association.

What is associated? Investigators asked whether associations are formed between observable stimuli and responses (S–R) or between subjective sensory impressions (S–S). One group that included Hull, Guthrie, and Thorndike took the relatively objective S–R position, while Tolman and others favoured the more introspective, perceptual S–S approach. For a time S–R theorists held popularity; behavioral responses are readily observable evidence of learning, and many included them in the associative process itself.

But the reduction of learning to mere external stimuli and overt responses raised discordant theoretical objections that the inner activities of the organism were being ignored. S–R theories failed to account for a host of learned phenomena. For example, people could be trained to say they heard sounds even when such auditory stimuli were absent. They said they dreamed about what they had learned, too; yet there need be no immediate external stimulus, nor does the dreamer always make the responses he dreams about.

Physiological psychologists and biologists found ways of delivering electrical stimulation directly to the brain; this eliminated the sensory stimuli and vocal or motor responses on which S–R theories hinge. Direct neural stimulation was found to be an adequate signal and the electrical response of the brain itself proved susceptible to conditioning. At this level of the nervous system, distinctions between stimulus and response mean less than at the periphery, and the S–S versus S–R controversy is no longer such a burning issue.

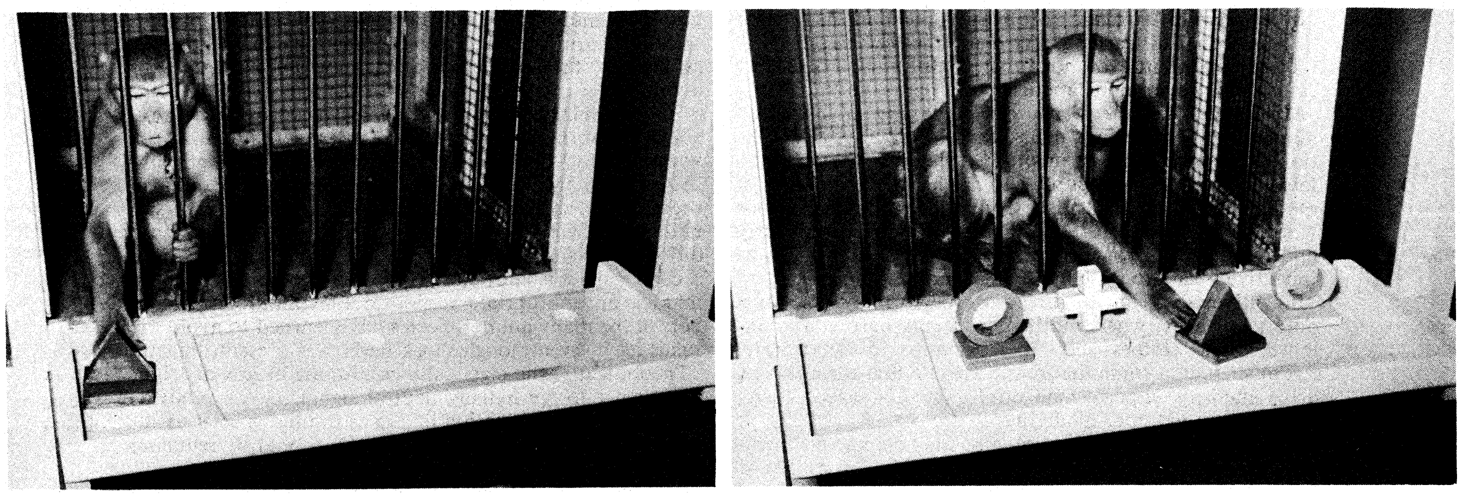
Direction of association. Classical conditioning dependably has been shown to proceed only forward in time. Bell must precede food if a conditioned reaction is to be established. If it had any effect, the reverse procedure (food before bell) would be called backward conditioning; but at most it only inhibits other reactions. There seems to be a relatively brief optimal interval in classical conditioning at which associations are most easily made. For quick reflexes such as the eyeblink, this interval is about one-half second; longer or shorter intervals are less effective. For slower reactions such as salivation the interval is longer, perhaps two seconds or so.

Forward and backward association; context association

In learning verbal associations the situation appears to be quite different. When one learns the Russian–English forward association da–"yes," he also learns the English–Russian backward association "yes"–da. Moreover, timing is much less critical than in classical conditioning. Verbal pairs are learned with almost equal ease whether presented simultaneously or separated by several seconds.

In what is called context association, the general environment may begin to elicit a response that is being conditioned to a specific stimulus. Thus, a dog may salivate simply on being brought into the experimental room—before any bell rings. Verbal associations also can be weakened by changes in the general situation.

Repetition. A major theoretical issue concerns whether associations grow in strength with exercise or whether they are fully established all at once. Evidence is that learning usually proceeds gradually; even when a problem is solved insightfully, practice with similar tasks tends



Learning-to-learn experiment by Harry *F.* Harlow.
The monkey has been trained to expect food after lifting an object. In the first picture, the monkey lifts the triangle after having been shown a sample triangular form. In the second picture, taken several minutes later, the monkey selects the triangle from among other forms. The process is repeated with the circle and the cross.

to improve performance. Some (perhaps most) learning theorists have concluded that repetition gradually enhances some underlying process in learning.

Stimulus-sampling, a statistical learning theory

The view that associations develop at full strength in a single trial leads to a typical question. How can the gradual nature of most learning be explained if all-or-nothing is the rule? One possible answer suggested by Guthrie has led to so-called stimulus-sampling theory. The theory assumes that associations indeed are made in just one trial. However, learning *seems* slow, it is said, because the environment (context) in which it occurs is complex and constantly changing. Given a changing environment, the sample of stimuli will differ from trial to trial. Thus, it is reasoned, it should take many trials before a response is associated with a relatively complete set of all possible stimuli.

In this light, the strength (or probability) of a response should increase with practice even if the elementary associative process occurs in a single trial.

These stimulus-sampling notions translate easily into mathematical form; they are an example of statistical learning theory, a more general development in the quantitative treatment of learning.

Reinforcement. Repetition alone does not ensure learning; eventually it produces fatigue and suppresses responses. An additional process called reinforcement has been invoked to account for learning, and heated disputes have centred on its theoretical mechanism.

Objectively reinforcement refers to the use of stimuli that have been found to facilitate learning. Under appropriate conditions, these include praise, food, water, opportunity to explore, sexual stimuli, money, electric shock, and direct brain stimulation.

More theoretically, the term reinforcement expresses various theoretical hunches about some specialized subjective quality all such stimuli might share. Food for a hungry animal is a well-established reinforcer, conceivably through its distinctive appearance and odour. It tends to elicit a set of responses: approaching, chewing, tasting, swallowing; these may produce additional perceptual activities that reduce the drive or desire for food (*e.g.*, by halting stomach contractions that are experienced as hunger pangs). But no single subjective quality imagined by theorists seems invariably effective in reinforcement studies. Perhaps some combination of introspective influences is critical, or it may be that perceptual processes apply differently from one learning situation to another.

Anti-associationistic positions. Not all psychologists have accepted the general validity of association theories; many have suggested that considerations other than association are crucial to learning.

Organization. Major critics of association theory included such Gestalt psychologists as Wolfgang Kohler (1887–1967), who held that learning often entails a perceptual restructuring of environmental relationships. Kohler cited his own studies of insightful learning by a chimpanzee. The animal learned to join two sticks (akin to a jointed fishing pole) as a tool to pull in a banana that was out of arm's reach and of either short stick alone. The ape was described as sitting quietly (as if in thought), and then suddenly fitting the sticks together to rake in the fruit. It was argued that the ability to perceive new ways of relating the sticks to the banana was essential in solving the problem.

Learning as perceptual organization

Similar organizational processes in perceiving can be demonstrated in serial verbal learning. Memorizing the list *thick, wall, it, tea, of, myrrh, seize, knots, trained* should demand some rehearsal. Yet, notice the phonetic resemblance to Shakespeare's famous line from *The Merchant of Venice:* "The quality of mercy is not strained . . . ." With that kind of perceptual organization, learning can become quick and easy.

A powerful argument also was made by psycholinguists who criticized what they took to be the associationistic account of language learning. Even assuming one-trial acquisition, it was held that such individually learned associations could not account for all combinations of words people use; there are simply too many. They suggested that learning a language requires some general organizing structure on which words are hung. Some proponents of this position hold that this structure does not depend on learning, being transmitted genetically from parent to child.

Inhibition. Gestalt interpretations often reject the associationistic hypothesis wholesale. Other theorists endorse the notion of association, but hold it to be less important than is a process of inhibition through which errors in learning are eliminated. Such theorists find support in evidence for the development of learning sets (what is called learning to learn).

For example, a monkey may learn a long series of discriminations; *e.g.*, red versus green, black versus white, round versus square, large versus small, triangle versus ellipse. After solving several hundred such problems, some monkeys learn to master each new one in a single trial, as if insightfully. The animal is said to have learned to learn such discriminations.

Learning to learn: error-factor theory

Evidence clearly shows that the monkey gradually abandons erroneous tendencies as learning proceeds. At first it might be prone to choose stimuli that are red, black, round, large, or triangular. Correct choices do not always correspond to the animal's initial biases, and their suppression (inhibition, extinction) eventually permits single-trial learning. Theoretically, organisms learn to learn by inhibiting erroneous behaviour; thus, Harry F. Harlow, a proponent of this view, called it an error-factor theory.

Motivation in learning. Motivation popularly is thought to be essential to learning. Yet many theorists suggest that motives make little or no direct contribution—that they simply tend to promote practice.

Motivation and performance. Learning was defined above as a change in a behavioral potentiality. Realization of such potential seems to be related to the learner's level of motivation. A pupil who has learned the names of all members of the British Commonwealth of Nations would be expected to recite them with particular energy under some sort of incentive (reward or punishment). The incentive is said to raise his level of motivation.

Incentives do seem to invigorate performance up to a point; however, when motivation seems particularly intense, some studies show performance to deteriorate. From such data some theorists conclude that the effect of drive intensity on performance follows a U-shaped course, first helping and later hindering.

Greatly increased motivation also may change performance qualitatively by introducing new inefficient modes of behaviour. A student may be so tautly driven to do well on an examination that his tension, fear of failure, and his visceral and muscular discomfort interfere with performance.

Motivation and learning. To show that motivation affects performance of what has been learned is not the same as demonstrating its effect on the process of learning itself. This would require that individuals learn under various levels of motivation and be tested under the same incentive levels. (This is to control for the effects of motivation on performance alone.) And, indeed, the best-controlled experiments of this design indicate learning effects to be the same under different levels of motivation.

Varieties of learning. It is debated whether all forms of learning represent the same process. This question applies even to relatively primitive phenomena such as classical and instrumental conditioning.

Classical and instrumental conditioning

In instrumental conditioning reinforcement is contingent on the learner's response; a rat receives food only if it presses the lever. In classical conditioning there is no such contingency; a dog is fed whether or not it salivates. But this is a distinction in experimental procedure. Whether the underlying process of learning is the same for both is quite another question.

Classical conditioning usually has been reported for glandular, autonomically mediated, involuntary responses (*e.g.*, salivation, heart rate). By contrast, voluntary movements of skeletal muscles more typically have been found to be conditionable instrumentally. However, to theorize that classical conditioning is exclusively effective for one class of responses while instrumental conditioning is uniquely applicable to others seems to be a mistake.

Evidence that seems to demolish such theorizing comes from a series of experiments directed by Neal E. Miller at the Rockefeller University in New York City. Rats were immobilized with curare; this drug blocks the junction between muscle and nerve to paralyze the skeletal muscles. However, a curarized individual still can show autonomic, involuntary signs of emotional activity such as a rapidly beating heart.

Electrical stimulation of selected parts of the brain seems to be rewarding; animals behave as if they seek such stimulation and will learn to press a switch for it (voluntary muscle function). Using curarized animals, Miller and others made the rewarding stimulation contingent on such typically involuntary responses as changes in heart rate, blood pressure, contractions of the bowel, and salivation. Their research has shown such instrumental conditioning to be effective for all these responses. The evidence appears to destroy the once-popular hypothesis that involuntary autonomic reactions are subject only to classical conditioning. In this sense the two primitive forms of learning seem to be the same.

Stages of learning. Should the basic process prove to be the same for all varieties of learning, there would still be reason to believe that it operates differently from one stage of practice to another. For example, in coping with painful stimuli (*e.g.*, electric shocks) laboratory animals seem to learn in two successive, distinguishable phases. Apparently they first learn to fear the situation, then to avoid it.

For example, when an animal learns to avoid painful shock (by turning a paddle wheel or by running away), a warning signal can be given; *e.g.*, with a flash of light or a buzzer. The two stages of learning then can be studied separately. The animal first is subjected to pairings of signal and unavoidable shock to establish (by classical conditioning) signs of fear in response to the signal. In the second stage it is allowed to stop the frightening signal by making an appropriate response. Preconditioned members of the many animal species have learned to avoid the signal itself, even though shock never was presented again.

The role of fear

Theoretically, the classically conditioned signs of fright in response to the initially neutral signal have a motivating function. Termination of that stimulus is seen as instrumental—that is, as rewarding the animal by reducing learned experiences of fear.

Classical conditioning. A two-stage process has been suggested even for classical conditioning. One theory is that in the first stage the subject learns that a neutral stimulus (a ringing bell) is to be presented along with another stimulus (food) whether or not it exhibits a reaction (salivation). Conditioning of any reaction is held to constitute the second stage of learning. The skimpy supporting evidence points to the first stage as a prerequisite, suggesting that responses can only be conditioned after the sensory conditions are recognized.

Verbal learning. Theories that interpret verbal learning as a process that develops in stages also have been worked out. In one variety of rote learning the subject is to respond with a specific word whenever another word with which it has been paired is presented. In learning lists that include such paired-associates as *house–girl*, *table–happy*, and parcel-chair, the correct responses would be girl (for house), happy (for table), and chair (for parcel). By convention the first word in each pair is called the stimulus term and the second the response term. Paired-associate learning is theorized to require subprocesses: one to discriminate among stimulus terms, another to select the second terms as the set of responses, and a third to associate or link each response term with its stimulus term. Although these posited phases seem to overlap, there is evidence indicating that the first two (stimulus discrimination and response selection) precede the associative stage.

Remembering and forgetting. Learning, remembering, and forgetting often have been considered separate processes. Yet these distinctions seem to blur in the face of contemporary research and theory.

Transient and enduring memory. Evidence for stages of learning comes from observations of learners over relatively extended series of trials (or comparatively long periods). The empirical data suggest that several alterations in memory function occur even during a single trial. The process that commits information to memory also seems to have several stages.

Immediate, short-term, and long-term memory

Most theorists attribute at least three stages to memory function: immediate, short-term, and long-term. Immediate memory seems to last little more than a second or so. For example, subjects may be asked to remember where specific objects are located within a complex array they have just seen. Their performance shows that considerable information is retained only briefly, rapidly fading unless it is given special attention.

Short-term memory lasts about 15–30 seconds, as after looking up a telephone number. One makes the call, discovers he has forgotten the number (perhaps in the midst of dialing), and has to look it up again. Nevertheless, such short-term retention does make information available long enough to be rehearsed; if the learner repeats it to himself, the number can be transferred to some sort of longer term storage.

Thus, rehearsal seems to facilitate transfer of data from short-term to long-term memory. Once committed to long-term memory, the results of learning tend to endure but can be abruptly abolished when specific parts of the brain are injured or removed; they also are vulnerable to interference from other learning. Nevertheless, conditioned responses may undergo little or no forgetting over periods of months or years. And electrical stimulation of the surgically exposed brain while a person is awake can make him remember experiences long thought forgotten. Recall is reported to be similarly enhanced during hypnosis.

Retrieval. The amount of information one readily can retrieve from what is stored in memory is prodigious. In locating an item in memory, he apparently activates a system that stores a set of related data; then he searches for the item within that system. For example, a person is shown a long, randomly mixed list of words that belong to different categories (*e.g.*, names of animals, plants, professions, tools). When asked to remember as many words as he can, he spontaneously will tend to group them by category; this is called clustering of recall. Thus, names of animals (spread throughout the original list) are likely to be remembered one after the other.

Clustering; tip-of-the-tongue phenomenon

Studies of the familiar tip-of-the-tongue experience yield analogous results. College students who heard definitions (of this sort: a small, open Chinese boat) were asked to supply the right word (in this case it would be sampan). Those who said they might have it somewhere on the tip of the tongue were significantly accurate in guessing the first letter and the number of syllables. Their tendency also to recall words that sounded the same or that had similar meanings is reminiscent of clustering.

Considerable evidence of this kind supports the theory that the process of retrieval first locates stored data in some sort of associative network and then selects an item with specific characteristics.

Forgetting. Whether immediate and short-term data simply decay or are lost through interference is a matter of controversy. However, evidence is clearer that interference affects retention of information in long-term storage. Retention of the word ***happy*** (learned as a paired associate of ***table)*** seems to be subject to the interference of a strong tendency to associate ***table*** with ***chair.*** Thus, the paired associate ***table–happy*** becomes more readily forgotten when followed by ***parcel–chair*** as the very next item in a list; this seems to help ***chair*** reassert its old tendency to be associated with ***table.*** In general, it is found that associations tend to interfere with or to inhibit one another. Interference deriving from earlier (and later) associations is called proactive inhibition (and retroactive inhibition). These two forms of inhibition commonly are accepted as major processes in forgetting, proactive inhibition being assigned greater importance.

Contemporary trends in learning theory. In the early 1930s the distinction between learned and inherited behaviour seemed clearer than it does now. The view that any bit of behaviour either was learned or simply developed without learning seemed straightforward. Studies based on these expectations led investigators to conclude that rat-killing behaviour among cats is learned rather than instinctive, that human fears are all acquired, or that intelligence is completely the result of experience. Learning theorists were saying then that most behaviour is learned and that biological factors are of little or no importance.

Imprinting, a special form of learning

Forty years later this position seemed grossly untenable. The once-implied sharp distinction between learned and inherited behaviour had become badly blurred. For example, it has been found that the young of many animal species automatically will learn to follow the first large, moving, noisy object presented (as if it were their mother). This special form of learning is called imprinting and seems to occur only during a critical early stage of life. Among mallard ducklings imprinting is most feasible about 15 hours after hatching. During this period a duckling will imprint as easily on an old man or on a rubber ball as it will on a mother duck. Is this instinctive or learned behaviour? Manifestly it is both. The instinctive tendency to be imprinted is part of the duckling's biological heritage; while the object on which it is imprinted is a matter of experience. What is significant for learning theory is that the contribution of biology cannot be ignored.

Learning theorists once ruled a number of concepts out of court on the ground that they seemed objectively unclean. Image, cognition, awareness, and volition, all are concepts that were denied acceptance on this basis. They sounded mentalistic, subjective, introspective, and unverifiable. Yet, by the 1970s all of them were being given more serious scientific consideration.

For example, the concept of image in learning has begun to show real viability. It has long been reported that the more meaningful a list of words is, the easier it will be to learn. Degree of meaningfulness for a word may be defined by the objectively observed probability that people quickly can give another word in response. Using such empirical scales of meaningfulness, a reliable and substantial relationship has been found between meaningfulness and ease of learning. However, meaningful words also may evoke vivid images that subjects can describe when asked. When they do evoke such imagery, they seem to be learned and remembered even more easily. Thus, learning theory seems to be enriched when introspective data are used.

A final fault in much learning theory stems from earlier tendencies to use the laws of physics as a model. Theorists once sought general laws of wide applicability that tended to obscure differences among individuals. For example, so complete was Hull's faith in universal "laws" of animal behaviour, that he based his hypothesis about the optimal interval for classical conditioning in humans, other mammals, and birds on the pattern of nerve conduction in the optic nerve of the horseshoe crab. There was little concern even for species differences. Within the same species, individual differences were viewed as a mere nuisance; it was believed that, by studying many subjects and by computing averages, basic laws of learning could be found. However, so-called laws were developed in this way that failed to represent even one individual whose behaviour contributed to the average. More than any other consideration, this has led learning theorists to take a belated look at the importance of individual differences and species differences in learning.

BIBLIOGRAPHY. J.F. HALL, ***The Psychology of Learning*** (1966), provides a comprehensive account of the empirical data that theories of learning are designed to integrate. E.R. HILGARD and G.H. BOWER, ***Theories of Learning,*** 3rd ed. (1966), is the standard reference on this subject. G.A. KIMBLE (ed.), ***Hilgard and Marquis' Conditioning and Learning,*** 2nd ed. (1961), describes theoretical issues as they apply to simple learning. The separate articles reproduced in KIMBLE, ***Foundations of Conditioning and Learning*** (1967), develop some of these arguments in more detail and also present synopses of the theoretical positions of Hull, Guthrie, and Tolman. G.A. KIMBLE and N. GARMEZY, ***Principles of General Psychology,*** 3rd ed. (1968), is a general textbook that covers several theoretical issues and should be particularly useful on the topics of memory and retrieval.

(G.A.K.)

Leather and Hides

Leather is animal hide or skin that has been processed for use by man. Large animals are said to have "hides" (cowhide, buffalo hide) while smaller animals have "skins" (goatskin, sheepskin). In either case, the hide or skin is composed of water and proteins and, unless preserved, decays quickly.

Basic steps in making leather. Leather is made from rawhide in three steps: (1) Removal of undesirable constituents such as hair, flesh, fat, and some interfibrillary matters, leaving a concentrated network of high-protein collagen fibres, greatly softened and interspaced with water. (2) Tanning; *i.e.*, treating the hide with an agent, called tannin, that displaces the water and then combines with and coats the collagen fibres. Tanning increases resistance to heat, hydrolysis (decomposition caused by water), and micro-organisms. (3) Finishing to obtain proper thickness, moisture, lubrication, and aesthetic appeal. Thus, leather is essentially animal skin protein combined with tannins, small amounts of oils, dyes, finishes, and moisture. The relative proportion and distribution of constituents varies with the type of leather.

By suitable choice of rawhide or skin and tanning method, the tanner obtains leather possessing such properties as the nonstretchiness in upholstery, the drape in clothing, and others.

Properties of leather for footwear

The properties that make leather eminently suitable for footwear are: (1) mechanical: resistance to abrasion, flexing, deforming, and stretch; tensile, tear, and burst strength; suitability for cementing, vulcanizing, and molding; (2) wearing comfort: permeability to air and water vapour; storage capacity for perspiration; thermal insulation; suppleness; (3) appearance: colour fastness; resistance to wet and dry rubbing; easy care.

Major types of leather. The many varieties of leathers produced throughout the world find uses in hundreds of applications. The following classification (condensed from Tanners' Council of America, *Dictionary of Leather Terminology*) lists the world's most important types.

Cattle group. This group includes steer (ox), cow, and bull hides, producing leather for boot and shoe soles, heels, inner soles, uppers; harness, saddles, skirting (for saddles), horse collars; travelling bags, suitcases, briefcases, straps; upholstery; fancy goods such as handbags, belts, gloves, garments; industrial leathers for aprons, buffing wheels, textile carders and combers, hydraulic packings and washers, lithographic purposes, machinery belting; footballs and other sporting goods; razor strops; rawhide.

Also included are kipskins (from large calves or undersized or small breeds of cattle) for shoe uppers; fancy leather goods and handbags; gloves and garments; shoe lining.

Calfskins for boot and shoe uppers and linings; gloves and garments; fancy leather goods and handbags fall under this heading; bookbindings; hat sweatbands, rawhide and parchment; military helmets and gas masks; grips for golf clubs; handicrafts.

Sheep and lamb group. Included are wooled skins, haired skins (cabrettas) for shoes, slippers, gloves, coats, hats; leather goods and handbags; aprons; chamois; parchment; piano action; rollers on textile machinery.

Goat and kid group. Primary uses are skins for shoe uppers; fancy leather goods and handbags; gloves and garments.

Equine group. Included in this group are horse, colt, ass, mule, and zebra hides for shoes; gloves and garments; sporting goods; luggage; belts.

Buffalo group. Domestic land and water buffalo provide leather for shoe soles and uppers, buffing wheels, luggage, and handbags.

Pig and hog group. This group provides pig, hog, boar, peccary, and carpincho leathers for fancy leather goods and luggage, gloves, harness saddlery, shoe uppers.

Aquatic group. Animals whose main habitat is water are seal, sea lion, and walrus for luggage, fancy leather goods, and buffing wheels; shark, whale, blackfish, dolphin, and porpoise for fancy leather goods, luggage, and shoe uppers; and alligator and crocodile for shoes, handbags, and luggage.

Miscellaneous. Skins of deer, kangaroo, ostrich, lizard, etc. are also tanned and made into various kinds of leather goods.

HISTORICAL BACKGROUND

Ice Age man used animal skins to protect his body against inclement weather and his feet against thorns and rocks. Preserved specimens of leather dating back to 5000 BC have been found. Evidence exists for the use of leather by ancient Sumerians (6000 BC), Egyptians, Indians, and Chinese, and later by Greeks and Moors.

Early uses of leather. Early uses can be grouped as follows: (1) apparel: trousers, shirts, footwear, gloves, headgear, belts; (2) containers and holders: wine and water casks, bags, pouches, luggage, tents, sheaths for knives, scissors, and swords; (3) transport and traction: chariots, whips, wagon covers, boats, saddles, bridles, harness; (4) recreation: musical instruments, puppets; (5) communication: parchment and vellum for writing and drums for transmitting messages; (6) war needs: slings, bows, quivers, shields, helmets, leg guards, ankle leather, armour, military clothing, powder horns; (7) interior uses: beds, cushions, upholstery, molded and ornamented articles, bookbinding, tapestries, and paintings.

The Industrial Revolution created other uses for leather such as washers, packings, industrial belting, and bellows; and present-day uses represent a continuous and continuing adaptation to changing circumstances.

Early manufacturing techniques. Leathers may have been man's earliest manufactured goods. Scraping the skin till it was more or less free of flesh by flint tools was probably the only operation carried out by primitive man. Sun drying prevented rapid decay but hides became hard. To make them soft and suitable for wear, animal fats and brains were rubbed in. Similarly, salt was applied to preserve hides, Skin, like meat, was also preserved by smoking.

The need for removal of hair, flesh, fat, and other constituents was slowly recognized. The processes of sweating and enzymatic hair removal are based on the early discovery that hair will fall out of a wet hide that has been allowed to rot slightly. Wood ash and lime were used in the Middle Ages. Much later, the cleaned hides were treated with dog, hen, and pigeon dung and drenched in fermented broth. These procedures were later replaced by acid deliming and bating with enzymes. Bating is a treatment of light types of leather to attain a smoother and clearer grain, or greater softness and pliability. In this process, hides are placed in vats containing ammonium sulfate or chloride as the deliming agent and certain enzymes that act selectively to remove proteins and also to improve colour.

Bating

Eskimos may have rubbed fish oils into animal skins to make the furs soft and durable. This may have been the beginning of the use of oils for tanning (a process termed oil tannage), and of chamoising (the art of making skins and hides extremely soft). Japanese white leather and Ethiopian red leather are still produced with rape and safflower oils.

Smoking of hides and skins involves a reaction with aldehydes, several of which today are used for tanning. Oxidation of oil also produces aldehydes. American Indians still make leather by a process that combines oil and smoke curing.

Development of tanning methods. *Vegetable tannage.* Vegetable tannage is quite ancient. The Hebrews used oak bark; the Egyptians, babul pods (400 BC), and the Arabs barks and roots. A wide variety of vegetable tans are used today. Synthetic tannins were introduced in 1911. In the classical method of vegetable tannage the pelts are placed in a pit or vat, in alternating layers with ground vegetable tanbark, pod, leaf, wood, or root. Water is poured on to cover, and the pelts left for 6 to 12 months. Even today, this "contact," or "sandwich," tanning method is employed with modifications. In another method, called "bag," or "bottle," tanning, the pelt is made into a bag, filled with tanning material and water, and tied to a pole. The water leaches from the material inside the bag, and the tannin diffuses osmotically through the pelt, completing the tanning in three to six days. Long before Christ, the Chinese cured skins with mud and alum. Alum, an accidental substitution for salt, led to tawing, the first mineral tannage. There is evidence for the early use of tawed leather in Assyria, Babylonia, Phoenicia, and India, and later by Greeks and Moors.

Two or more processes were sometimes combined; *e.g.*, alum and oil; alum and gallnuts or sumac leaf, producing soft nappa leathers. By the early 11th century AD, three basic tanning processes were used: (1) oil, (2) vegetable, and (3) alum.

Chemical tannage. A significant change came only toward the end of the 19th century. In 1858 the value of basic chrome salt for tanning was discovered. In 1884 a two-bath tannage process was patented; and in 1893, single-bath chrome tannage was introduced. Chrome tannage, today by far the principal tanning method for light leathers, is rapid; the leather produced has hydrothermal (heat and moisture) resistance to 120° C (248° F). Silica, aluminum, iron, and zirconium salts were also tried, but only zirconium and aluminum salts are used today to any extent.

Two-bath tannage

From early days, leather was made more decorative and adaptable by finishing. In the Middle Ages, vegetable dyes and earth pigments provided the various colours. Leather was frizzed (curled or tufted) to make nap or boarded to make Morocco leather. In boarding, the skin is doubled, grain surface inside, and pressure is applied in the required direction either by hand or with a cork-covered board, or by rotating cork-covered cylinders. The natural grain of the leather is enhanced or brought into sharper definition. The leather was also scented with birch tar oil and curried with grease. Today, a wide variety of dyes, oils, and finishing agents are used.

The earliest tanning tool was flint, used to scrape off flesh. Later, hair and flesh were removed by a curved blunt or sharp knife over a wooden beam. Leather was shaved to the required thickness with a sharp knife. Such hand tools were improved constantly. Machines were introduced in the early 19th century: a splitting machine in 1809 and fleshing and dehairing machines in 1840. Today, most operations may be done by machines, though the leather industry still defies automation because of the irregular size, thickness, and quality of hides handled. Empirical processing methods evolved from observation and experience. The scientific study of leather processing started only at the close of the 18th century. With progress in science, newer methods, materials, and machines have made possible a great variety of improved leathers.

MODERN LEATHER MANUFACTURE

Raw materials. Although any hide or skin can be tanned into leather, those most often used come from cattle, buffalo, sheep, goats, and pigs, and sometimes from horses, camels, crocodiles. snakes, and lizards. Skins of animals such as elephant, zebra, leopard, and tiger bring high prices. Animal skins vary in size, shape, texture, thickness, and quality. Quality depends on how and why the animal was reared, whether it died of old age or was slaughtered, and its age, sex, and environment. Damages of many kinds reduce the value of hides and skins. The most common defects encountered are those produced on the live animal by parasites and diseases, old age, and malnutrition; brand marks and barbed wire scratches; and on the dead animal by poor stripping of the skin, handling, and storage. With proper attention, many of these defects can be avoided.

Characteristics of animal skin

Mammalian hides and skins are divided into three layers distinct in structure and origin. These are (1) a thin outer layer of epithelial cells called the epidermis; (2) a thick layer called corium, or dermis; and (3) subcutaneous adipose or flesh layer. In tanning, the epidermis and flesh layers are removed; the corium is tanned into leather. One layer of the corium containing the grain membrane and hyaline layer, together with the arrangement of hair pores, gives a distinct grain surface pattern for each species of animal. The other corium layer is composed of large collagen fibre bundles interwoven at an angle in a three-dimensional network. The fibre structure varies in different parts of the skin (*e.g.*, belly-loose, butt-tight) and from one species to another (sheep-loose, goat-tight). Elastin fibres make leather that stretches. Fatty skins yield spongy leather.

Fresh hide is composed of 60 to 70 percent water by weight, 30 to 35 percent proteins, about 2 percent lipids, 0.5 percent carbohydrates, and 1 percent mineral salts and other substances such as pigments. Of the solid matter, 90 to 95 percent is made up of proteins, both fibrous and nonfibrous. Of the fibrous proteins, collagen accounts for over 85 percent of corium; elastin and reticulin are present in small quantities; hair and wool are made up of keratinous (horn-producing) fibres. The nonfibrous proteins are albumins (soluble in water), globulins (soluble in salt solutions), and mucins, mucoids, or glycoproteins (soluble in dilute alkalies). All soluble proteins are removed before tanning. The fibrous protein chains are held in position by chemical bonds giving a cohesive structure that may be broken down by heat and hydrolysis to form glue, or strengthened by tanning to produce leather. The science of leather manufacture is the science of skin proteins and their interactions with acids, bases, salts, and organic and inorganic tanning agents.

Preparation of hides for tanning. During preparation and shipping, protection against excessive heat, humidity, rain, and pests is essential. Raw hides are cured or preserved to prevent decay that begins within hours of slaughter. Curing consists of dehydration without disturbing skin structure. Common methods are simple air drying, which yields bony flint hides; salting, which includes treating the hide with a saturated solution (brined); rubbing the flesh side with salt (wet salted); further drying (dry salted); and pickling the pelt with acid and salt. Preservatives are also added to improve curing efficiency. Such methods as cold storage (5° C [41° F]), freeze drying, vacuum drying, irradiation, and solvent dehydration are relatively costly.

The purpose of pretanning, or beamhouse, operations is to remove undesirable constituents and to condition the skin for tanning. The first operation in the tannery beamhouse is the soaking of cured hides in water to rehydrate the hide to its original flaccid condition and to remove dirt, salt, and some soluble proteins. Flint hides need special care, as soluble proteins cement the fibres on air drying. Soaking is assisted by elevated temperature, agitation, and addition of wetting agents, protein dispersants, and preservatives. Well-soaked hides are washed, drained, and weighed.

Sweating and fermenting

Dehairing. Wool skins are still dehaired nonenzymatically by the old methods of sweating them in a hot moist room or keeping them overnight in a fermented bath. In the sweating process, the hide is allowed to rot partially; the hairs then fall out easily. Enzymes with specific chemical activity are available, but enzymatic dehairing is not popular because of the expense involved, and loss of commercial use of the hair, which dissolves or disintegrates. Liming, in which soaked hides are treated with lime for one to two weeks to dehair, is still an old standard practice. By addition of such agents as sodium sulfide, dehairing time is reduced to a few hours. For dehairing sheepskins, lime sulfide paste is applied on the flesh side to save the wool, which is pulled in 3 to 12 hours. Liming not only removes hair, fats, and soluble proteins but also swells and conditions fibre structure.

Deliming and bating. A hide with its hair and flesh removed is known as a pelt. Deliming is done partly or fully to remove excess alkali and is accomplished by treating with such mild acids as boric, acetic, lactic or such acid salts as ammonium chloride or sulfate and sodium bisulfite. The material is then bated to remove interfibrillary proteins and produce a clean white pelt. Bating is essential for special types of hides, such as those for gloving and glace kid leathers.

Pickling. Delimed, bated stock is pickled with a mixture of sulfuric acid and salt in a paddle or drum to prepare it for either long storage or mineral tannage. Fatty skins are degreased with detergent and paraffin solvents, washed, and repickled.

Modern tannery methods and machinery. ***Vegetable*** *tannage.* Vegetable tannage is still an important tanning method. Delimed pelts are treated with infusions of vegetable tanstuffs resulting in firm, full, solid leather. Almost every fibrous plant contains tannins. Some examples are: roots (canaigre, 25–30 percent tan); wood (chestnut, 6–8 percent); bark (mimosa or wattle, 38–40 percent; oak, 7-10 percent); leaves (sumac, 25 percent); fruits (myrobalan, 33–36 percent); pods (dividivi, 40 percent); parasitic growth (oak galls, 50–60 percent); rind (pomegranate, 20 percent); seed husk (cashew, 25 percent); and lignosulfonates, by-products of the paper industry.

Tanning material is ground, leached with water, and concentrated into solid or powdered extract. Sometimes it is sulfited and bleached to yield more soluble and light coloured extracts.

Vegetable tanstuffs contain tannins, which are amorphous, astringent, complex mixtures of polyphenols; and nontanning materials, including carbohydrates, salts, and acids, which also contribute to leather quality.

Vegetable tans are hydrolyzable or condensed. Hydrolyzable tannins are rich in acids and salts. They decompose with water into sugar and acids, and yield spongy leather. Condensed tans, most often used by tanners, yield red-coloured leather unless used in combination with hydrolyzable tans.

The classical year-long oak tannage starting with weak liquors in suspenders and with increasingly concentrated liquors in handlers and layers, or sandwiches, is seldom used now. Bag, or bottle, tannage is still practiced; two other modern methods are widely used. In the first, a delimed pelt is kept stationary and tan liquors are circulated in several sets of pits (rocker vats), terminating by hot pitting with concentrated liquors at 40" C (104" F) to get firmer leather; in the second, accelerated tannage is achieved by fully deliming a pelt; pretreatment with synthetic tanning agents, polyphosphates, or buffer salts; and then tanning with highly concentrated liquors or extracts in drums.

Tannage for belting and harness is the same except that loading and degree of tannage are lower, and stuffing is with 15 to 20 percent fat.

Light leathers

Where leathers are to be more flexible and light coloured, delimed skins are pickled, or pretreated with synthetic tannins, and tanned in paddles, or drums, with a blend of tan extracts for three to six hours. In dry or floatless tannage, powdered extract preceded by synthetic tannins is added onto the pelt in a running drum, leaving no effluent.

Synthetic tans. Synthetic tans originated from studies of the effect of formaldehyde on vegetable tanning materials. The first of them, patented in 1911, was based on phenols and cresols. Later, naphthalene was used. Synthetic tans must have a large polymer molecule and must also be soluble in water; they are made by condensing (forming into a polymer) simple phenol molecules and adding a sulfonate group to make the product soluble. The process also works in reverse, with sulfonation first and condensation second.

At present the wide variety of synthetic tannins are of three types: (1) auxiliary tans, strong simple sulfonic acids that are used to bleach chrome-tanned and vegetable-tanned leathers, to produce shrunken grain, and to aid dyeing; (2) combination tans, sulfonic acids of complex phenolic materials used for light tanning and for white leathers; (3) exchange, or replacement, tans, weak acids containing a large number of phenolic groups to substitute vegetable tans and to produce white, light fast leathers, but these are costly and not widely used. The aim at present is to make specialty products that will produce desired qualities in the leather.

Mineral tannages. The basis of mineral tannage is the use of protein carboxyl groups with a basic metallic salt to form rivets, giving high hydrothermal stability (120" C, 250" F) to leather. Chromium salt is widely used. Aluminum, iron, and zirconium salts are also used.

Chrome liquors are prepared by reducing orange-red acid dichromate to blue with such reducing agents as glucose, molasses, or sulfur dioxide. The liquors may be dried into crystal or powder form. Special extracts may also contain masking, wetting, tanning, and other agents.

Chrome tanning involves drumming the pickled belt in pickle or a separate bath with basic chrome liquor. Masking and other agents are added before, during, or after chrome tanning for special effects. Today the trend is toward the use of salt-free, masked, dry powder tannages. When tannage is complete in three to four hours, a small piece of leather is tested by plunging it into boiling water for two to three minutes (boil test). If it has been properly tanned, it should not curl.

In two-bath tannage the pelt is treated with chromic acid in the first bath. In the second bath the chromic acid is reduced with sodium thiosulfate (hypo) and acid, thereby fixing basic chromium sulfate within the pelt. Precipitated colloidal sulfur imparts strength to the leather and gives it a fine grain. Two-bath tannage involves much work and material waste; it has been almost completely displaced by single-bath tannage. Mixed single- and double-bath tannage is also possible.

Use of aluminum salts

Although an old alum tawing method is still used for dressing furs, basic aluminum sulfate masked with citrate or tartrate is more effective. Aluminum salts often are used in combination with formaldehyde to produce furs and white leathers; in pickling and pretannage for chrome; and in pretannage and retannage of vegetable leathers to give soft, full nappa leathers and perspiration-resistant insole leathers.

Recognized in 1907 and patented in 1933, zirconium tannage employs basic zirconium sulfates masked with acetate, citrate, and other agents to produce dense, dry, full white leathers. Zirconium salts are used as pretanning or retanning agents along with chrome and other tannages to produce kid, suede, and other leathers. The high cost and care required limit the use of this method, though using zirconium in conjunction with silica reduces the cost.

Silica's tanning potency, observed in 1862, was applied and described in 1915. Silica hydrolyzes, polymerizes, and precipitates. Silicate solutions gel readily and fix only on the surface. Sodium metasilicate is considered to give better tannage. Although silica is cheap and abundant, silica tannage is not used commercially because it is not complete and uniform, and leathers are not strong.

Miscellaneous tannages. The oldest oil tanning produces chamois leather, which, unlike other leathers, can be repeatedly wetted and dried without detrimental effects. The special properties of chamois leather result from its open structure. Chamois leather is tanned with aldehydes and peroxides, and coated with polymers from oxidation of fish oil used in the tanning process. Long liming, bating, and mechanical pressing open up and split the fibres; stocking and pounding with fish oil and hanging in heated rooms oxidizes the fish oil. Compounds of copper, manganese, and cobalt accelerate oxidation. Excess oil is washed off with washing soda solution or wetting agents. Pretanning with formaldehyde is common. Though cod oil is favoured, sardine, rape, and safflower oils are also used.

During World War II, sulfochlorinated hydrocarbons were substituted for scarce fish oil when producing white chamois leather. The pelt pretreated with formaldehyde is tanned with a mixture of sulfonyl chloride, wetting agent, and sodium carbonate for four to eight hours. The method is rarely used today, because of its high cost.

Commercially accepted aldehyde tannages include formaldehyde, glutaraldehyde, and dialdehyde starch. Bated pelts are tanned with formaldehyde solution for two to four hours and the excess flesh and bacterial matter in the hide is removed by treatment with magnesium acetate or hydrogen peroxide to produce white leathers. Formaldehyde is mainly used in combination with other tannages. Glutaraldehyde tanning gives leather a yellow colour and high resistance to perspiration and washing with soap, making it suitable for superior shoe and glove leathers.

Resin, or polymer, tannage, employing such materials as urea or melamine, produces fuller and tighter leathers. Engineering and economic problems of solvent tanning remain, but interesting results may be obtained; *e.g.*, completion of vegetable tannage in a few minutes, and production of leathers with a new variety of properties. Quinone, a simple chemical, has good tanning potency and gives good tear resistance to leather, but is seldom used.

The first tannage

Each tanning material imparts special characteristics to leather. Desired properties are obtained by combination of two or more tannages consecutively or simultaneously. The first tannage, however, fixes the character of the leather. Chrome leather is retanned with vegetable to give thicker chrome retan uppers. Vegetable tanned leather is retanned with chrome to give semichrome uppers and suede and glove leather. Invariably combination tannage is the current practice for most leathers.

MODERN LEATHER PROCESSING

Dyeing. After excess water and wrinkles are removed from tanned leather, it is shaved or split to uniform thickness and dyed. Leather dyes may be classified as follows: (1) cationic (basic) dyes, used mainly for vegetable or synthetically tanned leathers; (2) anionic (acid and direct) dyes, used on chrome, vegetable, and aluminum tanned leathers; direct dyes give good surface dyeing with no affinity to vegetable leathers; (3) amphoteric dyes, which easily penetrate chrome but not vegetable leathers; (4)

chrome mordant dyes, which give deep and fast shades; used in gloving leathers; (5) metal incorporated premetallized dyes, which are slow to penetrate but give good levelling and colour fastness despite exposure to alkali and washing; (6) reactive dyes, which will not run when dry cleaned: used mainly for suede and glove leathers.

Dyes are applied to leather either by brushing on one side, tray dyeing, drum dyeing, spray dyeing, solvent dyeing, vacuum dyeing, or dyeing through a tank and squeeze rollers. Fancy colouring is accomplished either by dabbing dye with a sponge, sprinkling it on folded skin, spraying, padding through stencils, or tying and dyeing. Levelness, penetration, richness of shade, and fastness to light, dry cleaning, and rubbing are affected by acidity, temperature, type of leather, and dye concentration and special additives.

Lubrication. Unless lubricated, leather dries hard. Dyed leathers are treated with oils and fats for lubrication, softness, strength, and waterproofing. Oils and fats are incorporated individually, or in blends, in natural condition, as emulsion, or in solvents, by hand or in a drum.

Vegetable tanned light leathers are oiled by swabbing groundnut (peanut) oil on the grain surface. Sole leather is drummed with a mixture of vegetable oil, mineral oil, and small amounts of sulfated oil, epsorn salts, and glucose. The oil keeps loose tanning material from rising to the grain during drying, and produces supple, light-coloured leather.

Belting leather is treated by hand or in a heated drum with a mixture of cod oil, tallow, wool grease, stearine, and paraffin wax. Currying is similar, incorporating such mixtures as a hot melt.

Fat-liquoring

Light leathers are fat-liquored in a drum with an oil and water emulsion. The uniform penetration of the leather by fat liquor gives a soft, stretchy, loose-grained leather; if the fat liquor is deposited only on the surface, the leather is resilient and tight. Raw oils mixed with emulsifiers give desired properties of softness and pliability to suede. Raw oils mixed with soaps or sulfated oils are commonly used. Such vegetable oils as castor, palm, and groundnut; animal oils as tallow and neat's-foot; marine oils as cod, sperm, and sardine; and mineral oils and fatty alcohols are sulfated with sulfuric acid at low temperatures. The greater the reaction, the greater the penetration and stability of the product. Sulfated oils are favoured for gloving, suede, and soft leathers. Oils may be introduced into leather along with a solvent and the solvent then evaporated.

Colloidal graphite and sulfur give mechanical slip to leathers to be used for washers and oil seals. Silicones, fatty acids, waxes, chlorides of chromium, aluminum, and other metals are used for shower proofing or waterproofing of leathers. To avoid the yellowing of aging, especially of white leathers, synthetic oils and sulfated coconut oils are used. The use of newer synthetic tannins, impregnants, and finishes, along with vulcanizing and cementing of shoes, makes constant new demands upon leather lubricants.

Drying and finishing. After dyeing and fat-liquoring, leather contains 45 to 60 percent water and is dried to about 14 percent moisture, chemical and physical reactions taking place. When leather dries to a paler shade, loose tannins, dyes, and oils spread uniformly, penetrate deeply, and are fixed firmly. Uneven drying causes the migration of unfixed tannin dye and oil to the surface, resulting in dark stains in loose areas. During drying, leather tends to shrink, particularly when the water content falls below 25 percent and drying temperatures are high. Vegetable tanned leathers shrink less than others.

Drying techniques. Among the most popular drying techniques are: (1) Air drying: skins are hung from hooks or on sticks or are placed on horizontal racks and dried by the natural passage of air or with the help of overhead fans. Vegetable tanned leathers are air dried. The process is cheap and yields slow drying and gives a uniform, light-coloured product, but productivity is low. (2) Tunnel, or cabinet, countercurrent drying: drying tunnels or cabinets with controlled temperature, humidity, and countercurrent air circulation provide efficient drying. Fresh dry warm air meets dry leather and subsequently moves toward wet leathers. Leathers may be hooked to a moving chain or held on moving toggle frames or plates. (3) Drying under tension: leathers are stretched out, nailed or tacked on wooden boards or stretched on a perforated metal frame by toggles or grip clips, and dried by either process (1) or (2). Toggling gives better air circulation on both sides. (4) Paste drying: leathers are pasted by the grain side on both sides of large plates of glass, porcelain, or metal and then travel through a tunnel drier consisting of four to eight zones of controlled temperature and humidity. In three to six hours, the dry leather is stripped off. Pasting units are expensive; thus they are used largely for upper, split, and lining leathers. They yield flat, smooth grain and larger area. (5) Vacuum drying: leather is spread out, grain down, on a smooth polished metal plate heated by a built-in thermostatically controlled heat exchanger, covered by an airtight hood. The air is then removed from under the hood. Drying to 14 percent moisture is complete in ten minutes for vegetable tanned leather at 50° C (125" F) and three minutes for chrome leather at 80" C (180" F). Vacuum driers are costly, but operate independently of weather conditions, and productivity is high. (6) Others: dyed, seasoned, finished leathers are dried by moving through a tunnel heated by infrared heaters. Radio-frequency heating has the potential of removing water without heating the leather itself.

Paste drying

Finishing. Finishing involves mechanical and chemical treatments. The dried tanned leather is first trimmed, conditioned with damp sawdust to obtain uniform moisture content (around 20 percent), and staked by hand over a steel blade or by machine to stretch and soften it.

Some leathers are impregnated with synthetic resins (acrylics, butadiene, and polyurethanes) to improve their properties. Polyurethanes give the best scuff resistance. Impregnated leathers are usually buffed with an abrasive paper to remove surface blemishes, and to lift nap fibres in suede leather.

Leather is further finished by coating the grain surface. A good coating adheres well to the leather surface, is elastic, and resists abrasion, cracking, peeling, rubbing, light, heat, cold, and moisture. A wide variety of colours, pigment, resins, lacquers, and waxes are used. In unpigmented seasoning, a simple glazing finish or seasoning may contain egg albumin, water, and glycerin; shellac, beeswax, and casein made soluble in mild alkali will also give a glossy surface; pigmented finishes may be aqueous or nonaqueous and usually contain pigment (6–50 percent), protein or resin binder to bind and disperse pigment (10–20 percent), plasticizer (5–20 percent) to soften, dyestuff (0.5–6 percent), a preservative (0.5–2 percent), and water or another solvent. Binder-free pigment finishes are concentrated pigment colours dispersed with a wetting agent. Pigments may be earth pigments, such as iron oxide; or manufactured inorganic pigments, such as lithopone, organic pigments, lakes, and black carbon. Binders may be proteins, such as casein and shellac (used mainly for glaze finish), or synthetic resins for matte finish. The pigment finishes cover the surface defects well; aniline finish is used for leathers that need a natural look. This finish, a casein-free organic pigment in emulsion, is applied with very little loading; lacquers used as finishes are based on nitrocellulose in solvent or in water emulsion, vinyls, urethanes, and alkyds. All are produced in clear, aniline, and pigmented form and applied where gloss and resistance to rubbing are required, as in upholstery, grain garments, and Morocco leathers. Urethanes, instead of partly boiled linseed oil, pigment, and driers, are specially used for patent leather.

The application of finishes

Finishes are applied by hand brush, pad, or spray (with or without air power); or by a seasoning machine, using mechanical padding on a conveyor system; or by means of a flow coater in which the leather passes through a curtain of finish. Automatic spraying is also used.

Water resistance is obtained by treating leather with silicones and waxes.

Glaze finishes may require further treatment by a glazing machine. Matte or resin finished leather is usually plated by passing it between polished, heated cylinders. Sometimes it is embossed with artificial designs by a hydraulic press. Certain types of leathers are boarded by rolling the leather upon itself by hand or machine.

Sole leathers are bleached with oxalic acid or synthetic tannin, seasoned, and rolled under pressure. Belting leathers are stuffed and stretched. Shoe upper leathers with corrected grain are impregnated, buffed, pigment finished, and top dressed with one or two coats of lacquer emulsion. Full natural-grain calf or kid leathers are aniline finished or dilute-protein coated after they have been glazed and ironed to get a glossy, smooth, natural grain.

By proper formulation and combination of materials and methods, desired effects can be obtained in finishing of leather to meet the specific end use.

TANNERY BY-PRODUCTS

Rawhide trimmings

Rawhide trimmings are used in the manufacture of edible gelatin; fleshings for glue, oil, manure, and animal fodder; hair for drugget (coarse cloth), carpets, felt, and manure; soak water for growing coconut trees; lime sludge for cement and road making; tanbark for cardboards and chipboards and to make activated carbon; leather trimmings and shavings for leather board and fertilizer. Effluent water may be treated and used in agriculture.

The leather industry is traditionally associated with bad odours and pollution. Tanneries are generally located close to a river to ensure a plentiful water supply for processing and effluent disposal. Tannery effluent includes proteins, hair, salt, lime sludge, sulfides, acids, chrome and other tanning agents, dyes, and oils. Treatment of this effluent involves screening of hair, precipitation settling and removal of chrome, vegetable tans, and proteins, and filtration and aeration of the effluent. Salt is the most difficult of all effluent ingredients to remove. Sulfides are decomposed by manganese oxidation. Several effluent treatment systems have been proposed, one being the so-called Dutch ditch raceway system, which degrades sludge by biological treatment. Effluent treatment adds a penny per square foot to the cost of leather. Another approach to the pollution problem is to reduce the volume of water and chemicals used and to centralize all tannery wet work up to pickling near the slaughterhouses.

ECONOMICS AND SCOPE OF LEATHER INDUSTRY

Leather is an international commodity and a valuable traditional industry. The total value of the world's leather and allied industries is estimated to be more than $2,000,000,000; the international leather trade is around $1,000,000,000 per year. The industry provides employment to a large number of people. Because a tannery can use either a great deal of labour and low capital investment or a great deal of capital and low labour supply, depending upon the processes used, this industry can be established in both developing and advanced countries. Leather is also a strategic material for defense. Leather's unique properties, rising world population and incomes, new uses for leather, rapid changes in fashion, and more intensive use of resources in developing countries have contributed to an ever-increasing demand for leather. The use of synthetics as leather substitutes, however, is growing. Man-made products in the advanced countries were supplanting 50 percent of leather goods, 70–80 percent of sole leather, and 2–15 percent of the upper leather in footwear in the early 1970s.

World hide production

The world produces around 6,500,000 metric tons of hides and about 1,300,000 metric tons of skins annually. The largest producers of hides are the Soviet Union, the United States, and India; goatskins, India and China; sheepskins, the Soviet Union, New Zealand, and Australia.

The world leather trade is largely concentrated in advanced countries (mostly in the Organization for Economic Co-operation and Development group) that trade among themselves. The major exporters of finished leathers are India, Italy, Japan, West Germany, and the United Kingdom. Italy is the largest exporter of footwear, followed by Japan.

Though the developing nations of Asia, Africa, and Latin America raise nearly 60 percent of the world's cattle, three-quarters of the goats, and more than 40 percent of the sheep, they do not realize the full value of the hides produced because slaughter is inefficient and poorly organized. Developing nations export mostly rawhides and skins and some leathers; they import finished goods.

Tanning is still a craft industry on the cottage level in the developing nations. Modern technology, however, promises to allow these nations fuller use of their animal resources through the establishment of efficient slaughterhouses and large-scale manufacturing units. The development of tanning industries will enable these nations to meet their own internal demands for leather and become exporters of leather and finished leather goods. In the more advanced countries, the scarcity and high cost of labour and the reluctance of workers to perform such operations as dehairing and fleshing, are requiring the purchase of more and more leather, rather than rawhides and skins, from the developing nations. Thus the leather industry may undergo a significant shift from the advanced countries to the developing nations.

(Y.N.)

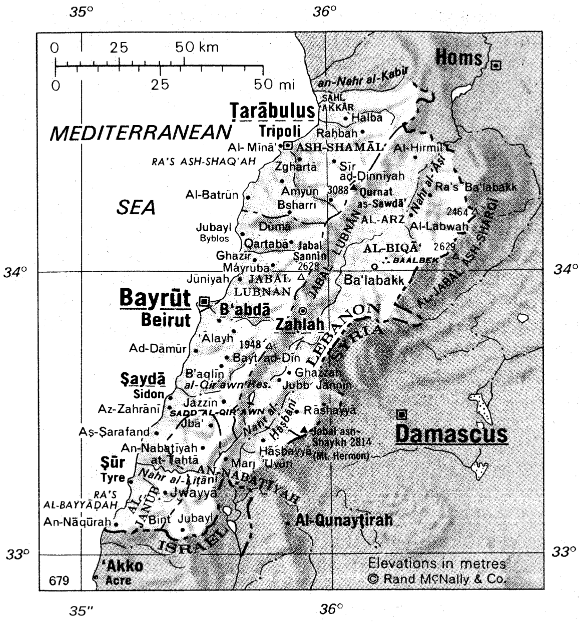
Lebanon

Boundaries

The Republic of Lebanon, a predominantly mountainous country of great scenic beauty, is an Arab republic situated on the eastern shore of the Mediterranean Sea. Consisting of a narrow strip of land about 135 miles (215 kilometres) long from north to south and 20 to 55 miles (30 to 90 kilometres) wide from east to west, it is bounded to the north and east by Syria and to the south by Israel. With an area of 3,950 square miles (10,230 square kilometres), Lebanon is one of the world's smaller sovereign states. The capital is Beirut. In 1978 the country's population was estimated by the United Nations at 3,152,000; the Civil War of 1974–76 led to the emigration of about half a million people, but by 1978 about half of these had returned.

Though Lebanon, particularly its coastal region, was the site of some of the oldest human settlements in the world—the Phoenician ports of Tyre (modern Ṣūr), Sidon (Ṣaydā), and Byblos (Jubayl) were dominant centres of trade and culture in the 3rd millennium BC—it was not until 1920 that the contemporary state came into being. In that year, France, which administered Lebanon as a League of Nations mandate, established the state of Greater Lebanon, which gave the country its present frontiers. Lebanon then became a republic in 1926 and achieved independence in 1943. It is a charter member of the Arab League.

As an Arab republic, Lebanon shares many of the cultural characteristics of the Arab world, yet it has evolved a distinct mode of life and some special socioeconomic and political attributes that differentiate it from many of its Arab neighbours. Its rugged, mountainous terrain has served throughout history as an asylum for diverse religious and ethnic groups and political dissidents.



LEBANON

This, along with the gradual movement of people in the Mediterranean area, has generated its uniquely cosmopolitan character and its receptivity to change. Lebanon is the second most densely populated country in the area. It has the highest rate of literacy. Until 1975 it had the highest standard of living, and—with the exception of the oil-rich states of the Persian Gulf—the highest per capita income. Although its prosperity is unevenly distributed, having bypassed large segments of its population, wealth and privilege appear to be evenly distributed among its middle-income group. Notwithstanding its meagre natural resources, Lebanon managed to become a busy commercial and cultural centre for the Middle East.

This outward image of vitality and growth nevertheless disguised some serious problems. Not only was Lebanon grappling with internal problems of social and economic organization but also, with its Arab neighbours, it was playing a role in a common struggle and was similarly vulnerable to the political vicissitudes of the Middle East. Its pluralistic communal structure gave legitimacy to the vertical hierarchies that dominate the political life of the country. Horizontal relationships that went beyond religious and sectarian affiliations did not have an interest in the system of government. Demands for a secular state were considered unrealistic. The pressures and the complex issues that arose from the absence of a solution to the Palestinian problem led to the breakdown of the system and to a crisis that remained almost unmanageable.

This article deals with contemporary Lebanon. For historical background, see CALIPHATE, EMPIRE OF THE; OTTOMAN EMPIRE AND TURKEY, HISTORY OF THE; and SYRIA AND PALESTINE, HISTORY OF. See also BEIRUT.

THE LANDSCAPE

The natural environment. ***Relief.*** As in any mountainous region, the physical geography of Lebanon is extremely complex and varied. Landforms, climate, soils, and vegetation undergo some sharp and striking changes within short distances. Four distinct physiographic regions may be distinguished: a narrow coastal plain along the Mediterranean Sea, the Lebanon Mountains (Jabal Lubnān), al-Biqāʿ (Beqaa) valley, and the Anti-Lebanon and Hermon ranges running parallel to the coastal mountains.

Physiographic regions

The coastal plain is narrow and discontinuous, almost disappearing in places. It is formed of river-deposited alluvium and marine sediments, which alternate suddenly with rocky beaches and sandy bays, and is generally fertile. In the far north it expands to form the ʿAkkār Plain.

The snow-capped Lebanon Mountains are the most prominent feature of the country's landscape. The range, rising steeply from the coast, forms a ridge of limestone and sandstone, cut by narrow and deep gorges. It is approximately 100 miles (160 kilometres) long and varies in width from 35 to six miles (55 to 10 kilometres). Its maximum elevation is at Qurnat as-Sawdā' (10,131 feet, or 3,088 metres) in the north, where the renowned cedars of Lebanon grow in the shadow of the peak. The range then gradually slopes to the south, rising again to a second peak, Jabal Ṣannīn, northeast of Beirut. To the south, the range gives way to the hills of Galilee, which are lower. The limestone composition of the mountains provides a relatively poor topsoil. The lower and middle slopes, however, are intensively cultivated, the terraced hills standing as a scenic relic of the ingenious tillers of the past.

Al-Biqāʿ

Al-Biqāʿ valley lies between the Lebanon Mountains in the west and the Anti-Lebanon Mountains in the east; its fertile soils consist of alluvial deposits from the mountains on either side. The valley, approximately 110 miles long and from six to 16 miles wide, is part of the great East African Rift System that stretches southward to Mozambique. In the south. al-Biqāʿ becomes hilly and rugged, blending into the foothills of Mt. Hermon (Jabal ash-Shaykh) to form the upper Jordan Valley.

Much like the Lebanon Mountains, the Anti-Lebanon (al-Jabal ash-Sharqi) starts with a high peak in the north and slopes southward until it is interrupted by the compelling heights of Mt. Hermon (9,232 feet).

Drainage. Lebanese rivers, though numerous, are mostly winter torrents, draining the western slopes of the Lebanon Mountains. If not fed by large springs they are only seasonal. The only exception is the Līṭānī (90 miles long), which rises near the famed ruins of Baalbek and flows southward in al-Biqāʿ to empty into the Mediterranean near historic Tyre. The two other important rivers are the Orontes (Nahr al-ʿĀṣī), which also rises in the extreme north of al-Biqāʿ but flows northward through Syria, and the Kabir, which forms the northern boundary between Lebanon and Syria. The Bārid, the Abū 'Ali, the Awwali, and others are only mountain streams.

Climate. There are sharp local contrasts in climatic conditions. Lebanon is included in the Mediterranean climatic region, which extends westward to the Atlantic Ocean. The winter storms formed over the ocean move eastward through the Mediterranean, bringing rain at that season; in summer the Mediterranean receives no rain. The climate of Lebanon is generally subtropical and is characterized by hot, dry summers and mild, humid winters. Mean daily maximum temperatures range from 90° F (32° C) in July, on the coast and in al-Biqāʿ, to 60° F (16° C) on the coast and 50° F (10° C) in al-Biqāʿ in January. Mean minimum temperatures in January are 45° F (7° C) or? the coast and 35° F (2° C) in al-Biqāʿ. At 5,000 feet (1,500 metres), the altitude of the highest settlements, these are reduced by about 15° F (8° C).

Nearly all precipitation falls in winter and averages 30 to 40 inches (750 to 1,000 millimetres) on the coast, rising to more than 60 inches in higher altitudes. Al-Biqāʿ is drier and receives 15 to 25 inches (400 to 600 millimetres). On the higher mountaintops, this precipitation falls as heavy snow that remains until early summer.

Cedar trees

Vegetation and animal life. ***Vegetation.*** Lebanon was heavily forested in ancient and medieval times, and its timber—particularly its famed cedar—was exported for building and shipbuilding. (There are many references to the cedars of Lebanon in the Bible; in I Kings 7:2, King Solomon's palace is called the House of the Forest of Lebanon.) The natural vegetation, however, has been grazed, burned, and cut for so long that little of it is regenerated. What survives is a wild Mediterranean vegetation of brush and low trees, mostly oaks, pines, cypresses, firs, junipers, and carobs.

Animal life. Few large wild animals survive in Lebanon, though bears are occasionally seen in the mountains. Among the smaller animals, deer, wildcats, hedgehogs, squirrels, martens, dormice, and hares are found. Numerous migratory birds from Africa and Europe visit Lebanon. Flamingoes, pelicans, cormorants, ducks, herons, and snipes frequent the marshes; eagles, buzzards, kites, falcons, and hawks inhabit the mountains; and owls, kingfishers, cuckoos, and woodpeckers are common.

THE PEOPLE

Lebanon has a heterogeneous society composed of numerous ethnic, religious, regional, and kinship groups. Primordial attachments and local communalism antedate the creation of the present territorial and political entity and continue to survive with remarkable tenacity. The small size of the country, an effective communications network, and the mobility of the Lebanese, however, are gradually attenuating traditional loyalties.

Ethnic and linguistic groups. Ethnically, the Lebanese compose a mixture in which Phoenician, Greek, Byzantine, crusader, and Arab elements are discernible. Throughout the ages there has been an influx of tribes and families from the Arabian Desert. While the dominant strain in the mountains is related to the Armenians of Asia Minor and the Caucasus, inhabitants of the coastal towns and al-Biqāʿ are descended from inhabitants of the hinterlands of Syria, Palestine, and Arabia.

Arabic is the national language, but French and English are widely spoken, and many educated Lebanese are trilingual. About 5 percent of the population is Armenian-speaking, and Syriac is used in the liturgies of some of the churches of the Maronites (Roman Catholics following an Eastern rite).

Religious groups. Perhaps the most distinctive feature of Lebanon's social structure is its varied religious composition. From the 7th century onward, Lebanon has served as a refuge for persecuted Christian and Muslim sects. The population today is estimated to be 60 percent Muslim and 40 percent Christian; altogether, there are 17 recognized religious sects. Although no official census has been taken since 1932, and although it is now believed that Shi'ite Muslims are the most numerous group, the Maronites have the largest representation in the National Assembly. Among the Christians, Maronites form the largest group (28 percent), followed by Greek Orthodox (10) and Greek Catholics (6). Among the three Muslim denominations, the Shi'ites are followed closely by the Sunnites; the Druzes have remained third, with about 6 percent of the population. There is also a minority of about 7,000 Jews.

Demography. There has been no full census since 1932. In 1978 the population was estimated at 3,152,000. There were about 400,000 Palestinian refugees in the country, and the civil war that was waged after 1974 led to the emigration of about half a million people. Pres. Elias Sarkis in November 1978 stated that, to that date, more than 30,000 Lebanese had been killed and nearly 200,000 mutilated; other estimates put the dead at around 60,000, but this figure includes Syrians and Palestinians.

A youthful population

Because of the country's relatively high fertility (it has a birth rate between 39 and 42 per 1,000) and its rapidly declining mortality rate (9.9 per 1,000), the Lebanese population is extremely youthful. Estimates made in 1978 indicated that 43 percent of the people were 14 years old or less. There was a sex ratio imbalance, with 49 percent female and 51 percent male. Infant mortality (about 14 per 1,000 live births) was much lower than the average rate for Arab countries (127 per 1,000).

One of the most salient demographic features of Lebanon is the uneven distribution of its population. While the country has an overall density of more than 800 persons per square mile (300 per square kilometre), density soars to about 69,000 per square mile (27,000 per square kilometre) in Bayrūt *muḥāfaẓah* (Beirut governorate) but diminishes to 123 in al-Biqāʿ governorate. In other governorates the density is: al-Janūb, 324; ash-Shamāl, 484; Jabal Lubnān, 1,106 (no estimate for an-Nabatiyah, created in 1975).

Before the civil war, the movement of people from rural areas was a major factor in the country's soaring rate of urbanization. About 60.1 percent of the population (1970) lived in urban agglomerations of 10,000 or more, only 39.9 percent in rural areas. Nearly two-thirds of the internal migration had been toward Beirut, which by 1970 had an estimated population of 940,000—86 percent of Lebanon's urban population and 44 percent of the country's total. The civil war led to a substantial return of people to their villages, but accurate figures are not available.

THE NATIONAL ECONOMY

Until 1974, Lebanon sustained a dualistic economy that reconciled traditional and modern elements. The traditional agriculture sector provided primary employment for approximately 20 percent of the labour force but generated only 9 percent of the national income; industry generated 21 percent of income, and services, which employed only 15 percent of the labour force, generated 70 percent. The growth of services was related mainly to international transport and trade and to the position of Beirut as a centre of international banking and tourism.

Economic losses after 1974

Per capita income grew from about $250 U.S. in 1950 to $1,070 in 1974. This figure, however, dropped below $1,000 as a result of the civil war. The war left deep scars on Beirut, several other cities, and many villages. Although only a preliminary inventory of private and public losses attributable to the war has been made, extensive destruction in all sectors, but especially in housing, trade, and public services, is evident, with damages roughly estimated at $2,500,000,000 U.S. Overall, the country's productive capacity was reduced by as much as 40 to 50 percent by the end of 1976, as compared with 1974. The greatest reduction in productive capacity seemed, according to a World Bank report of June 1977, to be in services, followed by industry and agriculture.

Sources of national income. ***Agriculture.*** Arable land is scarce, but the climate and the relatively abundant water supply from springs favour the intensive cultivation of a variety of crops on mountain slopes and in the coastal region. On the irrigated coastal plain, market vegetables, bananas, and citrus are grown. In the foothills, the principal crops are olives, grapes, tobacco, figs, and almonds. At higher altitudes (about 1,500 feet, or 460 metres), peaches, apricots, plums, and cherries are planted, while apples and pears thrive at an altitude of about 3,000 feet. Sugar beets, cereals, and vegetables are the main crops cultivated in al-Biqāʿ. New techniques in agriculture have done much to increase output; Lebanon was formerly an importer of apples, but in 1974 about 160,000 tons were exported. With the completion of the Sadd al-Qir 'awn (Karaoun Dam) across the Līṭānī River in 1965, the amount of irrigated land increased. The government also formulated a "Green Plan" (1964) to restore neglected land and to promote reafforestation. Poultry has become a major source of agricultural income.

Industry. The mineral resources of Lebanon are few. Minor deposits of high-grade iron ore, asphalt, coal, and phosphates are exploited. There are numerous building-stone quarries, and there is some high-quality sand, suitable for glass manufacture, as well as lime.

The industrial sector grew in the 1960s, particularly in quality and diversification of products. Before the war, leading industries were food processing, manufacture of textiles, plywood, and furniture, and printing. Chemicals, pharmaceuticals, and aluminum products were also growing in importance. There were two steel mills, three cement factories, and two oil refineries.

Oil reserves

In April 1975 the Ministry of Industry and Oil announced that commercially workable oil reserves had been discovered in the 'Akkar Plain, western al-Biqāʿ, and the Mayrūbā area near the central coast. Bids for concessions were postponed pending the end of the war. In January 1977, within weeks of the final cease-fire agreement, the government set up a new Higher Oil Committee, putting it in charge of oil imports, exploration agreements, and the country's refineries.

About 70 percent of the country's industry survived the civil war unscathed. Beirut's industrial belt was razed, but some of the country's big complexes were unharmed. Manufacturing in 1978 was back at 60 percent of the still existing capacity, restrained by limited labour mobility, difficulty in acquiring supplies, insufficient working capital, and difficulty in obtaining credit.

Trade and services. Until 1974, trade continued to reflect the mercantile character of the Lebanese economy. Almost anything for sale anywhere could have been bought in Beirut. An enormous propensity to consume generated a huge trade deficit, which was partly covered by "invisible" items such as foreign remittances and transit and tourist services. The trade pattern remained the same during the war, though at a reduced level.

Finance. The monetary unit is the Lebanese pound. The finance sector of Lebanon's economy, including banking and insurance, showed an impressive expansion before the war. Beirut had 72 officially recognized banks (35 Lebanese, 19 foreign, and 18 Lebanese with foreign participation). According to statistics of the International Monetary Fund, monetary reserves of Lebanon continued to rise despite political uncertainties. At the end of 1974, external reserves stood at $1,700,000,000 and, despite the two years of civil war and the extended period of domestic instability following that, reserves continued to rise, reaching $2,000,000,000 at the end of 1977 and $2,260,000,000 at the end of 1978. These amounts included, according to the same source, a considerable portion of gold, which, if valued at the market prices of December 1978, would increase these reserves by approximately $2,000,000,000 more.

Capital inflows

In the late 1970s the balance of payments indicated a surplus. Furthermore, the Lebanese pound appreciated, vis-a-vis the U.S. dollar, after the end of 1977. The strength of the Lebanese pound and of the balance of payments position continued to reflect large capital inflows, mostly from Lebanese living abroad (whose numbers rose considerably during and after the war) and from the high level of liquidity of commercial banks.

Beirut's well-developed seaport and airport and the country's free economic and foreign exchange systems, favourable interest rates, and banking secrecy law (modelled upon that of Switzerland) all contributed to the preeminence of trade and services. Until 1973, tourism was foremost among these services. The country's scenery, its biblical and other historic sites, its hotels, bars, nightclubs, and restaurants, its seaside and mountain resorts, its outdoor sports facilities, and its international cultural festivals had made tourism an all-year-round industry. Tourism was severely damaged by the 1974–76 crisis. As the war progressed, the prosperous hotel district in Beirut became the scene of some of the fiercest fighting, and hotel activity in 1975 dropped by 80 percent below the previous year. The closure of Beirut airport for nine months, the heavy destruction of the port, and the continued political unrest greatly damaged the service industry. The government in its reconstruction policy made plans, ready to be carried out upon the resolution of the security problem, to revive this sector of the economy.

Management of the economy. Lebanon has a liberal economy, characterized by a minimum of government intervention in the activities of private enterprise. There is, however, a government monopoly on the manufacture and sale of tobacco, and some of the railways and public transport systems are now operated by the government.

Though the country had no specific long-term economic development plan, the government spent (between 1971 and 1975), in addition to the regular budget, a sum of $250,000,000 U.S. on development schemes. One of the most important of these was the Līṭānī project, which, when completed, was expected to increase the irrigated area of Lebanon by 50,000 acres (20,000 hectares) and to make possible the production of an additional 626,000,000 kilowatt-hours of electricity per year.

Trade unions. Lebanon is one of the few countries in the Middle East with a comparatively well-developed labour movement. During the war, divisions in many of the trade unions weakened their normal functions, and many of their 60,000 members, distributed among about 170 licensed unions, joined the different warring factions. Many others emigrated. Though the trade unions have secured some tangible gains, such as fringe benefits, collective bargaining contracts, and better working conditions, the movement remains fragmented by regional, religious, and ideological divisions.

TRANSPORTATION

As in antiquity, Lebanon's situation makes it a vital crossroads between East and West.

Roads. A road network of about 2,500 miles (4,000 kilometres) traverses Lebanon, about 300 miles (500 kilometres) being international highways, forming part of major land routes connecting Europe with the Arab countries and the East. There are also about 700 miles (1,100 kilometres) of national highways, 500 miles (800 kilometres) of paved secondary roads, and 1,000 miles of unpaved roads.

Lebanon appears to be a society in perpetual motion; in 1976 there was a ratio of one motor vehicle per 13 persons. There is a low-priced bus and taxi service throughout the country, and regular bus services to Europe and to most Arab countries are available.

Railways. The railway system, which includes lines along the coast and up al-Biqāʿ valley and a cog railway across the Lebanon Mountains, connects with the rail systems of Europe and other Arab countries. Although there is daily passenger service to Aleppo, in Syria, the line is used mainly for long-distance bulk transport.

Port of Beirut

Ports. There are numerous ports along the Lebanese seacoast. Fishing boats and coastal steamers use Tyre, Sidon, and Jubayl (Byblos), all of which have been ports since Phoenician times. Oil tankers load offshore from the pipeline terminals at Tripoli and at az-Zahrānī near Sidon. There is a harbour for yachts and small craft at Jūniyah. The principal cargo and passenger port is that of Beirut, which has a free zone for duty-free handling and storage of transit shipments. About 3,000 ships and some 95,000 passengers utilized Beirut's port facilities in 1974. A major expansion and deepening of the port was completed in 1967, and a large storage silo (for wheat and other grains) was completed in 1970. The docks could hold 20 ships and move 3,500,000 tons of goods per year. Until 1974, traffic in the port of Beirut amounted to 4,000,000 tons annually, of which 1,000 tons was in transit for Arab countries. Port infrastructure remained unaffected by the war, but all superstructures—sheds, warehouses, cargo-handling equipment, workshops, and telephone and power lines—were either destroyed or severely damaged.

Air services. Beirut International Airport was one of the busiest airports in the Middle East before the war. Its runways can take the largest jet airplanes in service, and more than 30 international airlines used Beirut regularly; by 1978 that figure had increased to 40.

ADMINISTRATION AND SOCIAL CONDITIONS

Parliament

The structure of the government. ***The constitutional framework.*** Modern Lebanon is a republic with a parliamentary system of government. Its constitution, promulgated in 1926 during the French mandate and modified by several subsequent amendments, provides for a unicameral Chamber of Deputies (renamed National Assembly in 1979) elected, for a term of four years, by universal adult suffrage (women attained the right to vote and eligibility to run for office in 1953). By the electoral law of 1960, which imposed the principle of the secret ballot, membership of the chamber was increased from 66 to 99. Parliamentary seats are apportioned on a religious basis in the ratio of six Christians to five Muslims, making the total number always a multiple of 11. This sectarian distribution is also observed in all administrative appointments for public office.

The president of the republic is elected by a two-thirds majority of the National Assembly for a term of six years and is eligible for re-election only after the lapse of a further six years. By an unwritten convention, the president must be a Maronite, the premier a Sunni Muslim, and the speaker of the National Assembly a Shiʿite. The president, who is constitutionally invested with the power of chief executive, calls upon a Sunni Muslim to form a Cabinet whose portfolios must reflect the sectarian balance. The Cabinet, to remain in power, requires a vote of confidence from the Assembly. A vote of no confidence, however, is a constitutional right that is rarely exercised in practice. A Cabinet usually falls because of internal dissension or because the president withdraws his support.

Local government. Administratively, Lebanon consists of six *muḥāfaẓāt* (governorates): Bayrūt (Beirut), Jabal Lubnān, ash-Shamāl, al-Janūb, al-Biqāʿ, and an-Nabaṭīah. These are administered by the Ministry of Interior through the *muḥāfiẓ* (governor), who represents the central government in the region. The *muḥāfaẓāt* are further divided into *qaḍā'*s (districts), each of which is presided over by a *qā'im-maqām* (district chief), who, along with the *muḥāfiẓ*, supervises local government in his respective region. Municipalities (communities with at least 500 inhabitants) elect their councils, which in turn elect mayors and vice mayors. Villages and towns (more than 50 and fewer than 500 inhabitants) elect a *mukhṭār* (headman) and a council of elders, who serve on an honorary basis. All officers of local governments serve four-year terms.

Lebanon, Area and Population

	area		population*	
	sq mi	sq km	1961 est.†	1970 est.‡
Governorates (*muḥāfaẓat*)				
al-Biqa'	1,653	4,280	320,967	204,000
al-Janub	364	943	200,818	250,000
ash-Shamāl	765	1,981	506,079	365,000
Bayriit	7	18	298,129	475,000
Jabal Lubnan	753	1,950	622,284	833,000
an-Nabaṭiyah	408	1,058	203,607	...
Total Lebanon%	3,950	10,230	2,151,884	2,126,000‖

*Last complete census was taken in 1932.
†According to population registers. ‡Figures are based on a sample survey made on November 15, 1970, of resident (*de jure*) population; estimate excludes certain categories of persons not covered by the sample, such as Palestinian refugees (who numbered 181,764 in 1971). The total resident population of Lebanon comprised between 2,300,000 and 2,400,000 persons at the end of 1970. §Created in 1975; includes the districts of Nabaṭiyah, Bint Jubayl, Marj ʿUyūn, and Ḥāṣbayya, which were formerly part of al-Janūb. ‖Figures do not add to total given because of rounding.

The political process. The political system in Lebanon remains a curious blend of secular and traditional features. Until 1975, outwardly, the country appeared to support liberal and democratic institutions, yet, in effect, it had hardly any of the political instruments of a civil polity. Its political parties, parliamentary blocs, and pressure groups were so closely identified with parochial, communal, and personal loyalties that they often failed to serve the larger national purpose of the society. A National Pact, a sort of Christian–Muslim entente, sustained the national entity (*al-kiyān*), yet this sense of identity was neither national nor civic. In April 1975 the political process collapsed. The war that had engulfed the Lebanese exposed the vulnerability of the political system. The Syrians in January 1976 introduced suggestions for constitutional amendments that would have led to a more equitable sharing of power among Christians and Muslims, 50:50, rather than the constitutional ratio, which favours the Christian minority. In the light of subsequent developments, these "reforms," which were accepted by the then president, are not considered satisfactory solutions to the political problems facing Lebanon. The legitimate authority maintains the facade of continuity, while the process on which it is based was destroyed by the contending forces in the conflict that has continued to ravage Lebanon.

National Pact

Justice. The system of law and justice is mostly modelled on French concepts. The judiciary consists of courts of the first instance, courts of appeal, courts of cassation, and a Court of Justice that handles cases affecting state security. The Council of State is a court that deals with administrative affairs. In addition, there are religious courts that deal with matters of personal status (such as inheritance, marriage, and property matters) as they pertain to autonomous communities. Despite the country's well-developed legal system and a very high proportion of lawyers, significant numbers of disputes and personal grievances are resolved outside the courts. Justice by feud and vendetta continues.

Armed and security forces. In 1978 it was estimated that the strength of the armed forces amounted to 7,000 in the army, 500 in the air force, and 300 in the navy. Lebanon also had a paramilitary gendarmerie and police force of 5,000. During the civil war, the army practically disintegrated as splinter groups joined the different warring factions. After 1976, security was maintained principally by the 33,000-strong Arab Deterrent Force (ADF) created specifically for the purpose, as a transitional force pending the rebuilding of the army. Reconstruction of the Lebanese armed forces was under way, but the continued existence of private militias continued to prevent a return to full sovereignty by the central government.

Private militias

Social conditions. Lebanon in general has a relatively high standard of living, compared with most other Arab countries. In urban areas, modern health, medical, and sanitation services are easily accessible to all groups.

Education. A well-developed system of education reaches virtually all levels of the population. The estimated literacy rate is 88 percent, the highest in the Middle East. Education was once almost exclusively the responsibility of religious communities or foreign groups, but by the 1970s the number of students in public schools had risen to almost one-third of the total school enrollment.

The compulsory five-year primary school program is followed either by a seven-year secondary program (leading to the official baccalaureate certificate) or by a four-year program preparing students for technical or vocational training. In 1974, some 50,000 students (nearly 22,000 of whom were non-Lebanese) were receiving university education in the country's institutions of higher learning. The number of students in universities decreased during the war, but the prewar level was expected to be regained by 1979. The four major universities are the American University of Beirut, the Universite Saint-Joseph (subsidized by the French government and administered by the Jesuit order), the Lebanese University (Universite Libanaise), and the Beirut Arab University (an affiliate of the University of Alexandria).

Universities

Health and welfare. Public health services are still largely concentrated in the cities, although the government increasingly directs medical aid into rural areas. As in the field of social welfare, nongovernmental voluntary associations—mostly religious, communal, or ethnic—are very active. The Lebanese diet is generally satisfactory, and the high standard of living and the favourable climate have served to reduce the incidence of many diseases that are still common in other Middle Eastern countries.

In proportion to its population, the country also produces the largest number of skilled medical personnel in the Arab Middle East. There is approximately one doctor for 1,290 inhabitants. Hospital facilities are also adequate.

In 1963 the National Social Security Fund was established, covering sickness and maternity insurance, labour accident and occupational disease insurance, family benefits, and termination of service benefits.

Housing. In response to the need for low-cost housing, a Popular Housing Law was enacted in 1965, providing for the rehabilitation of substandard housing. The legislation also stipulated that, instead of investing government funds in low-cost housing, guarantees of mortgage payments would be provided to developers. Some 4,000 "popular houses" were constructed.

A study conducted in 1970 showed that 123,000 homes (23 percent) were without bathrooms and that 8,000 families, excluding the Palestinian refugees, were living in improvised accommodations. ***A Report on Housing*** by the United Nations Economic Commission for Western Asia in July 1977 indicated that there had been no improvement by the start of the war. The economic boom of 1973–74 attracted thousands of villagers to the capital, and the housing shortage worsened considerably. The war drastically increased the problem. Thousands of homes on the front line were destroyed, and entire villages were evacuated and others occupied. The result was chaos in which property rights were violated as a matter of course. The government, in an attempt to remedy the situation, in 1978 set up a Housing Bank with a capital of L.£50,000,000 ($16,800,000 U.S.) to make housing loans.

Housing bank

Wages and cost of living. A minimum wage is set by the Labour Code, and legislation provides for cost-of-living increases. The cost of living increased sharply prior to and during the civil war, mainly because of a substantial rise in the cost of rent, education, food, and petroleum products.

Social and economic division. Lebanese society was able for a long time to give a semblance of relative economic stability and convey an impression of social cohesion. The existence of a large middle-income group, in addition to the political and social legitimacy that kinship ties and religious and communal attachments had, reinforced the false veneer that masked the growing socioeconomic dislocations. The interaction of these factors covered up the growing class polarization, not only between the regions but also around the industrial belt that encircled the capital, Beirut. This rendered the body politic vulnerable. The explosion that ensued was attributable in part to the fact that the system of government was unresponsive to the acute social problems and grievances.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu. Historically, Lebanon is the heir of a long succession of Mediterranean cultures—Phoenician, Hittite, ancient Egyptian, Greek, Roman, Byzantine, and Arab. Its cultural milieu continues to show clear manifestations of a rich and diverse heritage. As an Arab country, Lebanon shares more than a common language with neighbouring Arab states; it also has a similar cultural heritage and common interests.

In the 19th century, Lebanese linguists were in the vanguard of the Arabic literary awakening. In more recent times, writers of the calibre of Khalil Gibran, Georges Shehade, and Michel Chiha have been widely translated and have reached an international audience.

While originally cultural life in Lebanon was predominantly centred around universities and affiliated institutions, in more recent times there has been an impressive proliferation of cultural activities. Beirut has five museums and a number of libraries, learned societies, and research institutions.

Music festivals

The state of the arts. Lebanon's antiquities and ruins have provided not only inspiration for artists but also magnificent backdrops for annual music festivals, most notably the Baalbek International Festival. International opera, ballet, symphony, and drama companies, of nearly all nationalities, competed to enrich the cultural life of Beirut. Lebanon has produced a number of gifted young artists who have shown a refreshing readiness to experiment with new expressive forms, from Surrealistic painting to Theatre of the Absurd. Several young Lebanese are active in European opera and theatre companies, while others are intent on creating a wider audience for classical Arabic music and theatre.

The cultural awakening encouraged the revival of national folk arts, particularly song, *dabkah* (the national dance), and *zajal* (folk poetry), and the refinement of traditional crafts. Although the Baalbek International Festival was suspended during the civil war, popular theatre flourished in the war-ridden country.

The communications media. In addition to the wide variety of foreign newspapers and magazines that can be found in Beirut, Lebanon has almost 470 registered publications in Arabic, English, French, and Armenian, of which about 40 are dailies.

Impressions suggest strongly that Beirut may be the movie-going capital of the world. Because of the wide choice of films, comfortable surroundings, and low prices, going to the pictures has emerged as the national pastime of the Lebanese. In 1965 UNESCO estimated per capita film attendance to be the 10th highest in the world.

By 1976 there were more than 420,000 television sets, which suggests that more than half of the population is exposed to the programming offered by Beirut's two private companies and by Egyptian and Syrian television.

With the advent of the transistor, Lebanon became virtually saturated with radios, with about 1,600,000 in 1976. The government-run radio station broadcasts Arabic, French, English, and Armenian programs. During the war, there was a proliferation of clandestine radio stations seeking to put forward the news and views of the warring parties. The government is trying to put an end to these radio stations as a manifestation of its commitment to national unity.

PROSPECTS FOR THE FUTURE

Lebanon is groping for a resolution of the conflicts that tore it apart after 1974. After the installation of Pres. Elias Sarkis, the government sought to ensure the restoration of public order with the aid of the Arab Deterrent Force, pending the reformation of the Lebanese national army. Reconstruction projects were suspended, awaiting the solution of the political and security problems.

Plans for constitutional and administrative reforms, however, are contingent on steps being taken toward an overall settlement of the Middle East crises. Despite the gloom that prevails and the suspicions that have developed among many sectors of the population, the prospects for the future cannot with certainty be said to be bleak. There may be sufficient exasperation, and there is a proved reservoir of resilience, to bring about a new order that will restore Lebanon to its historical role as a cultural, intellectual, and artistic centre of the Arab East.

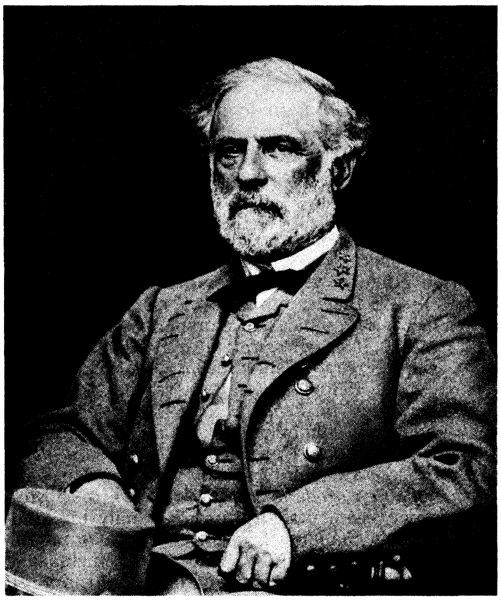
Lee, Robert E.

As commander of the most successful of the Confederate armies during the United States Civil War, Robert E. Lee became synonymous with the Confederacy's defense. Because he continued to confront the massed Federal forces after four years of war while the rest of the Confederacy collapsed, his surrender at Appomattox is commonly viewed as signifying the end of the Civil War. His subtler fame and more significant contribution came after the war, however, when, as the idol of a defeated people, he served as an example of fortitude and magnanimity during the ruin and dislocations, the anguish and bitterness of the war's long aftermath. In those years, Lee became an enduring symbol to the Southern people of what was best in their heritage.

By courtesy of the Library of Congress, Washington, D.C.



Robert E. Lee, 1865:

Heritage and youth. Robert Edward Lee was born at Stratford, Westmoreland County, Virginia, on January 19, 1807, the fourth child of Colonel Henry Lee and Ann Hill Carter. On both sides, his family had produced many of the dominant figures in the ruling class that had determined Virginia's colonial destiny and contributed leadership to the American Revolution.

Lee's father, "Light Horse" Harry Lee, had been a cavalry leader during the Revolution, a post-Revolution governor of Virginia, and the author of the famous congressional memorial eulogy to his friend, George Washington. Intermarriage with most of Virginia's ruling families was a tradition of both the Lees and 'the Carters, and Lee married a distant cousin, Mary Anne Randolph Custis, the great-granddaughter of George Washington's wife and heiress of several plantation properties.

Yet, with all his aristocratic connections, Lee lacked the advantages of wealth. His colourful father had no aptitude for finance and, dying when Lee was a child, left in straitened circumstances an ailing widow with seven children. Robert, the youngest boy, was the closest of all the children to his mother and was deeply influenced by her strength of character and high moral principles. All reports of his childhood and youth stress that the pinched gentility of his formative years, in such marked contrast to the lordly life on the great plantations of his kinspeople, was another strong influence goading him to excel at whatever task he was assigned.

Military education at West Point

Unable to afford a university education, Lee obtained an appointment to the United States Military Academy at West Point, where his high aspirations and native gifts produced what a fellow cadet, the Confederate general Joseph Johnston, called his natural superiority. Always near the top of his class, he won the appointment to corps adjutant, the highest rank a cadet could attain, and graduated in 1829. With handsome features, a massive head, and superb build, he combined dignity with kindness and sympathy with good humour, to win, as Johnston said, "warm friendship and command high respect."

Early military career. Commissioned into the elite engineering corps, later transferring to the cavalry because of slow advancement in the engineers, he did the best he could at routine assignments and on relatively uninspiring engineering projects. Not until the Mexican War (1846–48), when he was a captain on the staff of General Winfield Scott, did he have the opportunity to demonstrate the brilliance and heroism that prompted General Scott to write that Lee was "the very best soldier I ever saw in the field." In October 1859, while on leave at Arlington to straighten out the entangled affairs of his late father-in-law, he was ordered to suppress the slave insurrection attempted by John Brown at Harpers Ferry, Virginia. Although Lee put down the insurgency in less than an hour, the very fact that it was led by a white man made him aware of the gathering crisis between the North and the South.

Lee was back at his command in Texas when on February 1, 1861, Texas became the seventh Southern state to secede, and with the rest of the U.S. Army forces, he was ordered out of the state. Without a command, he returned to Arlington to wait to see what Virginia would do. On April 18 he was called to Washington and offered command of a new army being formed to force the seceded states back into the Union. Lee, while he opposed secession, also opposed war, and "could take no part in an invasion of the Southern states." Meanwhile, President Lincoln called on Virginia to furnish troops for the invasion. A Virginia convention, which had previously voted 2 to 1 against secession, now voted 2 to 1 against furnishing troops for an invasion and to secede, and Lee resigned from the army in which he had served for 36 years to offer his services to the "defense of [his] native state."

Role in Civil War. As commander in chief of Virginia's forces, Lee saw it as his first task to concentrate troops, armaments and equipment at major points where the invasion might be expected. During this period, Confederate troops joined the Virginia forces and subdued the Federal Army at the first Battle of Bull Run. The attempt at a quick suppression of the Southern states was over and, as Lee was one of the first to realize, a long, all-out war began. Between July 1861 and June 1862, Confederate president Jefferson Davis appointed Lee to several unrewarding positions, the last of which was the trying post of military adviser to the president. Here, however, Lee, working independently of Davis, was able to introduce a coherent strategy into the Confederacy's defense.

Commander of Virginia's forces

During May 1862, General Johnston was leading a heterogeneous collection of Confederate troops back toward Richmond from the east, before the methodical advance of Gen. George B. McClellan's superbly organized, heavily equipped Army of the Potomac. Lee collaborated with the then unknown Stonewall Jackson to concentrate scattered garrisons in Virginia into a striking force in the Shenandoah Valley, where he surprised the Federal forces into retreating and posed a threat to Washington. Jackson's threat from the valley caused Lincoln to withhold from McClellan the large corps of Gen. Irvin McDowell, with whom McClellan planned a pincer movement on Richmond from the east and north. On June 1, Johnston delivered a poorly organized attack on McClellan's forces seven miles east of Richmond in the indecisive Battle of Fair Oaks (Seven Pines). The battle became a turning point for Lee: Johnston was seriously wounded and Lee was at last given field command.

In three weeks he organized Confederate troops into what became the famed Army of Northern Virginia; he tightened command and discipline, improved morale, and convinced the soldiers that headquarters was in full command. McClellan, waiting vainly for McDowell to join the wing of his army on the north side of the Chickahominy River, was moving heavy siege artillery from the east for the subjugation of Richmond when Lee struck. Combin-

Seven Days' Battles

ing with Jackson, who moved in from the valley, Lee defeated Porter's right wing and was on McClellan's supply line to his base on the York River. In a series of hard fights, the Seven Days' Battles (around Richmond), McClellan withdrew his army to the wharves of Berkeley Plantation, where he was aided by the U.S. Navy. Because it was the first major victory for the Confederacy since Bull Run, and because it halted a succession of military reversals, Lee emerged overnight as the people's hero, and his soldiers developed an almost mystical belief in him.

Lee never believed that the Confederate troops had the strength to win in the field; for the next two years his objectives were to keep the enemy as far away as possible from the armament-producing centre of Richmond as well as from the northern part of the state, where farmers were harvesting their crops, and, finally, to inflict defeats of such decisiveness as to weaken the enemy's will to continue the war. To nullify the Federals' superiority in manpower, armaments, and supply, Lee always sought to seize the initiative by destroying the enemy's prearranged plans. Until the spring of 1864, he was successful in keeping the enemy away from Richmond and from the northern part of the state, twice expelling the enemy out of Virginia altogether. He inflicted several severe defeats on the enemy, most strikingly at the Second Battle of Bull Run (Second Manassas), August 29–30, 1862. To shift the fighting out of Virginia, Lee crossed into Maryland, where he hoped for support from Southern sympathizers. But his plans fell into Northern hands, and his forces were nearly destroyed at Antietam (Sharpsburg) on September 17, 1862. He was, however, able to withdraw the remnants across the Potomac, to reorganize his army, and to resume his series of victories at Fredericksburg in December of that year. At Chancellorsville (May 1–4, 1863) he achieved another notable victory, although outnumbered two to one, by splitting up his army and encircling the enemy in one of the most audacious moves in military history.

Gettysburg

But he was producing no more than a stalemate on the Virginia front, while Federal forces won important victories in other parts of the Confederacy, and time was against him. While the Federals always replaced their losses, Lee's army was dwindling in size, suffering an irreplaceable drain in its command—particularly through the loss of Stonewall Jackson, who had been mortally wounded at Chancellorsville—and increasingly acute shortages of food and clothing, which undermined the physical condition of the soldiers. Largely to resupply his troops and to draw the invading armies out of Virginia, Lee once more crossed the Potomac. The first invasion had ended with the Battle of Antietam and the second ended in Lee's repulse at Gettysburg (July 1–3, 1863). There, operating for the first time without Jackson, Lee was failed by three of his top generals in using the discretionary orders that had worked so effectively with Jackson, his "right arm."

Then, in May 1864, Ulysses S. Grant, the newly appointed commanding general of all Union forces, drove at Lee with enormous superiority in numbers, armaments, and cavalry. The horses of the troopers of Confederate general Jeb Stuart were in poor condition, and Stuart was killed early in the campaign. Grant could neither defeat nor outmanoeuvre Lee, however, and the superb army Grant inherited sustained losses of 50,000 men in the May and early June battles of the Wilderness, Spotsylvania Court House, the North Anna, and Cold Harbor. Grant, however, his losses replaced by fresh recruits, had advanced within seven miles of Richmond, while Lee, his soldiers too weakened physically and his officers too inexperienced to attempt countering manoeuvres, had lost the initiative. Lee himself was, moreover, physically declining and frequently incapacitated by illness. When Grant, abandoning his advance on Richmond, moved south of the James River to Petersburg—Richmond's rail connection with the South—Lee could only place his starving tatterdemalions in defensive lines in front of Petersburg and Richmond.

Beginning at Spotsylvania Court House, Lee had nullified Grant's numbers by using his engineering experience to erect fortifications that were in advance of any fieldworks previously seen in warfare. At Petersburg, Lee extended the field fortifications into permanent lines that presaged trench warfare. While Lee's lines enabled him to withstand Grant's siege of the two cities from late June 1864 to April 1, 1865, once his mobile army was reduced to siege conditions, Lee said the end would be "a mere question of time."

Surrender at Appomattox

The time came on Sunday, April 2, when his defensive lines were stretched so thin that the far right broke under massive assaults, and Lee was forced to evacuate Petersburg and at last uncover Richmond. When the survivors of his army pulled out of the trenches an agonizing week of a forlorn retreat began for him; his men fell out from hunger, animals dropped in the traces, and units dissolved under demoralized officers. At Appomattox Court House on April 9, 1865, his way west was blocked and there was nothing left except to bear with dignity the ordeal of surrender, which was made less painful for him by Grant's considerate behaviour.

Postwar years. Lee spent several months recuperating from the physical and mental strain of retreat and surrender, but he never regained his health. He was, moreover, deeply concerned about the future of his seven children, for his wife's Arlington plantation had been confiscated by the United States government and he was without income at the age of 58. Both to earn subsistence for his family and to set an example for his unemployed fellow officers, he accepted the post of president of Washington College (later Washington and Lee University) in Lexington, Virginia.

Lee was a surprisingly progressive educator; by employing his lifelong practices in economy, he placed the institution on a sound basis and awakened in his students—many of whom were veterans of the recent war—the desire to rebuild their state with the goal of good citizenship in a nation that in time would become reunited.

He died on October 12, 1870, in the president's home at Washington College.

Reputation. Although history knows him mostly as "the Rebel General," Lee was a disbeliever in slavery and secession and was devoutly attached to the republic that his father and kinsmen had helped bring into being. He was, moreover, very advanced in his rejection of war as a resolution of political conflicts—a fact that has been almost entirely ignored by posterity. As a U.S. Army colonel in Texas during the secession crises of late 1860, he wrote, "[If] strife and civil war are to take the place of brotherly love and kindness, I shall mourn for my country and for the welfare and progress of mankind."

BIBLIOGRAPHY. DOUGLAS SOUTHALL FREEMAN, *R.E. Lee*, 4 vol. (1934–35), is the definitive biography of Lee; its footnotes provide a rich source of bibliography. Material that has appeared since Freeman's book does not significantly alter the character presented in his work. New material has, however, caused a re-evaluation of Freeman's interpretation of the second day of the battle of Gettysburg. CLIFFORD DOWDEY, ***Lee*** (1965), is a one-volume biography that treats the second day at Gettysburg in the light of the new material now generally available; his ***Death of a Nation*** **(1958)**, is a narrative study of the Gettysburg campaign that also uses the new material on the second day.

CLIFFORD DOWDEY and LOUIS MANARIN (eds.), ***The Wartime Papers of Robert E. Lee*** **(1961)**, draws upon an enormous volume of letters and dispatches not previously published.

Among the most reliable reminiscences of Lee's contemporaries are JOHN WILLIAM JONES, ***Personal Reminiscences, Anecdotes, and Letters of Gen. Robert E. Lee*** (1874) and ***Life and Letters of Robert Edward Lee*** (1906); A.L. LONG, ***Memoirs of Robert E. Lee*** (1886)—Long was a literate member of Lee's early staff and later chief of Second Corps artillery; WALTER H. TAYLOR, ***Four Years with General Lee*** (1877) and ***General Lee: His Campaigns in Virginia, 1861–1865*** (1906)—Taylor was on Lee's staff to the end. There are scores of reminiscences and narratives of the Civil War by participants that include references to Lee. E.P. ALEXANDER, ***Military Memoirs of a Confederate*** **(1907)**, a sound standard work on the campaigns in Virginia, has the best account of Lee's reorganization of the Army of Northern Virginia. There are only two accounts of the last illness and death of Lee: MRS. ROBERT E. LEE, "Letter to Miss Mary Meade,

October 12th, 1870," *Virginia Magazine of History and Biography,* 35:23–26 (1927); and COLONEL WILLIAM PRESTON JOHNSTON, "Death and Funeral of General Lee," contained in Jones's *Personal Reminiscences . . . ,* pp. 44—60.

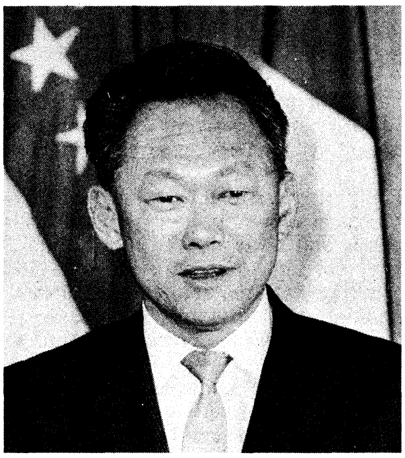
Two good books on Lee by an Englishman are SIR FREDERICK MAURICE, *Robert E. Lee, the Soldier* (1925) and *An Aide-de-Camp of Lee: Being the Papers of Colonel Charles Marshall* (1927). FRANKLIN L. RILEY (ed.), *General Robert E. Lee After Appomattox* (1922), is a collection of sketches, data, and reminiscences of Lee as president of Washington College; not entirely accurate, and lacking much detailed factual material, it is nonetheless valuable for the impressions of Lee by his students.

(C.Do.)

Lee Kuan Yew

Lee Kuan Yew, the first prime minister of the Republic of Singapore, became one of the leading political figures in Southeast Asia, as an anti-colonialist and anti-Communist supporter of parliamentary democracy. The strategic location of his country commanding the Strait of Malacca, between the China Sea and the Indian Ocean, has further served to enhance his position both in Asia and in the Commonwealth of Nations.

Keystone



Lee Kuan Yew.

Lee was born on September 16, 1923, into a wealthy Chinese family that had been established in Singapore since the 19th century. His first language was English; only upon entering politics did he acquire a command of Chinese as well as Malay and Tamil. After attending school in Singapore, Lee, a brilliant pupil, won a scholarship to Raffles College in Singapore, which he attended before going to England to enter the University of Cambridge. There he took a double first (first-class honours in two different subjects) in law and headed the honours list; he also became a Socialist. In 1950 he was admitted to the English bar. In the same year he married a Malayan, Kwa Geok Choo, who had also been a student at Cambridge. Instead of practicing as a barrister, however, Lee returned to Singapore. Appointed legal adviser to the Postal Union, he participated in negotiations to obtain higher wages for postal workers and subsequently did similar work for other trade unions.

Beginnings of Lee's political career

A British crown colony and the site of Britain's principal naval base in the Far East, Singapore was ruled by a governor assisted by a legislative council. Its members consisted primarily of wealthy Chinese businessmen, most of whom were appointed rather than elected. When, in the early 1950s, constitutional reform was in the air in Singapore, as elsewhere in Britain's colonial empire, Lee formed an alliance with two other political newcomers —David Saul Marshall, a lawyer, and Lim Yew Hock, a trade unionist—to challenge the hold of the businessmen on the council. Lee, however, soon broke with his two colleagues to take a more radical stand, becoming secretary general of his own party, the People's Action Party (PAP), which included some Communists, Lee having accepted some Communist support for some years.

In 1955 a new constitution was introduced increasing the number of elected seats on the council to 25 out of a total of 32. In the elections, the Labour Front, founded by Lee's former colleagues, won 13 seats, while the PAP won three—one of which, for a district inhabited by many of the poorest Chinese in Singapore, was won by Lee.

The following year Lee returned to London as a member of a delegation that unsuccessfully sought self-rule for the colony. Unrest followed during which a number of PAP leaders were imprisoned. In 1957 the London negotiations were resumed, again with Lee on the delegation. After agreement was reached on a measure of self-government, Lee won a by-election by an overwhelming majority, and a PAP power struggle ensued. In August Lee was ousted from the secretary generalship by the party's left wing but regained his post in October. The next year (1958) in London he helped negotiate the status of a self-governing state within the Commonwealth for Singapore. Elections were held under the new constitution in May 1959, but, despite the fact that Lee's party won a decisive victory, gaining 43 of the 51 seats, Lee refused to form a government until the British freed the left-wing members of his party who had been imprisoned in 1956. With their release, he then formed a cabinet and introduced a five-year plan that sought to promote reforms (such as the emancipation of women and the expansion of educational services) and industrialization. In 1961 the party's left-wing members broke away from the PAP to form the Barisan Socialis ("Socialist Front"), which shared sympathies with President Sukarno of Indonesia, who for some time had represented a challenge to Lee's leadership. In the following year, a national referendum resulted in an open confrontation between Lee and his left-wing opponents; its results were a victory for Lee.

In 1963 Lee took Singapore into the newly created federation of Malaysia. In elections held in 1964, however, Lee made the mistake of entering his party, 75 percent of whose members were Chinese, in the Malayan national elections. The growing tension between Chinese and Malayans resulted in communal rioting in Singapore itself. In August 1965 Lee was told by his Malaysian colleagues in the federal government that Singapore must leave the federation. Although Lee passionately believed in the multiracialism that the federation represented, Singapore had to secede. It then became a sovereign state with Lee as its first prime minister.

Leader of a new state

Lee's principal aims were to ensure the physical survival of the new state and to retain Singapore's national identity, traditionally marked by interracial tolerance. Surrounded by more powerful neighbours (including China and Indonesia), Lee did not press for the immediate withdrawal of British, Australian, and New Zealand forces from Singapore. Instead, he sought to phase them out slowly and to replace them with a Singapore force locally trained and patterned on the Israeli model. Under his leadership trade and industry prospered, and the new state achieved a high standard of living, with the second highest per capita income in Asia after Japan. At Commonwealth prime ministers' conferences, Lee also played a significant role, expressing support of a multiracial approach to Commonwealth problems in Africa and elsewhere.

Shrewd and resolute in political life, Lee is said to lead a frugal private life, living quietly at home with his wife, two sons, and daughter. Among the anti-colonial leaders of the Commonwealth, he represents a new prototype. Combining an Asian outlook with some Western methods, he has brought his country an efficient administration, a measure of economic prosperity, and an alternative to the tyranny of either racial demagoguery or ideological conformity.

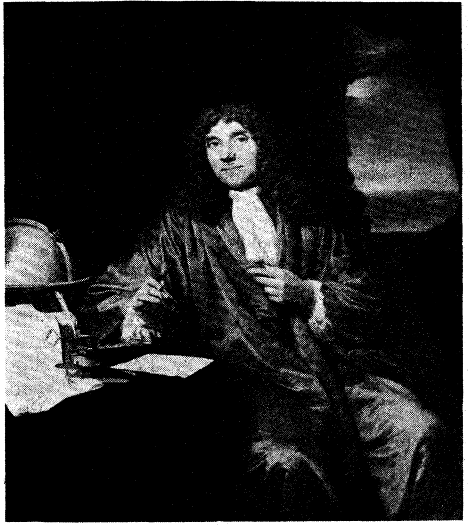
Leeuwenhoek, Antonie van

One of the most remarkable of the 17th-century microscopists, Antonie van Leeuwenhoek was the first man ever to observe bacteria and protozoa through a lens. Although there were only isolated observations of these organisms during the century following his death, his accurate interpretations of what he saw led to the sciences of bacteriology and protozoology.

By courtesy ot the Rijksmuseum, Amsterdam



Leeuwenhoek, portrait by Jan Verkolje (1650–93). In the Rijksrnuseurn, Amsterdam.

Leeuwenhoek was born at Delft, Holland, on October 24, 1632. Little is known of his early life, but it is certain that he did not have an extensive scientific education. When his stepfather died in 1648, he was sent to Amsterdam to become an apprentice to a linendraper. Returning to Delft when he was 20, he established himself as a draper and haberdasher. In 1660 he obtained a position as chamberlain to the sheriffs of Delft. His income was thus secure and sufficient enough to enable him to devote much of his time to his all-absorbing hobby of grinding lenses.

The "little animalcules"

High-quality single lenses of very short focal length were preferable to the compound microscope, which increased the problem of chromatic aberration. Although Leeuwenhoek's studies lacked the organization of formal scientific research, his powers of careful observation enabled him to make discoveries of fundamental importance. In 1674 he began to observe bacteria and protozoa, his "very little animalcules," which he was able to isolate from different sources, such as rainwater, pond and well water, and the human mouth and intestine; and he calculated their sizes.

In 1677 he described for the first time the spermatozoa from insects, dogs, and man, though Stephen Hamm probably was a codiscoverer. Leeuwenhoek studied the structure of the optic lens, striations in muscles, the mouthparts of insects, the fine structure of plants, and discovered parthenogenesis in aphids. In 1680 he noticed that yeasts consist of minute globular particles. He extended Marcello Malpighi's demonstration in 1660 of the blood capillaries by giving (in 1684) the first accurate description of red blood cells. In his observations on rotifers in 1702, Leeuwenhoek remarked that, "In all falling rain, carried from gutters into water-butts, animalcules are to be found; and that in all kinds of water, standing in the open air, animalcules can turn up. For these animalcules can be carried over by the wind, along with the bits of dust floating in the air."

A friend of Leeuwenhoek put him in touch with the Royal Society of England, to which, from 1673 until 1723, he communicated by means of informal letters most of his discoveries and to which he was elected a fellow in 1680. His discoveries were for the most part made public in the Society's *Philosophical Transactions.* The first representation of bacteria is to be found in a drawing by Leeuwenhoek in that publication in 1683.

His researches on the life histories of various low forms of animal life were in opposition to the doctrine that they could be produced spontaneously or bred from corruption. Thus he showed that the weevils of granaries (in his time commonly supposed to be bred from wheat as well as in it) are really grubs hatched from eggs deposited by winged insects. His letter on the flea, in which he not only described its structure but traced out the whole history of its metamorphosis, beginning with its first emergence from the egg, is of great interest, not so much for the exactness of his observations as for an illustration of his opposition to the spontaneous generation of many lower organisms, such as "this minute and despised creature." Some asserted that the flea was produced from sand, others from dust, etc., but Leeuwenhoek showed it to be "endowed with as great perfection in its kind as any large animal" and proved that it bred in the regular way of winged insects.

Leeuwenhoek also carefully studied the history of the ant and was the first to show that what had been commonly reputed to be ants' eggs were really their pupae, containing the perfect insect nearly ready for emergence, and that the true eggs were much smaller and gave origin to maggots, or larvae. He argued that the sea mussel and other shellfish were not generated out of sand found at the seashore or mud in the beds of rivers at low water but from spawn, by the regular course of generation. He maintained the same to be true of the freshwater mussel, whose embryos he examined so carefully he was able to observe how they were consumed by "animalcules," many of which, according to his description, must have included ciliates in conjugation, flagellates, and the *Vorticella.* Similarly, he investigated the generation of eels, which were at that time supposed to be produced from dew without the ordinary process of generation.

The dramatic nature of his discoveries made him world famous, and he was visited by many notables, including the Queen of England and Peter the Great.

Leeuwenhoek's microscopy

Leeuwenhoek's methods of microscopy, which he kept secret, remain something of a mystery. He ground over 400 lenses during his lifetime, most of which were very small—some no larger than a pinhead—and usually mounted them between two thin brass plates, rivetted together. A large sample of these lenses, bequeathed to the Royal Society, were found to have magnifying powers of between 50 and, at the most, 300 times. In order to observe phenomena as small as bacteria, Leeuwenhoek must have employed some form of oblique illumination, or other technique, for enhancing the effectiveness of the lens, but this method he would not reveal.

Leeuwenhoek continued his work almost to the end of his long life of 90 years. He died at Delft on August 26, 1723.

BIBLIOGRAPHY. Leeuwenhoek's contributions to the *Philosophical Transactions* amounted to 375, and those to the *Memoirs of the Paris Academy of Sciences* to 27. Two collections of his works appeared during his life, one in Dutch (1685–1718) and the other in Latin (1715–22); a selection was translated by S. HOOLE, *The Select Works of A. van Leeuwenhoek* (1798–1807). See also C. DOBELL, *Antony van Leeuwenhoek and His "Little Animals"* (1932); B. COHEN, "On Leeuwenhoek's Method of Seeing Bacteria," *J. Bact.,* 34:343–346 (1937), and *The Leeuwenhoek Letter* (1937).

Legal Education

The rise of legal education

Schools of law are of comparatively recent origin. The ancient Romans had schools of rhetoric that provided training useful to someone planning a career as an advocate, but there was no systematic study of the law. During the 3rd century BC, Tiberius Coruncanius, the first plebeian *pontifex maximus* (chief of the priestly officials) gave public legal instruction, and a class of nonpriests (*jurisprudentes)* who acted as legal consultants grew up. A student, in addition to reading the few lawbooks that were available, might attach himself to a particular *jurisprudens* and learn the law by attending consultations and by discussing points with his master. Over the ensuing centuries a body of legal literature developed, and some *jurisprudentes* set themselves up as regular law teachers.

In the medieval universities of Europe, including England, it was possible to study canon law and Roman law but not the local or customary legal system. The study of national laws at universities is, in most European countries, a development that began in the 18th century; the study of Swedish law at Uppsala dates from the early 17th century.

On the continent of Europe, the transition to the study of national law was facilitated by the fact that modern legal systems grew mostly from Roman law. In England, on the other hand, the national law, known as the common law, was indigenous. In medieval times, education in the common law was provided for legal practitioners by societies of lawyers called Inns of Court through reading and practical exercises. These methods fell into a decline in the late 16th century, mainly because students came to rely on printed books, and after the middle of the 17th century there was virtually no organized education in English law until the introduction of apprenticeship for solicitors in 1729. The famous jurist Sir William Blackstone lectured at Oxford in the 1750s, but university teaching of the common law did not develop significantly until the 19th century. The Council of Legal Education for barristers was established in 1852. In the United States, systematic legal education began with the founding of the Harvatd Law School in 1817.

THE AIMS OF LEGAL EDUCATION

Legal education generally has a number of aims, not all of which are pursued simultaneously. The emphasis placed on various objectives varies from one law school to another and from one teacher to another. One aim is to make the student familiar with legal concepts and institutions. Like most intellectual disciplines the law has its technical concepts, frequently expressed in technical terms. These terms are sometimes special legal words, such as "easement" (a landowner's right over some neighbour's land, such as a right of way), and sometimes ordinary words used in special legal senses, such as "distress" (a right to seize the goods of a tenant who has not paid his rent). All lawyers must become acquainted with the processes of making law, settling disputes, and regulating the legal profession. They must study the structure of government and the organization of courts of law, including the system of appeals and other adjudicating bodies such as social security tribunals in Great Rritain, administrative agencies in the United States, the Conseil d'État in France, and industrial arbitration bodies in Australia. Attention is also paid nowadays to plans of legal aid and advice for clients who are too poor to pay.

Traditional legal education also included the teaching of legal history. Once regarded as an essential part of any educated lawyer's equipment, legal history now receives much less emphasis. Separate courses in the subject are offered in fewer and fewer law schools and, when optional, are not very popular among students. But much legal history is taught in the context of other courses. The corpus of the law is a constantly evolving collection of rules and principles, and many teachers consider it necessary to trace the development of the branch of law they are discussing.

In countries where most parts of the law are codified (as in continental Europe, Ethiopia, Thailand, and Japan, for example) it is not generally necessary to go back beyond the code. On the other hand, in countries with a common-law system (England, most members of the British Commonwealth, and most parts of the United States), in which few branches of law are codified, knowledge of the law depends largely on the study of court decisions and statutes out of which common law evolved. This makes the study of legal history of more practical significance.

The place of the social sciences in legal education

Another aim of legal education is the teaching of law in its social, economic, political, and scientific context. While law schools have never ignored the social context of their subject, the 20th century has seen the development of a more or less scientific approach to social studies. It is now possible for lawyers to seek knowledge from professional psychologists, sociologists, economists, and statisticians, rather than relying solely on their own observations. Some law schools appoint psychiatrists or sociologists to their staffs, while others require or allow their students to take courses outside the law school as part of their work toward a degree. This awareness of the other social studies is thought to be more advanced in the United States than in Great Britain. In France and Italy nonlegal subjects are compulsory for a first degree in law; whereas in Germany and The Netherlands they are not. In Japan, the first year or two of the work toward a law degree is spent in liberal arts training.

The graduating law student is not expected to have studied the whole body of substantive law. He is, however, expected to be familiar with the general principles of the main branches of law. To this end, certain subjects are regarded as basic: constitutional law, governing the major organs of state; the law of contract, governing obligations entered into by agreement; the law of tort (or delicts), governing compensation for personal injury and damage to property, income, or reputation; the law of real (or immovable) property, governing transactions with land; and criminal (or penal) law, governing punishment, deterrence, and prevention of dramatically antisocial acts such as homicide and robbery. Less basic subjects include commercial law, the law of marriage and domestic relations, and tax law. A traditional subject like public international law, which deals with the legal relations between sovereign states, may be regarded as basic in one university and yet not even be offered in another. The chief materials are the same everywhere: codes (where these exist), reports of decided cases, legislation, government and other public reports, institutional books (in civil-law countries), textbooks, and articles in learned periodicals. The aim is not that the student should remember "the law" but that he should understand basic concepts and become sufficiently familiar with a law library to carry out the necessary research on any legal problem that may come his way.

Teaching method and procedure

The extent to which legal education aims to teach method and procedure varies from place to place. Attention is always given to the methods of ascertaining the law from the books but not always to the methods of using this knowledge of the law in various roles, such as legal adviser, advocate, draftsman, or judge. Discussion of these matters tends to be more widespread in universities in the United States and in other countries where the main part of qualification to practice the law is a university degree than it is in countries such as England, where professional examinations are largely divorced from academic study. Much the same is true with regard to the rules and principles of court procedure. Few English universities teach these, leaving them to the bar and solicitor's examinations though the law of evidence (governing what facts may be proved in court, and how) is usually an optional subject; some knowledge of civil and criminal procedure may be picked up incidentally during the study of substantive law. In other countries, courses in procedure are frequently compulsory in university law schools.

The establishment of a professional standard and the communication of professional ethics should perhaps be one of the aims of legal education. This receives more emphasis in countries where lawyers qualify to practice mainly by graduating in law at a university. In Great Britain such matters are imparted by the professional bodies and by personal experience rather than through formal instruction. In Japan, legal ethics is taught as a graduate course.

TEACHING METHODS

Pupillage or apprenticeship

The variety of approaches. Methods of legal education are constantly changing. In England and Wales a barrister (an advocate and consultant) may not practice at all without having undergone six months' pupillage in chambers and may not practice independently until he has been a pupil for a year. Pupillage causes some difficulty, partly because of the cost but mainly because of the shortage of places in chambers. To qualify as a solicitor (general legal adviser dealing with all kinds of legal business out of court and advocate in some of the lower courts) it is necessary to serve as an articled clerk for two or four years, depending on whether the candidate is a university graduate or not. In Scotland and Ireland there are similar requirements, though the arrangements differ in detail. In the United States, qualification to practice normally requires a law degree and the passing of state bar examinations; a handful of states require that the candidate serve an apprenticeship (six months as a law clerk). In continental European countries the requirements vary, some placing more emphasis on apprenticeship and others placing more emphasis on examination. Some newly independent countries that previously had no local facilities for legal education have established professional law schools to give practical training to graduates in lieu of pupillage (*e.g.*, the Nigerian Law School in Lagos).

University law schools tend to differ along national lines in their methods of teaching. In the United States, following pioneer work by Christopher Langdell at Harvard in the latter half of the 19th century, the case method came to prevail, in which the student reads reported cases and other materials collected in a case book and the class answers questions about them instead of listening to a lecture by the teacher. The case-book method has been adopted at some institutions in England and other common-law countries but has found scarcely any adherents elsewhere. Even in the United States, many law schools now use seminars and lectures as well. The case method has the advantage of emphasizing the fundamental feature of the common law—the evolution of principles from decisions in actual cases—and thus of focussing the student's attention on method. It has the disadvantage of being relatively time-consuming in relation to the amount of knowledge of legal principle that can be imparted.

The traditional teaching techniques in English universities have been lectures and tutorials (or seminars). In addition, moot courts have been an integral part of English legal education since the Middle Ages. The student argues a point of law before "judges" as if he were appearing in an appellate court. Organized over the centuries for students and young barristers by the Inns of Court, moots spread to the universities when these undertook the teaching of English law. They are sometimes organized by teachers and sometimes by student societies. Most law schools in the United States also have moot programs.

In continental European countries the backbone of legal education is the formal lecture. Class sizes are sometimes very large compared with those in the United States and Britain, and lectures tend to be magisterial performances. Attendance is frequently voluntary, and those who stay away are sometimes able to secure the text of what they have missed orally. Seminars are given too, particularly in the medium-sized and smaller law schools and for specialized subjects. Similar methods are used in other countries with large numbers of law students—*e.g.*, Japan, India, and Thailand.

The case method and the lecture

Teaching methods are not unrelated to the nature of the legal system. The fact that in common-law systems principles of law are largely derived by a process of inductive reasoning from very numerous decisions of superior courts lay behind the development of the case method. In continental Europe, the fact that law is found mainly in systematic codes is one of the chief reasons for the lecture method, in which the subject can be approached through its philosophical background. And there are other considerations. A high staff-to-student ratio makes more seminar work possible. A desire to expound a body of principle rather than a method of approach to materials calls for formal lectures, and this is reinforced in some of the newer countries where published reports of local court decisions and texts on the local law are as yet scanty.

Study and practice. To some extent, all law courses are out of harmony with legal practice, for a case in real life is not presented neatly by a client to his lawyer as a case, say, of contract or divorce. The case begins as a statement, often jumbled, of facts and problems that cut across pedagogical categories. A story of a road accident may involve the lawyer in considering questions, for example, of the civil responsibility for the cause of the accident; of contract (in relation to insurance); of criminal law (in relation to a traffic offense); and of other branches of law as well. It is therefore important, while making divisions of law for convenience of study and examination, to guard students against the danger of thinking in compartments. Lawyers must also contend in practice with branches of law in which they have received no formal education. Patent law, for example, is absent from most law-school curricula; and new legal structures come into existence during every lawyer's lifetime. His task may be eased if he has been trained in not too parochial a fashion and has learned to look to the experience of other countries. Since World War II many new countries have emerged with new constitutions, and lawyers working with them have had to seek assistance from the law of other countries. Thus, Indian lawyers just after 1950 could get little help from their British constitutional law background but did make considerable use of decisions of the Supreme Court of the United States. A good law school produces a graduate who is not constricted by pedagogy; rather, he is equipped to adapt himself to—and perhaps lead in bringing about—legal changes related to social, economic, and political developments.

The curriculum of the law school must also allow for the great diversity of careers followed by those who have been trained in the law. In most countries, large numbers of persons with a legal training seek a career outside the legal profession, commonly in the civil service, in municipal government service, in legal education, and in commerce and industry. Student requirements and tastes differ; and most law schools, therefore, offer a choice. It is common to prescribe a certain number of compulsory subjects, which are regarded as basic to any law student's education, and leave a freedom of selection as to other subjects, stipulating only the number of courses to be studied. There is not even uniformity from law school to law school within the same country as to which subjects are compulsory, and lists of optional subjects vary spectacularly. In the early 1970s more and more opportunities were being given to study comparative law, foreign legal systems, and transnational laws, such as those of the European Economic Community.

EXAMINATIONS AND QUALIFICATIONS

The process of selecting members of the legal profession begins in the universities and law schools and continues afterward in the form of professional entrance requirements.

School examinations. In the United States, Great Britain, and other common-law countries, students are generally required to pass an examination in each subject. Four or five subjects are studied simultaneously during the academic term, and students must take examinations in all of them at the end of the term.

In some countries more comprehensive examinations are the rule. In France, the law student must pass an examination at the end of each of his four years' study for the licence-en-droit, but that is not the general pattern in continental Europe. In West Germany, the course for the university law degree normally takes five years, with a single comprehensive examination at the end on everything studied during those five years. Students are admitted to the final examination if they produce certificates of satisfactory work in each subject, in a jurisprudence seminar, and in a course on economics and finance. The Netherlands has an intermediate system: the course for a first degree in law lasts five years, with an examination at the end of the second year and another at the end of the fifth.

The method of subject-by-subject examination is less taxing on the memory than the system of comprehensive examination. It may well enable the student to do more detailed work on the problems of each subject. It has the disadvantage of encouraging him to think in terms of separate subjects, whereas the comprehenisve examination leads him to consider legal problems in all their aspects. Being aware of the dangers of compartmentalized thinking, some law schools in the common-law world have introduced into their curricula "general" subjects, such as "common law," in place of separate courses in contract and tort, or they require the student to write papers about issues that relate to several of the subjects studied.

Limitations of formal tests

No formal test is wholly satisfactory as a method of screening potential lawyers. The type used most widely, in which students write answers to questions in an examination hall, has been criticized for placing too much emphasis on memory. This criticism is met to some extent in some universities by allowing candidates to consult books and reference materials during the examination, thus bringing the test a little closer to what a lawyer will do when confronted with a real problem. Another objection is that testing creates a situation of stress, in which a candidate does not necessarily demonstrate how he has benefitted from his legal education, and also that the skill demonstrated in the examination hall is not all the skill required of a lawyer. In particular, the examination does not test capacity for patient research nor the capacity for oral argument, which require theses and oral examinations. Examinations to be done outside orthodox examination halls have also been proposed, as a way of providing a more realistic mixture of law and fact and of relevant and irrelevant matter.

Some universities in Great Britain and the Commonwealth countries require one or more long essays or a short thesis or research paper as part of the work for a first degree in law (as opposed to the more substantial dissertation, or thesis, for a postgraduate law degree). This is commonly written during the final year, with no restriction on the resources employed. Universities in civil-law countries sometimes use this type of examination. Critics have noted that mediocre and poor students tend to get quite good marks in this type of exercise by cribbing from published works. Credit is also sometimes given for articles or notes published by students in law reviews. Such student publishing is commoner in the United States than elsewhere, partly because most U.S. law shcools have their own legal journals and partly because American law students are nearly always graduates. Such student work also enhances prospects of employment, particularly when the student becomes an editor of the law review.

Oral examinations are no longer widely used. British and overseas Commonwealth universities hold oral examinations to resolve doubtful results on written papers or as a prerequisite to the award of first class honours. In the United States oral examinations are rare. Some French universities have abandoned them. In Italy, where a law student has to present a thesis after passing his other examinations, the thesis has to be orally defended before examiners. The German law student, after passing his written examination, has an oral one. In Japan, for professional qualification at the Legal Training and Research Institute (see below), there is an oral examination in each of the compulsory subjects after the written examination has been passed.

National differences in requirements

Qualifications for practice. *Common-law countries.* In England a practicing lawyer must be either a barrister or a solicitor (see above *Teaching methods*). It is not necessary to hold a law degree or any university degree to qualify; in the 1960s just under half of those admitted as solicitors had graduated from a university. Barristers must pass two-part examinations in legal subjects, and graduates may obtain partial or total exemption from the first part, depending on their degrees. A barrister's work also includes practical courses and a period of pupillage administered under the authority of the senate of the Inns of Court. For a solicitor, there are also law examinations in two parts, as well as a (varying) period of articled clerkship under the authority of the Law Society.

In the United States, admission to the bar qualifies one for all types of legal work. The only formal requirements are the passing of state bar examinations after graduating from a law school; in a few states, the law degree alone is sufficient.

In both England and the United States as in many other common-law countries, becoming a judge or magistrate is a promotion (by appointment or election) from the ranks of the bar and there is no special training for the exercise of judicial functions. But in some other common-law countries, especially in Africa and Asia, a newly qualified lawyer may enter the government legal service and find himself appointed in a short time to a junior magistracy. Even in these countries there is generally no special training for the job of adjudicating, though refresher courses for those already serving are organized in some countries (*e.g.*, in Tanzania).

Civil-law countries. Various divisions of the legal profession exist in civil-law countries. In France, for example, a legal practitioner may be an advocate, an *avoué*, a notary, or a judge. Each receives a different training, but all will normally have gone through third- and fourth-year law degree courses. The advocate (roughly corresponding to the English barrister) will also have completed a one-year course at the university to train him for his profession and have been examined for his qualifying certificate by a panel of academic and practicing lawyers. The *avoué* (something of a cross between a junior barrister and a senior solicitor), serves a period of articled clerkship, the length of which depends on his degree, and undergoes a professional examination by practicing lawyers. The notary (who does the noncontentious work performed in England by a solicitor) need not be a graduate, but his period of training (six years in a notary's office) is shorter if he is; he also takes a professional examination. To be a judge, one must have a law degree and pass an entrance examination for the magistracy; this must be followed by 28 months of professional training, both theoretical and practical, at the National Centre for Judicial Studies.

In West Germany, the graduate in law who seeks a legal career must embark upon a period of practical training as a *Referendar*. This is a uniform program involving two and a half years of practical work in the courts, in the office of a lawyer in private practice, in the office of a public prosecutor, in the civil service, and, possibly, in the legal department of a commercial concern. Upon its completion, he must pass a state examination.

A somewhat similar procedure is followed in Japan. Law graduates who seek careers as judges, public procurators, or lawyers in private practice must (with the exception of summary court magistrates and assistant procurators) pass the National Law Examination for entrance to the Legal Training and Research Institute. This is an organ of the Supreme Court. Like his German counterpart, the *Referendar* training to become an *Assessor*, the Japanese student at the institute is paid but, unlike the *Referendar*, is not regarded as a civil servant during this period. The period of training at the Institute lasts two years. The bulk of the work consists of practical exercises and discussions, lectures on legal topics, and visits to institutions (such as prisons) of concern to lawyers. The training is uniform, leads to a single examination, and qualifies the graduate for any branch of legal practice.

LEVELS OF STUDY

Law degrees are first degrees in most countries. The student embarks upon the study of law at a university at about the age of 18. In France, the universities offer a course of two years in duration called the ***capacité-en-droit***, which may be taken by anyone at least 17 years of age, regardless of educational background. High marks in this entitle the candidate to enroll for the *licence-en-droit.*

In the United States, most law schools require the entrant to be a university graduate, and none will admit students without substantial liberal arts college education. Consequently, the U.S. student of law is generally in his early 20s. Other countries with this system include India and Pakistan.

University law schools

University law schools in many countries accept all candidates with a certain level of pre-legal education. One drawback of this system is a substantial failure rate in the examination at the end of the first year. In some countries, candidates are screened. In England, for example. each university imposes a quota on entry to its law school and selects among candidates on the basis, usually, of academic performance. (It is possible, however, to enter the legal profession without a law degree; anyone of good character who reaches a certain level of pre-legal education will be admitted to an Inn of Court or to training for qualification as a solicitor.) In the United States, candidates are selected on the basis of academic performance and their demonstrated aptitude for the study of law. In both the United States and England, entry requirements vary according to the prestige of the law school.

Most countries also provide for higher degrees in law. In common-law countries there is usually a series of steps, ascending through a degree of master of laws to a doctorate or senior doctorate. In civil-law countries it is normal to go straight from a first degree to a doctorate. Masters' degrees are, as a rule, based on advanced examination after courses of instruction, though sometimes they are awarded for research or for a combination of examination and dissertation. Doctorates are awarded for theses expounding the results of original research and senior doctorates for published contributions to scholarship in the subject. In many countries there are also specialized postgraduate diplomas or certificates in particular subjects, such as criminology, representing work in a narrower area than that for a master's degree.

TRENDS IN LEGAL EDUCATION

Expansion of legal studies

Modern legal education is expanding both in quantity and in scope. A big upsurge of the teaching of law has occurred in Africa, where newly independent countries have established universities and professional schools concentrating on local laws and practice. Civil-law universities have departed in some countries from the rigidity of prescribed syllabi to allow a greater range of student choice in selecting subjects. In France, for example, universities were empowered after 1968 to arrange their own curricula, which had previously been a matter for government regulation. In Italy, law students now submit their own study plans for approval. In most countries, more attention is paid than formerly to foreign legal systems and to comparative law. The expansion of law schools allows for greater specialization, larger libraries, new subjects, and more student choices.

In some countries, nonlegal subjects have long been part of the syllabus. In France, courses in economics and history are part of the study for the *licence,* and Japanese universities devote the whole of the first 18–24 months of the law curriculum to liberal arts. In some other countries where law as a first-degree specialization has hitherto comprised only law studies, there has been a tendency to include nonlegal studies, joint courses in law and social sciences, or a more sociological approach to law.

The opportunities for university and professional education in law increased greatly after World War II. Many governments have made provision, or greater provision, for the maintenance of students; and legal education has been opened to a larger cross section of society in many places. Nevertheless, the children of middle class parents continue to predominate in the field.

BIBLIOGRAPHY. For England and Wales, much interesting information may be found in the *Report of the Committee on Legal Education* ("Omrod Report," HMSO, 1971), which also contains, in Appendix D, a survey of legal education in Australia, Canada, France, West Germany, India, Italy, The Netherlands, New Zealand, Nigeria, Scotland, South Africa, Sweden, and the United States. In Great Britain the *Journal of the Society of Public Teachers of Law* (semi-annual), publishes articles on legal education, chiefly but not exclusively relating to the United Kingdom; a similar periodical in the United States is the *Journal of Legal Education* (quarterly). ALBERT J. HARNO, *Legal Education in the United States* (1953), is a survey with history and criticism; JULIUS STONE, *Legal Education and Public Responsibility* (1959), is devoted to professional ethics and standards in the United States. Legal education in parts of Asia is discussed in S.P. KHETARPAL (ed.), *1962 Regional Conference on Legal Education* (1965); HAKARU ABE, "Education of the Legal Profession in Japan," in ARTHUR T. VON MEHREN (ed.), *Law in Japan* (1963); and JAY MURPHY, *Legal Education in a Developing Nation: The Korea Experience* (1967). For Africa, see JACQUES VANDERLINDEN (ed.), *Conference on Legal Education in Africa* (1968).

(L.A.S.)

Legal Ethics

Sources of legal ethics

Legal ethics are the ethical principles that members of the legal profession are expected to observe in the practice of law. They are an outgrowth of the development of the profession itself.

Practitioners of law arose when legal systems became too complex for those affected by them to understand and apply the law. Certain individuals with the required ability mastered the law and offered their skills for hire. No prescribed qualifications existed, and these specialists were not subject to legal controls. The incompetent, unscrupulous, and dishonest charged exorbitant fees, failed to perform as promised, and engaged in delaying and obstructive tactics in the tribunals before which they appeared. Action to prevent such abuses was taken by legislation and by judicial and other governmental measures. The right to practice law came to be limited to those who met prescribed qualifications. Expulsion from practice and criminal penalties were introduced for various types of misconduct.

These measures did more than correct the abuses. They also gave recognition to the social importance of the functions performed by lawyers and identified those who were qualified to perform them. This marked the formal beginning of the legal profession. A consciousness developed within the profession of the need for standards of conduct. This became the core of legal, or professional, ethics.

Prior statutes, court rules, and other government directives remained in force along with the profession's self-imposed ethical standards. Taken together, they constituted the sum total of the restraints placed upon lawyers in regard to their professional conduct. This pattern has continued to the present time.

In many countries professional associations of lawyers have sought to reduce the principles of ethical conduct to written form, but a written code is not essential. Ethical principles may exist by common understanding, as well as in the literature and writings of the profession. This is the case in England. A code, however, makes ethically obligatory principles readily available to the practitioner and hence assures greater observance of them. When such a code does exist, it usually contains both statements of general ethical principles and particular rules governing specific problems of professional ethics. But no code can foresee every ethical problem that may arise in the practice of law. Hence, codes are supplemented by opinions rendered and published by committees of bar associations. In the United States, for example, the most important and influential of these are the so-called formal opinions of the committee of the American Bar Association. While not having the same authoritative status as codes of professional ethics, they nevertheless indicate what is deemed proper professional conduct. In England, the General Council of the Bar serves a similar function, all the more important in the absence of a formal code of professional ethics.

Differences among countries. Principles of legal ethics, whether written or unwritten, not only seek to control the conduct of legal practice but they also reflect the basic assumptions, premises, and methods of the legal system within which the lawyer operates. They reflect, as well, the profession's conception of its own role in the administration of justice. In western European legal systems the role of the practitioner, in both civil and criminal litigation, differs from what it is in Anglo-American legal systems, and this is reflected in the ethics of their legal professions. Practitioners in countries having a Communist form of government are ordinarily salaried employees of the government, and their ethical obligations consequently have a focus different from those in countries where lawyers engage in independent practice or are employed by private firms. In England and France, where the profession is divided into separate branches, the principles of professional ethics reflect the relationships incident to that division.

In western European and Anglo-American countries and others with similar systems of justice, such as Japan and India, in which the lawyer is not an employee of the state but engages in private practice to serve clients who employ him, professional ethics are addressed to two basic aspects of the lawyer's status. On the one hand, he is employed by clients to serve and represent their interests; on the other, he is participating in an important social function—the application of rules of law through advice, trial of cases, preparation of legal documents, and negotiation with others for his clients. Hence, the principles of legal ethics stress that the lawyer's chief interest lies in serving his client and in securing justice—not in promoting his own income. He is an agent of his client but deemed to retain a large measure of independent judgment as to the proper course to pursue. He represents his client's interests but may not engage in tactics that defeat the fair administration of justice. The lawyer is engaged, it is said, in a profession and not in a business.

The legal ethics prevailing in countries where the lawyer practices privately have been directed largely toward the general practitioner serving individual clients. They are not addressed to the ethical problems encountered by such specialists as the house counsel of corporations, government lawyers, lawyers employed by labour unions, law teachers, large metropolitan law firms serving important segments of the industrial, commercial and financial communities, and lawyers engaged in providing legal services for poor clients, supported either by private or by public funds.

Conflicting interests of client and society

Naturally the interests of client and society sometimes conflict, and the principles of legal ethics do not always indicate how these conflicts should be resolved. Should a lawyer cross-examine an adverse witness in such a way as to undermine or destroy his testimony, when the lawyer believes the witness is actually telling the truth? May he invoke rules of evidence to exclude points that would weigh against his case but that he considers to be probably true? May he take advantage of the errors of an unskilled opponent? Should he demand a jury trial for purposes of delay when a jury trial has no advantage for his client? These questions may be answered differently in legal systems that operate on different premises. A system in which a lawyer presents his client's case in the most favourable light permitted by law and in which the court must decide the merits of the case may well produce different answers than those produced in a system that assigns a higher priority to the lawyer's duty to the state to assure proper administration of justice.

Areas of application. ***Conflicting interests.*** A lawyer will at times be faced with the question of whether or not he may represent two or more clients whose interests conflict. Quite aside from his ethical obligation, the legal systems of the world generally forbid a lawyer from representing a client whose interests conflict with those of another, unless both consent. This applies not only to lawyers but also to other fiduciaries, such as agents, brokers, trustees, and guardians.

In Anglo-American legal systems the prohibition has three aspects. First, the attorney is not permitted to concurrently represent two or more clients if, in order to further the interests of one, he must forego advancing the conflicting interests of another. In short, he cannot be both for and against a client. Second, he cannot subsequently accept employment from another for the purpose of undoing what he had earlier been retained to accomplish. Third, he may not accept subsequent employment from another if it involves the use, the appearance of use, or possible use of confidential information received from his former client. Such actions are forbidden by law and by legal ethics.

Obligations to the client

To illustrate, an attorney may not ordinarily prepare an instrument for both buyer and seller in which their respective rights are defined. He may not prepare an instrument or negotiate a settlement for a client and later accept employment from another to defeat that instrument or settlement. He may not represent both a driver and his passenger in recovering damages from another party charged with negligent driving in a collision, since the passenger may have a claim against his own driver as well. He may not represent two or more defendants in a criminal prosecution if their respective defenses are inconsistent or, possibly, even when the case against one is stronger than the case against the other. The same principles apply with respect to interest of the attorney that may detract from the full and faithful representation of his clients. For example, he may not purchase property that he has been retained to acquire for his client, nor may he draw a will in which he is a beneficiary.

These conflict-of-interest prohibitions are not absolute. The client may consent to the representation after full disclosure of the actual or possible conflict. But the client's consent may not suffice if public interest is deemed to be adversely affected, as it would be if a lawyer undertook to secure a divorce for one spouse and also act as attorney for the other. Consent divorces are deemed against public policy.

The practicing lawyer who is also a member of a legislature is confronted with a conflict of interest whenever his clients enlist his support to promote or oppose legislation or to secure favourable decisions from administrative agencies that are dependent on legislative financial support. The problem is an important one in the United States, where members of legislatures frequently maintain private law practices, but it has received insufficient consideration by the U.S. legal profession.

Confidential communications. In Anglo-American countries judicial decisions, legislation, and professional ethics forbid a lawyer to testify about his client's communications to him unless the client consents. Similar provisions are found in such diverse legal systems as those of Japan, Germany, and the Soviet Union. In countries in which the attorney's obligation to protect state interests is given relatively greater emphasis, there may be a duty to disclose information when it is deemed to be to the state's advantage. In Anglo-American law the obligation does not apply when the client seems about to commit a fraud or crime. An attorney also may disclose his client's communication if it is necessary to refute a false charge made against him by the client. A similar obligation is recognized by members of the medical profession, clergymen, accountants, social workers, and journalists.

Dignity of the profession

Advertising and solicitation. It has been a long-standing principle of professional ethics in Anglo-American countries that an attorney must not seek professional employment through advertising or solicitation, direct or indirect. The reasons commonly given have been that seeking employment through these means lowers the tone of the profession, that it leads to extravagant claims by attorneys and to unrealistic expectations on the part of clients, and that it is inconsistent with the personal relationship that should exist between attorney and client. A more basic reason appears to have been the social necessity of restraining the motive of personal gain and of stressing the objective of service. Until 1977 the legal profession in all Anglo-American countries took the position that, with some exceptions, the prohibition must be complete. Many specific rules were laid down by bar associations, covering even such details as the content of a lawyer's business card, letterheads, office sign, and announcements of changes in partnerships and office locations. The rules also governed his relation to lay and professional groups that might serve as feeders to his practice and his participation in the publicity attending the trial of a case in which he served as counsel. The situation changed in the United States in 1977 when the U.S. Supreme Court ruled that lawyers could not be barred from advertising their fees. The American Bar Association subsequently revised its code of ethics to include provisions and guidelines for advertising, and suggested that lawyers limit their advertising to basic information about practice and fees.

Fees. Attorneys are ethically enjoined to keep fees reasonable, neither too high nor too low. Many state and local bar associations in the United States have issued minimum-fee schedules as guidance for their members but do not make it an ethical obligation to observe them.

The profession in the United States has assumed, in principle, the obligation to serve poor clients without compensation. The task, however, has become of such magnitude, especially in view of the expansion of the constitutional right to counsel in criminal cases, that ways of providing paid legal services for the poor have emerged, such as legal-aid societies and public defenders.

Fees that are contingent on the successful outcome of litigation or settlement are widely used in the United States, particularly in automobile-accident and other negligence cases, and they are accepted as ethical by the U.S. legal profession. The fee is usually an agreed percentage of the recovery. The justification given is that the injured poor are enabled to assert their claims in court. But contingent fees give the attorney a financial stake in the outcome of litigation—which is ordinarily frowned upon. An offsetting merit may be that in this type of case, where the outcome is difficult to predict, the lawyer also assumes the risk of losing his fee. Nevertheless, in countries other than the United States, contingent fees are generally not permitted. Nor are they permitted in the United States in criminal and divorce cases or to secure a pardon or in the enactment of legislation. Fees for the collection of money claims are frequently based on a percentage of the amount collected.

To avoid the cost of attorney's fees or to supply legal services to those who cannot pay the required fees, various groups in the United States, such as labour unions, corporations, and service organizations, have hired attorneys to provide their members with legal counsel. This practice has been resisted by the U.S. legal profession on several grounds. These include the ground that such action places an intermediary between the attorney and his client, thus diluting the direct personal relationship; and that the interests of the employing organization may at times be in conflict with those of the client. Some decisions of the United States Supreme Court have rejected these contentions and given constitutional status to the right of a labour union or of an organization representing a minority group to provide legal services to its members. But the full scope of this constitutional right remains to be determined.

Honesty in court

Criminal cases. Both the prosecution and the defense of criminal cases raise special ethical issues. The prosecutor represents the state, and the state's concern is not only in convicting the guilty but also in acquitting the innocent. The state's interest may also dictate that prosecution be foregone in some cases in which a conviction could be obtained, as when a person who could be prosecuted supplies evidence against others and thus aids the state in its case. The decision to prosecute must be governed by such considerations. The prosecutor also has an ethical and, in considerable measure, a legal duty to disclose to the defense any information known to him and unknown to the defense that might exonerate the defendant or mitigate the punishment. He must not employ trial tactics that may lead to unfair convictions, nor should he prosecute merely to enhance his political prospects.

The defense counsel has different concerns. Under Anglo-American law, an accused may compel the state to prove that he is guilty beyond a reasonable doubt. The defense counsel, therefore, becomes ethically obligated to require the state or produce such proof, whether or not the attorney believes his client to be guilty. His client's guilt is for the tribunal to determine. The attorney may not, however, deliberately resort to perjured or other false testimony. Similar principles hold in civil-law countries. When the client, against the attorney's advice, insists on testifying falsely, the ethical course to be pursued has not been fully settled. Some maintain that the attorney should withdraw, if possible, or else merely permit the client to testify without aiding him or asserting the truth of the testimony given.

Legal Profession

One definition of the legal profession calls it "the vocation based on expertness in the law and its application." This simple definition may be best, despite the fact that in some countries there are several professions and even some occupations (*e.g.,* police service) that require this expertness but may not be considered to be within the "legal profession" at all.

HISTORY

Distinct legal systems emerged relatively early in history, but legal professions of size and importance are relatively modern. It was previously thought that all law in ancient times grew out of situations where law, religion, and morals were fused, and that those who applied it necessarily combined an expertness in all three. In some cases, however, and notably in the early Mesopotamian system recorded in the Code of Hammurabi (18th century BC), the law was already substantially secular and distinct from religion and morals. It is likely, though less capable of proof, that a similar state of affairs existed in 3rd-millennium Egypt and China. The evidence of the Hebrew Bible, the Hindu Vedas and Upanišads, and the Muslim Qur'an points to a mixture of law, religion, and morals at *later* stages. On the other hand, early Greek and Roman records suggest a religious stage *before* the secular law became distinct.

But whether early archaic law was distinctly secular or "mixed," there is not the slightest trace in ancient times of a distinct legal profession in the modern sense. The earliest known legal specialist was the judge, and he was only a part-time specialist. The chief, prince, or king of small societies discharged the judicial function as part of the general role of political leader. As his power spread he delegated the function, though not to legal specialists; in the secular stages of the early systems, legal duties were taken over by royal officials who were "generalists." In the wake of powerful religious or quasi-religious movements, priests or savants often judged or advised the judges, a situation that persisted in Muslim countries and in China until the 20th century AD. It may be suspected that, in some of these cases, specialized legal aid to the ordinary citizen did exist, but at levels of social status below the notice of chroniclers or tomb inscriptions, and perhaps without benefit of official approval.

Classical beginnings of a legal profession. **A** distinct class of legal specialists other than judges first emerged in the Greco-Roman civilization, and as with the law itself, the main contribution was from Rome, in the period from 200 BC to 600 AD. In the early stages of both Greece and Rome, as later among the German tribes who overran the Roman Empire, there was a prejudice against the idea of specialists in law being generally available for fee. The assumption was that the citizen knew the customary law and would apply it in transactions or in litigation personally, with advice from kinsmen. As the law became more complex, men prominent in public life—usually patricians—found it necessary to acquire legal knowledge, and some acquired a reputation as experts. Often they also spent periods serving as magistrates and, in Rome, as priests of the official religion having special powers in matters of family law. Among the German tribes noble experts were allowed to assist in litigation, not in a partisan fashion but as interpreters *(Vorsprecher)* for those unready of speech who wished to present a case. The peculiar system of development of the early Roman law, by annual edict and by the extension of trial formulas, gave the Roman patrician legal expert an influential position; he became the jurisconsult, the first nonofficial lawyer to be regarded with social approbation, but he owed this partly to the fact that he did not attempt to act as an advocate at trial—a function left to the separate class of orators—and was prohibited from receiving fees.

The jurisconsult and his successors

The modern legal professional, earning his living by fee-paid legal services, first became clearly visible in the later Roman Empire, when the fiction that a jurisconsult received only gifts was abandoned and when at the same time the permissible fees were regulated. Changes in the methods of trial and other legal developments caused the jurisconsult to disappear in time. The orator, who now was required to acquire legal training, became the advocate. A subordinate legal agent of the classical system, the procurator, who attended to the formal aspects of litigation, took on added importance because later imperial legal procedure depended largely on written documents drawn by procurators. The jurisconsults had been important as teachers and writers on law; with their decline this function passed to government-conducted law schools at Rome, Constantinople, and Berytus, and their salaried professors. There was also a humbler class of paid legal documentary experts, the ***tabelliones,*** useful in nonlitigious transactions.

Medieval Europe. This late Roman pattern of legal organization profoundly influenced the Europe that arose after the barbarian invasions, from AD 1000 on; and even during the invasions the methods of Roman imperial administration never ceased to operate in some parts of southern France and central Italy. The Christian Church, which became the official Roman imperial church after AD 400, developed its own canon law, courts, and practitioners, and followed the general outline of later Roman legal organization. The church's success among the invaders established its jurisdiction in many matters of family law and inheritance. Hence both the idea of a legal profession and the method of its operation remained visible to offset Germanic and feudal objections to legal representation. After the revival of learning in the 12th century, in particular the revived study of Roman law at Bologna, the influence of the late Roman professional system was greatly strengthened.

Classes of legal practitioners

From then on, every country in continental Europe acquired, by various stages and with local variations, a legal profession in which four main constituents could be observed. Procurators attended to the formal and especially the documentary steps in litigation. (In France after the Revolution, the *procureurs* were renamed *avoués.*) Advocates, usually university graduates in Romanic learning, gave direct advice to clients and to procurators and presented oral arguments in court. Among a miscellany of legal scribes, the notaries acquired importance because, in addition to being drafting experts, they provided officially recognized document authentication and archives for internal as well as international purposes. University teachers of law took over the main task of explaining and adapting the mixture of Roman law and Germanic custom that produced the modern laws of the major European countries, and continued to dominate in the scholarly interpretation of the law even after the 19th-century codifications. The relative importance of these classes varied enormously from place to place and from century to century. At times the teaching doctors almost supplanted the advocates; in some courts the procurators swallowed up the advocates, and in others the converse occurred; only the notaries survived with little change.

England after the Conquest. England after the Norman conquest also was influenced by Roman example, and the clerics who staffed the Norman and Plantagenet monarchies and who provided the earliest of their judges enabled the notion of a legal profession, and especially of litigious representation, to be accepted. Only in the ecclesiastical and admiralty courts, however, did procurators (proctors) and doctors of the civil and canon laws become established as practitioners. The native "common law" was developed instead by a specialized legal university, the Inns of Court in London; there, through lectures and apprentice training, men acquired admission to practice before the royal courts. More particularly, they could become serjeants—the most dignified of the advocates, from whom alone, after about 1300, the royal judges were appointed. Various agents for litigation resembling procurators also became known. The "attorneys," authorized by legislation, at first shared the life of the Inns with the "apprentices" in advocacy, who themselves, in time, acquired the title of barristers. Indeed there were cases of men working as both barristers and attorneys. When in the 16th century the court of chancery was established as the dispenser of "equity," the appropriate agent for litigation was called a solicitor, but the common law serjeants and barristers secured the right of advocacy in that court. It was not until the 17th century that the attorneys and solicitors were expelled from the Inns and the division between advocate and attorney became rigid, and not until the 18th century that the barristers accepted a rule that they would function only on the engagement of an attorney—not directly for the client. Other types of legal agents also developed in England, but in the 19th century all the nonbarristers were brought under the one name, solicitor. The order of serjeants was wound up, leaving only barristers, of whom the most senior could be made "Queen's Counsel."

The English division

In its final development the English profession thus bore a resemblance to the European—particularly to that of northern France, where the *parlements* (courts) had a corporate life and apprentice training not unlike that of the Inns, and the Ordre des Avocats acquired a prestige and autonomy resembling that of the English bar. But there were four great differences between England and the Continent. No distinct class of great university teachers and commentators on the national law developed in England, and nonstatutory development of the law took place chiefly through precedent based on the reported judgments of the courts. The continental monarchies also developed a system of career judicial office, in which the young university licentiate went straight into government service, whereas in England appointment of judges from the senior practicing profession remained the settled practice. In addition, the division between barristers and solicitors ultimately became much more rigid in England than did the division between the advocate and procurator in Europe, and Europe never adopted an equivalent of the English practice requiring a barrister to be employed by a solicitor; procurator and advocate were separately and directly employed by the client. England never developed the profession of notary for internal purposes, so that the whole burden of transactional work fell on those who are now the solicitors, with legal advice from the bar.

The worldwide legal profession. The main patterns both of law and of legal practice were exported by Europe and England to their overseas colonies and possessions, and most of the noncolonial countries of the rest of the world imitated one or the other system. Thus the Romano-Germanic (frequently called civil law) practices became the norm for Scandinavia, Scotland, Latin America, most of the Muslim countries of the Middle East, for French-speaking areas, Portuguese and Spanish Africa, and for Japan, Thailand, and the former French parts of Southeast Asia. They have also influenced Communist practice. The English system provided the model for English-speaking North America, most former English colonies in Africa including South Africa, most of the Indian subcontinent, Malaysia, Australia, and New Zealand. The original model has undergone considerable modification by both the countries of export and the countries of influence. In particular, the specialization of procurator-advocate and solicitor-barrister has tended to be replaced by a "fused" profession of legal practitioners qualified to perform both functions and usually doing so. (Such a fusion also occurred in 19th-century Germany, producing a "Rechtsanwalt" corresponding to the U.S. attorney-at-law.) In Latin America, the fused profession is general, except that the specialized notary survives.

COMPOSITION AND CHARACTERISTICS OF THE PROFESSION

The legal profession has always had an ambiguous social position. Leading lawyers have usually been socially prominent and respected—the sections of the profession so favoured varying with the general structure of the law in the particular community. The family status of early Roman jurisconsults may have been more important than their legal expertise in securing such a position, but by the time of the Principate it was their legal eminence that made them respected. The English serjeants lived magnificently, especially in Elizabethan times, and the French Order of Advocates was established (14th century AD) by feudal aristocrats in circumstances reminiscent of early Rome—including an insistence on receiving gifts rather than fees. The early Italian doctors of the civil and canon law (12th–15th centuries) were revered throughout Europe. In England and the countries influenced by its system, the highest prestige gradually came to be concentrated on the judges, rather than on the order of serjeants, of which they were members; and the judges remain the only legal class in the liberal-capitalist common law countries of today to enjoy something like charisma. In the Romano-Germanic systems, it is the notaries and the advocates who have come to be most trusted or admired, the judiciary being more closely identified with the civil service.

The legal profession and social conflict

Yet along with this high repute, sustained over two millennia, lawyers have also been among the most hated and distrusted elements in society. In a few cases this has been the consequence of a powerful ideology in the society which was hostile to the whole idea of law, China being the most important example. Confucian teaching (6th century BC) was against the use of civil law as a major means of social control, and this influence remained powerful there and in Japan until the 20th century. In Communist Russia, the early leaders (1917–22) imagined that law and lawyers were peculiar to "exploiting" societies and would soon wither away in classless Communism, and this belief was revived in the early days of Chinese Communism (1947–55). Further experience persuaded the Communist governments that there was room for "socialist legality" and for lawyers to serve it, but a degree of mistrust remains and the repute of the legal expert is lower than that of the political and technological expert.

Most lawyers are conservative, because the law itself is predominantly intended to satisfy expectations arising from an inherited pattern of behaviour; in a particular social setting, this tends to identify the lawyer with the established and successful classes and to make him seem an enemy to oppressed classes or "new men." Individual lawyers have, nevertheless, often been on the side of rebels: Robespierre and Lenin were both lawyers. But the dominant attitude of the legal profession is for moderation. Thus many lawyers took the British side in the American Revolution, and even among the lawyers who took the other side, the predominant influence was against any attempt to turn the political revolution into a social revolution.

Along with these varying ideological and political reasons for popular distrust, and even more deep-seated, are the inherent difficulties associated with law and with some of the legal functions. Most men would like law to be so certain that its application in any case is equally certain, and so simple that any person of sense can see how it applies. In a discipline sharing the imperfection and complexity of society itself, no such situation is attainable, and the lawyers are blamed for the basic difficulty of their craft—which in some instances they worsen needlessly themselves by multiplying obscurities, contradictions, and complexities. The legal function likely to be most distrusted by the average person, though it also produces some of the law's heroes, is litigious advocacy, particularly in the criminal law. Plato and Aristotle condemned the advocate as one who was paid to make the better cause appear the worse, or endeavoured by sophisticated tricks of argument to establish as true what any man of common sense could see was false. The feeling against advocacy in the criminal law was so strong that, at least in the case of the more serious kinds of crime, a right to representation by a trained advocate was nowhere generally recognized until the 18th century AD.

Governments and the members of organized legal professions have from the infancy of the craft endeavoured to meet the basic problem of representation by a basic rule of professional ethics—that the dominant duty of the advocates is not to his client but to truth and the law. Since the later Roman Empire, advocates have been required to take oaths to this effect, and lawyers are often technically classed as "officers of court." The duty of the advocate is to fight for the rights of his client, but only up to the point where an honourable man could fairly put the case on his own behalf. He must not identify with his client's possible willingness to tell untruths, or to misrepresent the relevant law.

THE FUNCTIONS SERVED BY THE LEGAL PROFESSION

Private practice. Client-directed lawyers often are called counsellors, but in the original sense of that word—giving advice as to how the law stands—this is rarely an independent function; it is an inseparable part of the other functions. In his client-directed activities the lawyer is concerned with how the law affects specific circumstances, which can for convenience be divided into two main types: transactional and litigious.

In the transactional type, the lawyer is concerned with the validity or legal efficacy of a transaction, independent of any immediate concern with the outcome of litigation. Such activities comprise the largest area of professional activity, whether considered from the point of view of the number of lawyers involved, or of the time they have to spend on the task, or of the number of clients affected. If the events constituting the transaction in question happened before the lawyer is consulted, he can only advise on their legal significance and perhaps suggest methods of overcoming legal deficiencies in what has been done. If future conduct is involved, he is better placed to plan his client's course of conduct so as to secure the required end in the most economical fashion that the law permits. Transactions may concern words and acts, but characteristically they require the drafting of documents. In the Romano-Germanic systems these often require notarization. Typical activities falling in this category today are: transferring interests in property (especially if, as in the case of land, more than a mere expression of intention is required to satisfy formal legal requirements) ; transmitting property on death; settling property within a family; making an agreement (especially if a commercial agreement of some complexity and duration is involved); incorporating or winding up a corporate entity; varying the terms on which a corporate entity is conducted (classes of shares, managerial rights, distribution of profits, etc.); and adjusting the ownership and control of property and income so as to comply with the requirements of taxation laws and minimize their impact on the property and income in question, or so as to ensure the proper management of the assets and distribution of the proceeds among beneficiaries (estate planning), or both. In the Romano-Germanic systems many of these functions are discharged by notaries, and in the English and similar divided systems by solicitors, though in difficult situations the opinions of advocates or barristers may be obtained. In the fused professions of North America, some firms of attorneys specialize in business of this type and avoid, so far as they can, the litigious function. A frequent accompaniment of such work is the handling of clients' money, and in many contemporary legal systems it has become common for statutory regulation to require rigid accounting and the provision of a guarantee system to protect such funds.

Typical legal functions

The litigious function is subdivided into three main stages. First is the preparation of the case—interviewing the client and witnesses, investigating the circumstances in the light of the leads provided by the client, and attending to the formal requirements of the procedure in question, which may involve writs, summonses, filing of statements of claim or defense, gathering information through interrogatories and discovery of documents between the parties, and preparing for trial. Second is the trial proper, in which the facts and law are established and argued before the judge and a decision is made. Third is the execution of the judgment—obtaining payment of damages, delivery of property, or performance of obligation in civil cases; payment of fine or imprisonment, etc. in criminal matters. Similar stages arise on appeal. In the divided professions, the sharing of these functions is intricate and varies between one system and another. The advocate or barrister is especially responsible for the second stage, the day in court, but he may advise upon or draft many of the documents used in other stages. If incidental disputes concerning procedure have to be litigated, he is likely to conduct the proceedings; and if the procedure includes a pretrial conference, he is likely to represent the client. Otherwise the first and third stages are primarily the province of procurator or solicitor.

Public-directed practice. As noted above, the highest function served by the legal specialist today is that of judging, but it can be regarded as a separate profession. Where judges are elected, as they are in many instances in the U.S., they may return to practice at their term's end, and practitioners may consider judicial office as merely an interlude in their careers as attorneys. In England, senior barristers often accept positions as temporary judges—recorders, or chairmen of quarter sessions—while continuing in the main their professional career, though for a majority this is an apprentice stage before life appointment to a judicial post. In the Romano-Germanic systems, the judges traditionally have been considered a separate profession within the civil service, and in many respects subject to civil service rather than law-profession control. This, however, may be changing in some countries. Thus in West Germany and in Japan (whose modern legal profession and judiciary were modelled on the French and German systems), there is a contemporary move to extricate the judiciary from a primary identification with government service and associate them actively with the private practicing lawyers. As yet, however, appointment of judges from the advocates, though legally possible, is unusual.

Governmental roles of the legal profession

Governments have always themselves required a staff of legal specialists, and the scope for such employment today is enormous. There is usually a senior political officer—minister for justice, attorney general, solicitor general—who by convention needs to be a lawyer, and a government department concerned mainly with the legal problems of the government as client (in the English-derived systems, usually the department of the attorney general). Increasingly, however, it is found that the great departments of state need their own legal subbranch. In Communist countries, lawyers tend to work mainly for government and for collectivized industrial and farm organizations.

One of the oldest and still most difficult of the governmental legal functions is that of prosecutor in criminal cases. Prosecution is often in part carried on by private persons acting through private lawyers, but the trend is to concentrate the function in government legal officers. In most Commonwealth countries, the Crown or public prosecutor is a specialized officer under the general control of the attorney general. England has an independent "director of public prosecutions," concerned only with the most serious types of crime, but most prosecutions are conducted by private barristers briefed by him or by police. In the U.S. this function has come to be mainly local, and prosecutors are elected for short terms, the commonest title being district attorney. In the Romano-Germanic systems, prosecuting is a career service but often organized in substantial independence from other forms of government legal service.

The prosecuting function is particularly delicate because criminal prosecution can be used as an instrument of oppression and political persecution, even where conviction is not obtained, and because in most systems prosecutors are expected to act with a degree of fairness and restraint not necessarily expected of the parties to civil litigation. Many Romano-Germanic systems employ officers who keep a general supervision over the working of the courts and especially their criminal jurisdiction. This is the office of the "procurator general," or "officer of justice," and a similar service exists in most Communist countries.

Another branch of government, the legislature, usually requires legal assistance. For one thing the presiding officers apply complex standing orders with legal advice, such as that given by the parliamentarian at Washington and the standing counsel to the speaker at Westminster. Legislation also needs to be expressed in language readily applicable by judges and lawyers and to be framed in harmony with the existing body of law. This requires the service of parliamentary draftsmen who are expert lawyers. A further specialized branch of advisory activity associated with legislation has recently become prominent—the law reform commission or committee.

Teaching and scholarship. A prominent role for the legal profession since Roman times has been concerned with teaching and scholarship in the law. Until the 18th century, teaching of the English common law was vested exclusively in the Inns of Court, and a good deal of European teaching for professional practice—particularly in the case of notaries and procurators—was also professionally organized. Even university law teaching in Europe was rarely aloof from legal practice; there was usually a fruitful interchange between practitioner and teacher, exemplified in such great figures as the French 18th-century teacher, advocate, and judge Robert Joseph Pothier, whose commentaries provided the foundation for the Napoleonic Code of Civil Law. Much law teaching in the new university law schools that sprang up in the U.S., the United Kingdom, and the Commonwealth in the 19th and 20th centuries was carried on part-time by attorneys, barristers, and judges, and some still is. Blackstone, the first Vinerian professor of English law at Oxford, came from the bar and became a judge. Law teaching has today tended to become a distinct, full-time profession, usually carried on at a university. Teachers and practitioners contribute to an enormous professional literature in all countries, with students' texts, practical manuals, theoretical monographs, and a periodic literature whose bulk is coming to be almost as big a problem as the enormous bulk of reported judicial decisions that are consulted for guidance and precedent.

THE AUTONOMY OF LAW AND LAWYERS

At least since the classical Greeks, a recurring political theme has been the need for a government of laws rather than of men. Actually, however, as the legal philosopher Julius Stone has said, society of necessity has a government of laws and yet of men, and the demand for *legal* autonomy is often seen in practice as a demand for freedom of the *lawyers* from political dictation or influence. The main issue has been the independence of the judiciary, and democracies have been particularly assiduous in cultivating both a spirit and traditions that respect judicial independence. The details of their government structure or constitutional guarantees tend in that direction, offering obstacles to the ready dismissal of judges, charging their salaries on consolidated revenue, and prohibiting the vesting of judicial functions other than in duly constituted courts of law.

Political context of the judiciary

The special position of the judiciary in constitutional states is usually considered to be an aspect of the division of powers, but it should also be considered in its relation to the structure of the legal profession. Since later Roman times, admission to the practice of law and the regulation of the practicing profession has been habitually vested in the judiciary. The duty of the advocate to speak fearlessly for his client has often required courage in the face of political threats directed against the advocate and also against the court before which he appeared, so that judicial courage was also required. The legal profession as a whole is then seen defending "the rule of law" against the political regime.

The issue of judicial independence may sometimes, however, be seen in the context of tension between the judges and the advocates. In the Romano-Germanic systems, the judges often are subject to a strong corporate discipline within their own craft, and differences can occur between them and the body of advocates, and also between them and the university teacher-commentators. These differences may relate to questions of legal ethics, especially the limits of advocate identification with client, or to questions of legal doctrine; the judges are then apt to be considered as representing "the state" and the advocates and teachers the autonomy of the law. In the English-derived systems, judges are much less subject to corporate discipline, and disputes with the bar are more likely to arise with individual judges and to be highly personal. Even in stable countries, where the rule of law and the independence of judiciary and profession are respected, there is a less dramatic tension between the standards and tone of the lawyers on the one hand and the political administration on the other. For the lawyers, policy is largely concealed in the propositions that constitute the normative system, and legal reasoning usually involves definitions and processes of inference from the body of such propositions themselves rather than directly from the policies which the norms subserve. There have often been revolts against such "logic" within the legal profession itself, especially in the 20th century, but it still remains the commonest method of thinking among lawyers and it is doubtful whether one can speak of a "rule of law" at all unless a good deal of legal reasoning is conceptual in style. Politicians and administrators, on the other hand, are more likely to reason directly from policies and purposes and from the considerations relevant to their attainment. The classic illustration of the tension is that between the police officer, confident that he has the guilty man and intent only on putting him in jail, and the lawyers and judge, who insist on the need for "conviction according to law," which may involve the application of rules of evidence seeming artificial and even absurd to the police officer. In rigid consitutional systems where there is judicial review of legislation, politicians may be affronted at the way in which political issues are transformed by the lawyers into legal issues. In many modern countries there has been a tendency to remove certain kinds of dispute both from the courts and from the lawyers, and to vest their determination in administrative bodies before which lawyers are denied standing, so as to escape what has been regarded as the blight of legal reasoning; as often there have been reactions in favour of restoring the rule of "law" and the lawyers. In such disputes, it is often difficult to distinguish between lawyer attitudes that reflect the necessary features of a rule of law from those that merely reflect the temporary self-interest of particular lawyers or their clients.

ORGANIZATION AND DISCIPLINE OF THE PROFESSION

Since about 1800, most countries have brought their legal professions under systems of statutory control with three main principles: admission to practice automatically and compulsorily makes the lawyer a member of an appropriate professional association; those associations are given substantial powers in relation to legal education, admission to practice, and the disciplining of the profession, but subject to overriding powers vested in the courts and/or (especially in the Romano-Germanic systems) in government legal departments; the practice of law for reward is prohibited—generally or as to particular functions—to persons not admitted under the system. In the U.S., about half of the states have such a system, there called that of the "integrated bar"; in the other states, bar associations are voluntary and have few controlling powers. England has retained the traditional Inns of Court (in whose management the judges play a leading role) for barristers, but solicitors are subject to a statutory system as above. In some countries (*e.g.*, France) professional organization is regionalized to correspond with judicial organization, and in some federal countries (*e.g.*, the **U.S.**, Canada, and Australia) professional control is vested in the states; such situations create the problem of a national organization which is generally a voluntary federation of regional bodies and therefore lacking in compulsive authority. The American Bar Association, established 1878, is a leading example. In other federal countries (*e.g.*, West Germany, India) the central government has created national law associations responding to the system of control. The law associations, apart from the functions already mentioned, help their members to understand and apply professional ethics, and they develop canons of ethics to cover new problems. They are often active in policing the prohibition of legal practice by unqualified persons, which tends to bring them into dispute with other professions—*e.g.*, tax accountants and land salesmen—whose members wish to perform legal functions in relation to their tasks and often have considerable knowledge of the relevant law.

Profes-
sional
associa-
tions:
protection
and control

Where the profession is divided, it is today usually possible to transfer from one branch to another, though sometimes after delay or subject to additional training. In many of the Romano-Germanic systems, however, professional mobility is severely restricted by another factor—numerical limits on the numbers admitted to a branch of the profession. There are usually limits to the permitted numbers of procurators and notaries, and in some cases, notably the highest French courts, advocate and procurator functions have been combined in relation to a particular jurisdiction, and a limit has been placed on numbers; otherwise the number of advocates is generally not restricted. In the restricted cases a person admitted to practice can actually work in the profession only as an employee of an existing practitioner or after buying out such a practitioner.

The practical ability to enter or carry on in the profession can also be much influenced by the varying national rules as to legal partnerships. They are prohibited for English barristers and for most divided bars derived from that system, and among most of the Romano-Germanic specialized advocates and notaries; France now permits *avocats* to have partnerships, but they are rare. Incorporation of legal practitioners is almost universally prohibited. These restrictions result from the emphasis on personal responsibility of the individual lawyer to his client, to the court, and to the ethical system. In the fused professions, however, partnership is usually permitted, and in the U.S. some very large firms have developed, particularly among the "corporation lawyers"—referring to their clients—of New York. But even in the **U.S.** single-person practices and small partnerships are commonest.

THE FUTURE OF THE LEGAL PROFESSION

Law faces problems that are common to most professions, such as the consequences of rapidly growing size and complexity of society and of knowledge, and the impact of technological change; thus lawyers will have to adjust to the use of computers to store and retrieve information about the proliferating body of statutes and judicial decisions, and more and more frequently must use scientific and social expertise in the solution of specifically legal problems.

In many countries, changes in the demand for legal services are also compelling changes in organization. Generally, lawyers have in the past been readily available only to those with above-average means. Today there is a demand for making such services available in principle to all citizens. In the **U.S.** the particular case of legal aid to persons accused of crime became urgent because of the Supreme Court's interpretation of the Constitution as making such aid necessary, if requested, to the validity of convictions. There is also a demand for wider legal aid in civil matters. Britain and many Commonwealth countries have established systems for the provision of aid in both criminal and civil matters, which is jointly administered by government bodies and legal associations; the policy is to retain the principle of a private legal profession although financial support is provided by government. In other countries, chief reliance may be placed on legal aid wholly provided by government; this creates the problem of the independence of the aid, especially where government is also a party in a case. In the Communist countries, a situation where the lawyers' responsibility to the government or to the collectivity was very heavily stressed is

Legal aid

gradually giving way to one in which it is recognized that the individual requires some independent aid; in the U.S.S.R. this is difficult because the "cooperatives" of advocates available to individuals are heavily regulated, but less difficult in other European Communist countries where the lawyer cooperatives have greater freedom.

The need for legal specialization also creates problems. Early in the 20th century it seemed likely that the barrister-solicitor and procurator-advocate division would soon disappear entirely, as it has done in many countries, but later in the century it appeared that surviving cases of the division (notably England and Scotland) would continue; in some Australian states there has been reversion to a divided profession after earlier fusion measures. This testifies to the technical advantages of separating the functions of advocacy and specialist advice, but there are rigidities in the English situation that multiply costs; nor does the notary-procurator-advocate division altogether fit the contemporary needs of the Romanist systems where it survives. The very large partnerships that arise where there are fused professions allow some specialization to occur within the firm. In a regime of small general practitioners, specialization is more difficult because the individual attorney wishes to keep his client for all purposes; this difficulty can be mitigated by such devices as the "lawyer referral" services now operated by many U.S. bar associations, though these grew up to provide guidance on reliability rather than on specialized ability.

With the decline of apprentice law training and growth of full-time law teaching, there is a risk of discontinuity between teaching and practice. This is being bridged by the development of practical training and experience courses in law schools, such as legal-aid clinics and drafting seminars, and by teachers spending periods in government or private practice; but the cure is itself creating problems by placing excessive stress on the teaching of technique. The lawyer is caught between cross fires of demand; some would like him to be the chief moral conscience and applied sociologist of society, while others think he would do better as a specialized technician in his craft who leaves "generalizing" to others. In the open societies, lawyers will make their own diverse choices.

LCger, Fernand

Few 20th-century artists have accepted tbe Industrial Revolution and a possible era of the common man with as much enthusiasm as the French painter Fernand Léger displayed during a long and, although qualitatively uneven, remarkably consistent career. Beginning in the years before World War I with a personal variety of Cubism, he developed a vigorous style that combined forms reminiscent of machinery with elements of geometrical abstraction, bright, poster-like zones of colour, and a hint of the popular lithographs of around 1900. His favourite subject matter included acrobats, cyclists, and construction workers. Since his death in 1955 his reputation, although somewhat that of a period figure, has grown.

Léger, photograph by Arnold Newman, 1941.

Léger was born on February 4, 1881, at Argentan, a small town in Normandy. His father and his grandfather were peasants engaged in livestock raising. After completing his education in local secondary schools, he served a two-year apprenticeship in an architect's office at Caen and then, in 1900, went to work in Paris, first as an architectural draftsman and later as a retoucher in a photographer's studio. In 1903 he enrolled in the Paris Ecole des Arts Décoratifs and, although failing to get into the Ecole des Beaux-Arts, began to study under two of its professors as an unofficial pupil. A large retrospective of the work of Paul Ctzanne at the Paris Salon d'Automne of 1907 influenced him profoundly, as it did many other young painters who were looking at the time for a solid way forward from the form-dissolving dazzle of the Impressionists and the undisciplined colour of the recent Fauvist movement. "All of us," Léger said later, "had Cézanne as a point of departure." In 1908, the year Cubism began, he rented a studio at La Ruche (The Beehive), an artists' settlement on the edge of Montpamasse, and there he soon found himself in the centre of several avant-garde tendencies. Eventually, he got to know the painters Robert Delaunay, Marc Chagall, and Chaim Soutine; the sculptors Jacques Lipchitz, Henri Laurens, and Alexander Archipenko; and the poets Guillaume Apollinaire, Max Jacob, Blaise Cendrars, and Pierre Reverdy. Through the poets, in particular, there was a connection with the Cubist movement, the early centre of which was Montmartre, where Pablo Picasso and Georges Braque had their studios.

Léger had been painting in a style that mixed Impressionism with Fauvism; now, under the pressure of his new environment, he evolved rapidly. In 1909 he produced "The Seamstress" ("La Couseuse"; private collection, Paris), in which he reduced his colours to a combination of blue gray and buff and the human body to a construction of slabs and cylinders that resembled a robot. That same year he began "Nude Figures in a Wood," in which the geometrical volumes composing the figures are broken into large fragments. By 1913 he was painting, in brighter colours, the series of dynamic, sometimes completely abstract studies he called "Contrast of Forms" (Philadelphia Museum of Art, among other places); here his style, aptly nicknamed "tubism," was intended to illustrate his theory that the way to achieve a maximum of pictorial effect was to multiply contrasts of colour, contrasts of curved and straight lines, and contrasts of solids with each other or with flat planes. In 1914, in a lecture

Development of "tubism"

entitled "Les Révélations picturales actuelles" ("Contemporary Achievements in Painting"), he added to this aesthetic basis of his art an affirmation of his faith in modern life and popular culture:

> The breaks with the past that have occurred in our visual world are innumerable. . . . The advertisement hoarding, which brutally cuts across a landscape in obedience to the dictates of modern commerce, is one of the things that have aroused most fury among men of so-called good taste. And yet that yellow or red bill-board, shouting in a timid landscape, is the finest of possible reasons for the new painting; it knocks head over heels the whole sentimental and literary conception of art . . . .

During World War I, in which he fought as a sapper in the front lines, he acquired a strengthened sense of reality and a renewed interest in cylinders. "Without transition," he remembered, "I found myself at the level of the entire French people . . . . At the same time I was dazzled by the breech of a 75 [artillery piece] in full sunlight, by the magic of the light on the bare metal . . . . Total revolution, as man and as painter." Gassed at Verdun, he was hospitalized for a long period and was finally released from the army in 1917. That year he completed "Soldiers Playing at Cards," which he regarded as "the first picture in which I deliberately took my subject from our own epoch." By 1919 he was in what has been called his mechanical period, which was marked by a fascination for motors, gears, bearings, furnaces, railway crossings, and factory interiors. In the mid-1920s he was associated with the French formalist movement called Purism, which had been launched by the painter Amédée Ozenfant and the painter-architect Charles-Édouard Jeanneret (better known as Le Corbusier). But from then on, Léger's art was essentially figurative, and the only significant change in his style was a tendency, begun during World War II, to separate his bands of colour from his drawing and to leave them abstract.

Work in mediums other than painting

Léger took an interest in many arts besides painting. He designed sets for ballets and motion pictures, and in 1926 he conceived, directed, and produced ***Le Ballet mécanique*** ("The Mechanical Ballet"), a purely non-narrative film with photography by Man Ray and Dudley Murphy and music by the U.S. composer George Antheil. He was concerned all his life about the relationship of colour to public buildings, and he was able to realize some of his ideas in the mosaic facade of Notre-Dame-de-Toute-Grâce at Assy, in southeastern France (1949); in a mosaic for the crypt of the American memorial at Bastogne (1950); in a mural for the United Nations building in New York; and in several projects for stained-glass windows, such as those for Sacré-Coeur of Audincourt, France (1951). His desire to bring his art closer to the life of ordinary people may have been one of his reasons for deciding, in 1945, to join the French Communist Party—although in fact he never practiced the Social Realism that was then favoured by Communist leaders.

During the last years of his life his major paintings were "Les Constructeurs" and "The Great Parade." A large number of studies and variations can be linked to both pictures. Leger died on August 17, 1955, at Gif-sur-Yvette, in the suburbs of Paris. At Biot, in southern France, there is a museum devoted to his work.

MAJOR WORKS

PAINTINGS: "Nude Figures in a Wood" (1909–10; Rijksmuseum Kröller-Müller, Otterlo, The Netherlands); "Soldiers Playing at Cards" (1917; Rijksmuseum Kröller-Müller, Otterlo); "Acrobats in the Circus" (1918; Kunstmuseum, Basel, Switzerland); "The City" (1919; Philadelphia Museum of Art); "The Mechanic" (1920; Galerie Louis Carré, Paris); "Three Women" ("Le Grand Déjeuner," 1921; Museum of Modern Art, New York); "The Great Tug" (1923; Musée Fernand Léger, Biot, France); "Woman with Book" ("La Femme au livre," 1923; Nelson A. Rockefeller Collection, New York); "Composition" (1925; Solomon R. Guggenheim Museum, New York); "Three Musicians" (1925–44; Wright Ludington Collection, Santa Barbara, California); "Three Faces" (1926; private collection, New York); "The Vase" (1927; private collection, Chicago); "Still Life with Lamps" (1928; private collection, Chicago); "Divers on a Yellow Background" (1941; Art Institute of Chicago); "The Black Trellis" (1943–44; Solomon R. Guggenheim Museum, New York); "Leisure" ("Les Loisirs," 1944–49; Musée National d'Art Moderne, Paris); "The Great Julie" (1945; Museum of Modern Art, New York); "Les Constructeurs" ("The Builders," 1950; Musée Fernand Léger, Biot, France); "The Great Parade" (1954; Solomon R. Guggenheim Museum, New York).

MURALS: designs for the Swedish Ballet (1921–22; Paris); mosaics (1949; Notre-Dame-de-Toute-Grâce, Plateau d'Assy, France); memorial (1950; Bastogne, France); stained glass (1951; Sacré-Coeur, Audincourt, France); murals (1952; U.N. General Assembly auditorium, New York); stained glass (1954; church, Courfaivre, Switzerland).

BIBLIOGRAPHY. Excellent biographical and critical studies are PIERRE DESCARGUES, *Fernand Léger* (1955); and ROBERT DELEVOY, *Léger* (1962). DOUGLAS COOPER, *Fernand Leger et le nouvel espace* (1949), is a monograph with an extensive bibliography by HANNAH MULLER of the Museum of Modern Art, New York. The artist's principal writings have been collected in ***Fonctions de la peinture*** (1965).

(R.McMu.)

Leibniz, Gottfried Wilhelm

Gottfried Wilhelm Leibniz, whose universal genius has influenced such fields as logic, mathematics, mechanics, geology, jurisprudence, history, linguistics, and theology, dominated the intellectual life of Germany in the late 17th and early 18th centuries, influenced the German Idealists Johann Gottlieb Fichte and G.W.F. Hegel, reappeared as an intellectual force at the beginning of the 20th century, and became again in the 1970s, particularly through his scientific thought, one of the most relevant philosophers. His theory of monads—ultimate, simple, unextended, spiritual substances that are the basis of all composites—was the characteristic element of his Rationalist metaphysical system.

Leibniz, oil painting by A. Scheits, 1695. In the Herzog Anton Ulrich-Museum, Braunschweig.

Early life and education. Leibniz was born into a pious Lutheran family in Leipzig on July 1, 1646, near the end of the Thirty Years' War, which had laid Germany in ruins. As a child, he was educated in the Nicolai School but was largely self-taught in the library of his father, who had died in 1652. At Easter time in 1661, he entered the University of Leipzig as a law student; there he came into contact with the thought of men who had revolutionized science and philosophy—men such as Galileo, Francis Bacon, Thomas Hobbes, and René Descartes. Leibniz dreamed of reconciling—a verb that he did not hesitate to use time and again throughout his career—these modem thinkers with the Aristotle of the Scholastics. His baccalaureate thesis, ***De Principio Individui*** ("On the Principle of the Individual"), which appeared in May 1663, was inspired partly by Lutheran nominalism (the theory that universals have no reality but are mere names) and emphasized the existential value of the individual, who is not to be explained either by matter alone or by form alone but rather by his whole

Contact with new schools of science and philosophy being (entitate *tota*). This notion was the first germ of the future "monad." In 1666, he wrote De Arte *Combinatoria* ("On the Art of Combination"), in which he formulated a model that is the theoretical ancestor of some modern computers: all reasoning, all discovery, verbal or not, is reducible to an ordered combination of elements, such as numbers, words, sounds, or colours.

After completing his legal studies in 1666, Leibniz applied for the degree of doctor of law. He was refused because of his age and consequently left his native city forever. At Altdorf—the university town of the free city of Numberg—his dissertation De Casibus Perplexis ("On Perplexing Cases") procured him the doctor's degree at once, as well as the immediate offer of a professor's chair, which, however, he declined. During his stay in Nurnberg, he met Johann Christian, Freiherr von Boyneburg, one of the most distinguished German statesmen of the day. Boyneburg took him into his service and introduced him to the court of the prince elector, the archbishop of Mainz, Johann Philipp von Schonborn, where he was concerned with questions of law and politics.

King Louis XIV of France was a growing threat to the German Holy Roman Empire. To ward off this danger and divert the King's interests elsewhere, the Archbishop hoped to propose to Louis a project for an expedition into Egypt; because he was using religion as a pretext, he expressed the hope that the project would promote the reunion of the church. Leibniz, with a view toward this reunion, worked on the Demonstrationes Catholicae. His research led him to situate the soul in a point—this was new progress toward the monad—and to develop the principle of sufficient reason (nothing occurs without a reason). His meditations on the difficult theory of the point were related to problems encountered in optics, space, and movement; they were published in 1671 under the general title Hypothesis *Physica* Nova ("New Physical Hypothesis"). He asserted that movement depends, as in the theory of the German astronomer Johannes Kepler, on the action of a spirit (God).

Period in Paris. In 1672 the Elector sent the young jurist on a mission to Paris, where he arrived at the end of March. In September, Leibniz met with Antoine Arnauld, a Jansenist theologian (Jansenism was a nonorthodox Roman Catholic movement that spawned a rigoristic form of morality) known for his writings against the Jesuits. Leibniz sought Arnauld's help for the reunion of the church. He was soon left without protectors by the deaths of Freiherr von Boyneburg in December 1672 and of the Elector of Mainz in February 1673; he was now, however, free to pursue his scientific studies. In search of financial support, he constructed a calculating machine—a perfected version of an earlier machine developed by Blaise Pascal, a French scientist and writer—and presented it to the Royal Society during his first journey to London, from January to March 1673.

His circle of friends was also constantly expanding. While in London, he met many of the noted scientists and mathematicians, including Robert Boyle, John Pell, and possibly John Collins, a friend of the physicist Sir Isaac Newton. In Paris, he had already met Christiaan Huygens, a Dutch mathematician and astronomer who had first helped him with mathematics. Arnauld introduced him to many important Jansenists, particularly Étienne Périer, a nephew of Pascal who, in the summer of 1674, entrusted Leibniz with the unpublished papers of Pascal. During the first part of 1675, he spent some time with Nicolas Malebranche, another Cartesian philosopher and geometer, and in September 1675, he befriended Ehrenfried Walter von Tschirnhaus, a German mathematician.

Foundations of calculus and the dynamic theory of motion

Late in 1675 Leibniz laid the foundations of both integral and differential calculus. With this discovery, he ceased to consider time and space as substances—another step closer to monadology. He began to develop the notion that the concepts of extension and motion contained an element of the imaginary, so that the basic laws of motion could not be discovered merely from a study of their nature. Nevertheless, he continued to hold that extension and motion could provide a means for explaining and predicting the course of phenomena. Thus, contrary to Descartes, Leibniz held that it would not be contradictory to posit that this world is a well-related dream. If visible movement depends on the imaginary element found in the concept of extension, it can no longer be defined by simple local movement; it must be the result of a force. In criticizing the Cartesian formulation of the laws of motion, known as mechanics, Leibniz became, in 1676, the founder of a new formulation, known as dynamics, which substituted kinetic energy for the conservation of movement. At the same time, beginning with the principle that light follows the path of least resistance, he believed that he could demonstrate the ordering of nature toward a final goal or cause.

The Hanoverian period. Leibniz continued his work in Paris, but he was still without an income-producing position. By October 1676, however, he had accepted a position in the employment of John Frederick, the duke of Braunschweig-Liineburg (Brunswick-Liineburg; including the duchies of Zelle and Hanover), with whom he had been corresponding for some time; against his wishes he was forced to leave the French capital for Hanover by way of London and the Netherlands. In London he visited Collins, who allowed him to see some unpublished papers of James Gregory, a Scottish mathematician, and of Newton. In the Netherlands, he met the naturalists Jan Swammerdam and Antonie von Leeuwenhoek; he also stopped at The Hague, where he had long conversations with the Jewish Rationalist Benedict de Spinoza. He finally arrived in Hanover in mid-December.

Service under John Frederick. John Frederick, a convert to Catholicism from Lutheranism in 1651, had become duke of Hanover in 1665. He appointed Leibniz librarian, but, beginning in February 1677, Leibniz solicited the post of councillor, which he was finally granted in 1678. It should be noted that, unlike Descartes, Leibniz had no fortune, nor did he belong to a religious order as did Malebranche; and unlike Huygens he had not been granted a pension: among the great philosophers of his time, he was the only one who had to earn a living. As a result, he was always a jack-of-all-trades to royalty. In 1677 he was involved in simultaneous discussions about the reunion of the church with Bishop Cristóbal Rojas de Spínola, an envoy of the Emperor, and with Nicolaus Steno, a prelate who had been a scientist specializing in geology. In February 1679, he started a correspondence with Jacques Bénigne Bossuet, a French Roman Catholic bishop and renowned orator, that continued until 1702.

Jack-of-all-trades to royalty

For the negotiations conducted before the treaties of Nijmegen in 1678 and 1679, which made Louis XIV the arbitrator of Europe, Leibniz tried in vain to obtain the rank of ambassador for the members of the delegation from Hanover. Trying to make himself useful in all ways, Leibniz proposed that he inspect cloisters, that education be made more practical, that academies be founded; he worked on hydraulic presses, windmills, lamps, submarines, clocks, and a wide variety of mechanical devices; he devised a means of perfecting carriages and experimented with phosphorus (which Hennig Brand, a German alchemist, had just discovered). He also developed a water pump run by windmills, which ameliorated the exploitation of the mines of the Harz Mountains, and he worked in these mines as an engineer frequently from 1680 to 1685. Leibniz is considered to be among the creators of geology because of the observations he compiled there, including the hypothesis that the earth was at first molten; this hypothesis, from which Georges-Louis Leclerc, comte de Buffon, a French naturalist, later drew his inspiration, was presented in Protogeae, which was not published until 1749. These many occupations did not stop his work in mathematics: In March 1679 he perfected the binary system of numeration (*i.e.*, using two as a base), and at the end of the same year he proposed the basis for analysis situs, now known as general topology, a branch of mathematics that deals with selected properties of collections of related physical or abstract elements. He was also working on his dynamics and his philosophy, which was becoming increasingly anti-Cartesian. At this point, Duke John Frederick died on January 7, 1680, and his brother, Ernest Augustus I, succeeded him.

Service under Ernest Augustus. France was growing more intolerant at home—from 1680 to 1682 there were harsh persecutions of the Protestants that paved the way for the revocation of the Edict of Nantes on October 18, 1685—and increasingly menacing on its frontiers, for as early as 1681, despite the reigning peace, Louis XIV took Strasbourg and laid claim to ten cities in Alsace. France was thus becoming a real danger to the empire, which had already been shaken on the east by a Hungarian revolt and by the advance of the Turks, who had been stopped only by the victory of John III Sobieski, king of Poland, at the siege of Vienna in 1683. Leibniz served both his prince and the empire as a patriot. He suggested to his prince a means of increasing the production of linen and proposed a process for the desalinization of water; he recommended classifying the archives and in 1682 suggested publishing the periodical *Acta Eruditorum*, which was to become part of the *Journal des Savunts*. For the empire, in 1681, he made an analysis of the current stale of affairs; in 1683 he wrote, in both French and Latin, a violent pamphlet against Louis XIV, entitled *Mars Christianissimus* ("The Most Christian War God"); in the same year he expressed his thoughts on the war with Hungary, in the form of notes; and in 1684 he stated precisely the *Raisons touchant la guerre ou l'accommodement avec la France* ("Reasons concerning War or Settlement with France").

Development of Rationalistic system

During this same period Leibniz continued to perfect his metaphysical system through research into the notion of a universal cause of all being, attempting to arrive at a starting point that would reduce reasoning to an algebra of thought. He also continued his developments in mathematics; in 1681 he was concerned with the proportion between a circle and a circumscribed square and, in 1684, with the resistance of solids. In the latter year he published *Nova Methodus pro Maximis et Minimis* ("New Method for the Greatest and the Least"), which was an exposition of his differential calculus. Newton had also discovered calculus as early as 1665, but he had not published his findings; he had only hinted at them to Gregory and Collins. Leibniz' article, which appeared in *Acta,* and the discovery that he had seen some of Newton's writings opened up the question of the priority of the invention of calculus, one of the most famous disputes of the 18th century.

Leibniz' noted *Meditationes de Cognitione, Veritate et Ideis (Reflections on Knowledge, Truth, and Ideas)* appeared at this time and defined his theory of knowledge: things are not seen in God—as Malebranche suggested—but rather there is an analogy, a strict relation, between God's ideas and man's, an identity between God's logic and man's. In February 1686, Leibniz wrote his *Discours de métaphysique (Discourse on Metaphysics).* In the March publication of *Acta,* he disclosed his dynamics in a piece entitled *Brevis Demonstratio Erroris Memborabilis Cartesii et Aliorum Circa Legem Naturae* ("Brief Demonstration of the Memorable Error of Descartes and Others about the Law of Nature"). A further development of Leibniz' views, revealed in a text written in 1686 but long unpublished, was his generalization concerning propositions that in every true affirmative proposition, whether necessary or contingent, the predicate is contained in the notion of the subject. Contingent propositions (stating what can be or not be), which are the foundation of liberty, although they do not appear to be identified with the subject, nevertheless tend toward such an identity in the same way that a curve approaches but never reaches its asymptote. It can be said that, at this time, with the exception of the word monad (which did not appear until 1695), his philosophy of monadology was defined. In January 1687 he began corresponding with Pierre Bayle, the French philosopher and encyclopaedist who edited the influential journal *Nouvelles de la république des lettres*; ("News of the Republic of Letters"); in his letters, Leibniz established his independence from the Cartesians. This correspondence anticipated the *Essais de théodicée sur la bontk de Dieu, la libertk de l'homme et l'origine du mal* (1710; Eng. trans., *Theodicy,* 1952), his only large book on philosophy published in his lifetime.

In 1685 Leibniz was named historian for the House of Brunswick and, on this occasion, *Hofrat* ("court adviser"). His job was to prove, by means of genealogy, that the princely house had its origins in the House of Este, an Italian princely family, which would allow Hanover to lay claim to a ninth electorate. In search of these documents, Leibniz began travelling in November 1687. Going by way of southern Germany, he arrived in Austria, where he learned that Louis XIV had once again declared a state of war; in Vienna, he was well received by the Emperor; he then went to Italy. Everywhere he went, he met scientists and continued his scholarly work. The *Acta* published, in February 1689, his essays on the movement of celestial bodies and, in April 1689, on the duration of things. In November of that year he read Newton's *Principia* for the first time. He returned to Hanover in mid-July 1690. His efforts had not been in vain. In October 1692 Ernest Augustus obtained the electoral investiture.

Work on a history of the Earth

Until the end of his life, Leibniz continued his duties as historian. He did not, however, restrict himself to a genealogy of the House of Brunswick; he enlarged his goal to a history of the Earth, which included such matters as geological events and descriptions of fossils. He searched by way of monuments and linguistics for the origins and migrations of peoples; then for the birth and progress of the sciences, ethics, and politics; and, finally, for the elements of a *historia sacra.* In this project of a universal history, Leibniz never lost sight of the fact that everything interlocks. Even though he did not succeed in writing this history, his effort was influential because he devised new combinations of old ideas and invented totally new ones.

In 1691 Leibniz was named librarian at Wolfenbüttel. He renewed his correspondence with Bossuet and propagated his system and his discoveries by means of articles in scientific journals. In 1695 he explained a portion of his dynamic theory of motion in the *Système nouveau* ("New System"), which treated the relationship of substances and the pre-established harmony between the soul and the body: God does not need to bring about man's action by means of his thoughts, as Malebranche asserted, or to wind some sort of watch in order to reconcile the two; rather, the Supreme Watchmaker has so exactly matched body and soul that they correspond—they give meaning to each other—from the beginning.

In 1697, *De Rerum Originatione (On the Ultimate Origin of Things)* tried to prove that the ultimate origin of things can be none other than God. In 1698, *De Ipsa Natura* ("On Nature Itself") explained the internal activity of nature in terms of Leibniz' theory of dynamics.

All of these writings opposed Cartesianism, which was judged to be damaging to faith. Plans for the creation of German academies followed in rapid succession. With the help of his friend the electress Sophia Charlotte, daughter of Ernest Augustus and soon to become the first queen of Prussia (January 1701), the German Academy of Sciences in Berlin was founded on July 11, 1700; the academy, however, had no financial support until the time of Frederick II the Great, who became king of Prussia in 1740.

Service under George Louis. On January *23,* 1698, Ernest Augustus died, and his son, George Louis, succeeded him. Leibniz found himself confronted with an uneducated, boorish prince, a reveller who kept him in the background. Leibniz took advantage of every pretext to leave Hanover; he was constantly on the move; his only comfort lay in his friendship with Sophia Charlotte and her mother, Princess Sophia. Once again, he set to work on the reunion of the church: in Berlin, it was a question of uniting the Lutherans and the Calvinists; in Paris, he had to subdue Bossuet's opposition; in Vienna (to which Leibniz returned in 1700) he enlisted the support of the Emperor, which carried great weight; in England, it was the Anglicans who needed convincing.

Work toward the reunion of the church

The death in England of William, duke of Gloucester, in 1700 made George Louis, great-grandson of James I, a possible heir to the throne. It fell to Leibniz, jurist and historian, to develop his arguments concerning the rights of the House of Braunschweig-Liineburg with respect to this succession. He communicated with many important Englishmen: John Toland, a Deist who accompanied an ambassador sent to Hanover in June 1702; Gilbert Burnet, bishop of Salisbury, head of the Anglican Church; the poet and essayist Joseph Addison; and Lady Damaris Masham, at whose house John Locke, the Empiricist, died in 1704. Since 1696, Leibniz had been annotating Locke's *Essay Concerning Human Understanding;* Locke's death, however, dissuaded him from publishing these notes.

The *Théodicée* and the *Monadologia*

The War of the Spanish Succession began in March 1701 and did not come to a close until September 1714, with the Treaty of Baden. Leibniz followed its episodes as a patriot hostile to Louis XIV. His fame as a philosopher and scientist had by this time spread all over Europe; he was named a foreign member by the Academy of Sciences of Paris in 1700 and was in correspondence with most of the important European scholars of the day. If he was publishing little at this point, it was because he was writing *Théodicée,* which was published in 1710. In this work he set down his ideas on divine justice: metaphysical evil is inevitable because it is nothing other than the finite nature inherent in every creature; each creature is defined by his place in creation and by everything that he is fated to experience in virtue of his complete identity; therefore, each creature acts according to his own nature without the least material hindrance from others, with whom he is in tune in a universal harmony; each creature is autonomous and, if it is endowed with reason, free. Evil, moral or physical, is in no way positive; it is a lack that, like dissonance in music, increases the beauty of the whole. Finally, he held that God chose the best of all possible worlds.

Leibniz was impressed with the qualities of the Russian tsar Peter the Great, and in October 1711 the ruler received him for the first time. Following this, he stayed in Vienna until September 1714; and during this time the Emperor promoted him to the post of *Reichhofrat* ("adviser to the empire") and gave him the title of *Freiherr* ("baron"). About this time he wrote the *Principes de la nature et de la Grâce fondés en raison,* which inaugurated a kind of pre-established harmony between these two orders. Further, in 1714 he wrote the *Monadologia,* which synthesized the philosophy of the *Théodicée.*

In August 1714, the death of Queen Anne brought George Lewis to the English throne under the name of George I. Returning to Hanover, where he was virtually placed under house arrest, Leibniz set to work once again on the *Anrzales Imperii Occidentis Brunsvicenses* (1843–46; "Braunschweig [Brunswick] Annals of the Western Empire"). He also maintained a lengthy correspondence with Samuel Clarke, a close associate of Newton, about the concepts of space and time. At Bad-Pyrmont, he met with Peter the Great for the last time in June 1716. From that point on, he suffered greatly from gout and was confined to his bed. He died on November 14, 1716.

Leibniz was a man of medium height with a stoop, broad-shouldered but bandy-legged, as capable of thinking for several days sitting in the same chair as of travelling the roads of Europe summer and winter. He was an indefatigable worker whose manuscripts have not yet all been published, a universal letter writer (he had more than 600 correspondents), a patriot and cosmopolitan, a great scientist, and one of the most powerful spirits of Western civilization.

MAJOR WORKS

METAPHYSICS, EPISTEMOLOGY, AND THEOLOGY: *Disputatio Metaphysica de Principio lndividui* (1663); *Confessio Naturae Contra Atheistas* (1669); *Defensio Trinitatis per Nova Reperta Logica* (1669, printed 1841); "Dissertatio Praeliminaris" for an edition of *Marii Nizolii, . . . de Veris Principiis . . . Contra Pseudophilosophos Libri IV* (1670); *Meditationes de Cognitione, Veritate, et Ideis* (1684); *Discours de me'taphysique* (written 1686, printed 1846; *Discourse on Metaphysics,* 1902; new version, 1953 and 1961); *Brevis Demonstratio Erroris Memorabilis Cartesii et Gliorum Circa Legem Naturae Secundum Quam Volunt a Deo eandem Semper Quantitatem Motus Conservari* (1686); *Systema Theologicum* (written 1686, printed 1819; *A System of Theology,* 1850); *Système nouveau de la nature et de la communication des substances, aussi bien que de I'union qu'il y a entre l'âme et le corps* (1695); *Animadversiones in Partem Generalem Principiorum Cartesianorum* (drafts written 1697, printed 1844 and 1880); *De lpsa Natura, sive de Vi Insita, Actionibusque Creaturarum* (1698); *Conside'rations sur la doctrine d'un esprit universe1 unique* (written 1702 but not printed until 1839); *Nouveaux essais sur I'entendement humain* (written 1700–05, printed 1765; *New Essays Concerning Human Understanding,* 1898; new edition 1916); *Essais de théodicée sur la bonté de Dieu, la liberté de l'homme et l'origine du mal,* 2 vol. (1710; *Theodicy: Essays on the Goodness of God, the Freedom of Man, and the Origin of Evil,* 1952); *Causa Dei Asserta per Justitiam Ejus, cum Caeteris Ejus Perfectionibus Cunctisque Actionibus Conciliatam* (1710); *Principes de la nature et de la grâce fonde's en raison* (written 1714, printed 1718); *Principia Philosophiae, More Geometrico Demonstrata* (written 1714, printed 1720–21 and generally known as *Monadologia* or *La Monadologie; The Monadology,* 1898, 1925; new version 1930); *Entretien de Philarète et d'Ariste* (written *c.* 1715, printed 1720); *A Collection of Papers, Which Passed Between the Late Learned Mr. Leibnitz and Dr. Clarke, in the Years 1715 and 1716,* namely, the Leibniz–Samuel Clarke correspondence, with Leibniz' text in the original French, 2 parts (1717; new edition, *The Leibniz–Clarke Correspondence,* 1956).

LOGIC AND MATHEMATICS: *Dissertatio de Arte Combinatoria* (1666, with unauthorized republication as *Ars Combizatoria,* 1690); *Nova Methodus pro Maximis et Minimis, Itemque Tangentibus, Quae nec Fractas, nec Irrationales Quantitates Moratum, et Singulare pro Illis Calculi Genus* (1684); *De Geometria Recondita et Analysi Indivisibilium et Infinitorum* (1686); *Tentamen Anagogicum: Essai anagogique dans la recherche des causes* (*c.* 1690–95, printed 1890).

PHYSICS AND PRACTICAL SCIENCES: *Hypothesis Physica Nova* (1671); *Protogaea, sive de Prima Facie Telluris et Antiquissimae Historiae Vestigiis in Ipsis Naturae Monumentis Dissertatio* (written 1691 and published 1749); *Specimen Dynamicum* (1695); *Relatio . . . de Antidysenterico Americano* (1696); edition of *Miscellanea Berolinensia ad Incrementum Scientiarum* (1710); *Remarques sur le discours de Mr. H. S. . . . , touchant la manière de gouverner les horloges à pendule et les monfres à spirale* (1714).

LAW AND CONTEMPORARY POLITICS: *Specimen Quaestionum Philosophicarum ex Jure Collectarum* (1664); *Disputatio Juridic de Conditionibus* (1665); *Disputatio Inauguralis de Casibus Perplexis in Jure* (1666); *Nova Methodus Discendae Docendaeque Jurisprudentine* (1667); *Specimen Demonstationum Politicarum pro Eligendo Rege Polonorum* (1669); *Bedenken, welchergestalt Securitas Publica lnterna et Externa und Status praesens jetzigen Umständen nach im Reich auf festen Fuss zu stellen* (1670); *De Expeditione Aegyptiaca Regi Franciae Proponenda Justa Dissertatio* (1672; *A Summary Account of Leibnitz's Memoir, Addressed to Lewis the Fourteenth,* 1803), with synopsis *Consilium Aegyptiacum* (also 1672, both finally printed 1864); *Politische Betrachtung iiber gegenwaertigen Krieges-Zustand, zwischen Frankreich und Ober- und Nieder Teutsch-Land* (1674); *De Jure Suprematus ac Legationis Principum Germaniae,* published under the pseudonym Caesarinus Fuerstenerius (1677, enlarged edition 1678); *Entretien de Philarète et d'Eugène sur la question du temps, agite'e à Nimwègue, touchant le droit d'ambassade des électeurs et princes de l'Empire* (1678); *Mars Christianissimus* (1683); *De la tolerance des religions: de M. de Leibniz et réponses de M. de Pellisson* (1692); edition of *Codex Juris Gentium Diplomaticus* (1693; with appendix *Mantissa Codicis . . . ,* 1700); *Novissima Sinica Historiam Nostri Temporis Illustratura* (1697; 2nd ed., 1699); *Manifeste contenant les droits de Charles III, roi d'Espagne, et les justes motifs de son expe'dition* (1703); *Bericht iiber die Reunionssache an Clemens XI* (1710, printed 1903).

HISTORICAL RESEARCH: *Lettre sur la connexion des maisons de Brunsvic et d'Este* (1695); edition of J. Burchard, *Specimen Historiae Arcanae, Anecdotae de Vita Alexandri VI Papae* (1696 and 1697); edition of Albericus Trium Fontium (Aubry de Trois-Fontaines), *Chronicon* (1698); collection of *Accessiones Historicae, Quibus Utilia Superiorum Temporum Historiis Illustrandis Scripta Monumentaque Nondum Hactenus Edita inque Iis Scriptores Diu Desiderafi Continentur* 4 part (1698 and 2 vol. 1700); edition of *Scriptores rerum Brunsvicensium,* 3 vol. 1707–11); *Dissertatio de Numis Gratiani* (1709); *De Origine Francorum Disquisitio* (1715); collection of material for *Anrzales Imperii Occidentis Brunsvicenses* printed 1843–46).

PHILOLOGY AND GENERAL SYNTHESIS: *Dissertatio de Variis Linguis* (1715); *Collectanea Etymologica*, 2 pt. (1717); materials for a *Scientia Generalis* and for a related *Characteristica* drafted from *c.* 1670 onward (printed as a collection 1890).

BIBLIOGRAPHY

Collected editions of Leibniz' works: Editions, far from complete, of Leibniz' collected works were undertaken by R.E. RASPE (1765); by L. DUTENS, 6 vol. (1768); by G.H. PERTZ *et al.*, 13 vol. (1843–63); by A. FOUCHER DE CAREIL, 7 vol. out of 20 planned (1859–75); by O. KLOPP, 11 vol. (1864–84); by C.J. GERHARDT, 14 vol. (1850–63, 1875–90). The Berlin Academy, after plans concerted with the French Academy from 1900, began a definitive edition in 1923, and it is still in progress. Selections in English translation from Leibniz' philosophical writings appeared in 1890, in 1934, and in 1956; from his mathematical manuscripts in 1920; and from his logical papers in 1966.

Biographical and critical studies: G.G. GUHRAUER, *Gottfried Wilhelm, Freiherr v. Leibniz: Eine Biographie*, 2 vol. and suppl. (1842–46; with partial Eng. trans. by J.D. MACKIE, *Life of G.W. von Leibniz*, 1845), remains the fundamental work. WILHELM TOTOK and CARL HAASE, *Leibniz: Sein Leben, sein Werken, seine Welt* (1966), completes and corrects Guhrauer in several respects. KURT MULLER and GISELA KRONERT, *Leben und Werk von Gottfried Wilhelm Leibniz: Eine Chronik* (1969), gives references to the fundamental documentation. YVON BELAVAL, *Leibniz: Initiation à sa philosophie*, 3rd ed. (1969), places the philosophical development of Leibniz in the context of the history of his time. Still of value is the great work of BERTRAND RUSSELL, *A Critical Exposition of the Philosophy of Leibniz* (1900).

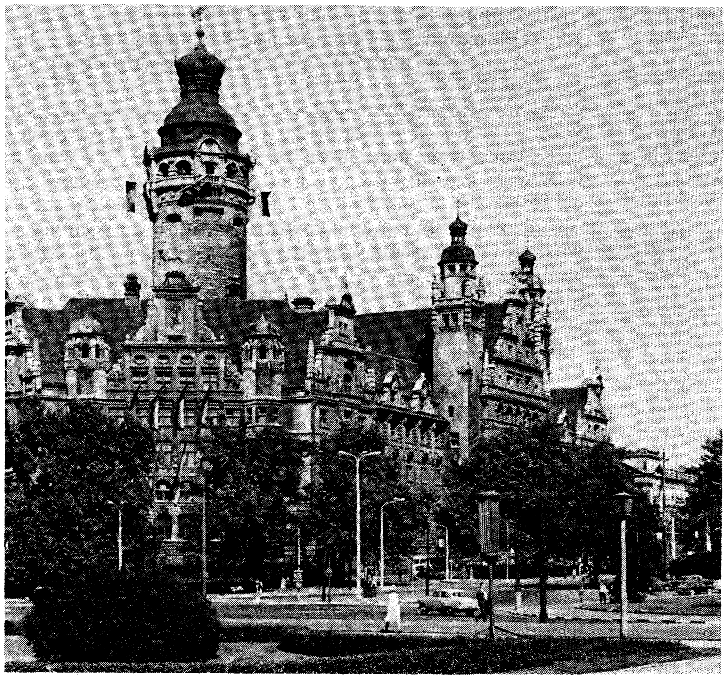
(Y.B.)

Leipzig

The character of the city

The home of about 566,600 persons in the mid-1970s, Leipzig is second only to East Berlin, the capital, among the cities of the German Democratic Republic. It lies in the south of the country, at the heart of the low-lying, fertile Leipzig Basin with its deposits of lignite (brown coal). Although encircled by a pleasant green belt of parks and gardens (the Schrebergärten), the city is a major industrial centre and transport junction and the core of the Halle–Leipzig metropolitan agglomeration. The fur-dressing and book-manufacturing industries of Leipzig are well known, but its contemporary industrial structure also includes emphasis on heavy constructional engineering and the electrical, textile, clothing, chemical, and machine tool industries. The annual Leipzig Fair is probably the most important forum for international East–West trade, and the city is also an intellectual centre, with a university (renamed Karl-Marx-Universität Leipzig in 1953) dating back to 1409. A quarter of what was known throughout Europe as an exceptionally beautiful city was destroyed in the last years of World War II, but Leipzig has since been rebuilt in the modern style. In addition to the restored historic buildings—notably the Altes Rathaus (Old Town Hall), the Alte Handelsborse (Old Commercial Exchange), the old residential and market squares, Auerbach's Cellar, and the 13th-century Church of St. Thomas (Thomaskirche)—the skyline of the modern city includes the new university tower and new hotels and commercial and residential buildings. (For related information see GERMAN DEMOCRATIC REPUBLIC.)

History. Located in the middle of a basin covered thickly with the windblown deposits known as loess, Leipzig developed from a small community on the periphery of the area of German settlement. It enters recorded history in AD 1015 as the fortified town of Urbs Libzi and was granted municipal status by 1170. Its position on important trade routes soon promoted a flourishing foreign trade. Its two annual markets, at Easter and at Michaelmas, were raised in 1497 to the rank of imperial fairs. Additional economic privileges enabled Leipzig to become the foremost German commercial centre by around 1700, a development that, in turn, promoted the growth of the network of roads converging on the town. Leipzig's focal geographical situation had another, less fortunate consequence: several important battles were fought in or near it. These included two at the village of Breitenfeld (now a suburb) in 1631 and 1642 and one at Lützen in 1632, during the Thirty Years' War; and in particular the Battle of Leipzig (or Battle of the Nations) in October 1813, in the Napoleonic Wars.



The Neues Rathaus (New Town Hall) in Leipzig, built 1899–1905 on the site of the Pleissenburg citadel in the southwestern corner of the inner town. The round tower of the former citadel is seen at upper left.

Karl Droste—Bavaria Verlag

The town's enviable economic status stimulated a notable cultural life, based particularly on the early development of the printing industry but also including the musical efflorescence associated with Johann Sebastian Bach. Trade continued to be the most important economic activity in the town (which had a population of about 70,000 by mid-19th century), the main commodities traded being books, furs, yarns, and textiles. As early as 1839 the first German overland railway was opened between Leipzig and Dresden, and the concomitant growth of banks provided capital for the growing textile and metallurgical industries. By the end of the 19th century, the contemporary pattern of heavy constructional engineering and machine tool enterprises had been established.

The development of industry also resulted in Leipzig's becoming a major centre of the German labour movement. After the devastation of World War II, the restoration and reconstruction of the city and its political and social institutions were carried out under the Communist policies of the German Democratic Republic. With renewed international attention being paid to the Leipzig Fair and other exhibitions and congresses held in the city, Leipzig continues to play an important role among European cities.

Location and boundaries. Leipzig covers 54 square miles (141 square kilometres) at the confluence of the Weisse Elster, Pleisse, and Parthe rivers; the city centre is 387 feet (118 metres) above sea level. The surrounding countryside is a plain, the original natural forest cover of which since the Middle Ages has been replaced by intensive farming on the predominantly brown soils. Within the city limits, the woodlands—Ratsholz, Nonne, Rosental, and Stadtforst—along the riverbanks have been partly converted to parks and fulfill an important recreational function; Leipzig's surroundings otherwise have few scenic attractions. To the north, the city boundary reaches out to the Halle–Dresden *Autobahn* (expressway); the Berlin–Munich *Autobahn* runs to the west; to the south, the city is edging toward the opencast lignite mines of Bohlen and Espenhain; and fertile farmlands lie to the east.

Demographic structure

The people. As early as the 17th century, Leipzig was the home of 20,000 persons. The population reached 41,000 by 1841 and 107,000 in 1871, when Leipzig became officially a city. The growth was accompanied by a corresponding increase in the urban area, yet at its peak, with 717,000 in 1931, Leipzig was one of Germany's most densely populated cities. Having suffered severely in World War II, Leipzig had only 608,000 inhabitants in 1946; and as an indirect result of the war (in terms of unfavourable age and sex distribution) the population was still decreasing slightly in the mid-1970s, when it numbered about 567,000—and this in spite of an in-migration of labour. More than 40 percent of the resident population is economically inactive because of extreme youth or age: about 20 percent are children and the other 20 percent retired. There are about 125 women for each 100 men. Of the 342,000 persons gainfully employed early in the 1970s, more than 125,000 worked in industry; some 30,000 were commuters.

Economic life. Leipzig generates about 5 percent of the entire industrial gross national product of the German Democratic Republic and half the industrial output of its district. There are almost 800 enterprises, about 30 of them very large, and half the work force is employed in metalworking. Products range from heavy construction equipment to computers, and every third book published in the German Democratic Republic is manufactured in the city.

Economic life is greatly influenced by the Leipzig Fair, which each spring attracts some 600,000 visitors (including scientists and businessmen) from all over the world. The fair has more than 420,000 square yards (350,000 square metres) of floor space. The international fur auction is also important.

Administration. Leipzig is an important political and administrative centre: it is the seat of administration of the district and of the municipal and rural *Kreise* (equivalent to the U.S. county) bearing its name. Early in the 1970s there were nearly 600 municipal district council members and 200 town councillors, representing a wide range of occupational backgrounds and a multiplicity of political and mass organizations. In addition, nearly 70 other permanent commissions were active in public affairs. Citizens were also active as lay judges and members of parents' advisory councils.

Transport services

Services. Leipzig's main railway station is one of the largest terminals and one of the most important passenger stations in central Europe. About 125,000 travellers pass through it each day, and their number rises by about 50,000 when the fair is in session. Leipzig is the focus of many railway lines and major roads, and there are two small airports, Leipzig–Mockau and Leipzig–Schkeuditz. Internal transportation is provided by streetcars (carrying 270,000 passengers daily), trolley buses (11,000), motor buses (33,000), and private and state-owned taxis. Parks and gardens cover, in all, an area of 612 acres (248 hectares).

The 25 or so hospitals provided about 128 beds for each 10,000 inhabitants by the early 1970s. There were also large numbers of ancillary health centres and nearly 30 homes for older persons. Schools included almost 200 kindergartens and more than 80 general education institutions, three-quarters of them general technical secondary schools. There were also 30 or more vocational training schools.

Cultural life. Leipzig is a major European intellectual and cultural centre. The university—attended by Goethe and Wagner, among others—has been joined by a number of other institutions of higher education. The academies of dramatic art, musical history, graphic arts, and bookmaking are well-known internationally; and the physical culture academy is largely responsible for East Germany's important showing in international sport. The Deutsche Bucherei (German Library) was set up as a national library and since 1913 has been collecting the entire range of German literary work. The Comenius-Bucherei (Comenius Library), founded in 1871, has become Europe's largest library specializing in education. The university library and the Stadt- und Bezirksbibliothek Leipzig (Leipzig City and District Library) and the Stadtarchiv (City Archives) are also of major significance.

Historical sites and museums (including the Museum für Geschichte der Stadt Leipzig, or historical museum, in the Altes Rathaus) are visited by well over 1,000,000 people each year. Musical traditions are carried on by the Thomaner Choir, the Gewandhaus Orchestra (Leipziger Gewandhausorchester), and the Radio Symphony Orchestra. Cultural centres and a fine opera house (1963) also ensure that cultural life flourishes. Finally, Leipzig is one of Europe's great convention cities, and economic, scientific, and sports congresses attract more than 2,000,000 people each year. Sports are particularly popular, and the central stadium seats more than 100,000 spectators.

BIBLIOGRAPHY. Accurate and detailed statistics on the history, economy, culture, and social life of the city and district of Leipzig may be found in the two annual *Statistische Jahrbiicher.* Detailed individual articles are published in the scientific periodicals *Geographische Berichte, Sachsische Heimatblätter,* and also in the *Wissenschaftliche Zeitschrift* of Karl-Marx-Universitat Leipzig. A standard comprehensive publication is the volume commemorating the decennial of the Geographical Society of the German Democratic Republic, *Das Leipziger Land* (1964), which contains physical, economic, and geographical studies. Another notable publication is WALTER FELLMANN and KARL CZOK, *Leipzig* (1971), a city guide, in German, that contains important information on the landscape, history, economy, and culture.

(H.-J.K./R.E.H.M.)

Lena River

The Lena (meaning in Yakut "Big River") is, in terms of water volume, the second largest river in the Soviet Union; in terms of length it is one of the largest rivers in the world, flowing 2,730 miles (4,400 kilometres) from its source in a small lake in the mountains west of Lake Baikal, in Central Asia, to the mouth of its delta on the Arctic Laptev Sea. The area of the river basin is about 961,000 square miles (2,490,000 square kilometres).

Physiography. The Lena has three main sections, each of about 900 miles (1,450 kilometres): the upper section from the source to the Vitim tributary; the middle course from the Vitim to the mouth of the Aldan; and the lower section from the Aldan to the Laptev Sea.

In the section from the source to the Vitim, the Lena flows in a deep-cut valley, the rocky and steep slopes of which are raised above the river, often up to 1,000 feet (300 metres). These slopes are formed on the right bank by the ledges of the Northern-Baikal Upland. The width of the river valley varies from one to six miles, but here and there it narrows in ravines to only 700 feet. The best known ravine, named Pyany Byk (Drunken Bull), is situated 147 miles below Kirensk.

In the first 110 miles from its source the Lena has a great number of shallow, rocky shoals, which occur as far as the Kirenga tributary. Below the mouth of the Kirenga the depth of the riverbed in the pools increases to 30 feet, and the rate of the flow decreases with a decrease in gradient. In the middle course, from the mouth of the Vitim to the Aldan, the Lena becomes a large, deep river. The water supply increases, especially after the junction with the Olyokma, and the width of the river reaches one mile. From the mouth of the Vitim to the Olyokma, the river skirts the Patom Plateau, on the right bank, forming an enormous bend; the width of the valley increases in places to 20 miles. Its slopes are gentle and green with forests, and along them run well-marked terraces formed by rivers. In this section of the valley there occurs an extensive water meadow, in which small lakes are scattered.

Scenic attractions

Below the Olyokma, the character of the valley changes sharply. In a stretch of about 400 miles, from Olyokma to Pokrovsk (60 miles above Yakutsk), the Lena flows along the bottom of a narrow valley with sheer, broken slopes. The enormous rocks sometimes resemble the ruins of a castle, or columns, or the figures of people and animals; and the area is a favourite place for tourists and rock climbers. In this section the Lena receives its largest tributaries. In addition to the Vitim and the Aldan, these include the Great Patom and the Olyokma, flowing in on the right, and the Nyuya, on the left. Below the mouth of the Aldan the width of the valley of the Lena extends 12 to 16 miles, and the width of the water meadow reaches four to nine miles. Here the Lena enters into the borders of the Central Yakut Plain. The water meadow abounds with lakes, often marsh-ridden, and the riverbed divides, forming many islands and branches. The depth is from 50 to 70 feet, but there are many shallow sections with sandbanks.

In the lower section between the island of Zholdongo and the beginning of the delta the Lena Valley becomes narrow, its width being about one mile. The islands of the delta are low-lying, and covered with peat bogs; some fossilized ice may be found.

Climate. The climatic features of the Lena Basin are determined by its location well inside the Asian continent. In winter a powerful anticyclone is formed, the spur of which occupies all of Eastern Siberia. Because of the anticyclone the winter is notable for its clear skies and prevailing calm. The frosts reach —76" to —94" F (—60" to —70" C), the average monthly air temperature in January being —22" to —40" F. In July averages range between 50° and 68" F (10" to 20° C). Due to its remoteness from the sea, the amount of precipitation in the basin is slight. Only in the southern mountains does the yearly total reach 24–28 inches; in most of the basin it is 8–16 inches and in the delta four inches. Between 70 and 80 percent of the precipitation falls in the summer in the form of steady rain. In winter, on the average, not more than two inches of snow fall, so that the snow cover is very slight.

The very cold temperatures result in large accumulations of ice in the form of icy knolls. These are formed of groundwaters that accumulate between the layers of soil frozen permanently over many years and layers of seasonally frozen soil. Sometimes the icy knolls disintegrate with considerable force, scattering ice blocks. The riverbeds and floodlands are also covered with permanent ice in some places.

Vegetation and animal life. The vegetation of the Lena Valley reflects the features of the natural zones across which the river flows. The main part of the river basin is covered with taiga (swampy northern coniferous forest); in the lower reaches are found tundra and scattered forest. Spruce, cedar, birch, and poplar predominate in the moister regions. In the central valley occur some expanses of steppe, a rare occurrence above latitude 60° N. Characteristic of the water-meadow area are peat bogs and swamps and thickets of willow, alder, and dwarfish birches. In the lower valley course appear tundra plants such as mosses and lichens, partridge grasses, whitlow grass, arctic poppy, and cotton grass.

The plankton of the Lena is rather poor and restricted in variety. More than 100 species of animals are found. Commercially important fish include sturgeon, salmon, roach, dace, and perch. The main concentration of these varieties is in the mouth region, where in the summer there is comparatively warm water.

Hydrography. More than 95 percent of the Lena's water is obtained from melting snow and from rain; 1 to 2 percent of the yearly flow comes from subsoil waters. Typical of the Lena Basin are high floods, especially flash floods, in summer, and very little flow in winter. Complete cessation of flow may occur with the freezing of the river through to the bottom. The average volume of the Lena at the mouth is 21,300 cubic yards (16,300 cubic metres) per second; the greatest volume is 260,000 cubic yards per second, and the minimum is 478 cubic yards per second. The total yearly volume approaches 100 cubic miles. During the high-water period the water level rises by an average of 30 to 50 feet, and in the lower course reaches 60 feet.

The river's volume

The highest temperature of the water in the upper course of the river reaches 66° F (19" C) and in the lower course about 57" F (14" C). The river is free of ice in the south for five to six months and in the north four to five months. The breakup of ice in the spring causes significant damage to the shores: the ice floes grind the rocks, pull trees out by their roots, and carry away large sections of the banks.

The Lena carries out into the sea about 12,000,000 tons of suspended alluvium and 41,000,000 tons of dissolved matter a year. The proportion of suspended alluvium in the water is small: even in floodwaters it does not exceed 50 to 60 grams per cubic metre. The mineralization of the water in the lower Lena during low water is from 80 to 100 grams per cubic metre, and in floodwaters 160 to 500 grams per cubic metre.

Human activity. ***Exploration.*** The first exploration of the Lena was conducted by Russians at the beginning of the 17th century. In 1631 a fortress and a settlement was founded at Ust-Kut. The first scientific research was conducted by the Great Northern Expedition in 1733–43. Cartography was begun in 1910. In 1912, in the icebreakers "Taymir" and "Vaygach," the delta was surveyed and mapped. Further surveying was conducted in the interwar period, and is currently being conducted by the Yakut branch of the Academy of Science of the USSR and by other government bodies.

Settlement. Among the peoples living in the Lena Basin, mainly on the banks of the river and its tributaries, are Russians, Evenks (Tungus) Yakuts, and Yukaghirs. There are many industrial and cultural centres, collective farms, and state farms. In the territory of the basin is found the Yakut Autonomous Soviet Socialist Republic, with the capital of Yakutsk.

Economic activity. The Lena is navigable by small boats in sections below Kachug and from Ust-Kut by larger vessels. The largest wharves are Bulun, Zhigansk, Yakutsk, Vitim, Kirensk, Osetrovo, Zhigalovo, and Kachug; Osetrovo is an important river port, equipped with modern machinery. The largest navigable tributaries are the Kirenga, Vitim, Olyokma, Aldan, and Vilyuy. Wood products, furs, gold, mica, industrial products, and food are the main cargoes.

Within the borders of the Central Yakut Plain various agricultural crops—barley, oats, wheat, potatoes, cucumbers, and others—are grown. The large meadows and pastures present successful livestock raising. Future prospects for the economic development of the Lena Basin are extremely good. The basin is rich in useful fossil minerals, and gold and coal occur in exploitable quantities. In 1955, in western Yakutia, rich deposits of diamonds were discovered in the Vilyuy Basin. To the east of the diamond-bearing region are found vast deposits of natural gas; near Olyokminsk are found salt beds, and to the south of Yakutsk, iron ore and coking coal.

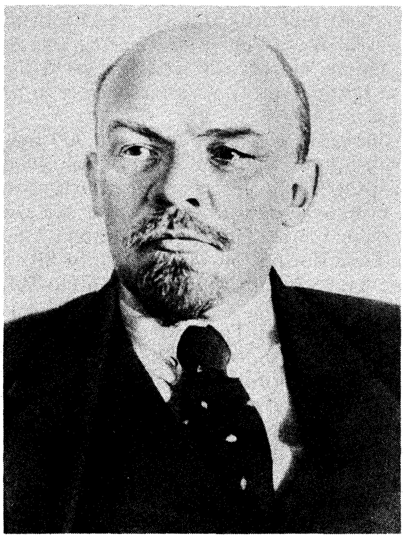
The hydroenergy potential of the Lena and its tributaries is about 40,000,000 kilowatts, and hydroelectric stations are planned at Lensk, Yakutsk, and Nizhne-Lensky. (I.V.P.)

Lenin

Militant Marxist, founder of the Russian Communist Party (Bolsheviks), inspirer and leader of the Bolshevik Revolution, Lenin was the architect, builder, **and first** head of the Soviet state. He was the founder of the Comintern (Communist International) and posthumous source of "Leninism," the doctrine codified and conjoined with Marx's works by Lenin's successors to form Marxism–Leninism, the Communist world view. If the Bolshevik Revolution is—as some people have called it—the most significant political event of the 20th century, then Lenin must for good or ill be regarded as this century's most significant political leader. Not only in the Soviet Union but even among many non-Communist scholars, he is regarded as both the greatest revolutionary leader and revolutionary statesman in history, as well as the greatest revolutionary thinker since Marx.

EARLY LIFE

The making of a revolutionary. Yet it is difficult to find anything in his childhood that might have turned



Lenin, 1918.
Tass—Sovfoto

him onto the path of a professional revolutionary. Vladimir Ilich Ulyanov was born in Simbirsk (renamed Ulyanovsk) on April 22 (April 10, old style), 1870. (He adopted the pseudonym Lenin in 1901 during his clandestine party work after exile in Siberia.) He was the third of six children born into a close-knit, happy family of highly educated and cultured parents. His mother was the daughter of a physician, while his father, though the son of a serf, became a schoolteacher and rose to the position of inspector of schools. Lenin, intellectually gifted, physically strong, and reared in a warm, loving home, early displayed a voracious passion for learning. He was graduated from high school ranking first in his class. He distinguished himself in Latin and Greek and seemed destined for the life of a classical scholar. When he was 16, nothing in Lenin indicated a future rebel, still less a professional revolutionary--except, perhaps, his turn to atheism. But, despite an ideal upbringing, all five of the Ulyanov children who reached maturity joined the revolutionary movement. This was not uncommon in tsarist Russia, where even the highly educated and cultured intelligentsia were denied elementary civil and political rights.

Execution of Lenin's brother

In adolescence Lenin suffered two blows that unquestionably impelled him to take the path of revolution. First, his father was threatened shortly before his untimely death with premature retirement by a reactionary government grown fearful of the spread of public education. Second, in 1887 his beloved eldest brother, Aleksandr, a student at the University of St. Petersburg (now Leningrad State University), was hanged for conspiring with a revolutionary terrorist group that plotted to assassinate Emperor Alexander III. Suddenly, at age 17, Lenin became the male head of the family, which was now stigmatized as having reared a "state criminal."

Fortunately his mother's pension and inheritance kept the family in comfortable circumstances, despite the frequent imprisonment or exile of her children. Moreover, Lenin's high school principal (the father of Aleksandr Kerensky, who was later to lead the Provisional government deposed by Lenin in November [October, O.S.] 1917) did not turn his back on the "criminal's" family. He courageously wrote a character reference that smoothed Lenin's admission to a university.

In autumn 1887 Lenin enrolled in the faculty of law of the imperial Kazan University (now Kazan [V.I. Lenin] State University), but within three months he was expelled, accused of participating in an illegal student assembly. He was arrested and banished from Kazan to his grandfather's estate in the village of Kokushkino, where his older sister Anna had already been ordered to reside by the police. In the autumn of 1888, the authorities permitted him to return to Kazan but denied him readmission to the university. During his enforced idleness, he met exiled revolutionaries of the older generation and avidly read revolutionary political literature, especially Marx's *Das Kapital.* He became a Marxist in January 1889.

Formation of a revolutionary party. In May 1889 the Ulyanov family moved to Samara (now Kuybyshev). After much petitioning, Lenin was granted permission to take his law examinations. In November 1891 he passed his examinations, taking a first in all subjects, and was graduated with a first-class degree. After the police finally waived their political objections, Lenin was admitted to the bar and practiced law in Samara in 1892–93, his clients being mainly poor peasants and artisans. In his experience at law he acquired an intense loathing for the class bias of the legal system and a lifelong revulsion for lawyers, even those who claimed to be Social-Democrats.

Exile in Siberia

But law was an extremely useful cover for a revolutionary activist. He moved to St. Petersburg (now Leningrad) in August 1893 and, while working as a public defender, made contact with revolutionary Marxists. In 1895 his comrades sent him abroad to make contact with Russian exiles in western Europe, especially with Russia's most commanding Marxist thinker, Georgy Plekhanov. Upon his return in 1895, Lenin and other Marxists, including L. Martov, the future leader of the Mensheviks, succeeded in unifying the Marxist groups of the capital in an organization known as The Union for the Struggle for the Liberation of the Working Class. The Union issued leaflets and proclamations on the workers' behalf, supported workers' strikes, and infiltrated workers' education classes to impart the rudiments of Marxism. In December 1895, the leaders of the Union were arrested. Lenin was jailed for 15 months, then exiled to Shushenskoye, in Siberia, for a term of three years. He was joined there in exile by his fiancée, Nadezhda Krupskaya, a Union member, whom he had met in the capital. They were married in Siberia, and she became Lenin's indispensable secretary and comrade. In exile they conducted clandestine party correspondence and collaborated (legally) on a Russian translation of Sidney and Beatrice Webb's *Industrial Democracy.*

Upon completing his term of exile in January 1900, Lenin went abroad and was joined later by Krupskaya in Munich. His first major task abroad was to join Plekhanov, Martov, and three other editors in bringing out the newspaper *Iskra* ("The Spark"), which they hoped would unify the Russian Marxist groups scattered throughout Russia and western Europe into a cohesive Social-Democratic party.

Up to the point that Lenin joined the *Iskra,* his writings had focussed on three problems: first, he had written a number of leaflets that aimed to shake the workers' traditional veneration of the tsar by showing them that their harsh life was caused, in part, by the support tsarism rendered the capitalists; second, he attacked those self-styled Marxists who urged Social-Democrats and workers to concentrate on wage and hour issues, leaving the political struggle for the present to the bourgeoisie; third, and ultimately most important, he addressed himself to the peasant question.

The principal obstacle to the acceptance of Marxism by many of the intelligentsia was their adherence to the widespread belief of the Populists (Russian pre-Marxist radicals) that Marxism was inapplicable to peasant Russia, in which a proletariat was almost nonexistent. Russia, they held, was immune to capitalism, owing to joint ownership of peasant land by the village commune. This view had been first attacked by Plekhanov in the 1880s. Plekhanov had argued that Russia had already entered the capitalist stage, as evidenced by the rapid growth of industry. Despite the denials of the Populists, the man of the future in Russia was the proletarian, not the peasant. Applying the Marxist scheme of social development to Russia, Plekhanov had come to the view that the revolution in Russia must pass through two discrete stages: first, a bourgeois revolution that would establish a democratic republic and full-blown capitalism; and second, a proletarian revolution after mature capitalism had generated a numerous proletariat that had attained a high level of political organization, socialist consciousness, and culture, enabling them to usher in full Socialism.

The peasant question

It was this view that Lenin adhered to after he read Plekhanov's work in the late 1880s. But almost immediately, Lenin went a step beyond his former mentor, especially in the peasant question. In an attack on the Populists published in 1894, Lenin charged that, even if they realized their fondest dream and divided all the land among the peasant communes, the result would not be Socialism but capitalism spawned by a free market in agricultural produce. The "Socialism" of the Populists would favour the growth of small-scale capitalism; hence the Populists were not Socialists but "petty bourgeois democrats." Outside of Marxism, which aimed ultimately to abolish the market system as well as the private ownership of the means of production, Lenin concluded, there could be no Socialism.

Even while in exile in Siberia, Lenin had begun research on his investigation of the peasant question, which culminated in his magisterial ***Development of Capitalism in Russia*** (published legally in 1899). In this work he argued that capitalism was rapidly destroying the peasant commune. The peasantry. for the Populists a homogeneous social class, was in actuality rapidly stratifying into a well-off rural bourgeoisie, a middling peasantry, and an impoverished rural "proletariat and semi-proletariat." In this last group, which comprised half the peasant population, Lenin found an ally for the extremely small industrial proletariat in Russia.

Iskra's success in recruiting Russian intellectuals to Marxism led Lenin and his comrades to believe that the time was ripe to found a revolutionary Marxist party that would weld together all the disparate Marxist groups at home and abroad. An abortive First Congress, held in 1898 in Minsk, had failed to achieve this objective, for most of the delegates were arrested shortly after the congress. The organizing committee of the Second Congress decided to convene the congress in Brussels in 1903, but police pressure forced it to transfer to London.

The congress sessions wore on for nearly three weeks, for no point appeared too trivial to debate. But the main issues quickly became plain: eligibility for membership and the character of party discipline; but, above all, the key issue focussed on the relation between the party and the proletariat, for whom the party claimed to speak.

In his *What Is To Be Done?* (1902), Lenin totally rejected the view that the proletariat was being driven spontaneously to revolutionary Socialism by capitalism and that the party should merely coordinate the struggle of the proletariat's diverse sections on a national and international scale. Capitalism, he contended, predisposed the workers to the acceptance of Socialism but did not spontaneously make them conscious Socialists. The proletariat by its own efforts in the everyday struggle against the capitalist could achieve "trade-union consciousness." But the proletariat could not by its own efforts grasp that it could win complete emancipation only by overthrowing capitalism and building Socialism, unless the party from without infused it with Socialist consciousness.

The "vanguard of the proletariat"

In his ***What Is To Be Done?*** and in his other works on party organization, Lenin created one of his most momentous political innovations, his theory of the party as the "vanguard of the proletariat." He saw the vanguard as a highly disciplined, centralized party that worked unremittingly to suffuse the proletariat with Socialist consciousness and served as mentor, leader, and guide, constantly showing the proletariat where its true class interests lie.

At the Second Congress the ***Iskra*** group split, and Lenin found himself in a minority on this very issue. Nevertheless, he continued to develop his view of "the party of a new type," which must be guided by "democratic centralism," or absolute party discipline. The party must be a highly centralized body organized around a small, ideologically homogeneous, hardened core of experienced professional revolutionaries, who were elected to the central committee by the party congress and who led a ramified hierarchy of lower party organizations that enjoyed the support and sympathy of the proletariat and all groups opposed to tsarism. "Give us an organization of revolutionaries," Lenin exclaimed, "and we will overturn Russia!"

Lenin spared no effort to build just this kind of party over the next 20 years, despite fierce attacks on his conception by some of his closest comrades of the ***Iskra*** days, Plekhanov, Martov, and Leon Trotsky. They charged that his scheme of party organization and discipline tended toward "Jacobinism," suppression of free intraparty discussion, a dictatorship ***over*** the proletariat, not ***of*** the proletariat, and, finally, establishment of a one-man dictatorship.

The Bolsheviks and the Mensheviks

Lenin found himself in the minority in the early sessions of the Second Congress of what was now proclaimed to be the Russian Social-Democratic Workers' Party (RSDWP). But a walkout by a disgruntled group of Jewish Social-Democrats, the Bund, left Lenin with a slight majority, Consequently, the members of Lenin's adventitious majority were called Bolsheviks (majoritarians), and Martov's group were dubbed Mensheviks (minoritarians). The two groups fought each other ceaselessly within the same RSDWP and professed the same program until 1912, when Lenin made the split final at the Prague Conference of the Bolshevik Party.

CHALLENGES OF THE REVOLUTION OF 1905 AND WORLD WAR I

The differences between Lenin and the Mensheviks became sharper in the Revolution of 1905 and its aftermath, when Lenin moved to a distinctly original view on two issues: class alignments in the revolution and the character of the post-revolutionary regime.

The outbreak of the revolution, in January 1905, found Lenin abroad in Switzerland, and he did not return to Russia until November. Immediately Lenin set down a novel strategy. Both wings of the RSDWP, Bolshevik and Menshevik, adhered to Plekhanov's view of the revolution in two stages: first, a bourgeois revolution; second, a proletarian revolution (see above). But the Mensheviks argued that the bourgeois revolution must be led by the bourgeoisie, with whom the proletariat must ally itself in order to make the democratic revolution. This would bring the liberal bourgeoisie to full power, whereupon the RSDWP would act as the party of opposition. Lenin defiantly rejected this kind of alliance and post-revolutionary regime. Hitherto he had spoken of the need for the proletariat to win "hegemony" in the democratic revolution. Now he flatly declared that the proletariat was the driving force of the revolution and that its only reliable ally was the peasantry. The bourgeoisie he branded as hopelessly counterrevolutionary and too cowardly to make its own revolution. Thus, unlike the Mensheviks, Lenin henceforth banked on an alliance that would establish a "revolutionary democratic dictatorship of the proletariat and the peasantry."

Nor would the revolution necessarily stop at the first stage, the bourgeois revolution. If the Russian revolution should inspire the western European proletariat to make the Socialist revolution, for which industrial Europe was ripe, the Russian revolution might well pass over directly to the second stage, the Socialist revolution. Then, the Russian proletariat, supported by the rural proletariat: and semi-proletariat at home and assisted by the triumphant industrial proletariat of the West, which had established its "dictatorship of the proletariat," could cut short the life-span of Russian capitalism.

Years of discouragement

After the defeat of the Revolution of 1905, the issue between Lenin and the Mensheviks was more clearly drawn than ever, despite efforts at reunion. But, forced again into exile from 1907 to 1917, Lenin found serious challenges to his policies not only from the Mensheviks but within his own faction as well. The combination of repression and modest reform effected by the tsarist regime led to a decline of party membership. Disillusionment and despair in the chances of successful revolution swept the dwindled party ranks, rent by controversies over tactics and philosophy. Attempts to unite the Bolshevik and Menshevik factions came to naught, all breaking on Lenin's intransigent insistence that his conditions for reunification be adopted. As one Menshevik opponent described Lenin: "There is no other man who is absorbed by the revolution twenty-four hours a day, who has no other thoughts but the thought of revolution, and who even when he sleeps, dreams of nothing but revolution." Placing revolution above party unity, Lenin would accept no unity compromise if he thought it might delay, not accelerate, revolution.

Desperately fighting to maintain the cohesion of the Bolsheviks against internal differences and the Mensheviks' growing strength at home, Lenin convened the Bolshevik Party Conference at Prague, in 1912, which split the RSDWP forever. Lenin proclaimed that the Bolsheviks were the RSDWP and that the Mensheviks were schismatics. Thereafter, each faction maintained its separate central committee, party apparatus, and press.

When war broke out, in August 1914, Socialist parties throughout Europe rallied behind their governments despite the resolutions of prewar congresses of the Second International obliging them to resist or even overthrow their respective governments if they plunged their countries into an imperialist war.

Denunciation of pro-war Socialists

After Lenin recovered from his initial disbelief in this "betrayal" of the International, he proclaimed a policy whose audacity stunned his own Bolshevik comrades. He denounced the pro-war Socialists as "social-chauvinists" who had betrayed the international working-class cause by support of a war that was imperialist on both sides. He pronounced the Second International as dead and appealed for the creation of a new, Third International composed of genuinely revolutionary Socialist parties. More immediately, revolutionary Socialists must work to "transform the imperialist war into civil war." The real enemy of the worker was not the worker in the opposite trench but the capitalist at home. Workers and soldiers should therefore turn their guns on their rulers and destroy the system that had plunged them into imperialist carnage.

Lenin's policy found few advocates in Russia or elsewhere in the first months of the war. Indeed, in the first flush of patriotic fervour, not a few Bolsheviks supported the war effort. Lenin and his closest comrades were left an isolated band swimming against the current.

Lenin succeeded in reaching neutral Switzerland in September 1914, there joining a small group of anti-war Bolshevik and Menshevik *émigrés.* The war virtually cut them off from all contact with Russia and with like-minded Socialists in other countries. Nevertheless, in 1915 and 1916, anti-war Socialists in various countries managed to hold two anti-war conferences in Zimmerwald and Kienthal, Switzerland. Lenin failed at both meetings to persuade his comrades to adopt his slogan: "transform the imperialist war into civil war!" They adopted instead the more moderate formula: "An immediate peace without annexations or indemnities and the right of the peoples to self-determination." Lenin consequently found his party a minority within the group of anti-war Socialists, who, in turn, constituted a small minority of the international Socialist movement compared with the pro-war Socialists.

Lenin's theory of imperialism

Undaunted, Lenin continued to hammer home his views on the war, confident that eventually he would win decisive support. In his ***Imperialism, the Highest Stage of Capitalism*** **(1917),** he set out to explain, first, the real causes of the war; second, why Socialists had abandoned internationalism for patriotism and supported the war; and third, why revolution alone could bring about a just, democratic peace.

War erupted, he wrote, because of the insatiable, expansionist character of imperialism, itself a product of monopoly finance capitalism. At the end of the 19th century, a handful of banks had come to dominate the advanced countries, which, by 1914, had in their respective empires brought the rest of the world under their direct or indirect controls. Amassing vast quantities of "surplus" capital, the giant banks found they could garner superprofits on investments in colonies and semi-colonies, and this intensified the race for empire among the great powers. By 1914, dissatisfied with the way the world had been shared out, rival coalitions of imperialists launched the war to bring about a redivision of the world at the expense of the other coalition. The war was therefore imperialist in its origins and aims and deserved the condemnation of genuine Socialists.

Socialist Party and trade-union leaders had rallied to support their respective imperialist governments because they represented the "labour aristocracy," the better paid workers who received a small share of the colonial "superprofits" the imperialists proffered them. "Bribed" by the imperialists, the "labour aristocracy" took the side of their paymasters in the imperialist war and betrayed the most exploited workers at home and the super-exploited in the colonies. The imperialists, Lenin contended, driven by an annexationist dynamic, could not conclude a just, lasting peace. Future wars were inevitable so long as imperialism existed; imperialism was inevitable so long as capitalism existed; only the overthrow of capitalism everywhere could end the imperialist war and prevent such wars in the future. First published in Russia in 1917, *Imperialism* to this day provides the instrument that Communists everywhere employ to evaluate major trends in the non-Communist world.

LEADERSHIP IN THE RUSSIAN REVOLUTION

By 1917 it seemed to Lenin that the war would never end and that the prospect of revolution was rapidly receding. But in the week of March 8–15, the starving, freezing, war-weary workers and soldiers of Petrograd (until 1914, St. Petersburg) succeeded in deposing the Tsar. Lenin and his closest lieutenants hastened home after the German authorities agreed to permit their passage through Germany to neutral Sweden. Berlin hoped that the return of anti-war Socialists to Russia would undermine the Russian war effort.

The Provisional Government

First return to Petrograd. Lenin arrived in Petrograd on April 16, 1917, one month after the Tsar had been forced to abdicate. Out of the revolution was born the Provisional Government, formed by a group of leaders of the bourgeois liberal parties. This government's accession to power was made possible only by the assent of the Petrograd Soviet, a council of workers' deputies elected in the factories of the capital. Similar soviets of workers' deputies sprang up in all the major cities and towns throughout the country, as did soviets of soldiers' deputies and of peasants' deputies. Although the Petrograd Soviet had been the sole political power recognized by the revolutionary workers and soldiers in March 1917, its leaders had hastily turned full power over to the Provisional Government. The Petrograd Soviet was headed by a majority composed of Menshevik and Socialist Revolutionary (SR), or peasant party, leaders who regarded the March (February, O.S.) Revolution as bourgeois; hence, they believed that the new regime should be headed by leaders of the bourgeois parties.

On his return to Russia, Lenin electrified his own comrades, most of whom accepted the authority of the Provisional Government. Lenin called this government, despite its democratic pretensions, thoroughly imperialist and undeserving of support by Socialists. It was incapable of satisfying the most profound desires of the workers, soldiers, and peasants for immediate place and division of landed estates among the peasants.

Only a soviet government—that is, direct rule by workers, soldiers, and peasants--could fulfill these demands. Therefore, he raised the battle cry, "All power to the Soviets!"—although the Bolsheviks still constituted a minority within the soviets and despite the manifest unwillingness of the Menshevik–SR majority to exercise such power. This introduced what Lenin called the period of "dual power." Under the leadership of "opportunist" Socialists, the soviets, the real power, had relinquished power to the Provisional Government, the nominal power in the land. The Bolsheviks, Lenin exhorted, must persuade the workers, peasants, and soldiers, temporarily deceived by the "opportunists," to retrieve state power for the soviets from the Provisional Government. This would constitute a second revolution. But, so long as the government did not suppress the revolutionary parties, this revolution could be achieved peacefully, since the Provisional Government existed only by the sufferance of the soviets.

Initially, Lenin's fellow Bolsheviks thought that he was temporarily disoriented by the complexity of the situation; moderate Socialists thought him mad. It required several weeks of sedulous persuasion by Lenin before he won the Bolshevik Party Central Committee to his view. The April Party Conference endorsed his program: the party must withhold support from the Provisional Government and win a majority in the soviets in favour of soviet power. A soviet government, once established, should begin immediate negotiations for a general peace on all fronts. The soviets should forthwith confiscate landlords' estates without compensation, nationalize all land, and divide it among the peasants. And the government should establish tight controls over privately owned industry to the benefit of labour.

Rise of the Bolsheviks

From March to September 1917, the Bolsheviks remained a minority in the soviets. By autumn, however, the Provisional Government (since July headed by the moderate Socialist Aleksandr Kerensky, who was supported by the moderate Socialist leadership of the soviets) had lost popular support. Increasing war-weariness and the breakdown of the economy overtaxed the patience of the workers, peasants, and soldiers, who demanded immediate and fundamental change. Lenin capitalized on the growing disillusionment of the people with Kerensky's ability and willingness to complete the revolution. Kerensky, in turn, claimed that only a freely elected constituent assembly would have the power to decide Russia's political future—but that must await the return of order. Meanwhile, Lenin and the party demanded peace, land, and bread—immediately, without further delay. The Bolshevik line won increasing support among the workers, soldiers, and peasants. By September they voted in a Bolshevik majority in the Petrograd Soviet and in the soviets of the major cities and towns throughout the country.

Decision to seize power. Lenin, who had gone underground in July after he had been accused as a "German agent" by Kerensky's government, now decided that the time was ripe to seize power. The party must immediately begin preparations for an armed uprising to depose the Provisional Government and transfer state power to the soviets, now headed by a Bolshevik majority.

Lenin's decision to establish soviet power derived from his belief that the proletarian revolution must smash the existing state machinery and introduce a "dictatorship of the proletariat"; that is, direct rule by the armed workers and peasants which would eventually "wither away" into a non-coercive, classless, stateless, Communist society. He expounded this view most trenchantly in his brochure *The State and Revolution,* written while he was still in hiding. The brochure, though never completed and often dismissed as Lenin's most "Utopian" work, nevertheless served as Lenin's doctrinal springboard to power.

Until 1917 all revolutionary Socialists rightly believed, Lenin wrote, that a parliamentary republic could serve a Socialist system as well as a capitalist. But the Russian Revolution had brought forth something new, the soviets. Created by workers, soldiers, and peasants and excluding the propertied classes, the soviets infinitely surpassed the most democratic of parliaments in democracy, because parliaments everywhere virtually excluded workers and peasants. The choice before Russia in early September 1917, as Lenin saw it, was either a soviet republic—a dictatorship of the propertyless majority--or a parliamentary republic—as he saw it, a dictatorship of the propertied minority.

Lenin therefore raised the slogan, "All power to the Soviets!", even though he had willingly conceded in the spring of 1917 that the Provisional Government was the "freest of all the belligerent countries." To Lenin, however, the Provisional Government was merely a "dictatorship of the bourgeoisie" that kept Russia in the imperialist war. What is more, it had turned openly counterrevolutionary in the month of July when it accused the Bolshevik leaders of treason.

From late September, Lenin, a fugitive in Finland, sent a stream of articles and letters to Petrograd feverishly exhorting the Party Central Committee to organize an armed uprising without delay. The opportune moment might be lost. But for nearly a month Lenin's forceful urgings from afar were unsuccessful. As in April, Lenin again found himself in the party minority. He resorted to a desperate stratagem.

Around October 20, Lenin, in disguise and at considerable personal risk, slipped into Petrograd and attended a secret meeting of the Bolshevik Central Committee held on the evening of October 23. Not until after a heated ten-hour debate did he finally win a majority in favour of preparing an armed take-over. Now steps to enlist the support of soldiers and sailors and to train the Red Guards, the Bolshevik-led workers' militia, for an armed take-over proceeded openly under the guise of self-defense of the Petrograd Soviet. But preparations moved haltingly, because serious opposition to the fateful decision persisted in the Central Committee. Enthusiastically in accord with Lenin on the timeliness of an armed uprising, Trotsky led its preparation from his strategic position as newly elected chairman of the Petrograd Soviet. Lenin, now hiding in Petrograd and fearful of further procrastination, desperately pressed the Central Committee to fix an early date for the uprising. On the evening of November 6, he wrote a letter to the members of the Central Committee exhorting them to proceed that very evening to arrest the members of the Provisional Government. To delay would be "fatal." The Second All-Russian Congress of Soviets, scheduled to convene the next evening, should be placed before a *fait accompli.*

Overthrow of the Provisional Government

On November 7 and 8, the Bolshevik-led Red Guards and revolutionary soldiers and sailors, meeting only slight resistance, deposed the Provisional Government and proclaimed that state power had passed into the hands of the Soviets. By this time the Bolsheviks, with their allies among the Left SR's (dissidents who broke with the pro-Kerensky SR leaders), constituted an absolute majority of the Second All-Russian Congress of Soviets. The delegates therefore voted overwhelmingly to accept full power and elected Lenin as chairman of the Council of People's Commissars, the new Soviet Government, and approved his Peace Decree and Land Decree. Overnight, Lenin had vaulted from his hideout as a fugitive to head the Revolutionary government of the largest country in the world. Since his youth he had spent his life building a party that would win such a victory, and now at the age of 47 he and his party had triumphed. "It makes one's head spin," he confessed. But power neither intoxicated nor frightened Lenin; it cleared his head. Soberly, he steered the Soviet government toward the consolidation of its power and negotiations for peace.

Saving the Revolution. In both spheres, Lenin was plagued by breaks within the ranks of Bolshevik leaders. He reluctantly agreed with the right-wingers that it would be desirable to include the Menshevik and Right SR parties in a coalition government—but on Lenin's terms. They must above all accept the soviet form of government, not a parliamentary one; they refused. Only the Left SR's agreed, and several were included in the Soviet government. Likewise, when the freely elected Constituent Assembly met in January 1918, the Mensheviks and Right SR majority flatly rejected sovietism. Lenin without hesitation ordered the dispersal of the Constituent Assembly.

The Allies refused to recognize the Soviet government; consequently it entered alone into peace negotiations with the Central Powers (Germany and her allies Austro-Hungary and Turkey) at the town of Brest-Litovsk. They imposed ruinous conditions that would strip away from Soviet Russia the western tier of non-Russian nations of the old Russian Empire. Left Communists fanatically opposed acceptance and preached a revolutionary war, even if it imperilled the Soviet government. Lenin insisted that the terms, however ruinous and humiliating, must be accepted or he would resign from the government. He sensed that peace was the deepest yearning of the people; in any case, the shattered army could not raise effective resistance to the invader. Finally, in March 1918, after a still larger part had been carved out of old Russia by the enemy, Lenin succeeded in winning the Central Committee's acceptance of the Treaty of Brest-Litovsk. At last Russia was at peace.

Treaty of Brest-Litovsk

But Brest-Litovsk only intensified the determination of counterrevolutionary forces and the Allies who supported them to bring about the overthrow of the Soviet government. That determination hardened when, in 1918, Lenin's government repudiated repayments of all foreign loans obtained by the tsarist and Provisional governments and nationalized foreign properties in Russia without compensation. From 1918 to 1920 Russia was torn by a Civil War, which cost millions of lives and untold destruction. One of the earliest victims was Lenin himself. In August 1918 an assassin fired two bullets into Lenin as he left a factory in which he had just delivered a speech. Because of his robust constitution, he recovered rapidly.

The Soviet government faced tremendous odds. The anti-Soviet forces, or Whites, headed mainly by former tsarist generals and admirals, fought desperately to overthrow the Red regime. Moreover, the Whites were lavishly supplied by the Allies with matériel, money, and support troops that secured White bases. Yet, the Whites failed.

It was largely because of Lenin's inspired leadership that the Soviet government managed to survive against such military odds. He caused the formation and guided the strategy of the Workers' and Peasants' Red Army, commanded by Trotsky. Although the economy had collapsed, he managed to mobilize sufficient resources to sustain the Red Army and the industrial worker. But above all it was his political leadership that saved the day for the Soviets. By proclaiming the right of the peoples to self-determination, including the right to secession, he won the active sympathy, or at least the benevolent neutrality, of the non-Russian nationalities within Russia, because the Whites did not recognize that right. Indeed, his perceptive, skillful policy on the national question enabled Soviet Russia to avoid total disintegration and to remain a huge multinational state. By making the industrial workers the new privileged class, favoured in the distribution of rations, housing, and political power, he retained the loyalty of the proletariat. His championing of the peasants' demand that they take all the land from the gentry, church, and crown without compensation won over the peasants, without whose support the government could not survive.

Because of the breakdown of the economy, however, Lenin adopted a policy toward the peasant that threatened to destroy the Soviet government. Lacking funds or goods to exchange against grain needed to feed the Red Army and the towns, Lenin instituted a system of requisitioning grain surpluses without compensation. Many peasants resisted—at least until they experienced White "liberation." On the territories that the Whites won, they restored landed property to the previous owners and savagely punished the peasants who had dared seize the land. Despite the peasants' detestation of the Soviet's grain requisitioning, the peasants, when forced to choose between Reds and Whites, chose the Reds.

The New Economic Policy

After the defeat of the Whites, the peasants no longer had to make that choice. They now totally refused to surrender their grain to the government. Threatened by mass peasant rebellion, Lenin called a retreat. In March 1921 the government introduced the New Economic Policy, which ended the system of grain requisitioning and permitted the peasant to sell his harvest on an open market. This constituted a partial retreat to capitalism.

From the moment Lenin came to power, his abiding aims in international relations were twofold: to prevent the formation of an imperialist united front against Soviet Russia; but, even more important, to stimulate proletarian revolutions abroad.

In his first aim he largely succeeded. In 1924, shortly after his death, Soviet Russia had won de jure recognition of all the major world powers except the United States. But his greater hope of the formation of a world republic of soviets failed to materialize, and Soviet Russia was left isolated in hostile capitalist encirclement.

Formation of the Third International. To break this encirclement, he had called on revolutionaries to form Communist parties that would emulate the example of the Bolshevik Revolution in all countries. Dramatizing his break with the reformist Second International, in 1918 he had changed the name of the RSDWP to the Russian Communist Party (Bolsheviks), and in March 1919 he founded the Communist, or Third, International. This International accepted the affiliation only of parties that accepted its decisions as binding, imposed iron discipline, and made a clean break with the Second International. In sum, Lenin now held up the Russian Communist Party, the only party that had made a successful revolution, as the model for Communist parties in all countries. One result of this policy was to engender a split in the world labour movement between the adherents of the two internationals.

The Communist International scored its greatest success in the colonial world. By championing the rights of the peoples in the colonies and semi-colonies to self-determination and independence, the International won considerable sympathy for Communism. Lenin's policy in this question still reverberates through the world today. And it offers another example of Lenin's unique ability to find allies where revolutionaries had not found them before. By taking the side of the national liberation movements, Lenin could claim that the overwhelming majority of the world's population, then living under imperialist rule, as well as the European proletariat, were the natural allies of the Bolshevik Revolution.

Thus Lenin's revolutionary genius was not confined to his ability to divide his enemies; more important was his skill in finding allies and friends for the exiguous proletariat of Russia. First, he won the Russian peasants to the side of the proletariat. Second, while he did not win the workers to make successful Communist revolutions in the West, they did compel their governments to curtail armed intervention against the Bolshevik Revolution. Third, while the Asian revolutions barely stirred in his lifetime, they did strengthen the Soviet Communists in the belief that they were not alone in a hostile world.

By 1921 Lenin's government had crushed all opposition parties on the grounds that they had opposed or failed to support sufficiently the Soviet cause in the Civil War. Now that peace had come, Lenin believed that their opposition was more dangerous than ever, since the peasantry and even a large section of the working class had become disaffected with the Soviet regime. To repress opponents of Bolshevism, Lenin demanded the harshest measures, including "show" trials and frequent resort to the death penalty. Moreover, he insisted on even tighter control over dissent within the party. Lenin's insistence on merciless destruction of the opposition to the Bolshevik dictatorship subsequently led many observers to conclude that Lenin, though personally opposed to one-man rule, nevertheless unwittingly cleared the way for the rise of Joseph Stalin's dictatorship.

Suppression of dissent

By 1922 Lenin had become keenly aware that degeneration of the Soviet system and party was the greatest danger to the cause of Socialism in Russia. He found the party and Soviet state apparatus hopelessly entangled in red tape and incompetence. Even the agency headed by Stalin that was responsible for streamlining administration was, in fact, less efficient than the rest of the government. The Soviets of Workers' and Peasants' Deputies had been drained of all power, which had flowed to the centre. Most disturbing was the Great Russian chauvinism that leading Bolsheviks manifested toward the non-Russian nationalities in the reorganization of the state in which Stalin was playing a key role. Moreover, in April 1922 Stalin won appointment as general secretary of the party, in which post he was rapidly concentrating immense power in his hands. Soviet Russia in Lenin's last years could not have been more remote from the picture of Socialism he had portrayed in ***State and***

Revolution. Lenin strained every nerve to reverse these trends, which he regarded as antithetical to Socialism, and to replace Stalin.

Illness and death. In the spring of 1922, .however, Lenin fell seriously ill. In April his doctors extracted from his neck one of the bullets he had received from the assassin's gun in August 1918. He recovered rapidly from the operation, but a month later he fell ill, partially paralyzed and unable to speak. In June he made a partial recovery and threw himself into the formation of the Union of Soviet Socialist Republics, the federal system of reorganization he favoured against Stalin's unitary scheme. But in December he was again incapacitated by semi-paralysis. Although no longer the active leader of the state and party, he did muster the strength to dictate several prescient articles and what is called his political "Testament," dictated to his secretary between December 23, 1922, and January 4, 1923, in which he expressed a great fear for the stability of the party under the leadership of disparate, forceful personalities such as Stalin and Trotsky. On March 10, 1923, another stroke deprived him of speech. His political activity came to an end. He suffered yet another stroke on the morning of January 21, 1924, and died that evening at Gorky, near Moscow.

The last year of Lenin's political life, when he fought to eradicate abuses of his Socialist ideals and the corruption of power, may well have been his greatest. Whether the history of the Soviet Union would have been fundamentally different had he survived beyond his 54th birthday, no one can say with certainty.

MAJOR WORKS

BOOKS: ***Chto Takoye "Druzya Naroda," kak oni voyuyut protiv Sotsial-Demokratov?*** (hectographic editions from 1894, printed from 1920; ***What the "Friends of the People" Are, and How They Fight the Social-Democrats,*** 1946); ***Razvitiye kapitalizma v Rossi*** (1899, augmented ed. 1908; ***The Development of Capitalism in Russia,*** 1956); ***Chto delat?*** (1902; ***What Is To Be Done?,*** 1929, 1933, 1950,1963); ***Shag vperyod, dva shaga nazad*** (1904; ***One Step Forward, Two Steps Back,*** 1941); ***Dve taktiki Sotsial-Demokraty v demokraticheskoy revolyutsi*** (1905; ***Two Tactics of Social-Democracy in the Democratic Revolution,*** 1935, 1947); ***Agrarny vopros i "Kritiki Marksa"*** (1908, first chapters already published in periodicals from 1901); ***Agrarnaya programma Sotsial-Demokratyi v pervoy russkoy revolyutsl 1905–1907 godov*** (1908, 1917; ***The Agrarian Programme of Social-Democracy in the First Russian Revolution,*** 1954); ***Imperializm, kak noveyshy etap kapitalizma*** (1917, later retitled ***Imperializm, kak vysshaya stadiya kapitalizma; Imperialism: The Latest Stage in the Development of Capitalism,*** 1924; and ***Imperialism, the Highest Stage of Capitalism,*** 1933, 1939, 1947); ***Gosudarstvo i revolyutsiya*** (1917; ***The State and Revolution,*** 1919); ***Proletarskaya revolyutsiya i renegat Kautsky*** (1918; ***The Proletarian Revolution and Kautsky the Renegade,*** 1920); ***Detskaya bolezn "levizny" v kommunizme*** (1920; ***"Left Wing" Communism: An Infantile Disorder,*** 1920, 1934, 1961).

MARXIST PERIODICALS EDITED OR CONTROLLED BY LENIN: ***Iskra,*** 51 numbers (1900–03); ***Zarya,*** 4 numbers (1901–02); ***Vperyod,*** weekly, 18 numbers (1905); ***Novaya Zhizn,*** daily, 28 numbers (1905); ***Proletary,*** weekly, 26 numbers (1905); ***Volna,*** daily, 25 numbers (1906); ***Vperyod,*** daily, 17 numbers (1906); ***Ekho,*** daily, 14 numbers (1906); ***Proletary,*** 50 numbers (1906–09); ***Sotsial-Demokrat,*** 58 numbers (1908–17, wholly Leninist from 1911); ***Zvezda,*** at first weekly, then more frequent, 69 numbers (1910–12); ***Rabochaya Gazeta,*** 9 numbers (1910–12); ***Prosveshcheniye,*** monthly, 31 numbers (1911–14 and 1 final number, 1917); ***Pravda,*** daily (1912–14 and from 1917 with numerous changes of name 1913–14 and July-October 1917); ***Kommunist,*** 1 double number (1915); ***Sbornik Sotsial-Demokrafa,*** 2 numbers (1916).

JOURNALISM AND PARTY THESES: "O zadachakh proletariata v dannoy revolyutsi" ***(The April Theses,*** 1951), "O dvoevlasti," and "Uroki revolyutsi" ***(Lessons of the Revolution,*** 1918), all in ***Pravda,*** 1917; "Ocheredniye zadachi Sovietskoy vlasti," ***Pravda*** (1918; ***The Soviets at Work,*** 1918; and ***The Immediate Tasks of the Soviet Government,*** 1951).

BIBLIOGRAPHY

Editions: The fifth and most complete collection of Lenin's works was published in Moscow, 55 vol. (1958–65, with index, 1966; reference volume in two parts, 1969–70). The ***Collected Works,*** 45 vol. (1960–70), is an English translation of the 4th Russian edition of Lenin's works, enriched by editorial notes from the 5th edition. ***Selected Works,*** 3 vol. (1967), includes most of the works mentioned in this article and many more.

Biographical and critical studies: LOUIS FISCHER, ***The Life of Lenin*** (1964), a major, detailed work, enlivened by the author's own reminiscences of Moscow in Lenin's time; MOSHE LEWIN, ***Le Dernier Combat de Lénine*** (1967; Eng. trans., ***Lenin's Last Struggle,*** 1968), a brief but incisive account of Lenin's effort to mobilize party forces to curb Stalin and remove him from power; ALFRED MEYER, ***Leninism*** (1957), the best analysis of Lenin's political philosophy; DAVID SHUB, ***Lenin,*** rev. ed. (1966), readable and informative; ADAM B. ULAM, ***The Bolsheviks: The Intellectual and Political History of the Triumph of Communism in Russia*** (1965), a learned political biography of Lenin; BERTRAM D. WOLFE, ***Three Who Made a Revolution: A Biographical History,*** 4th rev. ed. (1964), a pioneering work (biographies of Lenin, Trotsky, and Stalin) that demolishes many myths; NADEZHDA KRUPSKAYA, ***Reminiscences of Lenin*** (1970; Eng. trans. of the 2nd Russian ed., 1968), reticent, impersonal recollections by Lenin's widow; LEON TROTSKY, ***Lenin: Notes for a Biographer*** (1971; Eng. trans. of the 2nd Russian ed., 1924), an appreciation of Lenin of the ***Iskra*** period and 1917–18, the periods of Trotsky's closest collaboration with Lenin; NIKOLAI VALENTINOV, ***Encounters with Lenin*** (1968; orig. pub. in Russian, 1953), revealing observations on Lenin's personality by a former associate; DIETRICH GEYER, ***Lenin in der Russischen Sozialdemokratie*** (1962), a scholarly study of Lenin and the origins of the Bolshevik–Menshevik split.

(Al.Re.)

Leningrad

The second largest city of the Soviet Union and one of the world's major cities, Leningrad has played a vital role in Russian history—for two centuries as capital of the Russian Empire—and it maintains today outstanding importance as an industrial and cultural centre and as a seaport. Founded by Peter I the Great in 1703 as St. Petersburg, it was renamed Petrograd in 1914 and, finally, Leningrad in 1924. The city is particularly renowned as the scene of the February and October revolutions in 1917, as the besieged and fiercely defended city of World War II, and, architecturally, as one of the most splendid and harmonious cities of Europe.

Leningrad is sited on the delta of the Neva River, where it debouches into the head of the Gulf of Finland. The city spreads across nearly 100 islands of the delta and across adjacent parts of the mainland floodplain. The very low and originally marshy site has made the city subject to recurrent flooding, especially at the time of the spring thaw. Exceptionally severe inundations occurred in 1777, 1824, and 1924, the last two being the highest on record and flooding most of the city. A number of canals have been cut to assist drainage. These, together with the many natural channels (now embanked with stone), make Leningrad a city of waterways and bridges and have earned it the nickname of "Venice of the North."

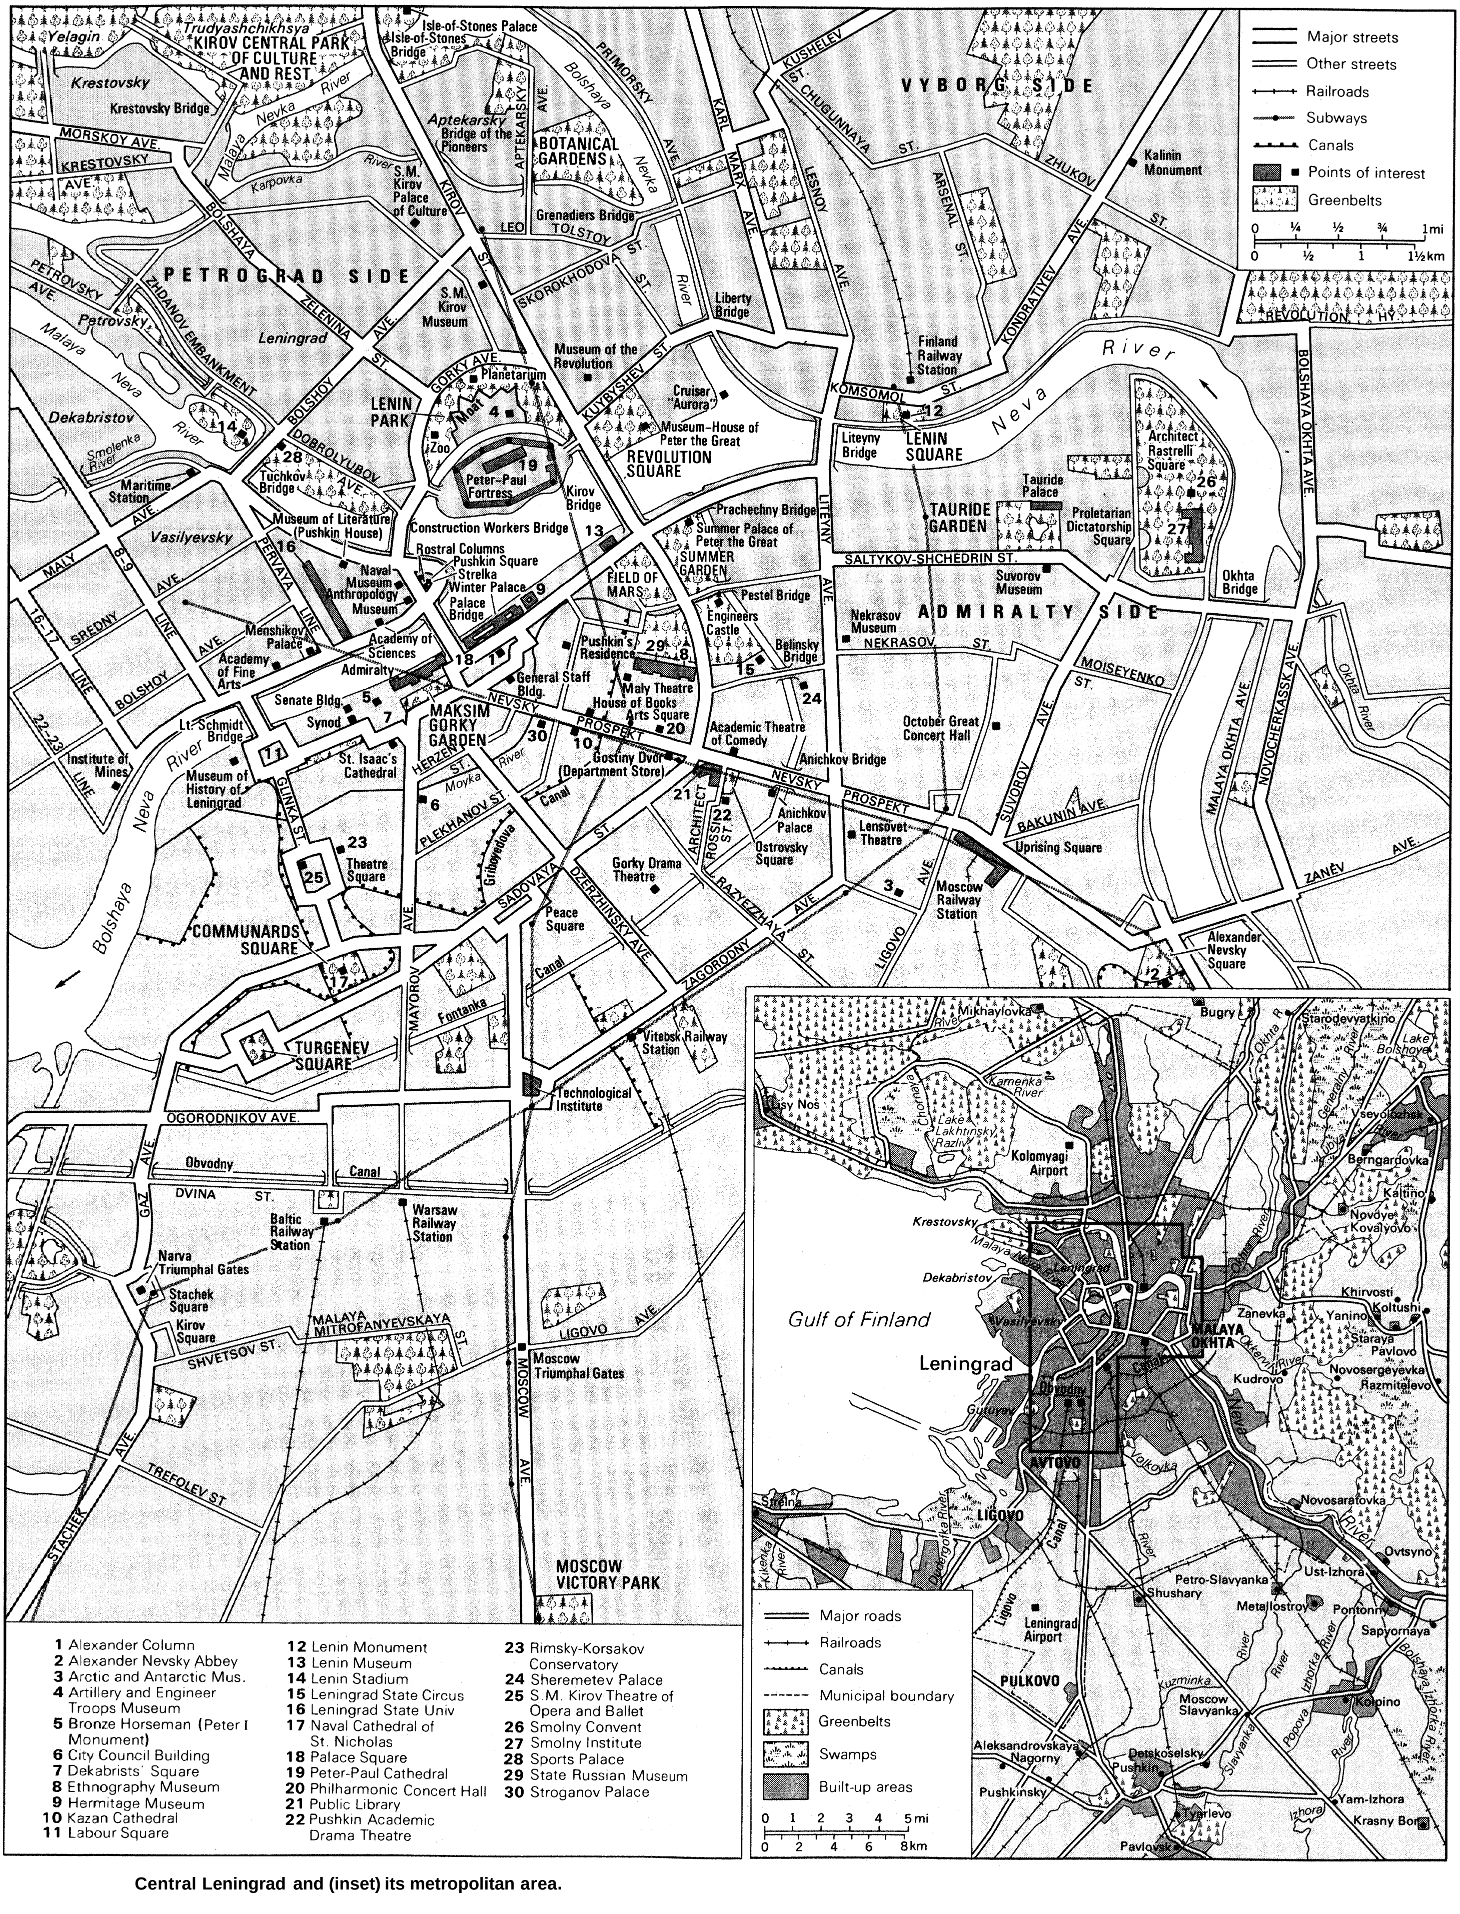
Floods

The climate is modified continental, with marked maritime influences. Winters are cold, with a February average temperature of 18" F (−8° C), more keenly felt because of the moist sea air. Snow cover lasts on average 132 days. The Neva begins to freeze normally about mid-November, and the ice is solid by the start of December; breakup begins in mid-April and is completed by the end of the month. Icebreakers prolong the navigation season. Summers are only moderately warm, with a July average temperature of 63.9" F (17.7" C). The mean annual precipitation is 23 inches (585 millimetres), the maximum coming in summer. The northerly location (latitude 60° N passes through Leningrad's northern suburbs) gives long winter nights, while the half-light "white nights" of early summer are a renowned feature of the city.

Greater Leningrad covers an area of 521 square miles (1,350 square kilometres), which includes a number of satellite towns and urban districts under the city administration. Its population in 1975 was 4,311,000, of whom 3,853,000 lived within Leningrad itself.

HISTORY

Foundation and early growth. Settlement of the region around the head of the Gulf of Finland by Russians began in the 8th or 9th century AD. Known then as Izhor-



Central Leningrad and (inset) its metropolitan area.

skaya Zemlya, or more commonly as Ingermanland, or Ingria, the region came under the control of Novgorod, but for long it remained very thinly populated and underdeveloped. In the 15th century the area passed, with Novgorod, into the possession of the grand princes of Moscow. Sweden annexed Ingria in 1617 and established fortresses along the Neva. During the Great Northern War of 1700–21, Peter I the Great, seeking a maritime outlet to the west for Russia, constructed a fleet on the Svir River (which connects Lakes Onega and Ladoga) and sailing across Lake Ladoga launched an attack on the fortress of Noteburg (later Shlisselburg, now Petrokrepost), where the Neva flows out of Ladoga. In 1703 Noteburg fell to Peter, and shortly afterward he captured the Swedish fortress of Nienshants on the lower Neva, thus gaining control of the delta and the head of the gulf.

Peter–Paul Fortress

On May 16 (May 27, new style), 1703, shortly after the fall of Nienshants, Peter himself laid the foundation stones of a new fortress in the delta, the Peter–Paul Fortress on Zayachy Island near the right bank of the Neva. This date is taken as the founding date of Sankt-Peterburg, or St. Petersburg. The massive fortification, the city's first structure, initially had earthen walls, but these were soon replaced by stone walls 40 feet high and 12 feet thick, with 300 cannon mounted on the bastions. In the spring of the following year Peter established the fortress of Kronshlot, later Kronshtadt, on Kotlin Island in the Gulf of Finland, to protect the approaches to the delta. At the same time he founded the Admiralty shipyard on the riverbank opposite the Peter–Paul Fortress; in 1706 its first warship was launched. Around the fortress and shipyard Peter began the building of a new city to serve as his "window on Europe." Just upstream of the Peter–Paul Fortress, the first small, single-storied house, built for Peter himself in the early days of the city's construction, is still preserved as a museum.

Although the first dwellings were single-storied and made of wood (and later, as a precaution against fire, of clay on wooden frames), it was not long before stone buildings were erected. The first stone palace, still preserved, was completed in 1714 for Prince Aleksandr Danilovich Menshikov, first governor of the city. From the start the city was planned as an imposing capital, on a regular street pattern, with broad avenues radiating out from the Admiralty and spacious squares. Architects, craftsmen, and artisans were brought from all over Russia and from many foreign countries to construct and embellish the new town. In 1712 the capital of Russia was transferred there from Moscow, although it was not until 1721 that Sweden, in the Treaty of Nystad, formally ceded sovereignty of the area to Russia. Members of the nobility and merchant class were compelled to move to the new capital and to build houses for themselves. Government buildings and private palaces and houses arose swiftly; among the earliest buildings were the Merchants' Exchange (now the Naval Museum), Customs House (now the Museum of Literature), and marine hospital, together with the Summer Palace. Canals for drainage were cut through the marshy left bank of the Admiralty Side. The first floating bridge over the Neva was constructed in 1727, and soon more than 370 bridges, some of them drawbridges, had been built across the many canals and river channels. The watercourses themselves were controlled with embankments of gray and pink granite.

A harbour was constructed, and Peter took measures to curtail traffic through Arkhangelsk on the White Sea, previously Russia's major port. In consequence, as early as 1726 St. Petersburg was handling 90 percent of Russia's foreign trade. In 1703 Peter had begun work on the Vyshnevolotsky Canal in the Valdai Hills to link the upper Volga to the Msta and so, by way of the Volkhov, Lake Ladoga, and the Neva, to St. Petersburg. The canal was opened to traffic in 1709, giving the capital a direct water link to central Russia and all the Volga Basin. Industry soon began to develop. The original and flourishing Admiralty shipyard was joined by enterprises to supply its needs and those of the growing fleet—a foundry to produce cannon, a gunpowder factory, and a tar works. Merchantmen as well as warships were built, and before the end of the 18th century papermaking, printing, and food, clothing, and footwear industries had been established; as early as the 1740s a factory was set up to make china. By 1765 the population numbered 150,300 and by the end of the century it had reached 220,200, of whom more than a third were in the armed forces or the administration.

The rise to splendour. The growing city displayed a remarkable richness of architecture and harmony of style. Initially the style was one of simple but elegant restraint, seen in the cathedral of the Peter–Paul Fortress and in the Summer Palace. In the mid-18th century an indelible stamp was put on the city's appearance by the architects Bartolomeo Rastrelli, S.I. Chevakinsky, and V.P. Stasov, working in the style known as Russian Baroque, which combined clearcut, even austere lines with richness of decoration and use of colour. To this period belong the Winter Palace, the Smolny Convent, and the Vorontsov and Stroganov palaces, among others; outside the city were built the summer palaces of Peterhof on the gulf shores and of Tsarskoye Selo. After a transitional period, dominated by the architecture of Jean-Baptiste de La Motte and Aleksandr Kokorinov, toward the end of the 18th century a pure Classical style emerged under the architects Giacomo Quarenghi, Carlo Rossi, A.N. Voronikhin, and others. The Kazan and St. Isaac's cathedrals, the Smolny Institute (the most famous girls' school of tsarist Russia), the new Admiralty, the Senate, and the Yelagin Palace and Mikhaylovsky palace (now the State Russian Museum) are notable representatives of the many splendid buildings of this period.

Russian Baroque architecture

The cultural life of the capital developed and flourished. In 1773 the Institute of Mines, one of the first higher technical colleges in Russia, was established. The University of St. Petersburg (now Leningrad State University) was founded in 1819. Many of the most celebrated names in Russia in the spheres of learning, science, and the arts are closely associated with the city: M.V. Lomonosov, D.I. Mendeleyev, Ivan Pavlov, Aleksandr Pushkin, Fyodor Dostoyevsky, and Leo Tolstoy among many others. As early as 1738 the first ballet school in Russia was opened in St. Petersburg; in the 19th century, under the guidance of Marius Petipa, the Russian ballet rose to worldwide pre-eminence and renown and produced such dancers as Vaslav Nijinsky, Tamara Karsavina, and Anna Pavlova. In 1862 the first conservatory of music in Russia opened its doors, and there the premieres of works by Tchaikovsky, Rimsky-Korsakov, Rachmaninoff, and other composers were performed. Over all, as focus and patron of the city's cultural life, stood the imperial court; its ostentatious splendour and wealth were legendary throughout Europe. Its presence fostered the growth of jewelry making and other luxury trades.

The road to revolution. The imperial magnificence, centred on the tsarist autocracy, was in sharp contrast with the other side of St. Petersburg's development, the growth of its industrial proletariat. The 19th century witnessed very great growth of industry in the city, accelerated by improvements in communications and extension of trade. Navigation was opened on the Mariinsky (1810) and Tikhvin (1811) canal systems, which linked the capital with the Volga Basin and replaced the old and inadequate Vyshnevolotsky system. In 1813 the first Russian steamship was built in St. Petersburg and in 1837 the first Russian railway was constructed from the city to the Summer Palace in Tsarskoye Selo (now Pushkin). Five years later work started on the railway to Moscow, opened to traffic in 1851. A line to Warsaw followed in 1861–62, followed by others that made the city a focus of rail routes. In particular, the cotton textile and metalworking industries flourished, the former using imported raw materials. By the 1840s more than 60 percent of Russian imports were entering by way of St. Petersburg, but the increasing size of vessels necessitated transshipment at Kronshtadt until 1885, when a channel was dredged to give access to the port. City growth and industrialization were greatly stimulated by the emancipa-

New lines of communication

tion of serfs in 1861, which allowed far greater mobility of labour. From 539,400 inhabitants in 1864 the population rose to 1,439,000 in 1900, largely by migration from rural areas; in 1910 only 32 percent of the population had been born in the city. By 1914 the total had risen to 2,100,000.

Politicized work force

With the development of metalworking and engineering as the primary industries, there arose a skilled labour force, increasingly alert politically. Moreover, the factory workers, who numbered nearly 250,000 in 1914, tended to be concentrated in plants of far larger size than was usual in Russia; the Putilov (now Kirov) armaments works alone employed about 13,000. It was thus easier for revolutionaries to spread their ideas and for workers' groups to organize themselves than it was elsewhere in Russia. At the same time the growth of the city was characterized by a very belated and slow development of public transport, making it necessary for workers to live close to their place of work, in conditions of exceptionally high population density (more than 180,000 per square mile in the centre), appalling overcrowding, squalor, and lack of sanitation. Throughout the period before 1917 the city administration was lacking in efficiency and often in funds, and the provision of all public services--even a water supply—was very inadequate. Outbreaks of serious epidemics were commonplace, and St. Petersburg was notorious as one of the most unhealthful capitals of Europe. For many of the inhabitants the conditions of life were extremely bad.

The first serious revolutionary outbreak in St. Petersburg came on December 14 (December 26, N.S.), 1825, the so-called Dekabrist (Decembrist) insurrection, organized largely by liberal aristocrats and army officers seeking a liberal constitution and an end to serfdom. It was ruthlessly suppressed. During the rest of the century, workers' revolutionary activity by many different groups and general unrest steadily increased, with ever more frequent strikes and outbreaks of violence. These culminated in the general strike of January 1905, when some 150,000 workers took part. On Bloody Sunday, January 9 (22, N.S.), a mass march to the Winter Palace, bearing a petition to the Tsar, was met by troops, who opened fire; more than 1,000 people were killed. The situation developed into revolution, spreading throughout Russia. Although it was again crushed, underground revolutionary activity continued.

The outbreak of World War I in 1914 saw an upsurge of patriotic fervour focussed on the Tsar. The Germanic form of the city's name was changed to its Russian version, Petrograd. The military disasters of the war and the worsening economic situation, however, revived and intensified discontent. Transport inefficiencies led to severe shortages of food and other supplies in Petrograd. On February 26 (March 11, N.S.), 1917, disorders broke out as a result of food shortage.' Authority was slow to act and lost all control. The city was in chaos and the Petrograd Soviet of Workers' and Soldiers' Deputies was formed on February 27 (March 12, N.S.). The Tsar was prevented from entering the city, and on March 2 (15, N.S.) he abdicated. A provisional government was set up, eventually under the premiership of Aleksandr Kerensky.

Return of Lenin

On April 3 (16, N.S.) Lenin returned to Petrograd from Switzerland and set about organizing the overthrow of the provisional government. A Bolshevik rising in July was suppressed, but on October 25 (November 7, N.S.) Communist-led workers and sailors stormed the Winter Palace, deposing the provisional government and establishing Lenin and the Communist Party in power. The battle cruiser "Aurora" of the Baltic Fleet, which bombarded the palace, remains berthed in the Neva as a museum.

The Russian Revolution of 1917, which changed the course of history, was in large measure the work of the Petrograd proletariat and the sailors from Kronshtadt. In January 1918 a Constituent Assembly met in Petrograd, but the Bolsheviks, who had won only 168 seats out of 703, dispersed it by force and consolidated their authority. In March 1921 the sailors of Kronshtadt rose in revolt against Lenin, but after a night attack on the fortress across the frozen gulf, the rising was put down with great severity.

The Soviet period. In March 1918 the capital of the young Soviet state was moved back to Moscow. The years of the civil war after the Revolution had a disastrous effect on the city's economy. Industry came very nearly to a standstill. The population fell sharply to 722,000 in 1920, a mere third of the pre-Revolutionary size. Many died of hunger. In 1924, following Lenin's death, the city was renamed Leningrad. With the ending of the civil war, recovery began. When in 1928 the era of five-year plans began, much of the initial burden of developing the national economy fell on Leningrad and its established industrial plant and work force, especially in the provision of power equipment and machinery. This stimulated further growth, and by 1939 the city was responsible for 11 percent of all Soviet industrial output and its population had passed the 3,000,000 mark.

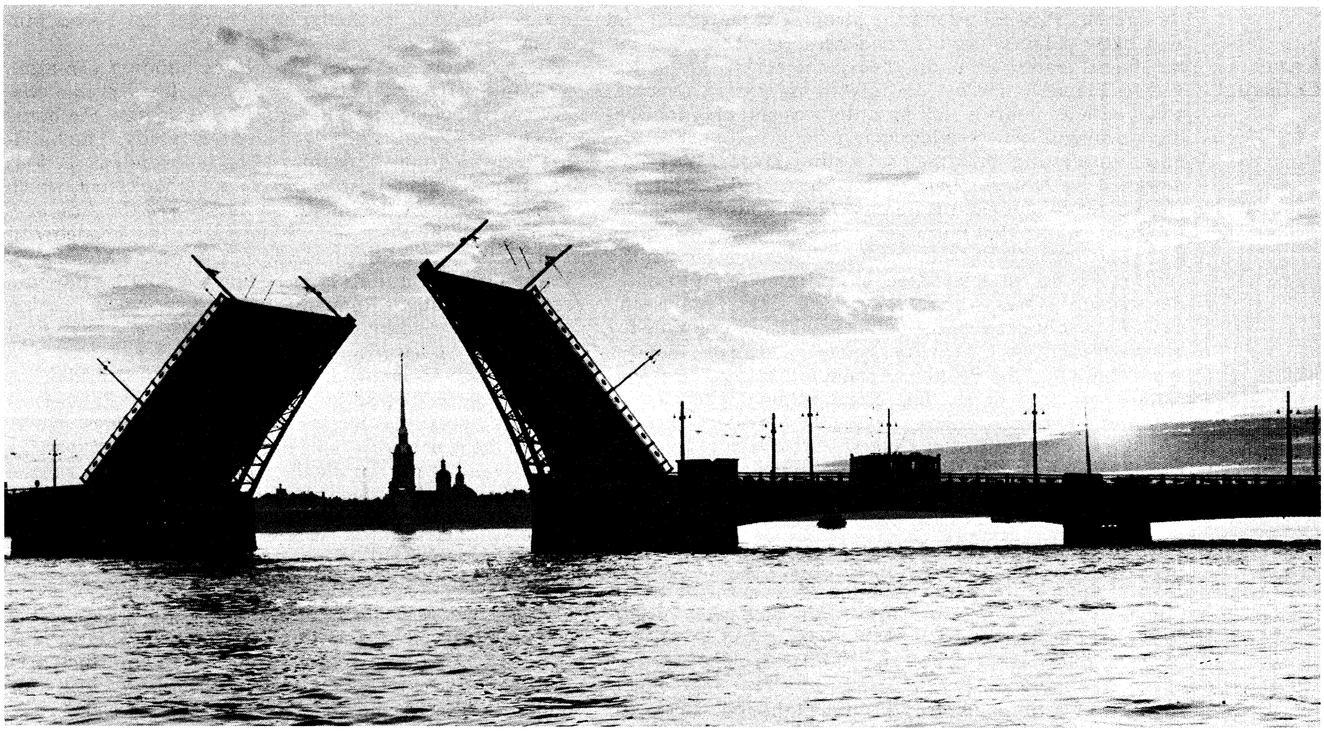
Then once again Leningrad was struck by a period of loss and destruction. It was one of the initial targets of the German invasion in 1941; by September of that year German troops were on the outskirts of the city and had cut off communication with the rest of the Soviet Union, while Finnish troops advanced across the Karelian Isthmus from the north. Many of the inhabitants and nearly three-quarters of the industrial plant were evacuated eastward ahead of the German advance. The remainder of the population and the garrison began what has become known as the 900-day siege; in fact it lasted 872 days, from September 8, 1941, to January 27, 1944. Leningrad put up a desperate and courageous resistance in the face of many assaults, constant artillery and air bombardment, and appalling suffering from shortages of supplies. An estimated one million people died, a very high proportion from scurvy and starvation. In particular the exceptionally bitter winter of 1941–42, when temperatures fell to —40" F (—40" C), was one of extreme hardship and loss of life. The only route for supplies was the "road of life" across the ice of Lake Ladoga; later an oil pipeline and electric cables were laid on the lake bed. The strict blockade was broken in January 1943, but it was another year before the Germans had been driven back from the outskirts. Enormous damage had been caused by the bombardment, and before retreating the Germans deliberately destroyed the palaces at Petrodvorets and Pushkin. So great was the city's loss that 15 years later, in the census of 1959, its population, 2,899,955, had still not regained prewar size. For its role in the war Leningrad was subsequently honoured with the title of Hero City, a special defense medal, and the Order of Lenin. To these were later added a second Order of Lenin, Gold Star, and Order of the October Revolution.

The 900-day siege

In Leningrad, the first postwar Five-Year Plan was devoted to reconstruction of the city. By 1950 industry was once more on its feet, and it has continued to expand and develop. The architectural heritage of the past was rebuilt and restored with meticulous care. By the census of 1970 the population had reached 3,512,974 in the city itself and 3,949,501 including the suburban towns within Greater Leningrad. From the late 1950s onward a program of housing construction added extensive new suburbs of apartment buildings, arranged in "micro-regions," or neighbourhood units, with populations usually of 3,000 to 8,000 and with local services of shops, cinemas, polyclinics, and schools. The apartment buildings, usually of five to nine stories in the 1960s, from the 1970s tended to be higher, with 12 to 20 or more stories. Great use has been made of standardized prefabrication in housing construction. Since 1966 development has been coordinated in a master plan, covering a 25-year period.

THE CONTEMPORARY CITY

Greater Leningrad, the city itself with its satellites, forms a large horseshoe around the head of the Gulf of Finland and including the island of Kotlin in the gulf. On the north it stretches westward along the shores for nearly 50 miles to include Zelenogorsk. This northern extension is an area of dormitory towns, resorts, sanatoriums, and holiday centres set among extensive conif-



Drawbridge rising over the Neva River, Leningrad. In the background on the right embankment is the Peter-Paul Cathedral (1712–33).

Novosti Press Agency—E. Ettinger

erous forests and fringed by fine beaches and sand dunes. Here many of the more important and influential citizens have summer cottages, or dachas. There are also many holiday camps for children. On the southern side of the gulf the metropolitan limits extend westward to include Petrodvorets (formerly Peterhof) and the towns of Pushkin (formerly Tsarskoye Selo) and Pavlovsk. Eastward, Greater Leningrad stretches up the Neva River to Ivanovskoye.

The central city. Leningrad is divided by distributaries of the Neva River into four sections. The Admiralty Side lies along the left (south) bank of the Neva itself. Between the two major arms of the Neva, the Bolshaya (Great) Neva and the Malaya (Little) Neva, is Vasilyevsky Island. The Malaya Neva and the distributary known as the Bolshaya Nevka enclose a group of islands known as the Petrograd Side, while east of the Bolshaya Navka lies the Vyborg Side.

The Admiralty

The Admiralty Side. The southern side of the Neva, known as the Admiralty Side, centres on the Admiralty. This, the nucleus of Peter's original city, was reconstructed in 1806–23 by A.D. Zakharov, as a development of the earlier building of I.K. Korobov, constructed in 1727–38, but retaining the layout of the original. Its elegant spire, topped by a weather vane in the form of a ship, is one of the principal landmarks of the city. The building today houses a naval college.

Just to the north lies the great Palace Square, the city's oldest. The 600-ton granite monolith of the Alexander Column (1830–34), tallest of its kind in the world, thrusts up for 155.8 feet (47.5 metres) near the centre of the square, so finely set that its base is not fastened.

Between the square and the river rises the huge and massive rectangle of the Winter Palace, the former principal residence of the tsars. The present structure, the fifth to be built, was the Baroque masterpiece of Rastrelli, and was built in 1754–62. Both the exterior and the interior of the palace were dazzlingly luxurious. In 1837 the building was destroyed by fire, and only the adjoining Hermitage survived; the Winter Palace was recreated in 1839 almost exactly according to Rastrelli's plans. The appearance of the palace is striking: the background is green, the columns white, and the stucco moldings golden, and 176 sculptured figures line the roof. The whole complex now houses the State Hermitage Museum, a treasure-house of fine art of worldwide significance that originated in 1764 as the private collection of the empress Catherine II.

Opposite the Winter Palace, the great crescent of Rossi's General Staff building (1811–29) dominates the square. The two wings of the building are joined by a huge triumphal arch, topped by heroic figures and crowned by a chariot containing a figure representing Glory, expressing the Russian victory in the war of 1812.

Dekabrists Square

On the western (downstream) side of the Admiralty stretches the expanse called Senate Square when that body moved to the city in 1763 and now called Dekabrists Square in commemoration of the revolt in 1825. The buildings of the former Senate and Synod (now housing archives) dominate the western side of the square, their decorated facades dating from the 1830s and representing the last great work of Rossi. They are separated by an arch looking across to the centre of the square where the equestrian statue of Peter I the Great, known as the "Bronze Horseman" and created in 1782 by Étienne Falconet, looks out to the Neva. Beside the Senate and Synod buildings stand two columns (1845) bearing statues of the goddess of glory; next to them rises the Classical front of the Horse Guards Riding School (1807), reminiscent of a Greek temple, and beyond, dominating the south side of St. Isaac's Square, is the cathedral of the same name, an outstanding monument of late Classical Russian architecture built by A. Montferrand (1818–58). St. Isaac's is one of the largest domed buildings in the world, and its golden cupola, 71.60 feet (21.83 metres) in diameter, soars to 331 feet (101 metres) and is visible all over Leningrad. Majestic and massive, the cathedral can hold 14,000 people. It is now a museum.

From the Admiralty and its surrounding squares radiate three great avenues, of which the most important and best known is the Nevsky Prospekt. One of the world's great thoroughfares, the Nevsky Prospekt cuts eastward across the peninsula formed by the northward loop of the Neva to the vicinity of the Alexander Nevsky Abbey, crossing the smaller Moyka River and Fontanka Canal. The Anichkov Bridge across the latter is graced by four groups of sculptured horses. The street has a special beauty; the architecture is majestic, the buildings graceful and finely proportioned, the construction complex. On

Kazan Cathedral

the Nevsky Prospekt stand the Stroganov, Shuvalov, and Anichkov palaces, private residences, and churches, but the finest feature is undoubtedly the Kazan Cathedral (1801–11), designed by Voronikhin in Russian Classical style, with an interior rich in sculptures and paintings behind a magnificent semicircular frontal colonnade. Another interesting building is Gostiny Dvor (1761–85), designed by Jean-Baptiste de La Motte and rebuilt 100 years later by Alexandre Benois. This building forms an irregular square that has a perimeter of half a mile or so and that opens onto four streets; formerly a mercantile centre, it is now a department store. In addition to other department stores, the Nevsky Prospekt contains the city's largest bookshop, the Saltykov-Shchedrin Public Library (located on Ostrovsky Square), and many theatres —most notably the Pushkin Academic Drama Theatre— restaurants, and cafes. The street is always noisy and humming with activity.

At the eastern end of the Nevsky Prospekt, Alexander Nevsky Square fronts the main entrance to the abbey of the same name and its surrounding gardens. Beyond the square's main entrance lie, on the left and right, respectively, monuments and sculptures of the 18th-century Lazarus Cemetery (where Lomonosov and many of the city's architects are buried) and the 19th-century Tikhvin Cemetery (containing the graves of such writers and composers as Dostoyevsky, Mussorgsky, and Tchaikovsky). Behind rise the spires and cupolas of the Cathedral of the Annunciation (1720, designed by Trezzini), which is now a museum, and Holy Trinity Cathedral (1778–90, designed by Ivan Starov).

Through the Admiralty Side and intersecting the radial avenues cut the canals that so characterize the city. The most important, in concentric order from the Admiralty, are the Moyka River and the Griboyedova, Fontanka, and Obvodny (Bypass) canals. Downstream of the northern entrance of the Fontanka into the Neva lies the Field of Mars, one of the most beautiful open spaces in Leningrad. Begun under Peter (when it was known as the Field of Amusement), it was intended for popular festivities and fireworks. A favourite haunt of the 18th-century nobility under the name Tsarina's Meadow, it derives its present name from a monument erected in 1801 and portraying the great Russian military leader A.V. Suvorov (buried in the Cathedral of the Annunciation) as the god of war. In the 19th century the square was used for military parades and exercises. The fallen of the 1917 February Revolution and defenders of the city during the civil war and foreign military intervention (1918–20) were buried here. Since 19.57 an eternal flame has commemorated the defenders of the Revolution.

Summer Palace

Just to the east lies the distinctive Summer Garden. Founded on an island in 1704, it has well laid out parks and gardens that contained more than 250 magnificent statues and busts, mostly the work of Venetian masters, by the end of the 18th century. The Summer Palace, Peter's first in the city, erected 1710–14 in early Russian Baroque style and designed by Trezzini, stands in the northeastern portion. The whole area suffered greatly in the great flood of 1777. The Neva embankment is fronted by an iron grille (1784) that is at the same time majestically monumental and light and delicate in design.

At the extreme eastern side of the central city, within the sharp bend of the Neva itself, lies the Smolny complex of buildings; these include the former convent, with the beautiful five-domed cathedral, built by Rastrelli in 1748–64, and the fine Classical building of the Smolny Institute constructed by Quarenghi in 1806–08. The institute was used as Lenin's headquarters during the events of 1917.

The Strelka. Opposite the Admiralty and Winter Palace is the eastern tip of Vasilyevsky Island, where the remarkable architectural complex known as the Strelka (literally, "Pointer") faces the bifurcation of the Neva. Behind the two great Rostral Columns, decorated by carved ships' prows, and across Pushkin Square, the point rises majestically to the Merchants' Exchange (Thomas de Thomon, 1805–lo), the city's finest example of early 19th-century style and reminiscent of a classical temple in appearance. The Exchange now houses the Naval Museum.

Farther back, the Twelve Colleges building (Trezzini, 1722–42), originally intended to house the supreme governmental bodies of Peter I the Great, is now the home of Leningrad A.A. Zhdanov State University. The building is divided into 12 identical but independent sections and runs at right angles to the Neva embankment, which is fronted here by the impressive facades of the Academy of Sciences, the Menshikov Palace, and the Academy of Fine Arts. On the far, or northern, side of the Merchants' Exchange, the Customs House (now the literary museum and the Institute of Russian Literature known as Pushkin House), designed by Lucchini (1829–32), is a crisp final link in the Classical complex of the Strelka.

Peter–Paul Cathedral

The Petrograd Side. Upstream of the bifurcation of the Neva is the Petrograd Side, where the great Peter–Paul Fortress faces the Strelka across the Malaya Neva. Above the squat horizontal lines of the fortress' massive stone walls soars the slender, arrow-like spire of the Peter–Paul Cathedral, a golden landmark for the city that reaches 400 feet (122 metres). The cathedral was built in 1712–33 by Domenico Trezzini, and all the tsars and tsarinas of Russia from the time of Peter the Great (except for Peter II and Nicholas II) are buried in it. Trezzini also designed St. Peter's (Petrovsky) Gate (1718) as the eastern entrance to the fortress. The Neva Gate, designed by N.A. Lvov, dates from 1787. From the early 19th century the fortress was used as a prison, chiefly for political prisoners and including a number of Dekabrists. Today it is a historical museum. At noon each day a signal cannon is fired from its battlements.

Just to the east of the Peter–Paul Fortress, at the beginning of the distributary known as the Bolshaya Nevka River, the cruiser "Aurora," which fired on the Winter Palace in 1917, is permanently moored as a museum and training vessel for the Naval College.

The Vyborg Side. Farther upstream and east of the Bolshaya Nevka is the Vyborg Side. It contains the Finland Railway Station, in front of which stands a statue of Lenin commemorating his return to the city in 1917.

The outer city. In general terms this may be defined as the area north of the Bolshaya Nevka and south of the Obvodny Canal. Buildings of historic or architectural interest are relatively few. Extensive industrial and residential suburbs spread north and south, those closest to the centre mostly of late 19th- or early 20th-century date. These parts, like the central city, are characterized by very high population densities, between 26,000 and 73,000 persons per square mile, although rehousing since the late 1950s has reduced the previously exceptionally high figures of the centre. The city now extends well to the north and south of the original delta site. The outer suburbs of later development include extensive open areas, reducing overall population densities to between 5,000 and 21,000 per square mile. The use of large apartment buildings with two- or three-room flats means that densities within the built-up area remain very high. It is in these outer parts, especially on the eastern and southern sides of the present built-up area, that future expansion is envisaged under the master plan of 1966. Other parts of the periphery are designated as green belt for amenity purposes, and urban development is prohibited. Scattered through the outlying sections of Greater Leningrad are the satellite towns and dormitories.

Petrodvorets. The communities around Leningrad are also rich in historic monuments. The most famous is Petrodvorets (Peterhof before 1944), whose unique garden-park setting, stretching in terraces rising above the Gulf of Finland, contains representative works from two centuries of Russian architectural and park styles. The Great Palace, former residence of Peter I, stands at the edge of the second terrace, its bright yellow walls contrasting with white stucco decorations and the gilt domes of its lateral wings. Built in the Baroque style (1714–28), it was reconstructed and expanded by Rastrelli in 1747–52. On the north, the building commands a view of the Grand Cascade, a grandiose structure including a grotto, 64 fountains, and two cascading staircases, which lead to an enormous semicircular basin that originally contained a giant statue of Samson wrestling with a lion that symbolizes the military glory of Russia.

This magnificent vista is all the more remarkable when it is remembered that much of it is a post-World War II restoration that at the beginning of the 1960s was still under way. The Nazis carried off the Samson statue and many other statues and left only the charred walls of the palace itself.

Pushkin. The town of Pushkin (before 1917 Tsarskoye Selo; called Detskoye Selo in 1918–37) arose in the beginning of the 18th century as one of the tsarist residencies. The palace of Catherine I (1717–23; enlarged by A.V. Kvasov and S.I. Chevakinsky, 1743–48; rebuilt by V.V. Rastrelli, 1752–57) is notable for its dimensions, the beauty and majesty of its form, and the wealth of its sculptural decoration. The golden suite of splendid halls (including the Amber Room) exemplifies Russian Baroque at its peak. The community also is the site of the Chinese Village (1782–96) in Alexander Park and the gallery (1780–90) named after the architect Charles Cameron, the terraces of which contain more than 50 busts of figures from ancient Greek and Roman history. The Lycte, a school for the offspring of the nobility, had the great Pushkin as a student. The town suffered severe destruction during the German onslaught but has been much restored to its former glory as a museum town.

The palace of Catherine

Pavlovsk. The town of Pavlovsk, a southern suburb, is the site of a remarkable late 18th- and early 19th-century palace-park ensemble in the Classical style created as a country residence for Tsar Paul I. The central Great Palace (1782–86; Cameron) is crowned by a dome supported by 64 columns. It, too, was severely damaged by the Nazis and has been restored. Some 60,000 of its destroyed trees have been replaced.

Gatchina. Another southern suburb, Gatchina, is noted for the palace built in 1766–72 by Rinaldi for Count Orlov, a favourite of Catherine II. Gatchina Park was created at the same time. Its monuments, sculptures, and gardens, like those of all Leningrad, are under state supervision that provides for protection and restoration.

ADMINISTRATIONAND THE URBAN ECONOMY

Since 1931 Leningrad has been designated a "city of republican subordination"—that is, its City Council (Soviet) is directly subordinate to the government of the Russian Soviet Federated Socialist Republic. The council consists of 640 members, elected for two-year terms. The city itself is divided into 19 administrative wards. In addition to these, there are five towns in the outer part of Greater Leningrad with status equivalent to that of the administrative wards—Kolpino, Petrodvorets, Pushkin, Sestroretsk, and the island of Kronshtadt. Two other towns, Zelenogorsk and Pavlovsk, and 17 urban districts are subordinate to the administrative ward councils. Leningrad is also the administrative centre of Leningrad *oblast* (region), which has an area of 33,200 square miles (85,900 square kilometres) and a population of 1,495,000 (1975 estimate), excluding the city. As a residue of the city's former status as capital, certain organizations still maintain their national headquarters in Leningrad, among them the all-union geographical, chemical, and medical societies.

Industry. Leningrad is second only to Moscow in the Soviet Union as a centre of industry, and more than half of its working population is employed in factories and the building trade. More than 4,000 enterprises produce about 6 percent of all Soviet industrial production. The entire Soviet Union forms the hinterland for the distribution of Leningrad's manufactures.

Engineering industries

Foremost position is taken by engineering, which accounts for more than half of the city's industrial output. Special emphasis is placed on those branches of engineering that require a skilled labour force and relatively small quantities of metal. Even so, Leningrad uses about a tenth of all steel made in the Soviet Union. Some steel, of specialized high-grade type, is made locally in the suburb of Kolpino, but the bulk of Leningrad's requirements comes from Cherepovets, 400 miles to the east on the Rybinsk Reservoir of the Volga. Leningrad's original industry, shipbuilding, is still of prime importance and the largest of its kind in the Soviet Union; it produces icebreakers (some atomic-powered), tankers, timber carriers, and fishing vessels. Other sectors of heavy engineering make armaments and rolling stock. Of outstanding national significance is the manufacture of electrical and power machinery, such as steam, hydraulic, and gas turbines, armatures, and generators. Precision engineering includes tools and instruments, refrigerators, radios, television apparatus, and other electric and electronic goods. Industrial machinery is produced for automated factories and for the knitwear and footwear industries.

Second to engineering is the group of chemical industries. These make a wide range of items, such as superphosphate fertilizers (using apatite from the Kola Peninsula), tires and other synthetic rubber goods, plastics and plastic goods, artificial and synthetic fibres, paints, and pharmaceutical preparations. Consumer goods industries also comprise a very wide range, with the city itself as their principal market. These include the production of cotton and woollen textiles, clothing, footwear, tobacco products, beer, and foodstuffs. Leningrad is the largest centre of the printing industry in the Soviet Union.

Electrical power for these industries comes from peat-burning generating stations near the city and from hydroelectric plants on the Volkhov, Svir, and Vuoksa rivers. Natural gas is piped to Leningrad from the southern regions of European Russia.

Electricity

Transport. Leningrad has a major function as the largest port of the Soviet Union. The main harbour, in the southwest of the city on the shores of the Gulf of Finland, is protected by breakwaters and is reached by a dredged channel from Kronshtadt. Imports to Leningrad include metal pipes, factory equipment, chemicals, sugar, cotton, and fruit, while machinery, timber, coal, potassium salts, and pyrites form the bulk of exports. Passenger liners maintain regular summer services through the Baltic and to Great Britain. Smaller seagoing ships have access by way of the Neva (all the bridges over which can open) to Lake Ladoga and thence throughout the inland waterway system of European Russia. From Lake Ladoga the Svir River, Lake Onega, and the White Sea Canal (Belomor Kanal) lead to the White Sea and thence by the Northern Sea Route all along the Arctic coast of the Soviet Union. From Lake Onega the Volga–Baltic Waterway system leads to the Volga Basin and Caspian Sea and, via the Volga–Don Canal, to the Black and Azov seas.

The city is a focus of rail routes, with 10 trunk lines radiating out to Helsinki and Warsaw as well as to Moscow and other major cities of the Soviet Union. There are five principal passenger rail termini—the Moscow, Vitebsk, Warsaw, Baltic, and Finland stations. A network of suburban electric services connects the outer parts of Leningrad and its satellite towns. Internal city traffic is carried by a subway system (begun in 1946 and opened in 1955) and a well-developed network of bus, streetcar, and trolleybus lines. Altogether some 6,000,000 people are transported daily, two-thuds of them on the buses and streetcars.

HEALTH. EDUCATION. AND CULTURE

Leningrad is fully equipped with the health services of a modern city. There are some 500 polyclinics providing medical and dental care and maternity and nursing services for the residential "micro-regions" and suburbs. The higher level of medical care is provided by 154 general and specialized hospitals.

The city is one of the most important centres for education and scientific research in the Soviet Union; no less than 15 percent of the total employed population is engaged in education, the arts, and the sciences. Heading the educational establishments is the Leningrad A.A. Zhdanov State University, founded in 1819; its main building is Trezzini's Twelve Colleges on the Bolshaya Neva opposite the Admiralty. No less renowned and even older are the Academy of Fine Arts, founded in 1757, the

Institute of Mines (1773), and the Military Medical Academy (1798). Altogether Leningrad has some 40 higher educational establishments, taking over a quarter of a million students from all parts of the Soviet Union. There are about 740 general schools and a further 86 specialist and technical secondary schools.

Library of the Academy of Sciences

A focus for research is the library of the Academy of Sciences of the U.S.S.R., which remained in Leningrad when the academy's headquarters moved back to Moscow after the Revolution. More than 40,000 scientific research workers are employed in approximately 400 research establishments. These include the Botanical, Forestry, and Zoological institutes of the Academy of Sciences, the Pulkovo Observatory, and the Geological Institute. The city is the principal Soviet centre for Arctic research, notably at the Arctic and Antarctic Research Institute and the Institute for the Study of Permafrost. In the 1970s plans were going forward for an academic satellite suburb for Leningrad, on the lines of that outside Novosibirsk. Eventually the university and other research and educational establishments will be located there.

There is a large number of libraries in the city, headed by the Saltykov-Shchedrin Public Library on the Nevsky Prospekt, established in 1795; its 14,000,000 volumes and many valuable manuscripts make it second only to Moscow's Lenin Library in the Soviet Union. Another important specialized collection is in the Pushkin House literary museum on Vasilyevsky Island. Leningrad has 15 theatres. The Kirov State Academic Theatre of Opera and Ballet, formerly the Mariinsky Theatre, has long enjoyed an international reputation, and its resident company is frequently on tour abroad. Other important theatres are the Maly (Little), Gorky, Pushkin, and Musical Comedy theatres. The largest of several concert halls is the October Great Concert Hall, which seats 4,000 people. Apart from the Hermitage, of world rank, there are 47 museums, notably the State Russian Museum founded in 1895, which specializes in Russian painting. Many books and journals and 125 newspapers are published in the city. There are three radio stations and a large television centre, transmitting on three channels. Leningrad is a significant centre of the motion-picture industry, with three studios. Provision of sports facilities is good; the Kirov Stadium, largest in the city, has seating for 80,000. Other forms of open-air recreation are catered for by the large zoo, the oldest botanical gardens in the Soviet Union, and numerous parks and gardens.

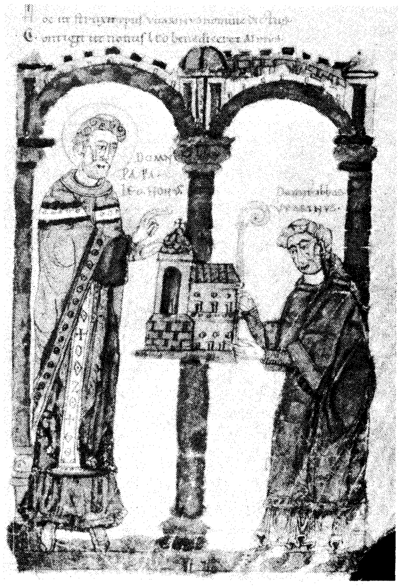
Leo IX, Saint and Pope



Leo IX (left) blesses Abbot Warinus in Metz; codex, 11th century. In the Burgerbibliothek, Bern, Switzerland (Cod. 292, f. 73).

By courtesy of the Burgerbibliothek, Bern. Switzerland

Leo IX, pope from 1049 to 1054, inaugurated the period of the great 11th-century reform of the Roman Catholic Church and began to make the papacy a focal point of western Europe. During his pontificate occurred the schism between the Eastern and Western churches (1054).

Bruno of Egisheim (in Alsace) was born into an aristocratic family on June 21, 1002. He was educated at Toul, where he first became canon and then was consecrated bishop on September 9, 1027, at the early age of 25. Dynamic, purposeful, and zealous in the cause of reform, he began to raise the moral standards of important monasteries in his diocese, as well as those of the secular diocesan clergy, by holding frequent meetings and by constant exhortations. In accordance with prevailing practice, he was appointed pope at the age of 47 by the emperor Henry III. He insisted, however, upon being elected by the people and clergy of Rome, an action that implicitly indicated his opposition to the firmly entrenched lay intervention, especially by the emperors, in purely ecclesiastical matters. After having obtained approval by the Romans, he was enthroned as pope on February 12, 1049.

Attack on concubinage, simony, and lay investiture

Leo IX's aim was the eradication of what he saw as the chief evils of the time—that is, concubinage (clerical marriage), simony (buying and selling of ecclesiastical offices), and lay investiture (conferment of an ecclesiastical office by a lay ruler). In order to achieve these ends it was necessary for the Roman Church itself to be made the centre of Christian society and life. Leo therefore called to Rome men whom he had known in his capacity as bishop of Toul. They not only were aware of the pressing need for reform but were also first-class scholars and administrators as well as men who realized the difficulties with which they were to be confronted. Among them were Humbert of Moyenmoutier, Frederick of Lorraine (later Pope Stephen IX), and Hugh of Remiremont, all of whom became cardinals. A notable monk at Cluny, Hildebrand, also obeyed the call to Rome, where he was destined to play a historic role as Pope Gregory VII, becoming the consummator of the reform initiated by Leo. These men and their assistants infused new blood into the Roman Church. Leo also entertained regular contact with other leading churchmen, such as Peter Damian and Abbot Hugh of Cluny, who by virtue of their reputations exercised great influence upon their immediate surroundings and thus prepared the way for the acceptance of measures to reform Christian society.

These men succeeded in transforming the papacy from a local Roman institution into an international power. This farsighted and able group was determined to make papal ideology a social reality. The pivotal point in this ideology was the primatial position of the pope as so-called successor of St. Peter—an ecclesiastical expression for papal monarchy. The organizational apparatus of the papacy experienced a great expansion at this time, notably the chancery, which became the nerve centre of the papacy in which the universally valid and applicable law and the instructions and mandates to distant ecclesiastical officers were drafted.

Although the immediate effect of these legal measures was not immediately conspicuous, they nevertheless prepared the ground for their subsequent successful implementation. During Leo IX's pontificate the cardinals became more and more prominent as the most intimate counsellors of the pope, and within a few years they were to form the body known as the Sacred College of Cardinals.

The validity of priestly ordinations administered by simoniac bishops proved a serious problem, because most theologians held that simony prostituted the sacrament of ordination. Leo IX ordered a number of simoniacally ordained priests to be "reordained." This order called forth a great spate of controversial literature but the problem was not solved until several decades later. A synod that was under Leo's presidency condemned as heretical in 1050 the views propounded by Berengar of Tours (died 1088) on the Eucharist (that the bread and wine only symbolically became the body and blood of Christ).

Leo IX was intent on making the primatial position of the pope real by his own physical presence outside Rome. To this end he held more than a dozen councils in Italy, France, Germany, and Sicily, which re-enacted the decrees of earlier councils and popes and initiated practical measures to eliminate the worst excesses from which Christian society suffered. The personal attendance of St. Peter's successor and his chairmanship of these councils were factors that powerfully contributed to the accelerated ascendency of the papacy. The frequent journeyings enabled the pope to establish direct contact with the higher and lower clergy as well as with leading secular personages.

The most significant event of Leo IX's pontificate—the actual break with the Eastern Church—resulted, at least partially, from an ill-fated military involvement.

After their settlement in Sicily in the second decade of the 11th century, the Normans presented considerable dangers to the existence of the papal state. In their marauding expeditions they plundered and devastated many churches and monasteries. In conjunction with Emperor Henry III, Leo resolved to undertake a military campaign against the Normans; but Henry withdrew and, with a weak and inexperienced army under his command, Leo had to face the Normans alone. They inflicted a crushing defeat upon the papal army, and on June 18, 1053, they took the Pope prisoner. He was nevertheless allowed to maintain contact with the outside world and to receive visitors. After nine months he was released.

The schism of 1054

The Norman venture, however, brought the papacy into conflict with the Eastern Church centred in Constantinople, which, since the 8th century, had exercised jurisdiction over large areas of southern Italy and Sicily. The forcefully enunciated papal theme of primacy in Leo's pontificate complicated the relations between Rome and Constantinople still further because the patriarch of Constantinople, Michael I Cerularius, considered this sheer provocation.

He closed the Latin (Western) churches in Constantinople and raised serious dogmatic charges against the Roman Church, notably in connection with the Eucharist. Cardinal Humbert attacked the Patriarch in a vitriolic and passionate manner by arguing the case for Roman primacy and also quoting extensively from the forged "Donation of Constantine" (allegedly bestowing sovereignty in the West on the papacy). A legation-under Humbert's leadership left for Constantinople in April 1054 to reach a settlement, but despite several meetings between Patriarch, Emperor, and legates, no concrete results emerged. On July 16, 1054, in the full view of the congregation, Humbert put the papal bull of excommunication—already prepared before the legation left Rome—on the altar of the church of Hagia Sophia in Constantinople. Thereupon the Patriarch excommunicated the legation and its supporters. This marked the final breach between Rome and Constantinople. This schism was to last, with short interruptions, until the modern age. Whether the excommunication of Michael I Cerularius was valid, because Leo had been dead for three months (he died suddenly on April 19, 1054), is merely a technical problem. The Roman legates were legates of the papacy and the bull of excommunication had been a measure of the reigning pontiff. In any case, the excommunication merely formalized in a dramatic and spectacular manner a state of affairs that had long existed. Although this occurred after the death of Leo IX, the outbreak of the formal schism correctly belongs to his pontificate, which in several ways therefore marked a caesura in the history of the papacy in medieval times.

Leo X, Pope

Pope Leo X, one of the most extravagant of the Renaissance popes, presided over the dissolution of the unified Western Church by refusing to accept with due seriousness the questions and actions of the founder of the Protestant Reformation, Martin Luther (1483–1546). By his lavish expenditures in making Rome a centre of European culture, he depleted the papal treasury that had been built up by his predecessor, Julius II (1445–1513), but by his political policies he made the papacy a significant power in Europe in the 16th century.

Born Giovanni de' Medici on December 11, 1475, in the city of Florence, he was the second son of Lorenzo the Magnificent, the ruler of the Florentine republic, and by

Leo X, contemporary medallion. In the coin collection of the Vatican Library.

Leonard von Matt—EB Inc.

custom thus destined for a religious life. At the early age of eight young Giovanni received the tonsure—a ceremony involving the cutting of hair from the head, thus indicating the change of status from lay to clerical—and five years later became the cardinal-deacon of Sta. Maria in Dominica. He received the finest education available in Europe at the court of his father under several tutors, including the philosopher Pico della Mirandola (1463–94). From 1489 to 1491 the youthful ecclesiastic studied theology and canon law at the University of Pisa. In 1492 he became a member of the Sacred College of Cardinals and attempted to take up residence in Rome. The death of his father later in the same year, however, brought him back to Florence where he lived with his older brother Piero.

The election of Pope Alexander VI took him back to Rome for the conclave (assembly of cardinals to elect the pope); otherwise he lived in Florence until he was exiled in November 1494 with the other members of the Medici family on the charge of their betraying the republic. For the next six years Cardinal de' Medici travelled throughout northern Europe. In 1500 he returned to Italy and settled in Rome. Upon the death of his brother Piero, Giovanni became the head of the Medici family. During 1503 he took part in the conclaves that elected first Pius III (September) and then Julius II (October). Named papal legate to Bologna and Romagna in 1511, he supervised the re-establishment of Medici control of Florence the following year; and although his younger brother Giuliano actually held the first place in the Florentine Republic, it was the Cardinal who ruled.

Election to the papacy

With the death of Julius II on February 21, 1513, the Sacred College of Cardinals was summoned to elect a successor. The conclave met on March 4, and with minimal deliberation the cardinals, who desired a peace-loving successor to the warlike Julius, elected Cardinal de' Medici on March 11. Taking the title of Leo X the pontiff-elect was ordained a priest on March 15 and consecrated bishop of Rome on the 17th. Two days later the papal coronation took place.

At 37 years of age the new Pope was the personification of the Renaissance ideals. Having spent his youth at the court of Lorenzo de' Medici he had acquired the mannerisms and tastes of one of the most brilliant societies of Europe and posed a sharp contrast to the soldier-pope whom he succeeded. He fit extremely well into the atmosphere of calm and quiet of which Rome was desirous after ten years of Julius II. Leo was lavish in his spending not only of the church's money but also of his own. Under his patronage Rome again became the cultural centre of the Western world. The construction of St. Peter's Basilica—initiated under Julius II—was accelerated, the holdings of the Vatican Library were greatly increased, and the arts flourished. Even the piety of the papacy was revised to some extent after the low reputation it had reached under the Borgia popes (Calixtus III and Alexander VI).

The fifth Lateran Council occupied the new Pope during the first five years of his pontificate. Called by Julius II two years before his death, the council was designed to nullify the efforts of nine rebellious cardinals who had called for a council to meet at Pisa in order to revive the conciliar movement—intending to place ecclesiastical authority in councils, rather than the papacy—of the previous century. Although "Pisa II" collapsed when first the German emperor (Maximilian I, 1459–1519) and then the French king (Louis XII, 1462–1515) withdrew their support, the Lateran Council opened in 1512. Leo X, who inherited the council before it was a year old, was little inclined to preside over the sweeping reforms that the church so desperately needed on the eve of the Protestant Reformation. Poorly attended, and dominated by Italian bishops, the council debated the principal issues of the day; but there was neither direction nor encouragement from the pontiff, nor the urgency and necessity that would spur on the Council of Trent some 40 years later. Thus the council was dissolved (March 16, 1517), without significant action, on the very eve of Martin Luther's posting of his 95 theses.

Political, economic, and religious issues

Leo X was not only the head of the Christian Church, he was the temporal ruler of the Papal States and head of the Medici family that ruled the Florentine Republic. To exert his influence in Italy he resorted to the common practice of nepotism (granting offices or benefits to relatives, regardless of merit). To the influential archbishopric of Florence he appointed his cousin, and future pope (Clement VII), Giulio de' Medici. He also named his younger brother Giuliano and his nephew Lorenzo to be Roman patricians. Giuliano's premature death in 1516 brought an end to the Pope's plan to create a central Italian kingdom for him. On July 1, 1517, following and as a result of an attempt upon his life earlier in the same year, Leo named 31 new cardinals, thus prejudicing the College of Cardinals with papal supporters. One cardinal (Alfonso Petrucci) was strangled in prison, and others were imprisoned and executed when they were implicated in the attempted assassination.

In his struggle to dominate Italy, Leo X was confronted by the awesome power of Spain and the determination of the French kings. Louis XII of France marched into Italy in 1513 to make good his claims to Milan and Naples. Reluctantly Leo formed the League of Mechlin, in which Spain provided the major military strength. The French were defeated at Novara, and Louis renounced his claims and withdrew his army. The peace was short-lived. The ascent of Francis I (1494–1547) in 1515 to the throne of France led to the renewal of the war. Although Leo renewed the coalition of Spain, the Empire, and England, Francis won the Battle of Marignano (September 14, 1515). The Pope made peace with the French king and then followed it up with the Concordat of Bologna. Promulgated in the form of a papal bull (Primitiva) on August 18, 1516, the concordat regulated church-state relations in France for the next 275 years. The French kings were given the power to nominate bishops, abbots, and priors, though the popes did retain the right to nominate candidates to fill vacant benefices in curia and certain other benefices. Though the pope always had the power to veto a nomination of the king's, in practice the lay monarch's choice was tantamount to an appointment. This control over the church in France on the part of the kings explains, in part, why the monarchy showed little interest in Protestantism during the 16th century.

The death of the Holy Roman emperor, Maximilian I, in 1519 brought Leo further into the political arena. The Habsburg candidate, Charles (1500–58) of Spain, had succeeded his maternal grandparents Ferdinand II of Aragon (1452–1516) and Isabella I of Castile (1451–1504) in 1516 and now sought to follow his paternal grandfather, Maximilian, to the powerful German throne. Both Francis I and Frederick the Wise (1463–1525) of Saxony, however, immediately put forward their candidacy. Leo—fearing that if the empire were joined to either France or Spain, Italy would come under the power of the victor—threw his support in favour of Frederick. The election of Charles I of Spain as Charles V of the Holy Roman Empire led to war between France and Spain, and although Leo would have preferred to remain neutral he cast his lot with the new emperor when Francis again invaded Italy.

The ever-pressing financial undertakings of the papacy kept Leo X in constant need of new means of raising revenue. The wars with France, his lavish support of the arts, the construction of St. Peter's, and a projected crusade against the Turks all contributed to the financial needs of the papacy. One important source of revenue had long been the dispensing of indulgences (remission of the temporal penalty for sins) for money. During the reign of Julius II, indulgences had been authorized for financial contributions for the construction of the great basilica in Rome, St. Peter's. Leo, who was very much interested in continuing this work, reaffirmed the indulgence shortly after his ascent. Nevertheless, because of its unpopularity in northern Europe, based primarily on economic reasons, it was not until early in 1517 that a Dominican friar actually began to preach the indulgence in the archdioceses of Mainz and Magdeburg (Germany). In response to this preaching, Martin Luther posted his 95 theses on the door of the Wittenberg Castle Church.

By the following year (1518) Luther's ideas had reached Rome, and Leo ordered the head of the Augustinian order, of which Luther was a member, to discipline the troublesome monk. When this failed the Pope tried to work through Frederick of Saxony, but again to no avail. During the course of the Leipzig debates in the summer of 1519, the Catholic theologian Johann Eck (1486–1543) manoeuvred Luther into publicly professing heresy on three accounts. On June 15, 1520, Leo issued a document condemning Luther of heresy on 41 accounts and ordered him to submit to the authority of Rome within 60 days or suffer excommunication. Luther, who by this time had gained the support of influential figures in Germany, openly defied the Pope. Thus, Leo was left no alternative but to issue a papal bull (Decet Romanum *Pontificem*) of excommunication on January 3, 1521.

Leo X had not taken the Lutheran movement with the seriousness that history later indicated was warranted. But the church, after all, had withstood the teachings of an English reformer, John Wycliffe (c. 1330–84), a Bohemian reformer, Jan Hus (c. 1372/73–1415), and was at the time weathering those of the Renaissance humanist Erasmus (c. 1466–1536). Leo viewed Luther as merely another heretic whose teachings would lead some of the faithful astray but that, as had happened in the past, the true religion would triumph in time. Furthermore, the political climate of Germany was not favourable for strong action against Luther and his supporters. Thus, the new movement spread rapidly in the north with relatively little interference from the papacy. On December 1, 1521, Leo X died suddenly, leaving behind him political turmoil in Italy and religious turmoil spreading across northern Europe.

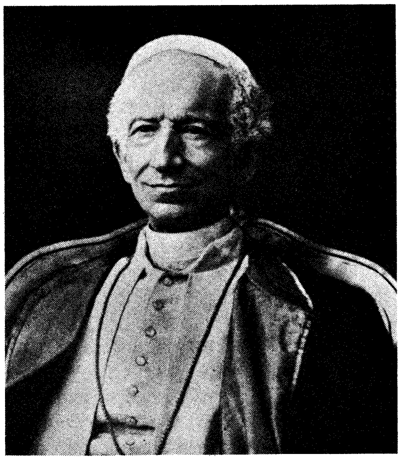
Leo XIII, Pope

Leo XIII, elected pope when he was almost 68 years old, was head of the Roman Catholic Church from 1878 to 1903. Although he kept to many of the paths trodden by his predecessors, he also brought a new spirit to the papacy, manifested in more conciliatory positions toward civil governments, by care taken that the Roman Catholic Church not be opposed to the needs of the times, and by a new conception of how the church should attempt to exercise its influence in society.

Early life and career

Vincenzo Gioacchino Pecci, born March 2, 1810, in Carpineto Romano, in central Italy, was the sixth child of a family of the lower nobility. After his early education in Viterbo and Rome, he completed his studies at the Accademia dei Nobili Ecclesiastici (Academy of Noble Ecclesiastics) in Rome. In 1837 he was ordained a priest and entered the diplomatic service of the Papal States. His superiors immediately appreciated his qualities: flexibility and lucidity and great energy, despite his delicate health. Thus promotions came quickly; he was made delegate (the equivalent of provincial governor) of Benevento in 1838 and was transferred in 1841 to the more important delegation of Perugia. In January 1843 he was appointed nuncio (a papal legate of the highest rank, permanently attached to a civil government) to Brussels and shortly after was consecrated an archbishop.

The Bettmann Archive



Leo XIII, 1878.

Pecci's stay in Belgium, lasting only three years, was an important stage in the life of the future pope. He discovered how Catholics in a modern constitutional government could profit from the parliamentary system and from freedom of the press. But the Belgian nunciature halted the young prelate's career, which had begun so auspiciously. Pecci showed initiative and independence in several delicate situations, but he was severely criticized at the time; and King Leopold I, considering him less docile than his predecessor, soon demanded his recall.

He was then named, early in 1846, bishop of Perugia, a small diocese to which he was confined for 32 years, despite his having been made a cardinal in 1853. He suffered from this obscurity and made many attempts to win Rome's favour, but in vain: his harsh judgment of the opposition in the Papal States to the Roman Revolution of 1848, and his concern to avoid useless conflicts with the Italian authorities after the annexation of Umbria in 1860, made Rome suspect him––quite wrongly— of liberal sympathies and of tepidity with respect to temporal powers.

A weaker personality would undoubtedly have been dulled and embittered by this prolonged period of disfavour, but for Pecci these years of retreat were extremely fertile. He zealously applied himself to the systematic reorganization of his diocese and to the spiritual and intellectual improvement of his clergy. He also had available a great deal of leisure time in which to read and meditate. He occupied himself with the renewal of Christian philosophy and studied particularly the writings of St. Thomas Aquinas, the 13th-century Scholastic philosopher, to whom he had been introduced by his brother Giuseppe, a Jesuit seminary professor. He was also led to reconsider the problem of the relations between the church and modern society and became increasingly convinced of the mistake committed by ecclesiastical authorities in taking a fearful, negative attitude toward the aspirations of the times. The fruits of this silent maturation were revealed to his surprised contemporaries in his pastoral letters of 1877 and 1878, which attracted attention even beyond Italy's borders. He also received notice when, in 1877, he was named camerlengo, the office of chief administrator of the church in the event that the pope dies.

Election to the papacy

At the death of Pius IX in February 1878, his name was mentioned frequently among those of the principal *papabili,* those considered possible successors to the papacy. His candidacy was strongly supported by most of the non-Italian cardinals, who were impressed by the self-control and energy with which he acquitted his duties as camerlengo and who noted that one who had been away for so long from Rome would be less compromised by the decisions of the preceding pope. Cardinal Pecci was elected on February 20, 1878, on the third ballot. He announced that he would take the name Leo in memory of Leo XII, whom he had always admired for his interest in education, for his conciliatory attitude toward temporal governments, and for his desire to create links with Christians who had separated from the Roman Catholic Church. The age of the new pope and his delicate health caused speculation that his pontificate would be brief. But, in fact, he directed the church for a quarter of a century.

The pontificate of Leo XIII's predecessor, Pius IX, had been long and controversial. From shortly after the beginning of his reign, Pius IX had been a strong, conservative authoritarian, both in his governing of the church and in his opposition to the new Italian government that annexed the Papal States. Although the pontificate of Leo XIII had a new spirit, the new pope was as intractable as his predecessor on the principle of the temporal sovereignty of the pope and continued to consider the traditional doctrine of the Christian state as an ideal. He reacted as strongly as had Pius IX against Freemasonry (a secret society that both popes viewed as opposed to Christianity) and secular liberalism. In church administration he continued to accentuate the centralization of authority in the papacy rather than in the national churches and reinforced the power of the nuncios. In addition, Leo XIII followed Pius IX in encouraging the devotion to the Sacred Heart of Jesus and to Mary. He renewed the condemnations of Rationalism—the theory that reason is the primary source of knowledge and of spiritual truth—and pursued with fresh vigour the re-establishment of the philosophy of St. Thomas Aquinas.

In other respects, however, there is no doubt that Leo XIII's pontificate was characterized by a new spirit. In his relations with civil governments, Leo XIII avoided inflamed protests and showed his preference for diplomacy. He achieved many incontestable successes through diplomacy, although his ability in this area was definitely less than is customarily asserted. The true greatness of Leo XIII was precisely that, in spite of his taste for politics, he was not exclusively a political pope. He was also an intellectual sympathetic to scientific progress and to the need for the Roman Catholic Church to demonstrate itself open to such progress, and he always remained a pastor who was concerned for the church's internal life and for the spreading of its message throughout the world.

This concern toward renewing the dialogue between the church and the world was manifested especially in his many encyclical letters giving instructions to Catholics throughout the world. In 1893 the encyclical *Providentissimus Deus* ("The Most Provident God"), now outdated but originally a pioneering work, defined in fairly broad-minded manner the principles on which Catholics should interpret the Bible. In several instructions he recommended that church and state live together in peace within the framework of modern society. The encyclical *Rerum Novarum* ("Of New Things") in 1891, though rather cautious in its approach, showed that the papacy had taken cognizance of the problems of the working class. He attempted to support the organization of the Catholic laity and was concerned about renewed dialogue with non-Catholics, as is demonstrated in the interest he showed in the attempt to create a link between the Anglican Church and Rome and in his respect for the traditions of the Eastern churches.

During the last years of Leo XIII's pontificate, until his death on July 20, 1903, there was a hardening of church policy and a more reserved attitude toward Christian democracy. Nevertheless, Leo XIII succeeded in gaining great prestige for the papacy, as was shown by the increase in countries having diplomatic relations with the Vatican, even non-Christian countries. He was a man gifted with a superior intelligence, an energetic temperament, a keen awareness of his personal worth, and a discriminating sense for public relations. Although his pontificate did not bring about many immediate changes in the relationship of the Roman Catholic Church to society, it did initiate many new attitudes that began to mature in succeeding decades.

BIBLIOGRAPHY. There is no biography that is completely scientific and objective. C. DE T'SERCLAES, *Le pape Léon XIII*, 3 vol. (1894–1906), gives the official Vatican viewpoint (the first two volumes were reviewed by the Pope himself); M. SPAHN, *Leo XIII* (1905), offers critical evaluations (in German) from the point of view of German "Reformkatholizismus" ("Critical Catholicism"); a French point of view is found in F. HAYWARD, *Leon XIII* (1937). The essay by R. AUBERT, "Léon XIII," in *I cattolici italiani dall'800 ad oggi*, pp. 189–220 (1964), utilizes the most recent works. On the various aspects of the work of Leo XIII as pope, see E.T. GARGAN (ed.), *Leo XIII and the Modern World* (1961); and E. SODERINI, *Il pontificato di Leone XIII*, 3 vol. (1932–33).

Leo III the Isaurian

Founder of the so-called Isaurian, or, more properly, Syrian, dynasty, Leo III was an important Byzantine emperor because of his success in halting Arab expansionism and because of his inauguration of Iconoclasm (destruction of religious images) as the state religious policy.

Leo III the Isaurian, gold solidus, 8th century. In the British Museum.
Peter Clayton

Military accomplishments. Born about 675–680 at Germanicea (Mar'ash) in northern Syria (modern Maraş, Turkey), as a youth he was taken by his parents (who apparently were prosperous) to Mesembria, in Thrace. Emperor Justinian II appointed the young man to the prestigious rank of *spatharius* (attendant) as a reward for assisting him in the recovery of his throne in 705. But the Emperor soon developed a distrust of him and therefore sent him to perform a perilous mission among the Alani on the remote eastern frontier, anticipating that he would never return. Despite the danger, Leo accomplished his assignment, managed to preserve his life, and ultimately, at the hands of a subsequent emperor, Anastasius II (713–715), received appointment as commander of the Anatolikon, the largest theme, or military-district army, in Asia Minor. As the result of a military revolt in 715, Anastasius was deposed, exiled to a monastery, and replaced by Theodosius III. Leo, in alliance with Artavasdos, the commander of the Armeniakon theme (the second largest in Asia Minor), refused to recognize the new emperor and continued to champion the cause of Anastasius. Meanwhile, Arab armies had invaded Asia Minor. Leo deceived them into believing that he would subjugate the empire for them, and thus he won their goodwill and support for his own attempt to seize the throne. After persuading them to spare Byzantine territory, he marched on Constantinople. The feeble Theodosius III abdicated, realizing that opposition was futile. Leo became emperor on March 25,717.

Defense against the Arabs

Leo's first task as emperor was the organization of the defense of Constantinople against the Arab troops under Maslamah ibn 'Abd al-Malik, who angrily perceived the deception. They besieged the city by land and sea from August 15, 717, to August 15, 718. Leo's skillful defense, which was aided by Greek fire (an igneous petroleum mix), a severe winter, desertions from the Arab fleet, and a Bulgarian assault upon those Arabs who had encamped in Thrace, compelled Maslamah to abandon the siege, which was the second and supreme Arab effort to capture Constantinople. Leo's victory marked an important check to Arab expansionism, preventing their establishment of a bridgehead in southeastern Europe. His complicated negotiations with the Arabs, as well as those earlier with the Alani, brought him a contemporary reputation for cleverness.

Leo consolidated his authority by crushing a rebellion in Sicily and a plot of army officers and officials to restore former emperor Anastasius II to the throne. Leo then sealed an alliance with his associate Artavasdos by marrying his daughter Anna to him. Throughout the reign, Artavasdos remained the second most powerful man in the empire by virtue of his control of several important military posts. Leo's wife, Maria, bore him a son, Constantine, whom he crowned in 720. An able diplomat, Leo married Constantine in 733 to a daughter of the Khagan of the Khazars; the marriage brought Leo a valuable military alliance with the Khazars in the trans-Caucasus against the Arabs.

Leo maintained peaceful relations with the Bulgarians to the north, enabling him to concentrate his military abilities against the Arab menace to Asia Minor. In 740 he won a major victory over the Arabs at Akroïnon (Afyonkarahisar). This victory freed Asia Minor from any immediate serious threat of Arab conquest, and it made possible the forceful counteroffensive and reconquest of some lost territory in the subsequent reign of his son Constantine V (741–775). He also repaired the extensive walls of Constantinople.

An energetic soldier-emperor, who personally led his troops in battle, Leo displayed great concern for the efficiency of his army. His victories improved army morale. He subdivided some of the very large military district armies, or themes, which had proved, as his own career demonstrated, so large and powerful that their commanders might attempt to seize the throne. Whether or not this administrative reorganization was itself responsible for subsequent stability, he did succeed in halting the vulnerability of the throne to military overthrow. He unquestionably left the army a more effective instrument at his death than he had found it on his accession. It no longer seems probable, however, that he planned or established a comprehensive system of social and institutional reforms.

Promotion of Iconoclasm

Religious policies. Leo's military achievements earned him great popularity with his soldiers and the people and may have given him the confidence to pursue his religious policies forcefully. He not only held firm religious opinions but he also had a profound belief in his duty as emperor to implement them as he understood them. In 722 he ordered the forcible baptism of Jews and Montanists (a Christian heretical group). He personally investigated but did not prosecute adherents of the Paulician heresy. The origins and nature of his policy of Iconoclasm, the most singular religious development in his reign, are obscure and controversial. He was deeply religious and seems to have become genuinely convinced of the sacrilegious character of religious pictures and relics as objects of veneration in worship services. It is uncertain whether any boyhood experiences in northern Syria, including contact with Muslims, influenced his Iconoclastic views, as his critics often charged. The lconoclastic opinions of certain bishops in western Asia Minor did, however, have some effect upon him. Thus, in 726 he began to speak out publicly against the use of sacred pictures. Opposition to his doctrines may have been the cause for an unsuccessful rebellion against him in the Cyclades Islands in 727. In 730 he proclaimed Iconoclasm the official policy of the empire and ordered the removal and destruction of sacred pictures in churches. When Patriarch Germanus I of Constantinople refused his demand for approval of these policies, Leo removed him and appointed a patriarch of his own choice, Anastasius. Where necessary, Leo employed harsh penalties, such as beatings and imprisonment, against recalcitrant ecclesiastics. His policies met particularly strong opposition from monastic circles. Popes Gregory II and Gregory III also strongly rejected his efforts to impose Iconoclasm upon Byzantine-controlled areas of Italy. Leo retaliated by halting financial contributions to the papacy from southern Italy, and he may also have removed the churches of Sicily, Calabria, and Illyria from papal jurisdiction and placed them under the patriarch of Constantinople. At any rate, his actions severely strained relations with the papacy, causing the popes to turn increasingly to the Frankish kings as alternative protectors of the Holy See in Rome and weakening the Byzantine position in the Italian peninsula. Other harsh taxation and administrative measures added to his unpopularity in Sicily and southern Italy. Although an able commander, Leo neglected to maintain strong naval forces in the western Mediterranean and thus further weakened Byzantine power there.

Revision of Roman law

Legal and other accomplishments. One of Leo's most important acts was the promulgation, in 726, of the Ecloga, a law code of modest length, which represented a revision of Roman legal practices as embodied in the 6th-century Corpus Juris Civilis (Body of Civil Law) of Emperor Justinian I. Consciously attempting to revise Roman law in accordance with Christian principles, Leo devoted much space in the Ecloga to the regulation of marriage and property rights. Amputation and mutilation often were substitutes in this new code for the former death penalties. Leo provided regular salaries for legal officials to discourage the corrupt custom of offering gifts or bribes to judges and bureaucrats. An important codification of military law, the so-called Soldiers' Law, is sometimes attributed to Leo, but its true ascription is uncertain.

Other than his sincere predilection for theological topics, Leo's intellectual interests are unknown. He possessed, doubtless from boyhood, a speaking knowledge of Arabic. Although there is little evidence of intellectual activity during his reign, the earlier charge that he halted higher education in Constantinople by closing an ecclesiastical academy (because of the faculty opposition to Iconoclasm) can no longer be credited with certainty. Similarly, there is little source material on economic or demographic developments during his reign, but the numerous earthquakes doubtless inflicted major damage on towns and the countryside.

Leo died on June 18,741, and was buried in the Church of the Holy Apostles at Constantinople. There is inadequate information on internal history in the last eight years of his reign, but he certainly failed to silence opposition to his Iconoclastic policies; in fact, Iconoclasm divided the empire for another century. He had instilled his Iconoclastic opinions and his grasp for military tactics in his son Constantine V, who ably followed and even intensified the policies of his father. Although Leo's memory was reviled by those later Byzantines who deplored his Iconoclasm, he was admired, especially in certain military circles, for his forceful and generally successful efforts to strengthen the state.

Leonardo da Vinci

The unique fame that the Florentine artist and scientist Leonardo da Vinci enjoyed in his lifetime and that, filtered and purified by historical criticism, has remained undimmed to the present day is based on the equally unique universality of his spirit. Leonardo's universality is more than manysidedness. True, at the time of the Renaissance and the period of Humanism, manysidedness was a highly esteemed quality; but it was by no means rare. Many other good artists possessed it. Leonardo's universality, on the other hand, was a spiritual force, peculiarly his own, that generated in him an unlimited desire for knowledge and guided his thinking and behaviour. An artist by disposition and endowment, he found that his eyes were his main avenue to knowledge; to Leonardo, sight was man's highest sense organ because sight alone conveyed the facts of experience immediately, correctly, and with certainty. Hence, every phenomenon perceived became an object of knowledge. ***Saper vedere*** ("knowing how to see") became the great theme of his studies of man's works and nature's creations. His creativity reached out into every realm in which graphic representation is used: he was painter, sculptor, architect, and engineer. But he went even beyond that. His superb intellect, his unusual powers of observation, and his mastery of the art of drawing led him to the study of nature itself, which he pursued with method and penetrating logic—and in which his art and his science were equally revealed.

LIFE AND WORKS

Early period: Florence. The illegitimate son of Ser Piero, a Florentine notary and landlord, Leonardo was born in 1452 on his father's family estate in Vinci, near Empoli. His mother, Caterina, was a young peasant woman who shortly thereafter married an artisan from that region. Not until his third and fourth marriage did Ser Piero's wives have children, the first one in 1476, when Leonardo was already an adult. Thus, Leonardo grew up in his father's house, where he was treated as a legitimate son and received the usual elementary education of that day: reading, writing, and arithmetic. As for Latin, the key language of traditional learning, Leonardo did not seriously study it until much later, when he acquired a working knowledge of it on his own. Not until he was 30 years old did he apply himself to higher mathematics—advanced geometry and arithmetic—which he studied with diligent tenacity; but here, too, he did not get much beyond the beginning stages.

Leonardo's artistic inclinations must have appeared early. When he was about 15, his father, who enjoyed a high reputation in the Florence community, apprenticed him to Andrea del Verrocchio. In Verrocchio's renowned workshop Leonardo received a many-sided training that included not only painting and sculpture but the technical-mechanical arts as well. He also worked in the next-door workshop of Antonio Pollaiuolo, where he was probably first drawn to the study of anatomy. In 1472 Leonardo was accepted in the painters' guild of Florence but remained five years more in his teacher's workshop. Then he worked independently in Florence until 1481. In the few extant works of this early period one may clearly trace the development of the artist's remarkable talent. Keenness of observation and creative imagination stand out. His early mastery is revealed in an angel and a segment of landscape executed by him in Verrocchio's painting the "Baptism of Christ" (Uffizi, Florence) and in two Annunciations (Uffizi, as well as the Louvre, Paris), both of them done in Verrocchio's workshop, as were the "Madonna and Child," the "Madonna Benois," and the portrait of Ginevra de'Benci, "Portrait of a Young Lady." This mastery reached its peak in two paintings that remained unfinished: "St. Jerome" and a large panel painting of "The Adoration of the Magi." In addition to these few paintings there are a great many superb pen and pencil drawings, in which Leonardo's mastery blazed new trails for this graphic art. Among the drawings are many technical sketches—for example, pumps, military weapons, mechanical apparatus—evidence of Leonardo's interest in and knowledge of technical matters at the outset of his career.

Evidence of early mastery

Unfolding of Leonardo's genius: first Milanese period (1482–99). In 1482 Leonardo entered the service of the Duke of Milan—a surprising step when one realizes that the 30-year-old artist had just received his first substantial commissions from his native city of Florence: the above-mentioned unfinished panel painting of "The Adoration of the Magi" for the monastery of S. Donato a Scopeto (1481) and an altar painting for the St. Bernard Chapel in the Palazzo della Signoria, which was never fulfilled. That he gave up both projects despite the commitments he had undertaken—not even starting on the second named—seems to indicate deeper reasons for his leaving Florence. It may have been that the rather sophisticated spirit of Neoplatonism prevailing in the Florence of the Medici went against the grain of his experience-oriented mind and that the more realistic academic atmosphere of Milan attracted him. Moreover, there was the fascination of Ludovico Sforza's brilliant court and the meaningful projects awaiting him there.

Leonardo spent 17 years in Milan, until Ludovico's fall from power in 1499. He was listed in the register of the royal household as ***pictor et ingeniarius ducalis*** ("painter and engineer of the duke"). Highly esteemed, Leonardo was constantly kept busy as a painter and sculptor and as a designer of court festivals. He was also frequently consulted as a technical adviser in the fields of architecture, fortifications, and military matters, and he served as a hydraulic and mechanical engineer.

In this phase of his life Leonardo's genius unfolded to the full, in all its versatility and creatively powerful artistic and scientific thought, achieving that quality of uniqueness that called forth the awe and astonished admiration of his contemporaries. At the same time, in the boundlessness of the goals he set himself, Leonardo's genius bore the mark of the unattainable so that, if one traces the outlines of his lifework as a whole, one is tempted to call it a grandiose "unfinished symphony."

The six paintings completed in the Milanese years

Painting and ***sculpture.*** As a painter Leonardo completed only six works in the 17 years in Milan: portraits of Cecilia Gallerani ("Lady with an Ermine") and a musician, an altar painting of "The Virgin of the Rocks" (two versions), a monumental wall painting of the "Last Supper" in the refectory of the monastery of Sta. Maria delle Grazie (1495–97), and the decorative ceiling painting of the Sala delle Asse in the Milan Castello Sforzesco (1498). Three other pictures that, according to old sources, Leonardo was commissioned to do have disappeared or were never done: a "Nativity" said to have belonged to Emperor Maximilian; a "Madonna" that Ludovico Sforza announced as a gift to the Hungarian king Matthias Corvinus; and the portrait of one of Ludovico's mistresses, Lucrezia Crivelli.

Also unfinished was a grandiose sculptural project that seems to have been the real reason Leonardo was invited to Milan: a monumental equestrian statue in bronze to be erected in honour of Francesco Sforza, the founder of the Sforza dynasty. Leonardo devoted 12 years—with interruptions—to this task. Many sketches of it exist, the most impressive ones discovered only a few years ago, when Leonardo's notebooks came to light again in Madrid. They reveal the sublimity but also the almost unreal boldness of his conception. In 1493 the clay model of the horse was put on open display on the occasion of the marriage of Emperor Maximilian with Bianca Maria Sforza, and preparations were made to cast the colossal figure, which was to be 16 feet (five metres) high—double the size of Verrocchio's equestrian statue of Bartolomeo Colleoni! But, because of the imminent danger of war, the metal, ready to be poured, was used for cannon instead, and so the project came to a halt. Ludovico's fall in 1499 sealed the fate of this abortive undertaking, which was perhaps the grandest concept of a monument in the 15th century. The ravages of war left the clay model a heap of ruins.

As a master artist Leonardo maintained an extensive workshop in Milan, employing apprentices and students. The role of most of these associates is unclear. Their activity involves the question of Leonardo's so-called apocryphal works, in which the master collaborated with his assistants. Scholars have been unable to agree in their attributions of these works, which include such paintings as "La Belle Ferronnière" in the Louvre, the so-called "Lucrezia Crivelli" in the Pinacoteca Ambrosiana, Milan, and the "Madonna Litta" in the Hermitage, Leningrad. Among Leonardo's pupils at this time were Giovanni Antonio Boltraffio, Ambrogio de Predis, Bernardino de' Conti, Francesco Napoletano, Andrea Solari, Marco d'Oggiono, and Salai.

Stimulus for Leonardo's scientific studies

Art and science: the notebooks. The Milan years also saw Leonardo's decided turn toward scientific studies. He began to pursue these systematically and with such intensity that they demanded more and more of his time and energy and developed into an independent realm of creative productivity. Within him there arose now a growing need to note and write down in literary form every one of his perceptions and experiences. It is a unique phenomenon in the history of art. Undoubtedly, the several treatises on art that appeared or were made available during those decades provided an external stimulus. Leon Battista Alberti's De re aedificatoria (Ten Books on Architecture) was first printed in 1485; Francesco di Giorgio's treatise on architecture was available in its first manuscript versions, and Leonardo had received a copy from the author as a gift. Moreover, Piero della Francesca in his De prospectiva pingendi ("On Perspective in Painting") had provided for his contemporaries a model text on the theory of perspective. Finally, there was the mathematician Lucas Pacioli, who had become an acquaintance of Leonardo's. In 1494 Pacioli published his Summa de arithmetica *geometria proportioni* et proportionalità, followed by his Divina proportione ("On Divine Proportion"), for which Leonardo drew figures of symmetrical bodies.

In this ambience Leonardo began to nourish the desire to write a theory of art of his own, and there arose in him the far-reaching concept of a "science of painting." Alberti and Piero della Francesca had already offered proof of the mathematical basis of painting in their analysis of the laws of perspective and proportion and thereby buttressed painting's claim to being a science. But Leonardo's claims went much further. Proceeding from the basic conviction that sight is the human being's most unerring sense organ, yielding immediate, accurate, and reliable data of experience, Leonardo—equating "seeing" with "perceiving'—arrived at a bold conclusion: the painter, doubly endowed with subtle powers of perception and the complete ability to pictorialize them, was the prime person qualified to achieve knowledge by observing and to reproduce that knowledge authentically in a pictorial manner. Hence, Leonardo conceived the staggering plan of observing all objects in the visible world, recognizing their form and structure, and pictorially describing them exactly as they are. Thus, drawing became the chief instrument of his didactic method.

In the years between 1490 and 1495 the great program of Leonardo the writer (author of treatises) began. In it, four main themes, which were to occupy him for the rest of his life, could be discerned and gradually took shape: a treatise on painting, a treatise on architecture, a book on the elements of mechanics, and a broadly outlined work on human anatomy. His geophysical, botanical, hydrological, and aerological researches also belong to this period and constitute parts of the "visible cosmology" that loomed before Leonardo as a distant goal. Over against speculative book knowledge, which he scorned, he set irrefutable facts gained from experience—from *saper* vedere ("knowing how to see").

The notebooks

All these studies and sketches were written down in Leonardo's notebooks and on individual sheets of paper. Altogether they add up to thousands of closely written pages abundantly illustrated with sketches—the most voluminous literary legacy any painter has ever left behind. Of more than 40 codices mentioned in the older sources—often, of course, rather inaccurately—21 have survived; these in turn sometimes contain notebooks originally separate and now bound together so that 31 in all have been preserved. To these should be added several large bundles of documents: an omnibus volume in the Biblioteca Ambrosiana, Milan, called Codex Atlanticus because of its size, was collected by the sculptor Pompeo Leoni at the end of the 16th century; its sister volume, after a roundabout journey, came to England and fell into the possession of the English crown. Today it constitutes the most highly prized object in the Royal Library, Windsor Castle. Finally there is the Arundel Manuscript (British Museum, MS. 263), which contains a number of Leonardo's "caricatures" on various themes.

It was during his years in Milan that Leonardo began the earliest of these notebooks. He would first make quick sketches of his observations on loose sheets or on tiny paper pads he kept in his belt; then he would arrange them according to theme and enter them in order in the notebook. Surviving are a first collection of material for the painting treatise (MSS. A and B in the Institut de France, Paris), a model book of sketches for sacred and profane architecture (MS. B, Institut de France, Paris), the treatise on elementary theory of mechanics (MS. 8937, Biblioteca Nacional, Madrid), only recently rediscovered, and the first sections of a treatise on the human body (Anatomical MS. B; Windsor Castle, Royal Library).

Two special features make Leonardo's notes and sketches unusual: his use of mirror writing and the relationship between word and picture.

Leonardo was left-handed; so mirror writing came easily and naturally to him. It should not be looked upon as a secret handwriting. Though somewhat unusual, his script can be read clearly and without difficulty with the help of a mirror—as his contemporaries testified. But the fact that Leonardo used mirror writing throughout, even in his fair copies drawn up with painstaking calligraphy, forces one to conclude that, although he constantly addressed an imaginary reader in his writings, he never felt the need to achieve easy communication by using conventional handwriting. Yet occasional examples of normal handwriting (drafts of letters, notes, and comments to be submitted to third parties) show that Leonardo was completely at home in it. In the overwhelming majority of his notes in mirror writing, therefore, one gets the strong impression of "monologues in writing." Finally, then, his writings must be interpreted as preliminary stages of works destined for eventual publication, which Leonardo never got around to completing. In a sentence in the margin of one of his late anatomy sketches, he implores his "neighbours" to see that his works are printed.

Function of Leonardo's illustration vis-à-vis text

The second unusual feature in Leonardo's writings is the new function given to illustration vis-à-vis the text. Leonardo strove passionately for a language that was clear yet expressive. The vividness and wealth of his vocabulary were the result of intense self-study and represented a significant contribution to the evolution of scientific prose in the Italian vernacular. On the other hand, in his teaching method Leonardo gave absolute precedence to the illustration over the written word; hence, the drawing does not illustrate the text; rather, the text serves to explain the picture. In formulating his own principle of graphic representation—which he himself called *dimostrazione*—Leonardo was a precursor of modern scientific illustration.

Thus, during Leonardo's years in Milan the two "action fields"—the artistic and the scientific—developed and shaped his future creativity. It was a kind of "creative dualism," with mutual encouragement but also mutual pressure from each field.

Second Florentine period **(1499/1500–06).** In December 1499 or at the latest January 1500—three months after the victorious entry of the French into Milan—Leonardo left that city in the company of Lucas Pacioli. He stopped first at Mantua, where, in February 1500, he drew a portrait of his hostess, Marchioness Isabella d'Este, and then proceeded to Venice (in March), where the Signoria (governing council) sought his advice on how to ward off a threatened Turkish incursion in Friuli. Leonardo recommended that they prepare to flood the menaced region. From Venice he returned to Florence, where, after a long absence, he was received with acclaim and honoured as a renowned native son. In that same year he was appointed an architectural expert to a committee investigating damages to the foundation and structure of the church of S. Francesco al Monte. A guest of the Servants of Mary order in the cloister of SS. Annunziata, Leonardo began there a painting of the "Virgin and Child with St. Anne," the composition of which won admiration from artists and art lovers of the city. He also painted (1501) a "Madonna with the Yarn-Winder," which has survived only in copies and which he probably never finished. Mathematical studies seem to have kept him away from his painting activity much of the time, or so the Marchioness Isabella d'Este, who sought in vain to obtain a painting done by him, was informed by her representative in Florence.

Service with Cesare Borgia

Only his omnivorous "appetite for life" can explain Leonardo's decision, in the summer of the following year (1502), to leave Florence and enter the service of Cesare Borgia as "senior military architect and general engineer." Borgia, the notorious son of Pope Alexander VI, had, as commander in chief of the papal army, sought with unexampled ruthlessness to gain control of the Papal States of Romagna and the Marches. Now he was at the peak of his power and, at 27, was undoubtedly the most compelling and at the same time most feared person of his time. Leonardo, twice his age, must have been fascinated by his personality. For ten months he travelled across the condottiere's territories and surveyed them. In the course of his activity Leonardo sketched some of the city plans and topographical maps that laid the groundwork—before the invention of printing—for modern cartography. At the court of Cesare Borgia, Leonardo also met Niccolò Machiavelli, temporarily stationed there as a political observer for the city of Florence.

In the spring of 1503 Leonardo returned to Florence to make an expert survey of a project for diverting the Arno River behind Pisa so that the city, then under siege by the Florentines, would be deprived of access to the sea. The plan proved unworkable, but Leonardo's activity led him to a much more significant theme, one that served peace rather than war; the project, first advanced in the 13th century and now again under consideration, was to build a large canal that would bypass the unnavigable stretch of the Arno and connect Florence by water with the sea. Leonardo developed his ideas in a series of studies; with panoramic views of the river bank, which are also landscape sketches of great artistic charm, and with exact measurements of the terrain, he produced a map in which the route of the canal (with its transit through the mountain pass of Serravalle) was shown. The project, considered time and again in subsequent centuries, was never carried out. Today the express highway from Florence to the sea covers the exact route Leonardo chose for his canal.

That same year (1503), however, Leonardo also received a prized commission: to paint a mural for the Hall of the Five Hundred in Florence's Palazzo Vecchio, a historical scene of monumental proportions (at 23 x 56 feet [7 x 17 metres], it would have been twice as large as the "Last Supper"). For three years he worked on this "Battle of Anghiari"; like its intended complementary painting, Michelangelo's "Battle of Cascina," it remained unfinished. But the cartoon and copies of the main scene of the battle, with standards flying, were for a long time, to quote the 16th-century art historian Giorgio Vasari, "the school of the world." These same years saw the portrait of "Mona Lisa" and a painting of a standing "Leda," which was not completed and has survived only in copies.

Scientific study during the Florentine period

The Florentine period was also, however, a time of intensive scientific study; Leonardo did dissections in the hospital of Sta. Maria Nuova and broadened his anatomical work into a comprehensive study of the structure and function of the human organism. He made systematic observations of the flight of birds, concerning which he planned a treatise. Even his hydrological studies, "on the nature and movement of water," broadened into research on the physical properties of water, especially the laws of currents, which he compared with those pertaining to air. These were also set down in his own collection of data, contained in the so-called Leicester Codex in Holkham Hall, Norfolk, England.

Second Milanese period **(1506–13).** Thus, during these years in Florence, Leonardo's productivity was also marked by his "creative dualism." Only sporadically did he work at his paintings. When, in May 1506, Charles d'Amboise, governor of the King of France in Milan, asked and was granted permission by the Signoria in Florence for Leonardo to go for a time to Milan, the artist had no hesitation about accepting the invitation. But what was originally a limited period of time became a permanent move under the stress of political circumstances. Florence let Leonardo go, and the monumental "Battle of Anghiari" remained unfinished. Unsuccessful technical experiments with paints seem to have impelled Leonardo to stop working on the mural. One cannot otherwise explain his abandonment of this great work—great both in conception and in realization.

Leonardo spent six years in Milan, interrupted only by a six months' stay in Florence in the winter of 1507–08, where he helped the sculptor Giovanni Francesco Rustici execute his bronze statues for the Florence Baptistery but did not resume work on the "Battle of Anghiari." Honoured and admired by his patrons Charles d'Amboise and King Louis XII, who gave him a yearly stipend of 400 ducats, Leonardo never found his duties onerous. They were limited to advice in architectural matters, tangible evidence of which are plans for a chateau for Charles d'Amboise and perhaps also sketches for an oratory for the church of Sta. Maria alla Fontana, which Charles funded. Leonardo also looked into an old project revived by the French governor: the Adda canal that would link Milan with Lake Como by water.

In Milan he did very little as a painter: two Madonnas, which he promised the King of France, were never painted. He continued to work on the paintings of the "Virgin and Child with St. Anne" and "Leda," which he had brought with him from Florence, as copies from the Lombard school of that period attest. Again Leonardo gathered pupils around him. With Ambrogio de Predis he completed a second version of "The Virgin of the Rocks" (1508), in the course of which protracted litigation between the purchasers and the artists had a happy ending. Of his older disciples, Bernardino de' Conti and Salai were again in his studio; new pupils came, among them Cesare da Sesto, Giampetrino, Bernardino Luini, and the young nobleman Francesco Melzi, Leonardo's most faithful friend and companion until his death.

The tomb sculpture for Trivulzio

An important commission in sculpture came his way. Gian Giacomo Trivulzio had returned victoriously to Milan as marshal of the French army and a bitter foe of Ludovico Sforza. He commissioned Leonardo to sculpt his tomb, which was to take the form of an equestrian statue and be placed in the mortuary chapel donated by Trivulzio to the church of S. Nazaro Maggiore. But after years of preparatory work on the monument, for which a number of significant sketches have survived, the Marshal himself gave up the plan in favour of a more modest one; so this undertaking, too, remained unfinished. Leonardo must have felt keenly this second disappointment in his work as a sculptor.

Compared with his almost cursory work in art, Leonardo's scientific activity flourished. His studies in anatomy achieved a new dimension in his collaboration with a famous anatomist from Pavia, Marcantonio della Torre. He outlined a plan for an overall work that would include not only exact, detailed reproductions of the human body and its organs but would also include comparative anatomy and the whole field of physiology. He even thought he would finish his anatomical manuscript in the winter of 1510–11. Beyond that, his manuscripts are replete with mathematical, optical, mechanical, geological, and botanical studies that must be understood as data for his "perceptual cosmology." This became increasingly actuated by a central idea: the conviction that force and motion as basic mechanical functions produce all outward forms in organic and inorganic nature and give them their shape and, furthermore, the recognition that these functioning forces operate in accordance with orderly, harmonious laws.

Last years (1513–19). In 1513 political events—the temporary ouster of the French from Milan—caused the now 60-year-old Leonardo to move again. At the end of the year he went to Rome, accompanied by his pupils Melzi and Salai as well as by two studio assistants, hoping to find employment there through his patron, Cardinal Giuliano de' Medici, brother of the new pope Leo X. Giuliano gave him a suite of rooms in his residence, the Belvedere, in the Vatican. He also gave him a considerable monthly stipend, but no large commissions came to him. For three years Leonardo remained in the Eternal City, off to one side, while Donato Bramante was building St. Peter's, Raphael was painting the last rooms of the Pope's new apartments, Michelangelo was struggling to complete the tomb of Pope Julius, and many younger artists such as Peruzzi, Timoteo Viti, and Sodoma were active there. Drafts of embittered letters betray the disappointment of the aging master who worked in his studio on mathematical studies and technical experiments or, strolling through the city, surveyed ancient monuments. A magnificently executed map of the Pontine Marshes (Royal Library, Windsor Castle; 12684) suggests that Leonardo was at least a consultant for a reclamation project that Giuliano de' Medici ordered in 1514. On the other hand, there were sketches for a spacious residence for the Medici in Florence, who had returned to power there in 1513. But this did not go beyond the stage of preliminary sketches and never came to pass. Leonardo seems to have resumed his friendship with Bramante, but the latter died in 1514. And there is no record of Leonardo's relations with any other artists in Rome.

Service with King Francis I of France

In a life of such loneliness, it is easy to understand why Leonardo, despite his 65 years, decided to accept the invitation of the young king Francis I to come to France. At the end of 1516 he left Italy forever, together with his most devoted pupil, Francesco Melzi. Leonardo spent the last three years of his life in the small palace of Cloux, near the King's summer residence of Amboise on the Loire. Premier peintre, architecte et *méchanicien* du Roi ("first painter, architect, and mechanic of the King") was the proud title he bore; yet the admiring King left him complete freedom of action. He did no more painting or at most completed the painting of the enigmatic, mystical "St. John the Baptist," which the Cardinal of Aragon, when he visited Amboise, saw in Leonardo's studio along with the "Mona Lisa" and the "Virgin and Child with St. Anne."

For the King he drew up plans for the palace and garden of Romorantin, destined to be the widow's residence of the Queen Mother. But the carefully worked-out project, combining the best features of Italian–French traditions in palace and landscape architecture, had to be halted because the region was threatened with malaria.

Leonardo still made sketches for court festivals, but the King treated him in every respect as an honoured guest. Decades later, Francis I talked with the sculptor Benvenuto Cellini about Leonardo in terms of the utmost admiration and esteem. Leonardo spent most of his time arranging and editing his scientific studies. The final drafts for his treatise on painting and a few pages of the anatomy appeared. Consummate drawings such as the "Floating Figure" (Royal Library, Windsor Castle; 12581) are the final testimonials to his undiminished genius. In the so-called "Visions of the End of the World," or "Deluge" (Royal Library, Windsor Castle), he depicts with overpowering pictorial imagination the primal forces that rule nature.

On May 2, 1519, Leonardo died at Cloux, near Amboise. He was laid to rest in the palace church of Saint-Florentine. But the church was devastated during the French Revolution and completely torn down at the beginning of the 19th century. Hence, his grave can no longer be located. Francesco Melzi fell heir to his artistic and scientific estate.

ANALYSIS AND EVALUATION OF LEONARDO'S ACHIEVEMENT

Painting. Leonardo's total output in painting is really not large; only 17 of the paintings that have survived can be definitely attributed to him, and several of them are unfinished. Two of his most important works—the "Battle of Anghiari" and the "Leda," neither of them completed—have only survived in copies. Yet these few creations have established the unique fame of a man whom Vasari, in his Lives, dividing art history into three ages, placed in the last "golden age of the arts." His works, unaffected by all the vicissitudes of aesthetic doctrines in subsequent centuries, have stood out in all periods and all countries as consummate masterpieces of painting.

Leonardo's art of expression

The many testimonials to Leonardo, ranging from Vasari to Peter Paul Rubens, Johann Wolfgang von Goethe, and Eugène Delacroix, make it unmistakably clear that it has been, above all, Leonardo's art of expression that has called forth the utmost admiration. It is, in fact, the core of his formation as a painter—from his earliest beginnings to his last work. This expression was nurtured by his power of invention but also by every technical means: drawing, colour, use of light and shadow. To Leonardo, expression became a key concept of art; it also included the basic demands of truth, beauty, and accuracy in everything depicted.

What Leonardo was striving for was already revealed in his angel in Verrocchio's "Baptism of Christ" (c. 1474–75): in the natural structuring of the angel's body based on movement in several directions, in the relaxation of his attitude, and in his glance, which takes in what is occurring but at the same time is directed inward. In his landscape segment in the same picture, Leonardo also found a new expression for "nature experienced," in reproducing the forms he perceived as if through a veil of mist. The landscape study dated 1473, a pen drawing, foreshadows in its treatment of transparent atmosphere by a 21-year-old his telling ability to transform verceived phenomena into convincing graphic forms.

In the "Madonna Benois" (1478) Leonardo succeeded in giving an old traditional type of picture a new, unusually charming, and expressive mood by showing the Christ child reaching for the flower in Mary's hand in a sweet and tender manner.

His "Portrait of a Young Lady" ("Ginevra de'Benci"; c. 1475–78) opened new paths for portrait painting with his singular linking of nearness and distance.

The emaciated body of his "St. Jerome" (c. 1480) is presented with realistic truth based on his sober and objective studies in anatomy; gesture and look give Jerome an unrivalled expression of transfigured sorrow.

The interplay of mimicry and gesture—"physical and spiritual motion," in Leonardo's words—is also the chief concern of his first large creation containing many figures, "The Adoration of the Magi" (1481). Never finished, the painting nevertheless affords rich insight into the master's subtle methods of work. The various aspects of the scene are "built up" from the base with very delicate, paper-thin layers of paint in chiaroscuro (the balance of light and shadow) relief. The main treatment of the Virgin and Child group and the secondary treatment of the surrounding groups are clearly set apart with a masterful sense of composition; yet thematically they are closely interconnected: the bearing and expression of the figures—most striking in the group of praying shepherds—depict all degrees and levels of profound amazement.

The two versions of "The Virgin of the Rocks"

"The Virgin of the Rocks" in its first version in the Louvre is the work that reveals Leonardo's painting art at its purest. The painting, according to Leonardo's first contract with the Confraternity of the Immaculate Conception, was to be the central panel of a large work for their chapel in the church of S. Francesco and was done in the years 1483–85. It never arrived, however, at the place it was originally destined for. It seems to have been prematurely taken from the Confraternity, perhaps by some highly placed interested party who removed it from Leonardo's workshop. Instead of this first painting, Leonardo and Ambrogio de Predis painted a second, slightly revised version, probably begun around 1494. This one gave rise to a ten-year litigation between the artist and the Confraternity regarding the price, a dispute that was not settled until 1506 in favour of Leonardo; whereupon, two years later, the painting was delivered as per contract. This second version remained in the chapel of S. Francesco until the Confraternity was dissolved (1781), and then, after changing owners frequently, it came finally in 1880 to the National Gallery in London. Art scholars are still discussing the authenticity of the two versions.

"The Virgin of the Rocks" depicts the apocryphal legend of the meeting in the wilderness between the boy John and the equally young Jesus returning home from Egypt. Leonardo's artistry makes of this theme a vision that the true believer experiences when he contemplates the devotional picture. In the visionary character of the picture lies the secret of its effect: it presents not a "reality" but a "manifestation." Leonardo uses every artistic means at his disposal to emphasize the visionary nature of the scene. The soft colour tones (his famous sfumato), the dim light of the cave from which the figures emerge bathed in light, their quiet attitude, the meaningful gesture with which the angel (the only one facing the viewer) points to John as the intercessor between the Son of God and humanity—all this combines, in a patterned and formal way, to achieve an effect of the highest expressiveness.

The "Last Supper"

Leonardo's "Last Supper" is among the most famous paintings in the world. In its monumental simplicity, the composition of the scene is masterful; the power of its effect comes from the striking contrast in the attitudes of the young disciples as counterposed to Christ. Leonardo did not choose the portrayal of the traitor Judas customary in the iconographic tradition; he portrayed, rather, that moment of highest tension as related in the New Testament, "One of you which eateth with me will betray me." All of the Apostles—as human beings who do not understand what is about to occur—are agitated, whereas Christ alone, conscious of his divine mission, sits in lonely, transfigured serenity. Only one other being shares the secret knowledge: Judas, who is both part of and yet excluded from the movement of his companions; in this isolation he becomes the second lonely figure—the guilty one—of the company.

In the profound conception of his theme, in the perfect yet seemingly simple arrangement of the individuals, in the temperaments of the Apostles highlighted by gesture and mimicry, in the drama and at the same time the sublimity of the treatment, Leonardo attained a height of expression that has remained a model of its kind. Untold painters in succeeding generations, among them great masters, such as Rubens and Rembrandt, marvelled at Leonardo's composition and were influenced by it. The painting also inspired some of Goethe's finest pages of descriptive prose. It has become widely known through countless reproductions and prints, the most important being those produced by Raffaello Morghen in 1800. Thus, the "Last Supper" has become part of humanity's common heritage and remains today one of the world's outstanding paintings.

Technical deficiencies in the execution of the work have not lessened its fame. Leonardo was uncertain about the technique he should use. He bypassed fresco painting, which, because it is executed on fresh plaster, demands quick and uninterrupted painting, in favour of another technique he had developed: tempera on a base mixed by himself on the stone wall. This procedure proved unsuccessful, inasmuch as the base soon began to be loosened from the wall. Damage appeared by the beginning of the 16th century, and deterioration soon set in. By the middle of the century the work was called a ruin. Later, inadequate attempts at restoration only aggravated the situation, and not until the most modern restoration techniques were applied after World War II was the process of decay halted.

The "Mona Lisa"

In the Florence years between 1500 and 1506, four great creations appeared that confirmed and heightened Leonardo's fame: the "Virgin and Child with St. Anne," "Mona Lisa," "Battle of Anghiari," and "Leda." Even before it was completed, the "Virgin and Child with St. Anne" won the critical acclaim of the Florentines; the monumental plasticity of the group and the calculated effects of dynamism and tension in the composition made it a model that inspired Classicists and Mannerists in equal measure. The "Mona Lisa" became the ideal type of portrait, in which the features and symbolic overtones of the person painted achieved a complete synthesis. The young Raphael sketched the work in progress, and it served as a model for his "Portrait of Madalena Doni." Similarly, the "Leda" became a model of the *figura serpentinata* ("sinuous figure")—that is, a figure built up from several intertwining views. It influenced such classical artists as Raphael, who drew it, but it had an equally strong effect on Mannerists such as Jacopo Pontormo.

In the "Battle of Anghiari" (1503–06) Leonardo's art of expression reached its high point. The preliminary drawings—many of which have been preserved—reveal Leonardo's lofty conception of the "science of painting"; the laws of equilibrium that he had probed in his studies in mechanics were put to artistic use in this painting. The "centre of gravity" lies in the group of flags fought for by all the horsemen. For a moment the intense and expanding movement of the swirl of riders seems frozen; this passing moment, the transition from one active movement to the next, is uniquely interpreted.

On the other hand, Leonardo's studies in anatomy and physiology influenced his representation of human and animal bodies, particularly when they were in a state of excitement. He studied and described extensively the baring of teeth and puffing of lips as signs of animal and human anger. On the painted canvas, rider and horse, their features distorted, are remarkably similar in expression.

The highly imaginative trappings take the event out of the sphere of the historical into a timeless realm. Thus, the "Battle of Anghiari" became the standard model for a cavalry battle. Its composition has influenced many painters: from Rubens in the 17th century, who made the most impressive copy of the scene from Leonardo's now-lost cartoon, down to Delacroix in the 19th century.

After 1507—in Milan, Rome, and France—Leonardo did very little painting. He did resume work on the Leda theme during his years in Milan and sketched a variation, the "Kneeling Leda." The drawings he prepared—revealing examples of his late style—have a curious, enigmatic sensuality. Perhaps in Rome he began the "St. John the Baptist," which he completed in France. Bursting all the boundaries of usual painting tradition, he presented Christ's forerunner as the herald of a mystic oracle; his was an "art of expression" that seemed to strive consciously to bring out the hidden ambiguity of the theme.

Last manifestation of Leonardo's art of expression

The last manifestation of Leonardo's art of expression was in his "Visions of the End of the World," a series of pictorial sketches that took the end of the world as its theme. Here Leonardo's power of imagination—born of reason and fantasy—attained its highest level. The immaterial forces in the cosmos, invisible in themselves, appear in the material things they set in motion. What Leonardo had observed in the swirling of water and eddying of air, in the shape of a mountain boulder and in the growth of plants now assumed gigantic shape in cloud formations and rainbows. The framework of the world splits asunder, but even its destruction occurs—as the monstrously "beautiful" forms of the unleashed elements show—in accordance with the self-same laws of order, harmony, and proportion that presided at its creation and that govern the life and death of every created thing in nature. Without any model, these "visions" are the last and most original expressions of Leonardo's art—an art in which his perception based on *saper vedere* seems to have come to fruition.

Sculpture. That Leonardo worked as a sculptor from his youth on is borne out by his own statements and those of other sources. In the introduction to his ***Treatise on Painting*** he gives painting precedence over sculpture in the hierarchy of the arts; yet he emphasizes that both arts exert similar effects. A small group of generals' heads in marble and plaster, works of Verrocchio's followers, are sometimes linked with Leonardo because a lovely drawing on the same theme from his hand suggests such a connection. But the inferior quality of this group rules out an attribution to the master. Not a trace has remained of the heads of women and children that, according to Vasari, Leonardo modelled in clay in his youth.

The two great sculptural projects to which Leonardo devoted himself wholeheartedly stood under an unlucky star; neither the huge, bronze equestrian statue for Francesco Sforza, on which he worked until 1494, nor the monument for Marshal Trivulzio, on which he was busy in the years 1506–11, were brought to completion. Leonardo kept a detailed diary about his work on the Sforza horse; it has recently come to light with the rediscovery of the Madrid MS. 8937. Text and drawings both show Leonardo's wide experience in the technique of bronze casting but at the same time reveal the almost utopian nature of the project. He wanted to cast the horse in a single piece, but the gigantic dimensions of the steed presented insurmountable technical problems. Indeed, Leonardo remained uncertain of the problem's solution to the very end.

The greatness of Leonardo's concept of sculpture

The drawings for these two monuments reveal the greatness of Leonardo's concept of sculpture. Exact studies of the anatomy, movement, and proportions of a live horse —Leonardo even seems to have thought of writing a treatise on the horse—preceded the sketches for the monuments. Leonardo pondered the merits of two types, the galloping or trotting horse, and in both cases decided in favour of the latter. These sketches, superior in the suppressed tension of horse and rider to the achievements of Donatello's Gattamelata and Verrocchio's Colleoni sculptures, are among the most beautiful and significant examples of Leonardo's art. Unquestionably—as ideas—they exerted a very strong influence on the development of equestrian statues in the 16th century.

A small bronze of a galloping horseman in Budapest is so close to Leonardo's style that, if not from his own hand, it must have been done under his immediate influence (perhaps by Giovanni Francesco Rustici). Rustici, according to Vasari, was Leonardo's zealous student and enjoyed his master's help in sculpting his large group in bronze of "St. John the Baptist Teaching" over the north door of the Baptistery in Florence. There are, indeed, discernible traces of Leonardo's influence in John's stance, with the unusual gesture of his upward pointing hand, and in the figure of the bald-headed Levite. Moreover, an echo of Leonardo's inspiration is unmistakable in the much-discussed and much-reviled wax bust of "Flora" in Berlin. It may have been made in France, perhaps in the circle of Rustici, who entered Francis I's service in 1528.

Architecture. Leonardo, who in a letter to Ludovico Sforza applying for service described himself as an experienced architect, military engineer, and hydraulic engineer, was concerned with architectural matters all his life. But his effectiveness was essentially limited to the role of an adviser. Only once—in the competition for the cupola of the Milan Cathedral (1487–90)—did he actually consider personal participation; but he gave this idea up when the model he had submitted was returned to him. In other instances, his claim to being a practicing architect involved sketches for representative secular buildings: for the palace of a Milanese nobleman (around 1490), then for the villa of a French governor in Milan (1507–08), and for the Medici residence in Florence (1515). Finally, there was his big project for the palace and garden of Romorantin in France (1517–19). Especially in this last named, Leonardo's pencil sketches clearly reveal his mastery of technical as well as artistic architectural problems; the view in perspective (Windsor Castle) gives an idea of the magnificence of the site.

Activity as a military engineer

Leonardo was also quite active as a military engineer, beginning with the years of his stay in Milan. But no definite examples of his work can be adduced. Not until the discovery of the Madrid notebooks was it known that in 1504, sent probably by the Florence governing council, he stood at the side of the Lord of Piombino when the city's fortifications system was repaired and that Leonardo suggested a detailed plan for overhauling it. Finally, his studies for large-scale canal projects in the Arno region and in Lombardy show that he was also an expert in hydraulic engineering.

But what really characterizes Leonardo's architectural studies and makes them stand out is their comprehensiveness; they range far afield and embrace every type of building problem of his time. Furthermore, there frequently appears evidence of Leonardo's impulse to teach: he wanted to collect his writings on this theme in a theory of architecture. This treatise on architecture—the initial lines of which are in MS. B (Institut de France, Paris), a model book of the types of sacred and profane buildings —was to deal with the entire field of architecture as well as with the theory of forms and construction and was to include such items as urbanism, sacred and profane building, and a compendium of the important individual elements (for example, domes, steps, portals, and windows).

In the fullness and richness of their ideas, Leonardo's architectural studies offer an unusually wide-ranging insight into the architectural achievements of his epoch. Like a seismograph, his observations sensitively register all themes and problems. For almost 20 years he was associated with Bramante at the court of Milan and again met him in Rome in 1513–14; he was closely associated with such other distinguished architects as Francesco di Giorgio, Giuliano da Sangallo, Giovanni Antonio Amadeo, and Luca Fancelli. Thus, he was brought in closest touch with all of the most significant building undertakings of the time. Since Leonardo's architectural drawings extend over his whole life, they span precisely that developmentally crucial period—from the 1480s to the second decade of the 16th century—in which the principles of the classical style were formulated and came to maturity. That this genetic process can be followed in the ideas of one of the greatest men of the period lends Leonardo's studies their distinctive artistic value and their outstanding historical significance.

Science. ***Science of painting.*** Notwithstanding Leonardo's abundant scientific activity, one must never lose sight of the fact that it was the intellectual output of a man who proudly and consciously felt himself an artist throughout his life. And he described himself as such. He first came in contact with science as an artist, in the task he set himself of writing a treatise on painting.

Treatise on Painting

Leonardo's famous book on painting, in the form known and read today, is not an original work by the master but a compilation of texts from various manuscripts by Leonardo, collected and arranged with loving care by his disciple and heir, Francesco Melzi. It is the Codex Urbinas Latinus 1270, now in the Vatican Library. It was prepared around 1540–50, but from its form one can see that it was still an unfinished rather than a completed manuscript. Many original texts known to exist are missing; whole sections of Leonardo's overall plan are not included.

The first printed edition of the treatise in Melzi's version, omitting the long introductory chapter concerning the "pecking order" among the arts, appeared in a luxurious binding in 1651 in Paris, published by Raffaelo du Fresne with illustrations after drawings by Nicolas Poussin. The first complete edition of Melzi's text did not appear until 1817, published by Guglielmo Manzi in Rome. The two standard modern editions are that of Emil Ludwig, three volumes, Vienna, 1882 (with German translation); and that of A. Philip McMahon, Princeton, 1956, two volumes (facsimile of the Codex Urbinas and English translation).

Leonardo's plan envisaged a much broader treatment of the theme, as his own allusions to it indicate. For, in addition to detailed practical instructions for painting and drawing, the treatise was to deal with every area involving the artist's perception and experience, which he could then convey as acquired criteria. Three main problems form the keynote of the work: the definition of painting as a science, which is briefly outlined above (see *Life and works; Art and science: the notebooks);* the theory of the mathematical basis of painting—that is, geometry, perspective, and optics—with the systematic study of light and shadow, colour, and aerial perspective; and the theory of forms and functions in organic and inorganic nature, as they are explained and made comprehensible to the painter trained in *saper vedere.* This theory of the forms and functions of the visible world sought first of all to describe the animal world, including man; next it sought to include the plant world; finally it endeavoured to explain how such phenomena of inorganic nature as water and earth, air and fire came into being.

Drawings for the *Treatise*

In the drawings for the *Treatise on Painting,* extending from the earliest Milan period to the final years of Leonardo's life in France, the progressive broadening and deepening of the theme can be followed. Many drawings were placed by the side of the text, and some of them were coloured; many studies of nature that are admired as art works, such as the famous rain landscape in Windsor Castle (12409) or the "Foliage" (Royal Library, Windsor Castle; 12431), can be identified as illustrations for the treatise. Manuscript C in the Institut de France, Paris, with its diagrams of the blending of lights and shadows, likewise represents a segment of this textbook. Leonardo's so-called grotesque heads are also closely linked with the treatise. They have often been erroneously described as caricatures; but actually, for the most part, they represent types and only occasionally individuals. They are variations of the human face in its gradations between the poles of the beautiful and ugly, the normal and abnormal, the dignified and vulgar. They are also related to anatomical-physiological studies, in which old age—with wrinkled skin and bulging tendons—is contrasted with youth. Representation of the human being was to be treated at length: his body, his proportions, his organs and their functions but also his attitudes in physical and spiritual movement. Here Leonardo's artistic and scientific aims intertwine.

Anatomical studies and drawing. Leonardo's anatomical studies are perhaps the best way of revealing the process by which, in Leonardo's mind, an increasing differentiation set in among his diverse spheres of interest; but it was a differentiation in which the seemingly divergent areas of study—likewise on a higher level—always remained interrelated. Thus, Leonardo's study of anatomy, originally pursued for his training as an artist, quickly grew into an independent area of research. As his sharp eye uncovered the structure of the human body, Leonardo became fascinated by the *figura istrumentale dell' omo* ("man's instrumental figure"), and he sought to probe it and present it as a creation of nature. The early studies dealt chiefly with the skeleton and muscles; yet even at the outset Leonardo combined anatomical with physiological researches. From observing the static structure, Leonardo proceeded to study the functions exercised by the individual parts of the body as they bring into play the organism's mechanical activity. This led him finally to the study of the internal organs; among them he probed most deeply into the brain, heart, and lungs as the "motors" of the senses and of life. He did practical work in anatomy on the dissection table in Milan, then in the hospital of Sta. Maria Nuova in Florence, and again in Milan and Pavia, where he received counsel and inspiration from the doctor-anatomist Marcantonio della Torre. By his own admission he dissected 30 corpses in his lifetime, thus acquiring an astonishing range of experience on his own. This experience was distilled in the famous anatomical drawings, which are among the most significant achievements of Renaissance science. Called *dimostrazione,* these drawings are based on a curious connection between natural and abstract representation; sections in perspective, reproduction of muscles as "strings" or the indication of hidden parts by dotted lines, and finally a specifically devised hatching system enable him to represent any part of the body in transparent layers that afford an "insight" into the organ. Here Leonardo's mastery of drawing proved most useful. The genuine value of these "demonstrations" and their superiority to descriptive words—as Leonardo proudly emphasized—lay in the fact that they were able to synthesize a multiplicity of individual experiences at the dissecting table and make the data immediately and accurately visible. The effect is unlike that of all dead anatomical preparations; in this way the "live quality" of the organism is retained.

Value of the "demonstrations"

This great picture chart of the human body was what Leonardo envisaged as a *cosmografia del minor mondo* ("cosmography of the microcosm"). From the advanced portions that have survived, it is apparent how much and how long it occupied his mind. And it provided the basic principles for modern scientific illustration. Leonardo has not sufficiently received his due in this domain. Thanks to a method of seeing that was peculiarly his own, he elevated the art of drawing into a means of scientific investigation and teaching of the highest quality.

Mechanics and cosmology. With Leonardo, mechanics also proceeds from artistic practice, with which he became quite familiar as an architect and engineer. Throughout his life Leonardo was an inventive builder; he was thoroughly at home in the principles of mechanics of his epoch and contributed in many ways to advancing them.

His model book on the elementary theory of mechanics, which appeared in Milan at the end of the 1490s, was only recently discovered in the Madrid Codex 8937. Its importance lay less in its description of specific machines or work tools than in its use of demonstration models to explain the basic mechanical principles and functions employed in building machinery. Leonardo was especially concerned with problems of friction and resistance. These elements—screw threads, gears, hydraulic jacks, swivelling devices, transmission gears, and the like—are described individually or in various combinations; and here, too, drawing takes precedence over the written word. As in his anatomical drawings, Leonardo develops definite principles of graphic representation—stylization, patterns, and diagrams—that guarantee a precise demonstration of the object in question.

Importance of primal mechanical forces to his thought

In the course of years his interest in pure mechanics merged increasingly with an interest in applied mechanics. Leonardo realized that the mechanical forces at work in the basic laws of mechanics operate everywhere in the organic and inorganic world. They determine animate and inanimate nature alike as well as man. Leonardo wrote on a page of his treatise on anatomy:

> See to it that the book of the principles of mechanics precedes the book of force and movement of man and the other living creatures, for only in that way will you be able to prove your statements.

So, finally, "force" became the key concept for Leonardo; as *virtù spirituale* ("spiritual property"), it shaped and ruled the cosmos.

Wherever Leonardo probed the phenomena of nature, he recognized the existence of primal mechanical forces that govern the shape and function of the universe: in his studies on the flight of birds, in which his youthful idea of the feasibility of a flying apparatus took shape and led to exhaustive research into the element of air; in his studies of water, the *vetturale della natura* ("conveyor of nature"), in which he was as much concerned with the physical properties of water as with its laws of motion and currents; in his researches on the laws of growth of plants and trees as well as the geological structure of earth and hill formations; and finally in his observation of air currents, which evoked the image of the flame of a candle or the picture of a wisp of cloud and smoke. In his drawings, especially in his studies of whirlpools, based on numerous experiments he undertook, Leonardo again found a stylized form of representation that was uniquely his own: breaking down a phenomenon into its component parts—the traces of water or eddies of the whirlpool—yet at the same time preserving the total picture, analytic and synthetic vision.

Thus, for all the separate individual realms of his knowledge, Leonardo's science offered a unified picture of the world: a cosmogony based on *saper vedere* ("knowing how to see"). Its final wisdom is that all the workings of nature are subject to a law of necessity and a law of order that the *Primo Motore,* the divine "Prime Mover," created. "Marvelous is Thy justice, O Prime Mover! Thou hast seen to it that no power lacks the order and value of your necessary governance."

Leonardo as artist-scientist. As the 15th century expired, Scholastic doctrines were in decline, and Humanistic scholarship was on the rise. Leonardo, however, was part of an intellectual circle that developed a third, specifically modern form of cognition. In his view the artist—as transmitter of the true and accurate data of experience acquired by visual observation—played a significant part. With this sense of the artist's high calling, Leonardo approached the vast realm of nature to probe its secrets. His utopian idea of transmitting in encyclopaedic form the knowledge thus won was still bound up with medieval Scholastic conceptions, but the results of his research were among the first great achievements of the thinking of the new age because they were based on the principle of experience in an absolutely new way and to an unprecedented degree.

Finally, Leonardo, although he made strenuous efforts to teach himself and become erudite in languages, natural science, mathematics, philosophy, and history, as a mere listing of the wide-ranging contents of his library demonstrates, remained an empiricist of visual observation. But precisely here—thanks to his genius—he developed his own "theory of knowledge," unique in its kind, in which art and science form a synthesis. In the face of the overall achievements of Leonardo's creative genius, the question of how much he finished or did not finish becomes pointless. The crux of the matter is his intellectual force—self-contained and inherent in every one of his creations. This force has remained constantly operative down to the present day.

MAJOR WORKS

PAINTINGS: "The Annunciation" (*c.* 1472–77; Uffizi, Florence); "The Annunciation" (*c.* 1472–77; Louvre, Paris); "Madonna and Child" (*c.* 1474; Alte Pinakothek, Munich); "Portrait of a Young Lady" ("Ginevra de'Benci"; *c.* 1475–78; National Gallery of Art, Washington, D.C.); "Madonna Benois" (1478–after 1500; Hermitage, Leningrad); "St. Jerome" (*c.* 1480; Vatican Museums, Rome); "The Adoration of the Magi" (1481; Uffizi); "The Virgin of the Rocks" (1483; Louvre); "The Musician" (*c.* 1490; Pinacoteca Ambrosiana, Milan); "Lady with an Ermine" ("Cecilia Gallerani"; c. 1490; Muzeum Narodowe, Kraków, Poland); "The Virgin of the Rocks" (1494–1508; National Gallery, London); "Last Supper" (1495–97; Sta. Maria delle Grazie, Milan); decoration of the Sala delle Asse (1498; Castello Sforzesco, Milan); "The Virgin and Child with St. Anne" (cartoon, *c.* 1499; National Gallery, London); "Virgin and Child with St. Anne" (1500; Louvre); "Madonna with Yarn-Winder" (1501; Duke of Buccleuch Collection, London); "Mona Lisa" ("La Gioconda"; 1503–06; Louvre); "Battle of Anghiari" (1503–06; Palazzo Vecchio, Florence); "St. John the Baptist" (before 1517; Louvre).

DRAWINGS AND NOTEBOOKS: Main collections: Institut de France, Paris; British Museum; Uffizi, Florence; Biblioteca Ambrosiana, Milan; Accademia, Venice; Royal Library, Windsor.

BIBLIOGRAPHY. MARIO POMILIO and ANGELA OTTINO (eds.), *L'opera completa di Leonardo pittore* (1967; Eng. ed., *The Complete Paintings of Leonardo da Vinci),* catalogs the paintings. The most informative account of Leonardo's workshop and pupils is W. SUIDA, *Leonardo und sein Kreis* (1929). ARTHUR E. POPHAM, *The Drawings of Leonardo da Vinci* (1945), is important for the study of Leonardo as a draftsman; the standard publication on the drawings is KENNETH CLARK and CARLO PEDRETTI, *A Catalogue of the Drawings of Leonardo da Vinci in the Collection of Her Majesty The Queen at Windsor Castle,* 2nd ed., 3 vol. (1968). A. MARIONI, "I manoscritti di Leonardo da Vinci," in *Leonardo: Saggi e richerche* (1953), is a concise summary of all manuscripts, their facsimile editions, and chronology. This collection contains other excellent essays by various authors on Leonardo as artist and scientist. LADISLAO RETI'S two articles in *Burlington Magazine,* vol. 110 (1968), discuss the two rediscovered codices in Madrid. AMOS P. MCMAHON, *Leonardo's Treatise on Painting,* is a facsimile edition of *Coder Urbinas Latinus 1270* accompanied by an English translation (2 vol., 1956). The best anthologies of Leonardo's literary heritage are JEAN P. RICHTER, *The Literary Works of Leonardo da Vinci,* 3rd ed., 2 vol. (1970); and EDWARD MCCURDY (ed.), *The Notebooks of Leonardo da Vinci,* 2 vol. (1955). For additional sources of information, see ETTORE VERGA, *Bibliografia Vinciana, 1493–1930,* 2 vol. (1931); and *Raccolta Vinciana,* fasc. 1–20 (1905–64). Two institutions devoted exclusively to the study of Leonardo are the Raccolta Vinciana, Castello Sforzesco, Milan, and the Elmer Belt Library of Vinciana at the University of California at Los Angeles. *Leonardo da Vinci,* 2 vol. folio, ed. by the ISTITUTO GEOGRAFICO DE AGOSTINI (1964), contains numerous essays and is the most richly illustrated compendium of Leonardo's artistic and scientific activity. The two standard publications on Leonardo sources are LUCA BELTRAMI, *Documenti e memorie riguardanti la vita e le opere di Leonardo da Vinci in ordine cronologico* (1919); and GOROLAMI CALVI, *I manoscritti di Leonardo da Vinci, dal punto di vista cronologico, storico e biografico* (1925). The following six monographs are among the most valuable of the countless studies: G. SEAILLES, *Léonard de Vinci: l'artiste et le savant* (1892); W. VON SEIDLITZ, *Leonardo da Vinci,* 2nd ed. (1935), accompanied by extensive documentation (in German); KENNETH CLARK, *Leonardo da Vinci: An Account of His Development As an Artist,* 2nd ed. (1952), also available in paperback; L.H. HEYDENREICH, *Leonardo da Vinci,* 2 vol. (Eng. trans. 1954); V.P. ZUBOV, *Leonardo da Vinci* (1968; orig. pub. in Russian, 1961); and PETER R. RITCHIE-CALDER, *Leonardo and the Age of the Eye* (1970). MORRIS PHILIPSON (ed.), *Leonardo da Vinci: Aspects of the Renaissance Genius* (1966), contains valuable contributions to the historical and psychological aspects of the phenomenon, Leonardo.

(L.H.H.)

Leonardo of Pisa

Leonardo of Pisa, or Leonardo Fibonacci, was the most distinguished mathematician of the Middle Ages. He helped introduce into mathematics the Hindu-Arabic numerals and the number sequence that bears his name.

Little is known about Leonardo's life beyond the few facts given in his mathematical writings. From the date of his first and best known work, the *Liber abaci* (1202; "Book of the Abacus"), it is probable that he was born in the 1170s. He was probably born in Pisa, Italy, but there is no evidence that he was. During Leonardo's boyhood, his father, Guglielmo, a Pisan merchant, was appointed consul, or chief magistrate, over the community of Pisan merchants in the North African port of Bugia (now Bejaïa, Algeria). Leonardo soon joined him. "With a view to future usefulness," the father sent his son to study calculation with an Arab master, and Leonardo later, in the *Liber abaci,* described his enjoyment in learning "the art of the nine Indian figures." Leonardo also travelled to Egypt, Syria, Greece, Sicily, and Provence, where he studied different numerical systems and methods of calculation but never found one as satisfactory as the Hindu-Arabic numerals.

The *Liberabaci*

When Leonardo's *Liber abaci* first appeared, Hindu-Arabic numerals were known to only a few European intellectuals through translations of the writings of the 9th-century Arab mathematician and astronomer al-Khwārizmī. Leonardo began his explanation of the notation by observing: "The nine Indian figures are: 9 8 7 6 5 4 3 2 1. With these nine figures and with the sign 0 . . . any number may be written, as is demonstrated below." The first seven chapters dealt with the notation, explaining the principle of place value, by which the position of a figure determines whether it is a unit, ten, 100, and so forth, and demonstrating the use of the numerals in arithmetical operations. The techniques were then applied to such practical commercial problems as profit margin, barter, money changing, conversion of weights and measures, partnerships, and interest. Most of the work was devoted to speculative mathematics—proportion (represented by such popular medieval techniques as the Rule of Three and the Rule of Five, which are rule-of-thumb methods of finding proportions), the Rule of False Position (a method by which a problem is worked out by a false assumption, then corrected by proportion), extraction of roots, and the properties of numbers, concluding with some geometry and algebra. In 1220, Leonardo produced a brief work entirely on geometry, the *Practica geometriae* ("Practice of Geometry"), which included eight chapters of theorems based on Euclid's *Elements* and *On Divisions.*

The *Liber abaci,* which was widely copied and imitated, drew the attention of the Holy Roman emperor Frederick II, whose patronage of science had earned him the epithet *Stupor mundi* (Wonder of the World). In the 1220s, Leonardo was invited to appear before the Emperor at Pisa, and there John of Palermo, a member of Frederick's scientific entourage, propounded a series of problems, three of which Leonardo presented in his books. The first two belonged to a favourite Arabic type, the indeterminate, which had been developed by a 3rd-century Greek mathematician, Diophantus. This was an equation with two or more unknowns for which the solution must be in rational numbers (whole numbers or common fractions). The third problem was a third-degree equation (*i.e.*, containing a cube), $x^3 + 2x^2 + 10x = 20$ (expressed in modern algebraic notation), which Leonardo solved by a trial-and-error method known as approximation; he arrived at the answer

$$1^{0}\,22^{\mathrm{I}}\,7^{\mathrm{II}}\,42^{\mathrm{III}}\,33^{\mathrm{IV}}\,4^{\mathrm{V}}\,40^{\mathrm{VI}}\left(1+\frac{22}{60}+\frac{7}{3{,}600}+\frac{42}{216{,}000}+\cdots\right)$$

in sexagesimal fractions (a fraction using the Babylonian number system that had a base of 60), which, when translated into modern decimals (1.3688081075), is correct to nine decimal places. Leonardo's solutions to the problems were a combination of ingenuity and accuracy.

For several years Leonardo corresponded with the Emperor and his scholars, exchanging problems with them; and he dedicated his *Liber quadratorum* (1225; "Book of Square Numbers") to the Emperor. Devoted entirely to Diophantine equations of the second degree (*i.e.*, containing squares), the *Liber quadratorum* may be considered Leonardo's masterpiece. It is a systematically arranged collection of theorems, many invented by the author, who used his own proofs to work out general solutions. Probably his most creative work was in congruent numbers—numbers that give the same remainder when divided by a given number. He worked out an original solution for finding a number that, when added to or subtracted from a square number, leaves a square number. Leonardo's statement that $x^2 + y^2$ and $x^2 - y^2$ could not both be squares was of great importance to the determination of the area of rational right triangles. Although the *Liber abaci* was more influential and broader in scope, the *Liber quadratorum* alone ranks its author as the major contributor to number theory between Diophantus and Pierre de Fermat, the 17th-century French mathematician.

The *Liber quadratorum*

In 1228, Leonardo revised the *Liber abaci,* dedicating it to Michael Scott, the Emperor's chief scholar. After that date, nothing is known of Leonardo until 1240, when Pisa granted him an annuity of 20 Pisan pounds, along with expenses, for services to the city. The date of his death is unknown.

Except for his role in spreading the use of the Hindu-Arabic numerals, Leonardo's contribution to mathematics has been largely overlooked. His name is known to modern mathematicians mainly because of the Fibonacci sequence (see below) derived from a problem in the *Liber abaci:*

> A certain man put a pair of rabbits in a place surrounded on all sides by a wall. How many pairs of rabbits can be produced from that pair in a year if it is supposed that every month each pair begets a new pair which from the second month on becomes productive?

The Fibonacci sequence

The resulting number sequence, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55 (Leonardo himself omitted the first term), in which each number is the sum of the two preceding numbers, is the first recursive number sequence (in which the relation between two or more successive terms can be expressed by a formula) known in Europe. Terms in the sequence were stated in a formula after the development of algebraic notation in the early 17th century by the French-born mathematician Albert Girard in 1634: $u_{n+2} = u_{n+1} + u_n$, in which u represents the term and the subscript its rank in the sequence. Later, the mathematician Robert Simson at the University of Glasgow in 1753 noted that as the numbers increased in magnitude, the ratio between succeeding numbers approached phi—the ancient mean and extreme ratio, or golden section—whose value is 1.6180 . . . , or $\frac{1+\sqrt{5}}{2}$. When, in the 19th century, the term Fibonacci sequence was coined by French mathematician Edouard Lucas, scientists began to discover the numbers in nature, such as in the spirals of sunflower heads, in pine cones, in the regular descent (genealogy) of the male bee, and the related logarithmic (equiangular) spiral in snail shells, in the arrangement of leaf buds on a stem, and in animal horns. A Fibonacci Association was founded in 1962 in California "to exchange ideas and stimulate research in the Fibonacci numbers and related topics."

Leopold I, Emperor

The name of the Holy Roman emperor Leopold I is linked with half a century of Austrian history. His reign (1658–1705) saw events that marked new departures in many respects and were to condition the development of the Habsburg monarchy during the next two centuries. From its struggles with the Turks and France, Austria emerged as a great power and was able to maintain this newly won position in spite of upheavals in Hungary. In internal politics, the rise of monarchical absolutism brought attempts at a more strictly centralized administration. If the Emperor, who had not been trained for the throne, rarely interfered with the course of events, he, nevertheless impressed contemporaries with an imperturbability founded in personal piety, which did not fail him even during the worst crises to his long reign. His biographer, the Jesuit Hans Jacob Wagner von Wagenfels (died 1702), quite aptly praises his magnanimity as his most conspicuous character trait. The interest Leopold took in all matters of learning, his gift for music, and his preoccupation with historiography made him a patron of renown and, notwithstanding the military conflicts of the time and his precarious finances, gave enormous impetus to learning and the arts throughout the Austrian countries and especially made Vienna a famous cultural centre. His reign saw the first flourishing of Baroque culture in Austria.

Early years

Leopold was born in Vienna on June 9, 1640. As the second son of Ferdinand III's first marriage, to his cousin Maria Anna, daughter of Philip III of Spain, he was destined for the church. He received a careful education by excellent teachers, among whom the cultured count Johann Ferdinand Portia was the leading personality. Made lord high steward by his pupil, Portia retained his influence with Leopold until his death in 1665. From an early age Leopold showed an inclination towards learning. He learned easily and became fluent in Latin, Italian,

Leopold I, portrait bust by an unknown artist, c. 1700. In the Kunsthistorisches Museum, Vienna.

BY courtesy of the Kunsthistorisches Museum, Vienna

and Spanish, but he did not like French and later would not have it spoken at court. Besides concerning himself with antiquarian studies, history, literature, natural science, and astronomy, his special interest was music, having inherited the musical talents of his father. The keynote of his personality was a deep devotion, which made him the personification of *pietas Austriaca,* the loyal Catholic attitude of his house. From his religiosity, however, also derived a fatalistic strain, which had its negative side for a ruling monarch. He rejected all political compromising on denominational questions.

Accession

When his elder brother, Ferdinand IV, died quite unexpectedly (July 9, 1654), Leopold suddenly found himself heir apparent to the Austrian Habsburg lands. In 1655 the Lower Austrian estates did homage, and he was elected and crowned king of Hungary, the Bohemian coronation following in 1656. Then, in 1657, his father died and a new imperial election was due. After long and difficult struggles against the opposition of France, Leopold was elected and crowned in the summer of 1658.

With untiring energy and a deep sense of duty, the young monarch settled down to the unwonted task of government. From the beginning he had to fight wars, first of all against the Turks. In 1683 they appeared before Vienna, and for the second time in its history the city suffered a Turkish siege. Leopold had left the capital with his court to await the outcome at Passau. An imperial army was summoned, and from the time of their repulse at Vienna the Turks were gradually forced into the defensive, especially after the military genius of Prince Eugene of Savoy appeared on the scene in 1696. In the Treaty of Carlowitz (1699), almost the whole of Hungary was freed from Turkish rule.

The Hungarian nobles, however, who were mostly Calvinists, did not want to exchange Turkish rule for a centralized Habsburg government, which threatened to introduce the Counter-Reformation. Their opposition had been a serious problem all the time, and Leopold, who usually showed clemency, took a firm stand for once, refusing to recall the cruel sentences after the so-called Nobles' Plot. Three of the most prominent Hungarian noblemen were executed, and Hungarian resistance flared up again in the fierce Kuruc risings.

The struggle with France

Though Leopold's policy toward Catholic France was undecided at first, he finally had to agree to a coalition with the Protestant naval powers: Holland and England. In the course of the long struggle with France, the empire scored several military successes; but in the end French diplomacy remained victorious, always dividing the enemy at the decisive moment. The Emperor was accused of a wavering attitude and lack of initiative, and these character traits were indeed partly responsible for the failure of his policies. The war ended in the unfavourable Treaty of Rijswijk (1697), under the terms of which Strasbourg had to be ceded to France, a great discredit to Leopold.

Apart from some contributions from the empire and subsidies from its allies, the financial burden of all these wars had to be borne by Leopold's hereditary countries, the finances of which were badly organized. During his long reign Leopold found it impossible to arrive at a sound financial basis; indeed, he was careless in these matters and for years suffered the treasury to be mismanaged by Count Sinzendorf.

Emperor Leopold was not always fortunate in the choice of his ministers. There was, for example, Count Eusebius Potting, with whom he had formed a warm friendship but who was not the right man for the post of ambassador to Madrid. On the other hand, councillors who had convinced the Emperor of their sincerity and honesty found excellent chances for a court career, even if they were middle class, like the Austrian court chancellor Johann Paul Hocher.

Leopold no longer regarded the empire as his primary responsibility; rather, in his view, concern for the power and prestige of the Habsburg dynasty and lands took the first place. By his first marriage—to his niece Margarita Teresa, daughter of Philip IV of Spain—Leopold had acquired a claim to the Spanish throne. From the outset the Spanish succession formed the central aim of his politics. What lay behind this was the idea of the unity of the House of Habsburg, the two lines being considered only as parts of the same entail. At the death of Charles II of Spain (who left no heir), Louis XIV of France claimed Spain for his grandson, Philippe, duc d'Anjou; there could be no question for Emperor Leopold that the Spanish heritage had to be defended by force of arms. On May 5, 1705, in the middle of the War of the Spanish Succession (1701–14), Leopold died. He was buried in the Habsburg mausoleum of the Capuchins at Vienna.

Personal traits

The Emperor was of medium size, rather slender in his youth but stout in later life. His face was pale, and he had dark hair and the typical Habsburg traits of a strongly developed lower lip and a protruding chin. A Turkish traveller described him as a cultivated man of extreme ugliness. His health was bad, and, when he fell dangerously ill in 1670, everybody expected the Austrian line of the Habsburgs to become extinct. He recovered, however, and in 1673 married Claudia Felicitas from the Tirolian branch of the Austrian Habsburgs. In 1676 the Emperor solemnized his third marriage, with Eleonore of Palatinate–Neuburg; this proved a happy union and produced ten children, among them the future emperors Joseph I and Charles VI.

In spite of the Emperor's great personal simplicity, the sums expended to maintain the imperial court were gigantic. At all occasions the Emperor was anxious to emphasize his imperial dignity; official journeys, such as his coronation journey to Frankfurt in 1658, as well as the numerous pilgrimages he undertook to assure divine assistance against his enemies, were used for ostentation. A special concern of the Emperor was to reshape Vienna into a worthy imperial residence. The Vienna court was famous for its costly theatricals, in which at times the emperor and empress also took part. Italian operas and ballets were lavishly staged, often with some additional music composed by Leopold himself. As the Emperor was very fond of hunting, courtly pleasures also included heron hawking and hunting wild boars and stags in the vicinity of the residence. Though Leopold undertook no more extensive journeys after 1693, he enjoyed these regular hunting expeditions until his death.

Leopold I was a devoted book collector and, in the director of the court library, Peter Lambeck, found a helper of great renown. He was known for the encouragement he extended to learning, whereby he tried to secure the services of famous scholars for his court.

BIBLIOGRAPHY. There is no modern monograph of Leopold I. The best presentation of his reign is still to be found in OSWALD REDLICH, *Weltmacht des Barock: Österreich in der Zeit Kaiser Leopolds I. (1927,* reprinted 1961) and ***Das***

Werden einer Grossmacht: bsferreich von 1700 bis 1740, 2nd ed. (1942, reprinted 1962), with references to source materials and a detailed bibliography. The most modern summary of recent research may be found in ERICH ZOLLNER, *Geschichte bsterreichs,* 4th ed. (1970), with bibliography.

(H.Di.)

Lepidoptera

The insect order Lepidoptera, with as many as 100,000 species, is second in size only to the Coleoptera, the beetles. In addition to the familiar butterflies and moths the order includes the skippers, a worldwide group intermediate between butterflies and moths. Because of their day-flying habits and bright colours, the butterflies are more familiar than the chiefly night-flying and dull coloured moths, but the latter are far more varied and abundant. With the exception of a few moths, all adult Lepidoptera have two pairs of wings. The name Lepidoptera is derived from the Greek, meaning "scaly winged," and refers to the characteristic covering of microscopic, dustlike scales on the wings.

The life cycle of Lepidoptera is that common to the higher orders of insects and consists of four stages: egg, larva (caterpillar), pupa (chrysalis), and adult (imago). The larva and adult are almost invariably plant eaters. The larvae do most of the eating, the majority of them feeding on foliage, although many species eat stems, roots, fruits, or flowers. A number of moths and a few butterflies are important pests in agriculture or forestry, invariably as larvae. The adults of many species are important pollenizers, visiting flowers for nectar. In the ecology of most land environments the Lepidoptera are important as transformers of immeasurably large amounts of plant matter into animal matter, which then serves as food for many other groups of animals.

Many members of the order, especially the butterflies, have appealed to the human imagination for thousands of years, as symbols of fragile and ephemeral beauty. References to them abound in literature; and they have been depicted in many paintings, have inspired the designs of jewelry, ornaments and textiles, and even occur in many heraldic devices and on postage stamps. They are the most popular of insects among amateur collectors and students of natural history.

GENERAL FEATURES

The members of the order show great diversity in size and development rates. The smallest moths have wing expanses as small as 4 millimetres, while the largest moths and butterflies may expand to nearly 300 millimetres (about 1 foot). Fast developing species may complete their development in as little as three weeks, while slower ones may take as much as two, or even three, years.

Both moths and butterflies occur on every continent except Antarctica. Though they are enormously more numerous and diversified in the tropics, at least some species occur at the limits of polar vegetation. There are many successful species in nearly every land environment, from arid deserts and high mountaintops to marshes and tropical rain forests. Most of the species have become adapted for life in relatively restricted ecological niches, and may be limited to only one or a small group of food plants, often to only a single part of one plant. They are therefore seldom abundant in more than one type of habitat. A few species, however, with broader food habits, may occasionally reach peaks of abnormal abundance and defoliate large areas of such environments as deciduous forest or grassland. Some of the insects most injurious to man's interests in agriculture, forestry, and households are members of the Lepidoptera.

Geographic distribution

The large family-level groups, and many smaller ones, are worldwide, with such families as Noctuidae, Geometridae, Pyralididae, and Nymphalidae being dominant elements of the insect fauna everywhere. A few families, some subfamilies and a great many genera, however, are characteristically more abundant in one faunal region than in others. Thus, the Neotropical region (mainly Central and South America) is characterized by great diversity of such moth families as the Dioptidae, Pericopidae, and Ctenuchidae and such butterfly subfamilies as the Riodininae, Heliconiinae, Ithomiinae, Morphinae, and Dismorphiinae. The North American (Nearctic) and Eurasian (Palaearctic) faunas show many evidences of close recent connections, chiefly between Asia and western North America. Each region has, however, many distinctive generic-level groups; for example, in the Palaearctic, ***Erebia*** and other satyr butterflies, and the parnassians (Papilionidae); in the Nearctic, the underwing moths *Catocala* (Noctuidae) and the silverspot fritillaries (Nymphalidae); in the Ethiopian (African) region, the butterfly genera *Charaxes* (Nymphalidae) and ***Teracolus*** (Pieridae), and many members of the papilionid subfamily Acraeinae; in the Oriental region, ***Troides*** (Papilionidae) and *Delias* (Pieridae).

Many Lepidoptera occur in isolated colonies as relict (remnant) populations, cut off from relatives elsewhere by geologic or climatic changes. Australia and New Zealand have unusually diverse relict populations of the primitive Micropterigidae and Hepialidae. In North America, Europe, and Asia many relict species have survived since the Pleistocene glaciations on isolated southern mountaintops. They include members of such genera as ***Oeneis*** and ***Erebia*** (Satyridae), *Boloria* (Nymphalidae), *Parnassius* (Papilionidae), ***Anarta*** (Noctuidae), and ***Pediasia*** (Pyralididae).

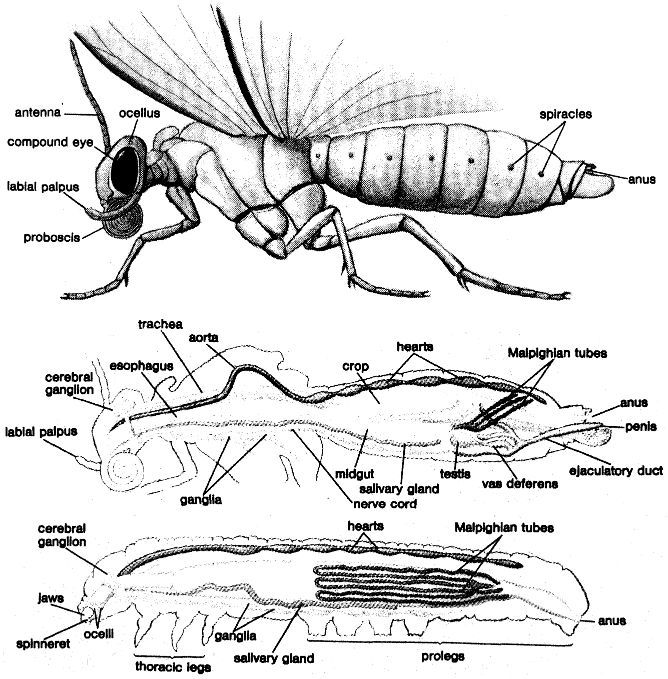

Figure 1: Body plan of generalized male adult butterfly or moth and caterpillar.

IMPORTANCE TO MAN

Many hundreds of Lepidoptera injure plants useful to man, including some of his most important sources of food, fabrics, fodder, and timber. The great majority of the injurious species are moths, and the most injurious life stage always is the larva. Unlike members of other insect orders, the Lepidoptera do not act as carriers of plant diseases, nor are any of them parasites or predators of man or domestic animals.

The list of valuable plants subject to damage by Lepidoptera is a long one, including many grains, sugar beets and cane, cotton, tobacco, some root crops and leaf crops, many fruits, and timber and shade trees. The damage may involve the leaves, stems, roots, or fruit. Woollens, furs, silk, and even feathers are eaten by tineid moths of several genera (clothes moths). The wax moth (***Galleria*** *mellonella*) causes considerable damage in beehives.

A few Lepidoptera are directly beneficial to man. Nearly all silk is obtained from the completely domesticated silk-

Lepidoptera beneficial to man

worm, Bombyx mori, originally Asiatic. Such other silks as shantung and tussah are the products of various Asiatic Saturniidae. The larvae and sometimes the adults of a few species are used for food. The larvae of a skipper, *Rhopalocampta libeon*, are collected in large quantities in the Congo, and the caterpillars of giant skippers (Megathymidae), known in Mexico as *gusanos de* maguey, are canned and exported for consumption as hors d'oeuvres.

The South American cactus moth, Cactoblastis *cactorum*, has been highly beneficial in weed control, clearing more than **60** million acres of Australia of prickly pear cactus. Doubtless man benefits also from much unrecognized weed eating by caterpillars and flower pollination by adults.

Many Lepidoptera are valuable in biological research, including work in ecology, biogeography, systematics, genetics, and physiology. Much of the present knowledge of endocrine controls of insect development has come from studies of the silkworm moth (Bombyx mori) and various saturniid moths. The study of industrial melanism (an increase in the frequency of black individuals in a population, brought on by the environmental changes that accompanied the Industrial Revolution) in the British peppered moth (*Biston* betularia) has profoundly influenced modern ideas about rates of evolutionary change (see EVOLUTION).

NATURAL HISTORY

Types of food taken

Feeding habits. The habits of Lepidoptera are extremely diverse, depending on the adaptations of the species or group to climate, environment, type of food plant, way of feeding, and many other factors. The great majority of food plants are seed plants (Spermatophyta), the dominant land plants. Primitive plants such as mosses, liverworts and ferns, and some lichens are eaten by a few groups. Nearly all parts of the plant are eaten by various specially adapted forms. Flowers are eaten by many larvae (*e.g.*, lycaenid butterflies, plume moths, some geometrid moths), and nectar by many adults. Cones and fruits and their seeds are eaten by others (*e.g.*, prodoxid and olethreutid moths, some owlet moths). Some seed eaters have become household pests, feeding on stored grains and cereals. Buds or soft, succulent stems are bored into by members of many families. Several lepidopteran groups (*e.g.*, the pine moths, Rhyacionia) specialize on the terminal shoots of conifers. Many groups feed on the turf of grasses and sedges. Three families (Cossidae, Aegeriidae, and Hepialidae) bore in woody stems and rootstocks, the Cossidae in particular tunnelling deep into hardwoods. **A** good many lepidopterans (especially members of the Tineidae, Blastobasidae, and Pyralididae) feed on dead and decaying plant matter, particularly moldy debris. In comparison with other orders of insects, relatively few Lepidoptera live in plant galls or eat animal matter. Some tineids feed on fur and feather debris, and a few exceptional species are predators or parasities of other animals.

Life cycle. Egg. The number of eggs laid varies greatly from fewer than a hundred in some species to more than a thousand in others. The eggs are almost always laid in a specific way, usually on or in a suitable foodplant. Those of many species are laid singly and widely dispersed; in others they are laid in masses that may be covered with a hardened secretion of the female's abdominal glands. In a few groups the terminal segments of the female's abdomen are greatly elongated and bladelike, and the eggs are laid in soft plant tissues or in narrow slits or crevices. In some of the primitive hepialid moths and in some butterflies the female may merely scatter the eggs in flight in the general vicinity of a suitable foodplant. Development of the embryo and emergence of the young larva is often controlled by a mechanism of physiologically enforced inactivity (diapause), which has the effect of timing the emergence of the larva to coincide with suitable conditions of weather and the growth of the foodplant. Respiration in the egg is carried on through an aeropyle, a system of air passages in the chorion (shell) that enables oxygen exchange with the environment to occur whether the egg is dry or wet. In a few species (some tineid moths and pierid butterflies) the larvae hatch in the uterus of the female.

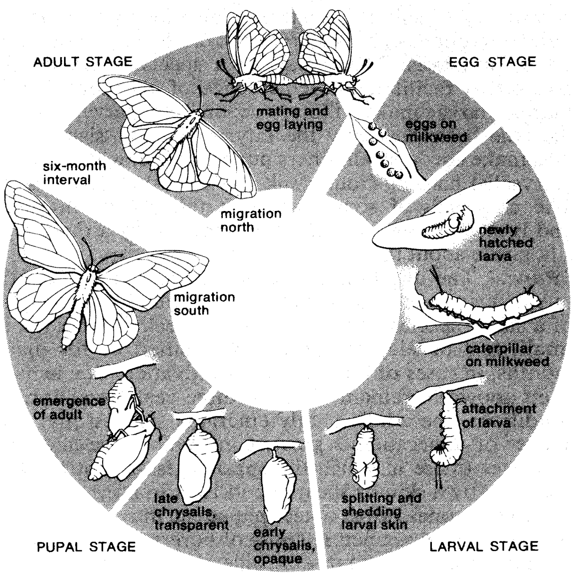

Figure 2: Life cycle of the monarch butterfly *(Danaus plexippus).*

Production of silk

Larva. The larva is the chief, often the only, nutritive stage of the life cycle, its function being simply to transform very large quantities of plant matter into animal matter, and to stay alive during the process. The larval stage is followed by the pupa, a resting stage in which the individual undergoes a major rebuilding of body tissues, to emerge as a sexually active adult. Plant foods being relatively easy to find and eat, it is not surprising that lepidopterous larvae are fundamentally quite uniform, despite their apparent diversity. Most larvae continually spin silk threads that adhere to the surfaces on which they live, thus giving them an almost unshakable grip. Silk is also used in the construction of various nests, cases, and shelters that protect the larvae from the elements and from enemies. Silk also serves in the final cocoon, in which the larva will change into the pupa. The larvae of leaf miners are mostly very small, greatly flattened, and more or less legless, well adapted for life inside a flat leaf. The larvae of borers are relatively plain and unornamented, while those that live in the open, exposed to the attacks of predators, have evolved a multiplicity of protective adaptations of form, colour, texture, and habit. Some possess chemical repellants. The proper timing of the larval development and activities is important in species in which hibernation, or estivation, is necessary. In some species (*e.g.*, nymphalid butterflies of the genus *Limenitis*) the larvae of the summer generation grow right on through without pause, but those of the next year's generation hibernate while still very young. In certain groups larval development is very slow, for reasons not understood, so that there may be only one generation a year. The larvae of the carpenter moths (Cossidae), feeding on poorly nutritious wood, may take two years to develop. Larvae of many Arctic and northern species, regularly have two-year cycles. The usual number of molts (ecdyses) is four or five, but some of the small leaf miners molt only twice. When starved, clothes moth larvae (Tineola) have been known to have a dozen molts, sometimes accompanied by a decrease in size.

Construction of the cocoon

Larvae seldom travel far from the plants where they began life. In some species there is dispersal of very young larvae, which, hanging from threads, are blown by the wind. Swarms of army worms (Pseudaletia, Noctuidae) may travel large distances, driven by crowding and lack of food. Just before pupation many larvae stop eating and crawl some distance before settling down to pupate. Many species pupate in the soil, with little or no cocoon; many others form cocoons in the soil, in trash, or under loose bark. Some cocoons are fastened to twigs or branches or rolled in leaves. The cocoons of leaf miners are usually formed in the "mine" or near it. Cocoons are commonly of silk alone but may also incorporate larval hairs, secretions or waste products, or chewed wood pulp, trash, or leaves. There may be a special seam on the cocoon to facilitate the emergence of the adult moth. Skipper larvae make a flimsy cocoon in the larval nest. Of the true butterflies only the satyr and parnassian butterflies make cocoons; all others pupate naked, with the pupa (chrysalis) hanging from a silk pad by a stalk (cremaster). The chrysalids of some butterflies (pierids, swallowtails, and lycaenids) are additionally supported by a threadlike silk girdle about the body.

Pupa. The duration of the pupal stage differs greatly in various groups and sometimes in different generations of a single species. It may last only a week or ten days, in small, fast developing species in summer, or for many months, in cases of hibernation or estivation. Pupae have been known to remain alive for three years in abnormal conditions, the adults finally emerging successfully. The danger of desiccation is greatest in small pupae and exarate ones (those in which the appendages are not fixed to the body by a skin or sheath) and least in large or obtect (compact) ones. Most obtect pupae can move only one or two abdominal segments. Those of borers can often wriggle along the tunnel to its exit, aided by rows of backward pointing abdominal spines that give purchase on the walls of the cocoon.

The adult. Although fully formed as an adult, the individual may remain quiescent within the pupal case for a long time, until conditions are right for its emergence. In some groups, the pupa has cocoon cutters, such as the movable mandibles of certain primitive moths, or saw-toothed structures on the head (leaf blotch miner moths). In saturniid moths the adult has bladelike structures on the wing bases. In puss moths (Cerura) and others the cocoon is partially dissolved by alkaline secretions.

Once out of the cocoon, the adult crawls upward to where it can hang head up or back down. Small pads on the thorax contain the incompletely developed wings in a compressed state. The insect then forces its body fluids into the thorax by contracting its abdomen and pumps blood out into the small wing pads, expanding them to form the full wings. The adult may be able to fly in a few minutes or may have to hang for several hours until its wings have stiffened sufficiently for flight.

As the larvae is the nutritive stage of the life cycle, the adult is the reproductive stage. Its mobility is necessary to bring the males and females together for copulation and to disperse the species into new areas. Nutrition is also an essential adult function in many primitive groups, such as the Micropterigidae. In the majority of lepidopterans it is important, but not essential, although in most of the highly mobile species much of the energy necessary for flight is obtained from nectar or other liquid foods taken in by the adult. The most advanced condition in this respect is found in the groups in which the adult mouthparts have become so reduced that they cannot function; here all the nutrition is unquestionably concentrated in the larval stage.

Behaviour. Food selection by the *adult*. Adults locate their food sources by both sight and scent, the former being especially important in the diurnal species, the latter in many diurnal species and in the nocturnal ones. The chief source is floral nectar, but sap (especially if fermenting), overripe fruits, homopteran honeydew, fecal matter, and carrion are sometimes used, usually by special groups. There are mutualistic relationships of a broad sort between the species of Lepidoptera with flower-visiting adults and the plants whose flowers they visit and pollenate, but these are seldom specific or obligate, since only rarely are the plant and the lepidopteran mutually dependent. Exceptions are some members of the orchid and morning glory families with very deep, tubular flowers. These appear to be pollinated only by certain hawkmoths with very long proboscises ("tongues"). The mutualism of the yucca moths (Prodoxidae) and yucca plants is obligate; the moth larvae feed only in yucca fruits and the latter can develop only from moth-pollinated flowers. The female yucca moth has special tentacles on the first maxillae, with which it gathers and carries balls of pollen.

Use of odours in courtship

Courtship and mating. The sequence of mating activities is usually initiated by the female, who gives off specific odorous substances (pheromones), sometimes even before she emerges from the pupa. These are detected by scent sensilla on the male's antennae. Males with very large, feathery antennae, such as saturniid moths, can locate females from some miles away and may form courting swarms about them. A species may have a particular time of day or night for this release of the female pheromones. Males of some species, such as the European ghost moth, Hepialus humuli, may at dusk form dancing swarms, into which the females fly.

Once the male has located the female, a more or less elaborate courtship may ensue. The sight of characteristic colours and patterns may be a requisite for this, as in the bright butterflies. Male pheromones also play an essential part. Distributed from special scent scales (androconia) on the wings, body or legs, the pheromones ensure the receptivity of the female. Finally the accessory genitalic structures must fit together, not only mechanically, but also so as to stimulate sensory nerve organs of the female. Some butterfly courtships are very active (*e.g.*, in sulphurs) the male and female flying high in the air, with elaborate behavioral sequences in which each act serves as a releaser, a stimulus for the next act. Such highly specific sequences are important barriers to hybridization between otherwise similar species.

The males of many species show definite territorial behaviour, defending a particular perch and area against the intrusion of other males, and darting out at passing females. Among butterflies, certain admirals (Limenitis), coppers (Lycaena), and hackberry butterflies (*Asterocampa*) are noted for this. Congregations of males of many butterflies about hilltops may have a certain territorial and premating function. So may the aggregations, sometimes very large, of many butterflies in wet places. In many instances these consist of young, unmated males that come together because of a mutual attraction, not merely to sip water.

Migration. Many Lepidoptera are famous migrants. The American monarch butterfly (Danaus plexippus) is the only species known to perform an annual two-way migration, the same individuals flying southward in the autumn and northward in the spring. The species has also crossed the Pacific Ocean, colonizing Hawaii and Australia, and occasionally reaches Africa and Europe. The cosmopolitan painted lady (Vanessa cardui) stages mass flights nearly everywhere it occurs; these are one-way flights with no returns and must be classed as emigrations, rather than true migrations. Many other species in Europe and North America fly northward in large numbers, often reaching regions in which they cannot survive the winters.

In Europe the painted lady and many moths reach Britain and Scandinavia from central Europe. In North America the painted lady, the cloudless sulphur butterfly (Phoebis eubule), and many noctuid moths often reach Canada. Many spectacular migrations occur in the tropics, in which swarms numbering many millions may fly out to sea and be lost. The best known species are pierid butterflies, but large migrations of the large diurnal moths *Urania leila* and *U. fulgens* have also been recorded. The usual explanation of such mass population movements—*i.e.*, the advantage of possibly extending the range of the species—is far from adequate in many such instances.

Ecology. Environmental hazards. As primary consumers of green plant material, the Lepidoptera are enormously important in food chains, not only because of the very large number of species in the order and the diversity of their food habits, but also because of the abundance of individuals. In most land environments they, in turn, are eaten by a host of other animals: predators, parasites, and scavengers. All stages in their life cycles are thus under continual attack.

The major invertebrate predators on Lepidoptera include centipedes, spiders, mantids, bugs, ground beetles, ants, and both social and solitary wasps. Important predators among vertebrates include toads and tree frogs, lizards, birds, rodents, bats, and monkeys. Some of the invertebrates locate their prey by scent, others by sight; most of the vertebrates hunt by sight, except for the bats, which hunt by acoustic echolocation (the so-called bat "sonar").

Predators and parasites

The chief groups of parasites that attack Lepidoptera are tachinid flies (Tachinidae) and many families of wasps, chiefly of the Ichneumonoidea, Chalcidoidea, and Cynipoidea. More precisely called parasitoid predators, they are probably more important than the direct predators. The female parasitoids locate suitable hosts, chiefly by scent, and lay their eggs in, on, or near them. The parasitoid larvae live inside their hosts, gradually feeding on the host tissues and almost invariably consuming them almost completely. Lepidoptera seem to have evolved few defenses against parasitoids, unless some of their toxic or repellent secretions serve to discourage them. The high reproductive rate is important as a counter against loss to parasitoids, as well as against other adverse factors.

Small, red trombiculid mites often ride about on adult Lepidoptera, probably doing them no harm. A few other mites, however—*e.g., Myrmonyssus*—live and breed in the tympanic cavities of noctuid moths, destroying their auditory structures. Curiously, they regularly settle in only one of a moth's two tympanic cavities and thus only half deafen it. It is believed that, by leaving the moth with one good ear, the mite reduces the likelihood of the moth (and hence the mite itself) being captured and eaten by a bat. Lepidoptera are subject to attack by a considerable number of protozoa, roundworms, bacteria, viruses, and fungi that affect the larvae chiefly during peaks of abundance and crowding. Some of these organisms have been used by man as a means of controlling injurious species.

Protection against danger. It is chiefly against the sight-hunting predators that the Lepidoptera have evolved a multiplicity of defense mechanisms that are unequalled by those of any other group of animals.

The adults of many groups, such as skippers, many butterflies, hawk moths and many underwing moths, have fast erratic flight. When escaping they dart or fall to cover and often remain immobile for some time. They have a good chance of escaping, especially if they are coloured like their surroundings. Larvae, especially when small, drop suddenly when disturbed, either dangling from a silk thread or falling to concealment on the ground. The larvae of some noctuids can jump several inches. Dense, loose hairs and scales make many moths slippery and may facilitate escape from sticky spider webs.

Certain noctuid moths and possibly some geometrids and pyralids, subject to predation by bats, are able to receive and identify the navigational sound pulses of the bats. Upon hearing bat pulses, these moths perform violent evasive flight movements (when the bat sound is loud, hence close) or dive to the ground (when the bat pulse is weaker, indicating that the danger is further away).

Targets, such as prominent colour spots or tails on the hindwings, attract the attention and focus the attacks of predators onto parts of the prey less vulnerable to injury. Such spots are likely to be seized and torn off, but this does the moth or butterfly no real harm and gives it time to escape without vital injury.

Concealment and camouflage

Many species manage to hide very effectively from predators. Many cutworms (Noctuidae) and other larvae hide in litter by day, feeding only at night. Many moths hide in crevices, often under loose bark, and some seem to have especially flattened bodies for this purpose. Hibernating butterflies spend the winter in hollow trees or hanging immobile among dead leaves. The larvae of a great many moths, of most skippers and of many butterflies, live in individual nests of rolled, folded, or webbed leaves or grass. Sod webworms live in silk-lined tunnels in turf. Wood borers, especially those in rootstocks and deep tunnels, are relatively secure. Many larvae aggregate in communal nests such as those of the tent caterpillars (Malacosoma), the larvae of the ermine moth (*Yponomeuta*), and those of the Mexican social white butterfly (*Eucheira* socialis). The larvae of the bagworms (Psychidae) and casebearers (Coleophoridae) live and pupate in individual, portable cases that are often masked with bits of leaf or twig. Some larvae, such as those of the green geometrid moths (*Synchlora*), attach bits of leaves or flower petals to themselves. Cocoons are frequently masked with leaves or debris; those of the puss moths and some dagger moths (Apatela) are hard, woody, and inconspicuous.

A cryptic (camouflaged) appearance conceals something only in appropriate surroundings, and only when accompanied by proper behaviour, usually immobility. Great numbers of larval, pupal, and adult Lepidoptera are thus protected in their natural environments, chiefly on or about plants. Leaf-eating larvae usually blend into leafy environments. Many caterpillars (*e.g.*, Sphingidae, Geometridae) have stripes that simulate leaf veins. The saw-toothed elm caterpillar (Nerice) has a jagged outline resembling the edge of an elm leaf. A great many measuring worms (Geometridae) are notably twiglike, with long, slender, stiffly held bodies. Many other caterpillars, especially Notodontidae, have irregular shapes that resemble twisted dead leaves. Likewise, many adult moths that rest during the day among leaves or on bark are cryptically coloured and patterned; moreover, their behavioral mechanisms lead them to select matching backgrounds on which to rest.

Many larvae and adults are disruptively marked; *i.e.*, have bold, contrasting patches or bands of colour that "break up" their outlines into two or more seemingly unrelated masses. Many adult moths and butterflies have "flash coloration," which serves to startle, and thus to delay momentarily, an attacker. Moths with cryptic forewings, and butterflies with cryptic undersides, show only these surfaces when they are at rest. If, when disturbed, they suddenly expose brilliantly coloured and marked hindwings, such as in undenving moths (*Catocala*), or upper surfaces (for example, morpho, hairstreak, and anglewing butterflies), the effect is startling. When the animal lands, the bright surfaces are suddenly hidden, causing it to "disappear." A similar "startle" effect protects larvae that have prominent spots simulating large eyes.

Startling sounds are produced by members of many groups. Larvae of hawkmoths (Sphingidae) and the pupae of many lycaenid butterflies make squeaking or grating sounds when disturbed. The adult death's head moth (Acherontia atropos) makes a loud chirping sound. *Ageronia* butterflies (Nymphalidae), when startled into flight, make a loud, clicking sound by means of a structure on the wings. This may have a startling, and therefore a delaying, effect on a predator.

Chemical defenses

Certain butterflies and moths possess repellent or toxic substances that provide protection against predators. Sometimes these are secured directly from the plant on which the larva feeds, such as the toxins (glycosides) that occur in high concentration in many milkweeds eaten by danaid butterflies. More often, the toxin is secreted by the insect itself. The toxin often occurs generally in the blood (*e.g.*, hydrogen cyanide in zygaenid moths) or in the gut, or may be the product of special glands, which release it at the time of an attack. Tiger moths (Arctiidae) give off bubbling drops of repellent from glands on the prothorax. Many groups show autohemorrhization, or reflex bleeding, from leg and body joints when disturbed. The larvae of swallowtail butterflies (Papilio) and tussock moths (Liparidae) give off strong smelling, volatile substances from extrusible scent organs (osmeteria). Many notodontid moth larvae spray formic acid from ventral prothoracic glands. Many larvae and some adults introduce toxins that cause severely painful nettling effects by means of hollow, barbed hairs; the slug caterpillar moths (Eucleidae), flannel moths (Megalopygidae), io moths (Saturniidae), and some liparid moths are noted for this. A few adult moths (*e.g.*, Arctia *caja*, some Sphingidae) inject toxins through sharp spines on their hind legs. Besides those already mentioned, the chief groups that are chemically protected are the moth families Ctenuchidae, Pericopidae, and Dioptidae and the butterfly groups Heliconiinae, Ithomiinae, Acraeinae, and the swallowtails (*Battus*) that feed on birthwort. The great majority of these and other protected forms are aposematic; *i.e.*, have markings, shapes, and behaviour that draw attention. They are thus easily recognized and remembered by predators which, after seizing only one or two individuals, will thereafter leave other similar ones alone.

The protective advantage gained by a distasteful or dangerous insect and accompanied by aposematic coloration or acoustic warning may be utilized by harmless and edible insects, through the evolution of close resemblances, known as mimicry. (For background information of this phenomenon, see MIMICRY.) The distasteful insect, known as the model, may even be a member of an insect order different from that of the mimic. Members of various lepidopteran families mimic wasps, bees, and beetles. The clearwing moths (Aegeriidae) are particularly effective mimics of certain stinging wasps, the resemblance being carried to details of the shape and coloration of the wings, abdomen, and legs. Mimicry occurs widely in the moth families Dioptidae, Chalcosiidae, Callidulidae, and Zygaenidae and in the butterfly families Nymphalidae, Papilionidae, Pieridae, and Riodinidae.

Not all warning mechanisms are visual. Inedible arctiid and pericopid moths make high-pitched grating sounds by means of timbal (drumlike) organs. These sounds, above the frequency range audible to man, but within that audible to bats, may function to warn the bat of the moth's inedibility, avoiding capture and tasting that would be injurious to the moth. Some authorities believe that these sounds may interfere with the bats' acoustic orientation system, preventing the detection of the moth.

Polymorphism

The occurrence in a population of two or more distinct hereditary variants, or morphs, is known in many Lepidoptera. Each morph may have a different adaptive value, linked with such physiological features as resistance to cold, or to toxins in the environment. Striking variation in appearance may have great adaptive value by confusing predators, making it more difficult to learn the appearance of the prey. Mixed populations of both light and dark (melanic) individuals may survive better in mixed light and dark environments, and actually be prepared for a shift of the environment to a predominance of dark, through the normal succession of forest growth or through man-made industrial pollution. In England investigations of the peppered moth Biston betularia have abundantly documented the evolution of "industrial" and "natural" melanism and shown major genetic population changes taking place very rapidly.

Striking polymorphisms occur in some mimetic species, notably the African swallowtail, Papilio dardanus. The occurrence of different species of inedible butterflies ("models") in various regions has been accompanied by the evolution of correspondingly different mimetic females of the single species of swallowtail. The North American tiger swallowtail, P. glaucus, has mostly black females where it coexists with the black distasteful pipevine swallowtail, *Battus* philenor. Where B. philenor does not occur, however, the P. glaucus females tend to be all nonmimetic yellow like the males, black having no protective significance. Some very striking mimetic polymorphism occur among Neotropical Heliconius butterflies and their various models and mimics.

FORM AND FUNCTION

Within the limitations imposed by their almost entirely planteating habits, the Lepidoptera show a great diversity of size, structure, and many other characteristics. Furthermore, some members of the order have retained many primitive features, while others have evolved very advanced and specialized ones. This broad range, from primitive to advanced and from generalized to specialized, is evident not only in the adults but also in the larvae and pupae, and to some degree in the eggs.

The adult. Nearly all external surfaces of the adult animal are covered with scales, which may be broad and flat or very long and hairlike. Each of these is the outgrowth of a single epidermal cell. Similar scales occur in a few groups of other insects, but never to the same extent.

Like most insects, adult lepidopterans have three distinct body segments, or tagmata, the head, the thorax, and the abdomen, each with special functions (Figure 1). The head bears the main sensory organs and those of food-getting and ingestion. The thorax is chiefly concerned with locomotion. The abdomen contains the chief organs of digestion, excretion, and reproduction and bears the external accessory reproductive structures.

Head. The head is relatively small and round or elliptical. Evolutionarily, it is derived from the six anterior somites or metameres (the primitive body segments), but these have become so coalesced that none of the primitive segmentation is evident. The antennae are prominent and many segmented, with many microscopic receptors for detecting odours. In most moths the antennae are slender and tapering; in a few moths the surface area of the antennae is greatly enlarged by many side branches that make them comblike or featherlike. In skippers and butterflies the terminal part is broadened, forming a "club," on which most of the sensilla are concentrated. In many families there is also a cluster of sensory bristles, the chaetosema, on each side of the head, near the eye. On either side of the head is a large compound eye, sometimes consisting of thousands of units (ommatidia). Most moths have, in addition to the compound eyes, a pair of very small, simple eyes (ocelli), which have a very limited function.

Sense organs

The compound eyes are very efficient for distinguishing motion, but not for resolving clear images of distant objects. Diurnal species may be able to distinguish flower shapes, and courting individuals respond to specific wing patterns. Colour perception, especially in the blue-violet end of the spectrum, is acute in some species. Moths are generally able to see by ultraviolet, to which they are often strongly attracted at night.

The sense of smell is acute in some groups, especially in males with large antennal surfaces. The sense of taste is also acute, especially for sugars, through receptors located chiefly on the palpi and on the soles of the tarsi (feet).

Hearing is acute in the moths, with special membranes (tympana) most of which are located in the thorax, some of which react to sound waves above the range of human hearing. Mechanical information, including sound, is also received by chordotonal (stretch) receptors in a number of locations, especially in the antennae.

A relatively primitive set of chewing mouthparts occurs in the adults of the most primitive moths (Micropterigidae) as well as with larvae of nearly all Lepidoptera. Basically these consist of an anterior flap, the labmm; a pair of chewing jaws, the mandibles; a pair of complex first maxillae; and a pair of similar second maxillae joined together behind the mouth to form a structure called the labium. Each of the first and second maxillae bears a jointed, sensory appendage, or palpus, the maxillary and labial palpi respectively. Such mouthparts function for chewing and manipulating solid foods. In the vast majority of adults the mandibles are either vestigial and nonfunctional or absent. Parts of the first maxillae (the galeae) are elongated to form the two halves of a tubular proboscis, or haustellum, through which liquids may be sucked. The segmented palpi of the first and second maxillae are present and function as sensory organs. Not all adults, however, have all of these parts fully formed and functional. In numerous families the proboscis has become considerably reduced and even vestigial, so that the adult cannot feed. In advanced moths and in skippers and butterflies, the maxillary palpi are vestigial or lost, so that only the labial palpi remain functional.

Mouthpart reductions appear to have occurred independently in a number of evolutionary lines, the result being to limit feeding to the larval stage and to enable the adult to concentrate on reproduction and dispersal.

Thorax. The thorax consists of three segments, the prothorax, mesothorax, and metathorax, each derived from a primitive segment (metamere). The prothorax bears the first pair of legs and a pair of respiratory apertures (spiracles). The much larger mesothorax bears the second pair of legs and the pair of forewings, The metathorax bears the third pair of legs and the pair of hindwings. In many moths the metathorax bears a pair of complex auditory organs (tympana), and in many of these it also bears a pair of sound-producing timbal organs.

The wings begin development in the maturing larva as sacs infolding (invaginating) from the epidermis. As the pupa is formed these outfold (evaginate) to lie externally and become large and flat. Within them, branching tubes (tracheae) carry an air supply and also mark the pathways along which will develop the tubular "veins" that support the fully formed wings. The wings are expanded to full size when the adult emerges from the pupa. On the wing the scales lie in rows, overlapping like shingles. The usual scale is a flattened, rigid, air-filled sac (Figure 4) attached by a peglike base. It is usually ribbed longitudimally and toothed terminally. Many males have special, glandular scent scales (androconia) scattered or concentrated in patches (brands or stigmata) on the wings, sometimes forming expansible, hairlike tufts. These have a scent-distributing function essential in specialized courtship. Very primitive moths have the wing membrane aculeate; *i.e.*, more or less covered with microscopic bristles (setae or aculeae).

H.E. Hinton

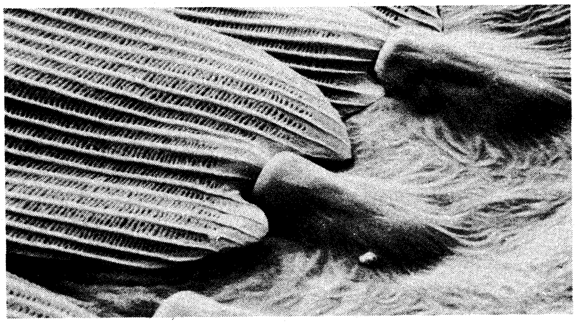

Figure 4: Detail of scales from the wing of butterfly, *Danaus plexippus* (magnified about 2,600 X).

The scales and hairs of the adults, especially on the wings, are responsible for colours and patterns. There are many different pigments of several chemically diverse types such as melanins, uric acid derivatives, and flavones. In addition, the microstructure of hairs and scales refract light in various ways so as to produce colours as well as metallic, pearly, iridescent, and white effects. Very fine parallel ridges in scales may produce an iridescence by acting as diffraction gratings. More common are the effects of very thin, superimposed layers (laminae) in the walls of the scales, a colour phenomenon comparable to that produced by a thin film of oil on water. Many of the most striking effects are caused by combinations of pigmental and structural colours.

Coupling of the fore and hind wings

The fore and hind wings on each side are coupled together in various ways. In primitive moths a fingerlike lobe (jugum, or fibula) on the forewing overlaps the base of the hindwing. In most moths a strong bristle or cluster of bristles (frenulum) near the base of the hindwing engages a catch (retinaculum) on the forewing. In some moths and in the skippers and butterflies the frenulum mechanism has been lost, and the wings are coordinated by the friction of the overlapping areas. In the most primitive moths the forewings and hindwings are similar in size, shape, and veins. In most moths and in the skippers and butterflies reduction of the hindwings has taken place; they have become shorter and more rounded, with reduced veining except in the anal cell area (the posterior wing section). The costal (anterior) edge of the forewing is thickened, with stronger veins, while the outer and anal (posterior) margins are thinner and weaker. This accords with the function of the wings as airfoils, the costal margin being the leading edge of the wing.

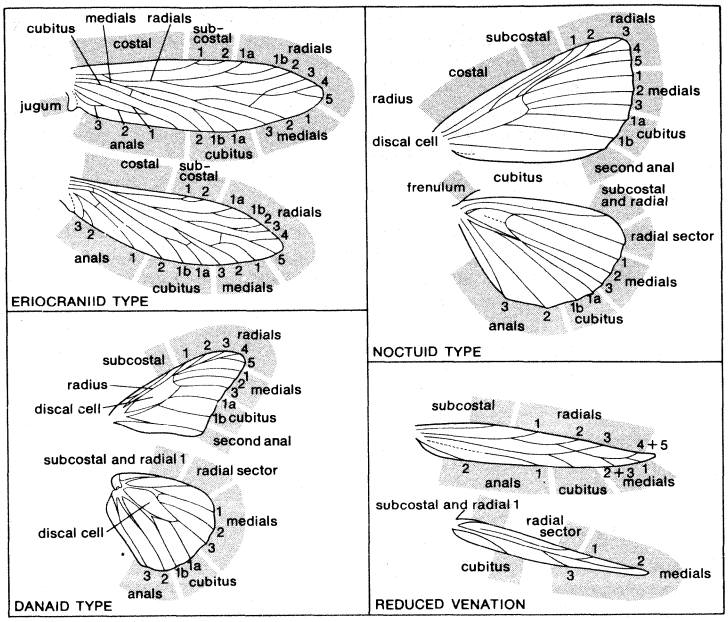

Figure 5: Types of wing venation.

From (top left) J. Comstock, *The Wings of Insects*, Comstock Publishing Co.; (top right) *An Introduction to the Study of Insects*, 3rd ed. by Donald J. Borror and Dwight M. DeLong, copyright © 1964, 1971 by Holt, Rinehart and Winston, Inc., copyright 1954 by Donald J. Borror and Dwight M. DeLong, reproduced by permission of Holt, Rinehart and Winston, Inc.; (bottom right) J. Comstock, *An Introduction to Entomology* (1956), Comstock Publishing Co.

The wings are characteristically considerably modified in various families. In many moths of the superfamily Tineoidea both wings have become extremely narrow, with reduced, degenerate venation but with long, dense fringes along the margins, maintaining the functional wing area. In one family (Pterophoridae) the wings are deeply cleft into two or three narrow plumes; and in the Orneodidae each wing is cleft into six plumes. In a number of moth families the females are wingless, although the males are fully winged (Psychidae, some Liparidae). In the aquatic pyralid genus ***Acentropus*** some females are wingless, while the others and the males are winged.

There are eight main wing veins, each with a characteristic pattern. These are usually designated according to the modified Comstock-Needham system. The names of the veins (with their symbols in parentheses) and the usual number of branches of each (subscript designations) are as follows, in progression from the costal margin of the wing to the anal, or inner, margin:

Costa (C), along the anterior margin, no branches;

Subcosta (Sc), usually with no branches, rarely with two (Sc_1, Sc_2);

Radius (R), typically with five branches (R_1 - R_5);

Media (M), with three branches (M_1 - M_3; four in some other insects);

Cubitus (Cu), primitively with three branches (Cu_{1a}, Cu_{1b}, Cu_2);

Anal Veins, First (1A), Second (2A), and Third (3A), all unbranched.

Abdomen and genitalia. The abdomen has ten segments, although the posterior ones are indistinct. Each of the first eight segments bears a pair of spiracles. The first or second segments bear paired auditory organs in the pyralid and geometrid moths. Segmental appendages are absent except for vestiges that may form parts of the genitalia. Various segments may bear special structures that produce and disperse pheromones. The genitalia of both sexes are often complex and bear characteristic spines, teeth, setae, and scale tufts. These structures are important in complex courtships and matings, preventing hybridization between unsuitable males and females.

In males (Figure 6) a ringlike structure (vinculum) is the base of attachment for a number of dorsal structures (tegumen, uncus, and gnathos) and a pair of lateral clasping organs (valvae). In copulation a median, tubular organ (the aedeagus) is extended through an eversible sheath (vesica) to inseminate the female. These structures evolutionarily derive from the body-wall plates, or sclerites (lateral tergites and ventral sternites), of segments eight and 10 and from vestiges of abdominal appendages.

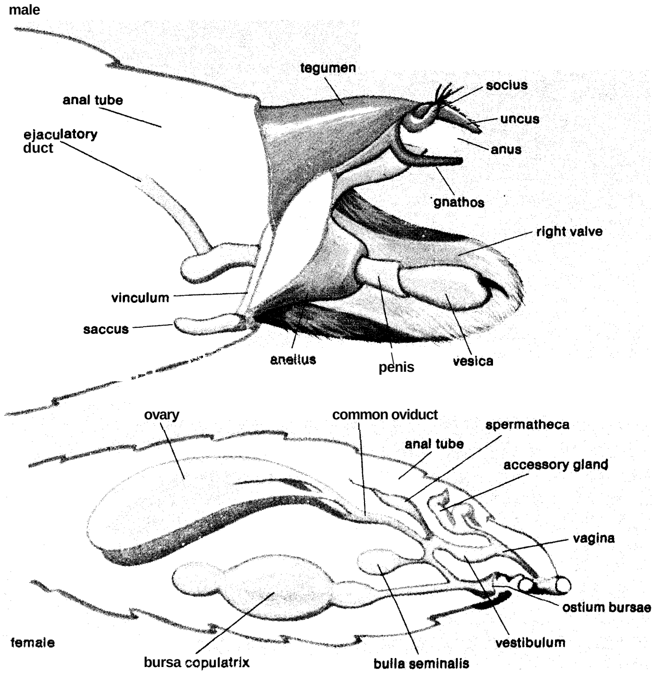

Figure 6: Genitalia and associated structures of the male and female Lepidoptera.

The female genitalia exhibit a number of different patterns of the internal ducts and the openings, varying from a condition in which there are no special genital openings, insemination and egglaying (oviposition) taking place through a single aperture, shared with the excretory system, to one in which there are two specialized openings, one for insemination and one for oviposition, both distinct from the anus.

Internal reproductive system

The internal reproductive systems of both sexes contain the organs typical of most insects. The testes of the male are paired in primitive lepidopterans but fused into a single organ in advanced forms. In both cases, the sperm ducts are paired. As in other insects, the sperm pass from the testes down paired ducts (vasa deferentia) for storage in sacs called seminal vesicles. Accessory glands, providing fluids that lengthen the life of the sperm, open into the vasa deferentia.

The female reproductive system consists of paired ovaries, paired accessory glands that provide the yolks and shells of the eggs, and a system of receptacles and ducts for receiving, conducting, and storing sperm. The individual oviducts join to form a common oviduct that leads to the vagina. In copulation, the male deposits a sperm capsule (spermatophore) in a receptacle (bursa copulatrix) of the female. The spermatophore releases the sperm, which swim into the oviduct and thence to the seminal receptacle (bulla seminalis) where they are stored until egg laying, which may be hours, days, or months after mating.

The egg. The egg is enclosed in a protective shell, the chorion, through which a system of tiny canals, the micropyle, permits the entrance of sperm. In some groups the micropyle is at the side, in others on the surface away from the substrate. Formed in one of the paired ovaries, the egg passes along the individual oviduct and through the common oviduct to the vagina. Here, just before it is laid, it comes into contact with a droplet of seminal fluid that has been stored in the female. Fertilization now takes place. Most eggs are more or less spherical, but some (Eucleidae, Lycaenidae) are flat, while others (Pieridae) are long and tapered at the ends. The surface may be strongly sculptured with pits, sharp projections, or raised ridges.

The larva. Compared with the highly specialized adult, the larva is simple and primitive. Many of the primitive characters retained in the larva are important in the classification of the suborders, superfamilies, and families, and in phyletic speculations. The head bears a pair of very short antennae and on each side a cluster of minute, simple eyes (ocelli or stemmata). A short liplike labrum lies anterior to the mouth. Behind the labrum are paired jaws (mandibles), short, broad and powerful. Next is a pair of small first maxillae, each with a segmented palp; and then, more or less connected with the maxillae, the labium-hypopharynx, a complex structure with a pair of labial palps and a median, tubular spinneret (a protrusion through which silk is extruded). Each of the three thoracic segments bears a pair of short, segmented legs. The remaining ten segments constitute the abdomen. Each of segments three through six and ten bears a pair of fleshy appendages called prolegs, which may be homologous with the primitive segmental appendages. Each proleg has one or two curved rows of minute hooklets (crochets) and an eversible, soft end, the planta. The prothorax and abdominal segments one to eight have each a pair of spiracles.

External ornamentation of the larva

The larval epidermis bears a number of bristles, known as primary setae, on the head and each body segment. These setae are constant in position and number in each species and important in classification. There are often many secondary setae, sometimes forming a dense, hairy vestiture. Larvae that live and feed as borers, burrowers, or miners are mostly plain. Those that live and feed in the open often show a great diversity of shape, colour, pattern, and ornamentation. Many have wartlike projections (verrucae) that may bear tufts of setae or spiny projections; or there may be prominent hornlike or spiny processes (*e.g.*, Saturniidae, Sphingidae) or fleshy filaments (Danainae).

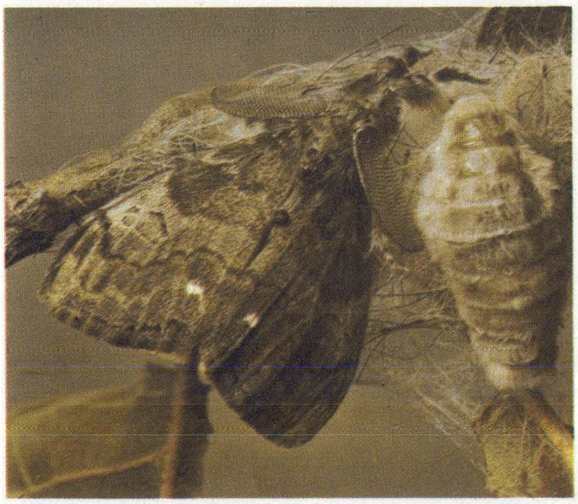
In some families the number of the prolegs has been modified. In the measuring worms (larvae of the Geometridae) the prolegs of segments three, four, and five are missing, and in some noctuid moths one or two pairs have been lost. In Drepanidae and some Noctuidae the last pair has been lost; and in the puss moth caterpillars this pair has evolved into a pair of long, eversible whiplashes (stemmatopoda). The larvae of some leaf miners (Gracillariidae, Lyonetiidae) have lost some or all of the prolegs. Micropterigid larvae have eight pairs of abdominal legs, which are more like true legs.

Internally, the larva is relatively simple, the very large digestive tract being the most prominent organ. The paired silk glands are often very large, extending far back into the abdomen. The ovaries and testes, which begin to develop during embryonic life, continue to develop in the larva, as do the wings. Many special glands secrete repellant or toxic substances, which may circulate in the blood or be extruded from special openings as a means of defense.

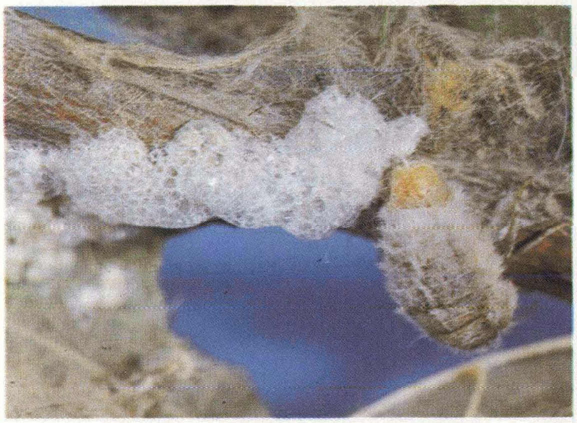
Larval vision can detect little more than differences between light and darkness. Taste is acute, depending on delicate sensory receptors in the antennae and palpi. Food discrimination is keen and many larvae will starve rather than eat abnormal food plants. The sense of touch depends on setae well distributed over the outer surface. Some of these appear to react to sound waves of low pitch, well within the limits of human hearing.

The pupa. Lepidopterous pupae show the same sort of evolutionary gradation from primitive to advanced as do larvae and adults. In the primitive Micropterigidae and

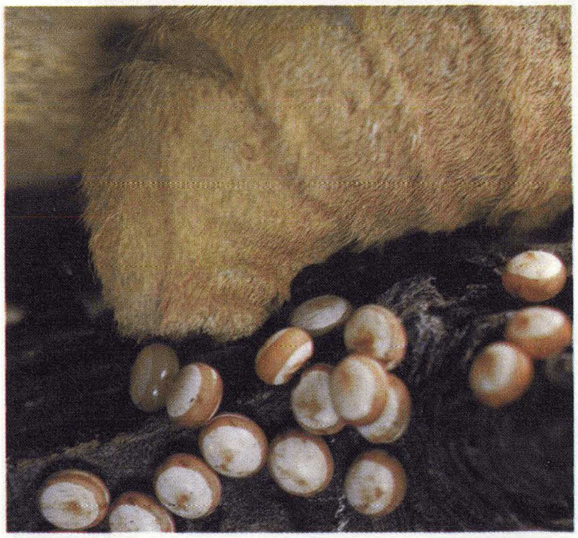
Mating and egg laying



Tussock moths (Notolophus *leucostigma)* on female cocoon. The wingless adult female lives solely for the purpose of oviposition.



Female tussock moth laying eggs in masses on the surface of her old cocoon. She covers the eggs with a sticky secretion that becomes dry and brittle.



Polyphemus moth depositing eggs. Because the larvae feed on a variety of trees and shrubs, site selection for egg deposition is haphazard.

Degginger, (below centre left, below centre right) Alexander B. Klots, (bottom left) William E. Ferguson

Eriocraniidae the pupa is exarate, having the appendages free and movable, and decticous, having functional mandibles. In some less primitive groups the pupa, called incomplete, has retained considerable powers of motion of some appendages. In the higher moths and the butterflies the pupa, called obtect, has all appendages tightly fastened and immobile and is able to wriggle only one or two abdominal segments. In a few groups (Sphingidae, Lycaenidae) the pupa has special stridulating rasps for sound production. Nearly all of the external structures of the adult can be seen on the pupa. The wings are prominent, folded down flat along the ventral surface, with the proboscis halves, the legs, and the antennae between them. At the posterior end is a spiny pad or spike, the cremaster, which in many groups attaches the pupa to silk fibres spun by the larva.

Except for a very slight respiratory exchange and a little water loss, the pupa is physiologically almost self-sufficient. Within it most of the cells and tissues of the larva undergo considerable histolysis (breaking down), as the adult structures are built up from the existing rudiments. Some structures begin developing as far back as the first larval stages.

Growth, molting, and metamorphosis. As in other insects, growth and its structural changes are controlled by an interacting set of hormones. These are chiefly secreted by the corpora allata and other parts of the brain, and by paired prothoracic glands. The prothoracic gland hormone is necessary for larval molting, metamorphosis to the pupa, and formation of adult characteristics. On the other hand, a hormone secreted by the corpora allata inhibits metamorphosis until late larval development. A hormone secreted by neurosecretory cells in the pupal brain stimulates the prothoracic glands and thereby brings about differentiation of the adult and the end of the obligatory resting stage (diapause) of the pupa.

EVOLUTION AND PALEONTOLOGY

The Lepidoptera belong to an important group of insect orders, the panorpoid complex, the ancestral stem of which began in the Permian. This stem split into a number of branches, from which evolved the modem orders Mecoptera (scorpion flies), Megaloptera (dobsonflies), Neuroptera (lacewings), Diptera (true flies), Trichoptera (caddisflies), and the Lepidoptera. The nearest living relatives of the Lepidoptera are the caddisflies and, in fact, the very primitive moths, the Micropterigidae, have been grouped with the caddisflies by some students. As the Lepidoptera developed into a distinctive group certain major trends began to be emphasized. The adult mandibles disappeared and were replaced by the proboscis formed from the galeae of the maxillae, broadening the food base exploitable by the species to include not only sap and other plant juices but nectar and fruit juices as the flowering plants evolved. Various groups, however, independently lost the proboscis and concentrated on the larval stage as the sole source of nutrition. The characteristic vein pattern evolved, with the long, veinless discal cell in each wing, and an emphasis on the strength of the forewing and a de-emphasis of the hindwing, forming a particular pattern of aerodynamic efficiency. Related, also, was the replacement of the primitive jugum, for wing coupling, with the more efficient frenulum mechanism. However, some efficient flyers, such as the bombycoid moths, the skippers, and the butterflies, subsequently lost the frenulum; and quite a few groups of small moths, settling into restricted ecological niches where strong flight is not a necessity, evolved a great deal of wing reduction.

Evolution of the proboscis

Concurrent with changes in the adults, the larvae were evolving a multiplicity of different ways of feeding on the evolving seed plants. As both larval and adult differentiations accumulated, it became more and more necessary that the pupal stage be a passive, resting phase, to allow time for the metamorphosis of larva into adult.

Very few fossil Lepidoptera are known. The earliest undoubted ones, small moths related to the Eriocranioidea and Tineoidea, are from the Early Tertiary Period. The order must have existed long before then, however. The closely related caddisflies are known from the Jurassic Period of the Mesozoic Era. The best known fossil butterflies are relatively recent, being from the shales of Florissant, Colorado, generally considered to be Middle Tertiary. Some of these are not only undoubted Nymphalidae but are very close to modern genera.

CLASSIFICATION

Distinguishing Taxonomic Features. The chief characters used in the ordinal, subordinal, and family-level classification of the Lepidoptera are: the mouthparts, ranging from mandibulate to haustellate (with a proboscis) or degenerate; the venation and shape of the wings, homoneurous (the venation of the forewings and hindwings alike) or heteroneurous (forewings and hindwings different), aculeate (more or less covered with specialized bristles called microsetae) or nonaculeate, and type of coupling (jugum or frenulum); the anatomy of the female reproductive system; the exarate or obtect condition of the pupa; and the larval structure and pattern of the primary setae.

Wing venation

The venation of the wings is perhaps the most important single criterion for establishing both differences and relationships in the classification. It must be considered in terms of the evolution of venation changes from primitive to advanced conditions on a number of different phyletic lines. The most primitive groups (Figure 5, top left) tend to have the maximum number of veins and branches in each wing. More advanced groups (Figure 5, top right and bottom left) lack some veins or branches in the forewing and have the hindwing venation considerably reduced, especially by the reduction of free radial branches, the unbranched stem of R_2 - R_5, being called the radial sector (R_s).

Genitalia

The structures of the genitalia are extremely important in classification, often serving better than any other characteristics to distinguish the species. The various parts have

From A. Imms, Textbook of General *Entomology;* Methuen & Co. Ltd.

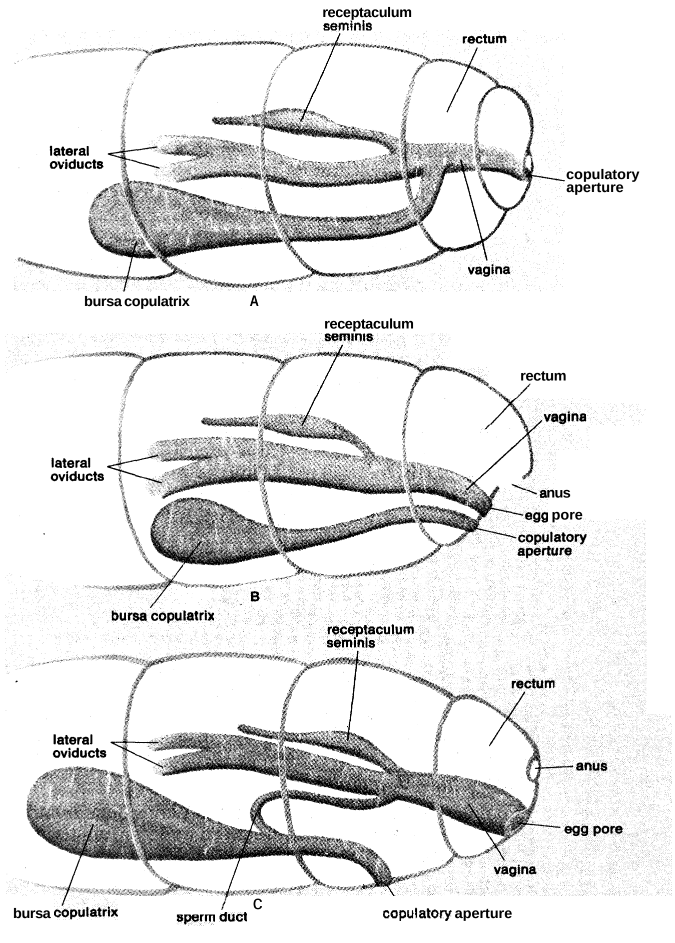

Figure 7: ***Relationships of female reproductive ducts and rectum in Lepidoptera.***
(A) Micropterigid type. (B) ***Hepialid type.*** (C) Ditrysian ***type.***

been homologized with each other, thus enabling comparative studies of families and genera as well as studies of species.

Types of genitalia

The female genitalia (Figures 6 and 7) show a number of different types of organization of the internal genital ducts and the openings. These are considered so fundamental that the subordinal classification is largely based on them, in correlation with characteristics of the mouthparts, wings, and early developmental stages. These genitalic types are as follows:

1. No special genital openings. Both insemination and oviposition take place through the cloaca, a chamber common to both the reproductive and excretory systems, the aperture being the anus.
2. A separate genital opening for insemination (reception of seminal fluid) but oviposition through the cloaca and anus.
3. Separate genital openings for insemination and oviposition, both close together and both close to the anus.
4. Separate openings for insemination and oviposition, the latter still close to the anus but the former removed some distance ventrally, in the eighth segment.

Type 1 characterizes the extremely primitive suborder Zeugloptera, the mandibulate Micropterigidae. Type 2 occurs in the superfamilies Eriocranioidea, Nepticuloidea and Incurvarioidea of the generally primitive suborder Monotrysia.

Type 3, sometimes called "exoporian," characterizes the monotrysian superfamily Hepialoidea, also quite primitive in other ways. Type 4 characterizes the most advanced suborder Ditrysia, containing the great majority of Lepidoptera.

Annotated Classification. The classification given here largely follows that of the British entomologist A.D. Imms, itself a synthesis of the suggestions of several earlier authors. This classification incorporates changes on the family level that have been suggested recently. There is no clear evidence for the phyletic relationships of numerous families, especially in the greatly reduced tineoid moths.

ORDER LEPIDOPTERA

Insects with complete metamorphosis; the wings covered with flat scales; larval mouthparts mandibulate; adult mouthparts mandibulate to haustellate, sometimes vestigial; wings with venation ranging from primitive (complex) to considerably reduced, especially in the hindwings; pupae exarate to obtect; almost all phytophagous (herbivorous).

Suborder Zeugloptera

Female with no special genital openings. Larvae, pupae, and adults functionally mandibulate; wings aculeate, homoneurous, jugate.

Family Micropterigidae (mandibulate moths). Small, a few species in the Palaearctic and Nearctic, more in Australia and New Zealand. The adults eat pollen; the larvae eat mosses and liverworts.

Suborder Monotrysia

Females with 1 or 2 genital openings near anus. Adults at least partly haustellate. Wings homoneurous to heteroneurous, at least partly aculeate. Jugum present in some, frenulum in others. As a group intermediate between Zeugloptera and Ditrysia.

Superfamily Eriocranioidea

Females with 1 genital opening, a long cloaca, and a piercing ovipositor. Wings homoneurous and aculeate. Adults with a short proboscis. Pupae with functional mandibles.

Family Eriocraniidae (eriocraniid moths). A small, widely distributed family, chiefly Nearctic and Palaearctic. Adults nectar feeding, often brilliantly coloured. Related families: Mnesarchiidae (New Zealand), Mesopseustidae (India and Taiwan).

Superfamily Hepialoidea

Females with 2 genital openings. Wings homoneurous and aculeate. Adult mouthparts reduced and nonfunctional, antennae very short.

Family Hepialidae (swifts and ghost moths). Medium-sized to very large moths, some brilliantly coloured. Larvae mostly borers in turf or wood. About 300 species; worldwide, chiefly in Australia and New Zealand. Related families, less known: Prototheoridae (Africa and Australia), Palaeosetidae (Australia), Anomosetidae (Australia).

Superfamily Nepticuloidea

Females with 1 genital opening and a soft ovipositor. Wings somewhat aculeate, heteroneurous, and somewhat narrowed and with reduced venation.

Family Nepticulidae (midget moths). Very small to minute moths. Antennae with broad "eyecaps" basally. Larvae mostly leaf and bark miners, a few gall makers. Worldwide. Also called Stigmellidae.

Families Opostegidae and Tischeriidae. Worldwide families of small moths with narrow, long-fringed wings. Larvae leaf, stem, or bark miners.

Superfamily Incurvarioidea

Family Incurvariidae (fairy moths). A small but worldwide family of small moths, many being brilliantly coloured diurnal flower visitors. Male antennae often several times as long as forewings. The mutualistic relationships of the yucca moths (Prodoxinae) with their food plants are biologically famous. Family sometimes split into families Incurvariidae, Adelidae and Prodoxidae. The related Heliozelidae (shield bearers) are worldwide.

Suborder Ditrysia

Females with 2 genital openings, the receptive one on the 8th abdominal segment. Wings strongly heteroneurous, nonaculeate, mostly with frenulum but this is degenerative or lost in some. Contains the great majority of Lepidoptera: higher moths, skippers, and butterflies.

Superfamily Zygaenoidea

Wings broad to very broad with short fringes and some primitive venational and larval features. Pupae quite primitively mobile.

Family Eucleidae (slug caterpillar moths). Larvae broad and flat ventrally, with reduced prolegs; move glidingly with head hidden beneath prothorax; many with toxic, irritant setae. Adults with heavy hairy bodies and vestigial proboscises. Also called Limacodidae.

Family Megalopygidae (flannel moths). Larvae like those of Eucleidae, but with prolegs normal, plus traces of some additional ones; setae very toxic and nettling. Almost limited to New World.

Family Zygaenidae (burnet and forester moths). Adults usually diurnal flower visitors, with bright colours and strong proboscises. Strongly protected by high concentrations of hydrogen cyanide in blood. Larvae, leaf skeletonizers. Related families: Aididae and Chalcosiidae (Old World tropics); Pyromorphidae and Dalceridae (New World).

Superfamily Tineoidea

A large group of families of mostly small moths of diverse habits. All have some primitive venation features and life cycles. Wings narrow to very narrow.

Family Tineidae (clothes moths and others). Small, narrow-winged moths with rough, hairy heads and often long, folded maxillary palpi. Larvae often casemakers, feeding on debris and fungi. Worldwide. Clothes moths (*Tineola, Tinea, Trichophaga)* often serious household pests. Related family: Acrolophidae, burrowing sod webworms.

Family Psychidae (bagworms). Larvae live and pupate in often elaborate cases. Adult males with broad, thin scaled wings; females wingless, often greatly degenerate and never leaving larval cases. Worldwide.

Family Epipyropidae (parasitic moths). Small family, chiefly Oriental. Larvae live as external parasites on plant hoppers (Homoptera). Related family: Cyclotornidae, Australian, larvae living similarly when young, then moving to ants' nests.

Family Coleophoridae (casebearer moths). Small, very narrow-winged moths. Larvae mostly mine leaves when young, then live in portable cases with distinctive shapes. Worldwide. Some are pests of fruit trees.

Families Gracillariidae, Lyonetiidae, Elachistidae and Douglasiidae. A group of worldwide families, totalling about 2000 species. Adults with narrow, long-fringed wings often with metallic markings. Larvae mostly leaf miners, sometimes greatly flattened, with degenerative legs and mandibles.

Superfamily Gelechioidea

A group of worldwide families totalling more than 12,000 species. Adults mostly larger and broader winged than Tineoidea. Larvae seldom leaf miners. Pupae obtect, relatively immobile.

Family Gelechiidae (gelechiid moths). Small to minute moths. Larvae diverse, mostly leaf tiers, rollers, and crumplers; stem, fruit, and tuber borers; a few gall makers. Hindwing often concave below apex. Worldwide. Some are serious economic pests; *i.e.*, the pink bollworm of cotton (Pectinophora *gossypiella*) and the Angoumois grain moth (Sitotroga *cerealella*).

Family Cosmopterygidae (cosmopterygid moths). Many adults are very narrow winged with bright, often metallic markings. Small moths. Larvae leaf miners; borers in stems, fruits, or seeds; leaf tiers; or scavengers. Related families; Lavernidae, Momphidae, Walshiidae.

Family Oecophoridae (oecophorid moths). Adnlts tend to be somewhat broader winged than related groups, and flat bodied; all small. Related families: Ethmiidae, Stenomatidae, Xylorictidae.

Family *Blastobasidae* (blastobasid moths). The adults small, often drab; reduced mouthparts. Larvae mostly scavengers, a few predators on scale insects.

Superfamily Yponomeutoidea

A limited, not very distinctive superfamily, the adults with close scaling and venation peculiarities. the larvae with distinctive primary setation.

Family Aegeriidae (wasp or clearwing moths). Almost worldwide: adults diurnal, flower visitors, often brightly coloured with yellow, orange, or scarlet, the wings usually mostly transparent, often very striking mimics of wasps. Larvae borers in stems, twigs, and rootstocks, often injurious; *e.g.*, the peach tree borer (*Sanninoidea exitiosa*). Also called Sesiidae.

Family Yponomeutidae (ermine moths). Adults brightly coloured, especially in tropics. Larvae often webbing leaves or living in shoots, buds, or fruits. Pupae of some make lacework cocoons. Widespread and not uncommon. Related families: Plutellidae, Glyphipterygidae, Heliodinidae, Scythrididae.

Superfamily Cossoidea

Family Cossidae (carpenterworm or goat moths). Medium to large moths. Adults with some primitive venation features, close-scaled wings, very heavy bodies, ranging up to 250 mm wing expanse, the heaviest Lepidoptera. Larvae wood borers, penetrating even solid heartwoods; may require at least 2 years to mature. Some species very destructive; *e.g.*, the coffee borer (Zeuzera *coffeae*) and leopard moth (Z. pyrina).

Superfamily Casfnioidea

Family Castniidae (castniid moths). A small family of medium sized to large diurnal moths of the New World and Indo-Australian tropics. Adults powerful, heavy bodied and broad winged; with clubbed antennae, bright colours, and often a strong mimetic resemblance to protected butterflies and diurnal moths. The larvae are often stem borers.

Superfamily Tortricoidea

The families included here comprise one of the major, worldwide groups. They have fairly broad, short-fringed wings that seldom span more than *25* mm. Maxillary palpi missing; labial palpi short. Most have cryptic colours and patterns. Larvae mostly leaf folders and rollers, but many bore in fruits and seeds and soft stems.

Family Tortricidae (leaf roller moths). Characteristics of the superfamily. Separated from Olethreutidae (below) by wing venation. Larvae of the green Tortrix viridana of Europe defoliate oak forests: those of the spruce budworm (*Choristoneura fumiferana*) are the worst forest pests of North America. Some species of Peronea and *Acleris* show most extraordinary polymorphisms of colour and pattern.

Family Olethrerrtidae (olethreutid moths). Separated from other tortricoid families by wing venation. Many are serious pests; *e.g.*, the pine shoot moths (Rhyacionia), the apple codling moth (Laspeyresia pomonella), and the oriental fruit moth (L. *molesta*). Chief subfamilies, the Olethreutinae, Eucosminae, and Laspeyresiinae, are often ranked as families. Related smaller families: Phaloniidae (chiefly Northern Hemisphere), Chlidanotidae (Indo-Australian and Neotropical) and Carposinidae (chiefly Indo-Australian, sometimes considered a separate superfamily).

Superfamily Pyralididoidea

An enormous group of about 20,000 species. Worldwide. Veins Sc and R_1 of the hindwings are typically close together or fused to beyond the cell. Most members have a pair of tympanal organs on the 1st abdominal segment. Adults usually slender bodied with long legs; many with narrow forewings and broad, often folded, hindwings.

Family Pyralididae (pyralid moths). Small moths, mostly plain, often abundant. Separated from other families by wing venation. Palps often large and held forward. Family contains many important pest species. Third largest family of the Lepidoptera. The subfamily Pyraustinae is the largest; most of the larvae live in rolled or tied leaves, or bore in soft stems or roots. The small subfamily Nymphulinae has aquatic larvae with tracheal gills, living in still or running freshwaters. The larvae of the Pyralidinae are mostly scavengers, as are those of the Galleriinae, many of which live in bee or wasp nests. Larvae of the Crambinae are either sod webworms or bore in soft stems. The larvae of the large subfamily Phycitinae have very diverse habits: most are leaf tiers or wehbers, but many are borers, others are scavengers, others pests in stored foods, and some are predators on scale insects. Other important subfamilies are: Chrysauginae, Schoenobiinae, Endotrichinae, and Ancylolominae. Many subfamilies have been separated as families. Probably related is the small, chiefly tropical family Thyrididae.

Family Pterophoridae (plume moths). Adults with very long, slender legs and bodies, the wings usually deeply cleft into plumes. Larvae spin webs on and eat the leaves of various plants.

Family Orneodidae (feather-winged moths). Small, but worldwide, family of uncertain relationships. Each wing is very deeply cleft into *6* or more narrow plumelike divisions.

Superfamily Bombycoidea

Adults large to very large. Frenulum usually lacking; proboscis reduced and nonfunctional; tympanic organs and maxillary palpi lacking; male antennae pectinate.

Family Bombycidae (silkworm moths). A very small family consisting of the domesticated silkworm (*Bombyx* mori) and a few relatives, all Asian. Related family: Eupterotidae.

Family Lasiocampidae (tent caterpillar and lappet moths). Larvae usually hairy and brightly coloured, some living gregariously in silk nests. Adults medium sized, stout bodied, short winged, exceptionally hairy. Widespread.

Family Saturniidae (giant silkworm moths). Every continent has some well known species—*e.g.*, the North American cecropia (Hyalophora cecropia), io (Automeris io), polyphemus (Antheraea polyphemus), and luna (Actias *luna*); European giant peacock or emperor (Saturnia pavonia); and Indo-Australian Attacus atlas and Coscinoscera hercules, the last with wing expanses up to *275* mm (11 in.). Males with broadly branched antennae; often with bright colours and striking wing shapes and patterns. Larvae very large and fleshy, often with brightly coloured knobs and spines. Most species spin firm cocoons of brown, green, or silvery silk. Wingspread up to 275 mm (in hercules moth, Coscinoscera hercules). Worldwide.

Family Citheroniidae (regal moths). Medium to very large, heavy bodied moths, often brightly coloured. Larvae often with long spines; *e.g.*, the North American Citheronia (hickory and pine horned devils). Pupation in the ground, with no cocoon. New World only. Related families: Brahmaeidae (African and Indo-Australian) and Lacosomidae (New World).

Superfamily Geometroidea

Adults with frenulum and abdominal tympana. Some authorities place each of the 3 major families as a separate superfamily.

Family *Geometridae* (measuring worm moths). Larvae ("measuring worms" or "inch worms") long, slender, lacking most of posterior abdominal prolegs, crawling with characteristic looping gait. Pupation usually in the soil, with no cocoon. Adults and larvae commonly very cryptic, resembling bark, dead leaves, and twigs. Many species destructive to foliage; *e.g.*, cankerworms (Alsophila and Palaeacrita) and the winter moth (Operophtera brumata). The second largest moth family, worldwide and abundantly represented nearly everywhere.

Family Uraniidae (uraniid moths). Chiefly tropical. Some adults—*e.g.*, Chrysiridia (Madagascar) and Urania (Neotropits)—are large, brilliantly iridescent diurnal moths. The Oriental Epicopeia (sometimes separated as the family Epicopeiidae) mimic protected swallowtail butterflies.

Family *Drepanidae* (hooktip moths). A small, worldwide family, chiefly Indo-Australian. Many of the adults have the forewing apexes strongly hooked. Larvae usually with last pair of prolegs lacking. Related families: Thyatiridae and Epiplemidae, both worldwide.

Superfamily Sphingoidea

Family Sphingidae (hawk or sphinx moths). Adults medium sized to large; powerful, with long, narrow forewings, thick antennae and usually strong proboscises; feed by hovering before flowers and drawing nectar through the extended proboscis. Some are diurnal, most are active at twilight. Larvae large, fleshy, mostly smooth; most with a single, long, posterior, dorsal horn; typically rest with head and thorax reared up, fancifully like the Sphinx in profile. Worldwide.

Superfamily Noctuoidea

Adults with frenulum and a pair of complex tympanic organs on metathorax.

Family Noctuidae (owlet moths). The largest family of Lepidoptera, with abundant members everywhere in a great diversity of size, colour, and habit. Sizes range from a wing expanse of 10 mm *(Hypenodes)* to 275 mm *(Thysania).* Many species brightly coloured, but the majority plain and cryptic. Nearly every type of plant food is exploited: foliage, flowers, fruits, stems, rootstocks, and woodland litter. A few genera (*e.g., Cosmia)* cannibalistic. Family includes the army worms and cutworms, among the most injurious of all moth larvae to man's interests.

Family Agaristidae (forester moths). A small, worldwide group; many adults brightly coloured, diurnal, and aposematic or mimetic.

Family Notodontidae (prominents). Adults mostly dull, cryptic. Larvae very diverse: cryptic, disruptive, or aposematic; some highly protected by toxic secretions; posterior prolegs often modified or aborted; chiefly foliage eaters.

Family Arctiidae (tiger moths). Adults, especially in tropics, mostly brightly coloured, aposematic, with protective and toxic secretions. Timbal organ for making very high pitched sounds on each side of metathorax. Larvae often with much secondary hair. Worldwide. Several other families, chiefly tropical, are closely related, also have timbal organs.

Families Dioptidae and Pericopidae. Similar to Arctiidae, separable by wing venation. Many are boldly coloured and marked, diurnal, members of mimicry complexes, often mimicking wasps. New World only.

Family Ctenuchidae (ctenuchid moths). Similar to Arctiidae; separable by wing venation. Includes many diurnal mimics of protected wasps and beetles. Worldwide. Related Lithosiidae also contain many aposematic species; their larvae feed on lichens.

Family Liparidae (tussock moths). Many larvae have prominent tussocks and pencils of hair, poison spines, and osmeteria (protrusions that emit repellant odours). Adults are broad winged, the females heavy bodied, sometimes wingless. Some species—*e.g.*, the gypsy moth *(Lymantria dispar)* and the nun moth *(L. monacha)*—are very destructive to forests. Closely related Thaumetopoeidae of the Old World are best known for the habits of the gregarious larvae (processionary caterpillars), which move in orderly columns.

Superfamily Hesperioidea (skippers)

The skippers (like the true butterflies) are distinguished from moths by diurnal habits, clubbed antennae, a functional proboscis, lack of ocelli, and lack of a frenulum. Adult skippers are fast flying, with short, usually pointed forewings, broad heads, antennae usually hooked beyond the club, and all veins arising from the forewing cell simple. Larvae usually have a pronounced, necklike collar, often with a dorsal sclerotized area.

Family Euschernonidae (regent skipper). A single anomalous Australian species; the male has a frenulum, like a moth; the female lacks it.

Family Megathymidae (giant skippers). A small, New World family of relatively large skippers, whose larvae bore in stems of agaves and yuccas, constructing silk-lined tubes. Adult wingspan to about 90 mm.

Family Hesperiidae (typical skippers). With more than 3,000 species, the adults range from small, drab species to large, often iridescent, tropical ones. Larvae mostly living concealed in individual leaf nests or in webs among grasses, forming flimsy cocoons. Worldwide.

Superfamily Papilionoidea (true butterflies)

Adults with antennae clubbed, but not hooked, flight slower and not darting; larvae lacking "neck". General evolutionary trend from a primitive condition with the forelegs fully developed in both sexes (Pieridae, Papilionidae) to one in which they are greatly reduced and useless for walking (Nymphalidae). Intermediate conditions occur in Lycaenidae. Pupae ("chrysalids") often brightly coloured and irregularly shaped, not enclosed in cocoons; either hanging head down (Nymphalidae) supported from cremaster, or additionally supported by a silk girdle (Pieridae, Papilionidae, Lycaenidae). All families worldwide.

Family Pieridae (whites and sulphurs). Small to medium sized; mostly white, yellow, or orange, often with dark tips on wings. Pupae usually with a frontal horn on head. Many species noted for mass migrations.

Family Papilionidae (swallowtails and parnassians). Medium to large; often brightly coloured. Many have the "swallowtails" on the hindwings. Some females of the Indo-Australian genus *Troides* are the largest butterflies. Larvae often curiously patterned, with eversible, protective scent organs (osmeteria). Adults of many are highly distasteful and much mimicked. Worldwide. Parnassians sometimes placed in a separate family, Parnassiidae.

Family Lycaenidae (blues, coppers and hairstreaks). A large diverse family of small butterflies. Many species are iridescent blue, green, or, in the coppers (Lycaeninae), metallic coppery. Larvae somewhat sluglike, hairy, many secreting honeydew and having mutualistic relationships with ants; some prey on the ant brood or on other insects. Many pupae have stridulatory structures on the abdomen.

Family Riodinidae (metalmarks). Small to medium sized. Closely allied to the Lycaenidae. Family has an unequalled diversity of wing shapes and colors. Many South American species have complex mimicry relationships. Chiefly tropical American.

Family Libytheidae (snout butterflies). Long, protruding palpi. Some are strongly, but unpredictably, migratory. Worldwide, but with only about a dozen species.

Family Nymphalidae (nymphalid butterflies). The largest family of butterflies, so diverse that it is often split into several families, here considered subfamilies. The Nymphalinae is the main group, with many familiar species such as the fritillaries, admirals, checkerspots and anglewings. Many tropical species brilliantly iridescent. Satyrinae contains the familiar wood nymphs, meadow browns, and heaths, usually with eyespots on the wings; the larvae distinctively pointed posteriorly and spinning crude cocoons. The very large Brassolinae and iridescent Morphinae are Neotropical, as are the highly distasteful, aposematic Heliconiinae and Ithomiinae that, with the worldwide Danainae, are models in many mimicry complexes. Most of the pantropical Acraeinae are also highly protected and aposematic models.

Critical Appraisal. The terms microlepidoptera and macrolepidoptera are applied, for convenience, to two nontaxonomic divisions of the order Lepidoptera. The microlepidoptera include the suborders Zeugloptera and Monotrysia, and the superfamilies Zygaenoidea through Pyralididoidea of the Ditrysia. The remaining superfamilies of the Ditrysia, consisting of the bombycid, geometrid, sphingid, and noctuid moths, the skippers, and the true butterflies, comprise the macrolepidoptera. Although, in general, the microlepidoptera are smaller than the macrolepidoptera, some of the former, such as certain hepalids and cossids, are among the largest moths, with adult wingspans up to *250* mm, while some macrolepidoptera have adult wingspans of only 10 mm.

BIBLIOGRAPHY. The literature on Lepidoptera is enormous and includes books and articles published in nearly all countries. The following gives a representative sample, including major works with extensive bibliographies.

General works: "Lepidoptera," in A.D. IMMS, *A General Textbook of Entomology*, 9th ed. rev. by O.W. RICHARDS and R.G. DAVIES (1957); and "Lepidoptera," in D.J. BORROR and D.M. DE LONG, *An Introduction to the Study of Insects*, rev. ed. (1964), give a key to families of Lepidoptera in North America; E.B. FORD, *Butterflies* (1945) and *Moths* (1955), are replete with details of natural history, ecology, physiology, and evolution, chiefly of British species; M. HERING, *Biologie der Schmetterlinge* (1926), covers life histories and ecology, particularly of European groups; A.B. KLOTS, *The World of Butterflies and Moths* (1958), covers natural history and ecology, with striking illustrations. See also P.J. PORTIER, *La biologie des Lépidoptères* (1949), for many details of the biology; C.B. WILLIAMS, *The Migration of Butferflies* (1930); and F.A. URQUHART, *The Monarch Butterfly* (1960). *Lepidopterorum Catalogus*, published in many parts by various authors, is the definitive scientific listing of all genera and species, with bibliographies.

Regional Works: (North America:) P.R. EHRLICH *et al.*, *How to Know the Butterflies* (1961), is an excellent handbook of the North American species; W.T.M. FORBES, *Lepidoptera of New York and Neighboring States,* 4 pt. (1923–1960), is the definitive work for eastern North America for technical classification, especially larvae, life histories, and foodplants; W.J. HOLLAND, *The Moth Book* (1914, reprinted 1968), and *The Butterfly Book*, rev. ed. (1931), are the long-

time standards, with many colour illustrations; A.B. KLOTS, *Field Guide to the Butterflies of North America, East of the Great Plains* (1951), covers all the species of butterflies and skippers of eastern North America, with much on life histories, biology, and ecology, with many illustrations. *(Europe:)* The following are more or less local in scope, covering the butterflies and moths of various countries or regions: L.T. FORD, *A Guide to the Smaller British Lepidoptera* (1949); W. FORSTER and T.A. WOHLFAHRT, *Die Schmetterlinge Mitteleuropas,* 3 vol. (1954–60); S. HOFMEYER, *Die Danske Ugler* (1962); T.W. LANGER, *Nordens dagsommerfugle* (1958); F. NORDSTROM and E. WAHLGREN, *Svenska fjarilar* (1941); R. SOUTH, *The Moths of the British Isles* rev. ed., 2 vol. (1939); A. SPULER, *Die Schmetterlinge Europas und ihre Raupen,* 4 vol. (1908–10); and M. STURANI, *Vita delle Farfalle* (1947). *(other regions:)* A. SEITZ *et al.* (eds.), *Macrolepidopfera of the World* (1906–), English, French, and German editions, 16 vol. (1–4 Palaearctic, 5–8 American, 9–12 Indo-Australian, 13–16 Ethiopian), was issued in parts, by many authors, with supplements; although out of date in much nomenclature and taxonomy, it is still the standard for most of the world for identification. The following are books covering specific regions giving many details about life histories and biologies and mostly illustrated very fully: D.A. SWANEPOEL, *The Butterflies of South Africa: Where, When, and How They Fly (1953);* G. VAN SON, *The Butterflies of Southern Africa* (1949–*64);* G.A. WATERHOUSE and G. LYELL, *The Butterflies of Australia* (1914); and M.A. WYNTER-BLYTH, *Butterflies of the Indian Region* (1957).

(A.B.K.)

Lermontov, Mikhail

Mikhail Yuryevich Lermontov, the foremost Russian Romantic poet and novelist, is recognized for the technical perfection and unusual emotional depth of his poetry and for his novel *A Hero of Our Time,* a work basic to the development of Russian psychological realism.

BY courtesy of the State Tretyakov Gallery, Moscow

Lermontov, oil painting by Pyotr Yefimovich Zabolotsky, 1837. In the State Tretyakov Gallery, Moscow.

Life and works. He was born in Moscow on October 15 (3, old style), 1814, the son of Yury Petrovich Lermontov, a retired army captain, and Mariya Mikhaylovna, *née* Arsenyeva. At the age of three he lost his mother and was brought up by his grandmother, Yelizaveta Alekseyevna Arsenyeva, on her estate in Penzenskaya province. Russia's abundant natural beauty, its folksongs and tales, its customs and ceremonies, the hard forced labour of the serfs, and stories and legends of peasant mutinies all had a great influence in developing the future poet's character. As the child was often ill, he was taken to spas in the Caucasus on three occasions, where the exotic landscapes created lasting impressions on him.

In 1827 he moved with his grandmother to Moscow, and, while attending a boarding school for children of the nobility (at Moscow University), he began to write poetry and also studied painting. In 1828 he wrote the poems *Cherkesy* and *Kavkazsky plennik* in the vein of the English Romantic poet Lord Byron, whose influence then predominated over young Russian writers. Two years later his first verse, *Vesna,* was published. The same year he entered Moscow University, then one of the liveliest centres of culture and ideology, where such democratically minded representatives of nobility as Aleksandr Herzen, Nikolay Platonovich Ogarov, and others studied. Students ardently discussed political and philosophical problems, the hard fate of serf peasantry, and the recent Decembrist uprising. In this atmosphere he wrote many lyrical verses, longer, narrative poems, and dramas. His drama *Stranny chelovek* (1831) reflected the attitudes current among members of student societies: hatred of the despotic tsarist regime and of serfdom. In 1832, after clashing with a reactionary professor, Lermontov left the University and went to St. Petersburg (Leningrad), where he entered the cadet school. Upon his graduation in 1834 with the rank of subensign (or cornet), Lermontov was appointed to the Life-Guard Hussar Regiment stationed at Tsarskoye Selo, close to St. Petersburg. As a young officer, he spent a considerable portion of his time in the capital, and his critical observations of aristocratic life there formed the basis of his play *Maskarad* (1835; publ. 1842). During this period his deep—but unreciprocated—attachment to Varvara Lopukhina, a sentiment that never left him, was reflected in *Knyaginya Ligovskaya* and other works.

Exile to the Caucasus

Lermontov was greatly shaken in January 1837 by the death of the great poet Aleksandr Pushkin in a duel. He wrote an elegy that expressed the nation's love for the dead poet, denouncing not only his killer but also the court aristocracy, whom he saw as executioners of freedom and the true culprits of the tragedy. As soon as the verses became known to the court of Nicholas I, Lermontov was arrested and exiled to a regiment stationed in the Caucasus. Travel to new places, meetings with Decembrists (in exile in the Caucasus), and introduction to the Georgian intelligentsia—to the outstanding poet Ilya Grigoryevich Chavchavadze, whose daughter had married a well-known Russian dramatist, poet, and diplomatist, Aleksandr Sergeyevich Griboyedov—as well as to other prominent Georgian poets in Tiflis (now Tbilisi) broadened his horizon. Attracted to the nature and poetry of the Caucasus and excited by its folklore, he studied the local languages and translated and polished the Azerbaijanian story "Ashik Kerib." Caucasian themes and images occupy a strong place in his poetry and in the novel *Geroy nashego vremeni* (1840, *A Hero of Our Time),* as well as in his sketches and paintings.

Return to St. Petersburg

As a result of zealous intercession by his grandmother and by the influential poet V.A. Zhukovsky, Lermontov was allowed to return to the capital in 1838. His verses began to appear in the press: the romantic poem *Pesnya pro tsarya Ivana Vasilyevicha, molodogo oprichnika i udalogo kuptsa Kalashnikova* (1837), the realistic satirical poems *Tambovskaya kaznacheysha* (1838) and *Sashka* (written 1839, published 1862), the drama *Maskarad* (1835–36, published 1842)—a remarkable work of Russian dramatic composition that exposes the evils and vices of fashionable society—and the romantic poem *Demon.* Soon Lermontov became popular; he was called Pushkin's successor and was lauded for having suffered and been exiled because of his libertarian verses. Writers and journalists took an interest in him and fashionable ladies were attracted to him. He made friends among the editorial staff of *Otechestvennye zapiski,* the leading magazine of the Western-oriented intellectuals, and in 1840 he met the prominent progressive critic V.G. Belinsky, who envisioned him as the great hope of Russian literature. Lermontov had arrived among the circle of St. Petersburg writers.

At the end of the 1830s, the principal directions of his creative work had been established. His freedom-loving sentiments and his bitterly skeptical evaluation of the times in which he lived are embodied in his philosophical lyric poetry ("Duma," "Poet," "Ne ver sebye . . .") and are interpreted in an original fashion in the romantic and fantastic images of his Caucasian poems, *Mtsyri* (1840) and *Demon,* on which the poet worked for the remainder of his life. Finally, Lermontov's mature prose showed a critical picture of contemporary life in his novel ***A Hero of Our Time,*** containing the sum total of his reflections on contemporary society and the fortunes of his generation. The hero, Pechorin, is a cynical person of superior accomplishments who, having experienced everything else, devotes himself to experimenting with human situations. This realistic novel, full of social and psychological content and written in prose of superb quality, played an important role in the development of Russian prose.

Second exile

In February 1840 Lermontov was brought to trial before a military tribunal for his duel with the son of the French ambassador at St. Petersburg—a duel used as a pretext for punishing the recalcitrant poet. On the instructions of Nicholas I, Lermontov was sentenced to a new exile in the Caucasus, this time to an infantry regiment that was preparing for dangerous military operations. Soon compelled to take part in cavalry sorties and hand-to-hand battles, he distinguished himself in the heavy fighting at Valerik River, which he describes in "Valerik" and in the verse "Ya k vam pishu. . . ." The military command made due note of the great courage and presence of mind displayed by the officer-poet.

As a result of persistent requests by his grandmother, Lermontov was given a short leave in February 1841. He spent several weeks in the capital, continuing work on compositions he had already begun and writing several poems noted for their maturity of thought and talent ("Rodina," "Lyubil i ya v bylye gody"). Lermontov devised a plan for publishing his own magazine, planned new novels, and sought Belinsky's criticism. But he soon received an order to return to his regiment and left, full of gloomy forebodings. During this long journey he experienced a flood of creative energy: his last notebook contains such masterpieces of Russian lyric poetry as "Utes," "Spor," "Svidanye," "Listok," "Net, ne tebya tak pylko ya lyublyu," and "Prorok," his last work.

On the way to his regiment, Lermontov lingered on in the health resort city of Pyatigorsk for treatment. There he met many fashionable young people from St. Petersburg, among whom were secret ill-wishers who knew his reputation in court circles. Some of the young people feared his tongue while others envied his fame. An atmosphere of intrigue, scandal, and hatred grew up around him. Finally, a quarrel was provoked between Lermontov and another officer, N.S. Martynov; the two fought a duel on July 27 (15, O.S.), 1841, that ended in the poet's death. He was buried two days later in the municipal cemetery, and the entire population of the city gathered at his funeral. Later, Lermontov's coffin was moved to the Tarkhana estate, and on April 23, 1842, he was buried in the Arsenyev family vault.

Assessment. Only 27 years old when he died, Lermontov had proved his worth as a brilliant and gifted poet-thinker, prose writer, and playwright, the successor of Pushkin, and an exponent of the best traditions of Russian literature. His youthful lyric poetry is filled with a passionate craving for freedom and contains calls to battle, agonizing reflections on how to apply his strengths to his life's work, and dreams of heroic deeds. He was deeply troubled by political events, and the peasant mutinies of 1830 had suggested to him a time "when the crown of the tsars will fall." Revolutionary ferment in western Europe met with an enthusiastic response from him (verses on the July 1830 revolution in France, on the fall of Charles X), and the theme of the French Revolution is found in his later works (the poem ***Sashka).***

Central themes of his work

Lermontov's creative work grew out of the historical reality of the 1830s, though the heroic traditions of Russian history, the Romantic poetry of Pushkin's era, and the influence of Byron (which Pushkin had also felt) all nourished it. Byronism satisfied a particular quality in Lermontov, for it helped him to express his passionate ideals and to assert the idea of personal freedom, the central theme of his work. But Lermontov's Romanticism, also includes realistic concepts of the world; these are particularly characteristic of his poems based on historical events and real subjects. Lermontov gradually discarded the romantic stock phrases and images that had filled his early works, overcoming, as he stated, their "false tinsel" and "deafening language." In the late works, noted for their richness of genre and style, the Romantic approach to reality gave way to objective depiction, to the reproduction of a specific social environment, daily life, and characters from the people.

Civic and philosophical themes as well as subjective, deeply personal motifs were closely interwoven in Lermontov's poetry. He introduced into Russian poetry the intonations of "iron verse," noted for its heroic sound and its unprecedented energy of intellectual expression. His enthusiasm for the future responded to the urgent spiritual needs of Russian society and the emancipation movement. His creativity promoted a new golden age of Russian literature, and his influence can be seen in the work of Ivan Turgenev, Leo Tolstoy, Fyodor Dostoyevsky, and N.A. Nekrasov, as well as in the poetry of A.A. Blok and V.V. Mayakovsky. Lermontov's legacy has found varied interpretations in the works of Russian artists, composers, and theatrical and cinematic figures. His dramatic compositions have played a considerable role in the development of theatrical art, and his life has served as material for many novels, poems, plays, and films.

MAJOR WORKS

NOVEL: ***Geroy nashego vremeni*** (1840; ***A Hero of Our Time,*** trans. by P. Longworth, 1964).

VERSE: "Parus" (1832), lyric; ***Pesnya pro tsarya Ivana Vasilyevicha, molodogo oprichnzka i udalogo kuptsa Kalashrzikova*** (1837; ***A Song About Tsar Ivan Vasilyevitch, His Young Body-Guard, and the Valiant Merchant Kalashnikov,*** trans. by J. Cournos, 1929); ***Mtsyri*** (1840); ***Demon*** (1841; Eng. trans. by G. Shelley, 1930). Lermontov's poems are collected in English in ***Selected Poetry,*** trans. by C.E. L'Ami and Alexander Welikotny (1965).

BIBLIOGRAPHY

Collections of works: *Сочинения* ***М.Ю. Лермонтова*** 6 vol. (1889–91), the first complete edition; ***Полное собрание сочинений*** 5 vol. (1910–13), the complete works; ***Полное собрание сочинений*** 5 vol. (1935–37), illustrated complete works; ***Стихотворения*** 3 vol. (1940–50), verse; ***Избранные произведения в двух томах*** (1949), selections; ***Three Russian Poets: Selections from Pushkin, Lermorztov and Tyutchev in*** new translations by VLADIMIR NABOKOV (1944); ***A Lermontov Reader,*** ed. and trans. by GUY DANIELS (1965).

Biographical and critical studies: Most of the works on Lermontov have been published in Russian—V.G. BELINSKIY (1940), articles and reviews; N.G. CHERNYSHEVSKIY (1947), an outline of the Gogol period of Russian literature; A.I. GERTSEN (1937), on the development of revolutionary ideas in Russia; N.L. BRODSKIY (1945), a biography; and V.A. MANUYLOV (1950), on Russian dramatic compositions. English-language studies include JANKO LAVRIN, ***Lermontov*** (1959); JOHN MERSEREAU, ***Mikhail Lermontov*** (1962); and C.E. L'AMI and ALEXANDER WELIKOTNY, ***Michael Lermontov: Biography and Translation*** (1967). See also A. HEIFETZ (comp.), ***Lermontov in English: A List of Works by and About the Poet*** (1942).

LeSniewski, Stanislaw

Stanisław Leśniewski, a Polish logician and mathematician, was a cofounder of the Warsaw school of logic, its leading representative, and one of the greatest logicians of all time. Working along lines laid down late in the 19th century by Gottlob Frege in Germany and early in the 20th century by Bertrand Russell in Great Britain, Leśniewski developed one of the most complete, precise, and rigorous systems of logic and of the foundations of mathematics that have so far been devised. In collaboration with the logician Jan Lukasiewicz and the mathematicians Wactaw Sierpiński and Stefan Mazurkiewicz, he made the University of Warsaw, during the period between World Wars I and II, a renowned centre for research in logic, mathematics, and metalogic (on characteristics of formal systems and logical calculi). Despite the disruption caused by World War II, which killed many members of the school and destroyed their manuscripts, leading representatives were able to reach the United States and Great Britain, where they have continued the work begun by Leśniewski, as has a new generation of students in the revived universities of Poland.

His life. Leśniewski was born March 30, 1886, in Serpukhov, Russia, where his father was one of the civil engineers chiefly responsible for the construction and supervision of the trans-Siberian railroad.

Influence of Twardowski and Łukasiewicz

Education. After preliminary schooling in Russia and the gymnasium in Siberia, he attended—as was the custom of the time—several universities in continental Europe, finally taking his doctoral degree in 1912 at the Polish University of Lwów (now Lvov, U.S.S.R.), then a part of Austria. His dissertation was approved by Kazimierz Twardowski, who, for his wide-ranging influence on Polish intellectual life, is known as the father of contemporary Polish philosophy. Twardowski, like Edmund Husserl (the founder of Phenomenology), was a student in Vienna of Franz Brentano, an Aristotelian and Scholastic philosopher who, although not himself interested in formal logic, was noted for his precise and thorough analysis of philosophical problems. Under his influence, Leśniewski's first scholarly interests focussed upon problems of philosophical logic, such as those that had concerned John Stuart Mill in 19th-century England and Husserl and others of the Austrian school. Thus, his doctoral dissertation of 1911 dealt with the analysis of existential propositions.

Period of his early writings. The intellectual activity of Leśniewski divides into three distinct periods. The first extends from his dissertation to the appearance in 1916 of his first work on the theory of collective sets. Leiniewski attributed the discovery of his true intellectual vocation to the influence of Jan Łukasiewicz, also a pupil of Twardowski and then a *privat dozent* at the University of Lwów. Already learned in the history of logic, to which he was to make outstanding contributions, Lukasiewicz was at the time studying the work of the German logicians Gottlob Frege and Ernst Schroder, the importance of which he was mainly responsible for making known in Poland, and teaching his first course in mathematical logic. It was Łukasiewicz' book *O Zasadzie Sprzeczności u Arystotelesa* (1910; "On the Principle of Contradiction in Aristotle") that awakened Leśniewski from his dogmatic slumber. From it he became interested in the problem posed by the discovery of the antinomies, or paradoxes, in logic and mathematics that threatened to undermine the foundations of all deductive science. His efforts to overcome and solve these antinomies, with which Frege and Russell were also wrestling, eventually led to the great discoveries for which he is known.

Turn from distrust to use of symbolic logic

Although Leiniewski then definitely turned his back on philosophy in favour of logic—he later spoke of himself as a renegade from philosophy—his initial impression of mathematical logic was not at all favourable. He distrusted its technical formal notation, the scant attention given to its relation to ordinary language, and the resulting equivocations in the use of such terms as class, implies, true. In attempting to clear away the equivocations in the work of Russell, however, he soon became convinced that the formal and artificial language of mathematical logic was essential for his work, that ordinary language was too clumsy and imprecise. The writings of this period were completed, however, before he had adopted the rigorous methods of mathematical logic and were all later repudiated by him.

Period of intensive research. The period from 1916 to 1927 was one of intensive and creative research in which he accumulated a mass of results but refrained from publishing them.

In 1915, upon the reopening of the University of Warsaw, Lukasiewicz had been called from Lwów to become professor of philosophy. Leśniewski, after teaching for two years at a Warsaw gymnasium and spending the war years in Moscow, followed his friend and colleague to Warsaw in 1919 as professor of the philosophy of mathematics. They soon established a thriving centre of research that attracted talented students from all sides.

Period of maturity and publication. LeSniewski finally felt constrained to start publishing some account of his findings, even though they were not yet in as perfect a form as he would have desired. Beginning with the publication, in 1927, of his first mature work on the foundations of mathematics and extending until his death, in 1939, he published a series of papers expounding the main lines of his theories of logic and mathematics. These publications gained a worldwide reputation for the Warsaw school. Yet, just as it was reaching its height, Leśniewski died suddenly and unexpectedly on May 13, 1939, on the eve of the war that shortly engulfed the school in the common fate of Poland.

Many of Leiniewski's findings remained unpublished at his death. Although all of his manuscripts were destroyed by the war, many of the unpublished results of his researches have since been made known through the work of his students, particularly that of Bolesław Sobociński and Alfred Tarski.

The notion of distributive and collective classes

His three logical systems. The distinctive and original contribution of Leśniewski consists in the construction of three interrelated logical systems, to which he gave the names, derived from the Greek, of protothetic, ontology, and mereology. The logical basis of the whole theory, and hence its name (*prōtos*, "first"), is provided by protothetic, which is the most comprehensive theory yet developed of the relations between propositions. The other two systems are based on a distinction the lack of which, Leiniewski claimed, was the source of Russell's difficulties with the antinomies: that between a distributive and a collective class. In its distributive use, a class expression is identical with a general name; thus, to say that a person belongs to the class of Poles is to say that that person is a Pole. Hence, ontology (*on* "being") is the logic of names; and, combined with protothetic. it yields all of the theorems of syllogistic (traditional Aristotelian logic) and of logical algebra, as well as of the logic of sets and relations. Mereology (*meros*, "part") is the logic of a whole conceived as though physically constituted by its parts; *i.e.*, of the collective class, as the class of all automobiles in Chicago consists of the entire collection of them. Hence, mereology is a general theory of the relation between part and whole.

In developing these theories, LeSniewski gave great care to the statement of their metalogic and, for this purpose, elaborated a general theory of semantical categories, which is analogous, on the one hand, to the traditional doctrine of the parts of speech and, on the other, to Husserl's "meaning categories."

His intuitive formalism

Leśniewski developed the systems with a clarity and precision that established a new standard for mathematical rigour. In their powers of implication, they are strong enough to provide a logical foundation for all of classical mathematics. They also overcome the antinomies in a way that Leiniewski claimed is better and truer than any other solution. In his opinion, modern mathematicians and logicians are often too neglectful, if not contemptuous, of man's naïve and basic intuitions of the way things are. For this very reason, Alfred Tarski, one of his students who later went to the United States, described his position as "an intuitive formalism." Leśniewski was openly critical of a pure formalism that would consider logic and mathematics as nothing more than a game of symbols. It is true that he advocated and employed formalist methods for their rigour and precision, but he maintained that a theory ultimately must be judged for its accord with reality. Nevertheless, he maintained that his logical systems are neutral in that they make no metaphysical assumptions and are equally well adapted to diverse and even conflicting philosophical interpretations.

BIBLIOGRAPHY. Z.A. JORDAN, *Philosophy and Ideology: The Development of Philosophy and Marxism-Leninism in Poland Since the Second World War* (1963), a comprehensive background history of the Warsaw school, with much information about Leśniewski and his associates and a full bibliography; TADEUSZ KOTARBINSKI, *Elementy Teorii Poznania, Logiki Formalnej i Metodologii Nauk*, 2nd ed. (1961; Eng. trans., *Gnosiology: The Scientific Approach to the Theory of Knowledge,* 1966), a Polish classic, which for more than two decades provided the only elementary account of Leśniewski's work and influence, and is still of value, having been written by a lifelong friend and colleague of Leśniewski, in a position to supply information otherwise unpublished; CZESLAW LEJEWSKI, "Leśniewski" entry in the *Encyclopedia of Philosophy*, vol. 4, pp. 441–443 (1967), with good bibliog-

raphy; EUGENE C. LUSCHEI, *The Logical Systems of Leśniewski* (1962), the only book-length study of LeSniewski and his work, contains a comprehensive analytical bibliography of sources to 1962; STORRS MCCALL (ed.), *Polish Logic, 1920–1939* (1967), original papers in English translation with an introduction by TADEUSZ KOTARBINSKI, "Notes on the Development of Formal Logic in Poland in the Years 1900–39," including papers by Leśniewski and his associates, together with a slightly revised version of Z.A. JORDAN, "The Development of Mathematical Logic in Poland Between the Two Wars"; BOLESLAW SOBOCINSKI, "L'Analyse de l'antinomie Russellienne par LeSniewski," in *Methodos*, 1:94–107, 220–228, 308–316 (1949) and 2:237–252 (1950), containing, besides the analysis, backgound information about Leiniewski's theories, especially his ontology and mereology; and "In Memoriam Jan Lukasiewicz," in *Philosophical Studies* (Ireland), 6:3–49 (1956), containing background information about Leiniewski's outlook and research; ALFRED TARSKI, *Logic, Semantics, Metamathematics: Papers from 1923 to 1938* (1956), containing Leśniewski's ideas on semantics and related topics.

(O.A.B.)

Lesotho

The Kingdom of Lesotho in southern Africa has an area of 11,720 square miles (30,355 square kilometres) and a population of about 1,000,000. It is one of only two independent states in the world (the other is the Republic of San Marino in western Europe) completely encircled by a single country on whom it must depend exclusively for access to the outside world. It forms an enclave within the Republic of South Africa, bordering on three of the latter's provinces—Natal, the Orange Free State, and Cape Province. This physical dependence on its neighbour is further accentuated by Lesotho's own grave lack of resources which makes it necessary for about 20 percent of its able-bodied male population to live and work, mainly as migrants, in South Africa. For this reason, it is sometimes described as a "hostage state." It is a member of the Commonwealth of Nations and of the Organization of African Unity. Before its independence on October 4, 1966, it was one of the three British High Commission Territories—the other two being Bechuanaland (now Botswana) and Swaziland. Its constitution was suspended after its first postindependence crisis in January 1970.

"Lesotho" is the name of the country and "Basotho" the name of the people; a single individual is referred to as a "Mosotho"; Sesotho is the language. The capital is Maseru. For an associated physical feature see ORANGE RIVER; for historical aspects see SOUTHERN AFRICA, HISTORY OF.

The plateau

The landscape. *Relief.* Two-thirds of the country consists of mountains, which rise to its highest peak, the Mont Aux Sources, which is 11,425 feet above sea level. The Drakensberg Range forms the eastern boundary with Natal. The Maloti spurs, running north and south, join the main range in the north, where they form a plateau between 9,000 and 10,500 feet in altitude. This plateau is the source of South Africa's two largest rivers—the eastward-flowing Tugela and the westward-flowing Orange River, as well as tributaries of the Caledon—hence, Lesotho's claim to be the "sponge" of South Africa. The mountain area divides into the highlands and the foothills. The foothills, which have average altitudes of between 6,000 and 7,000 feet, descend in undulating slopes to the west, where the lowlands bordering on the Orange Free State average 5,000 to 6,000 feet in altitude.

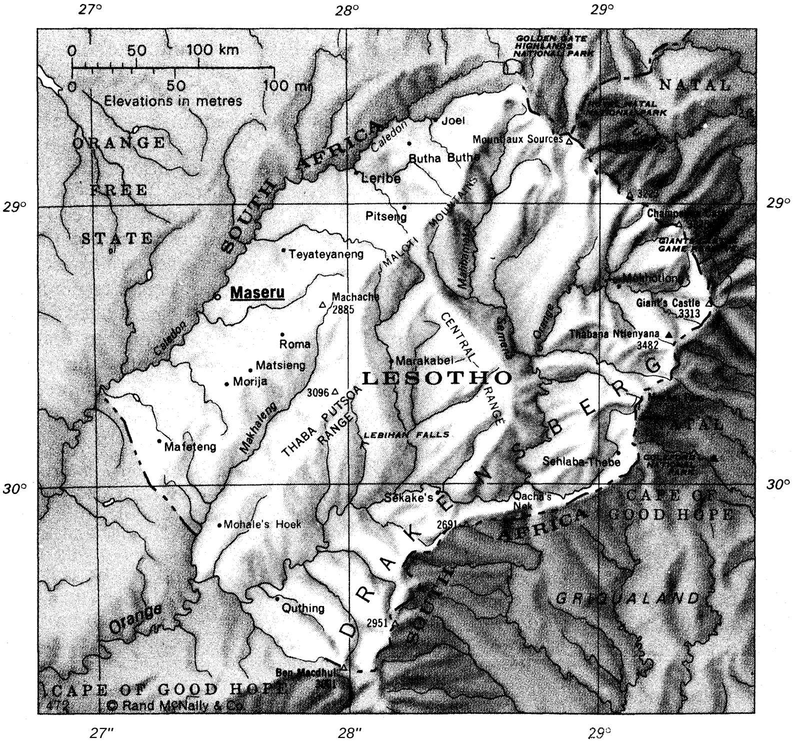
The mountain soils are of basaltic origin and are shallow but rich. The soils of the lowlands derive mainly from the underlying sandstone. Extensive erosion has severely damaged soils all over the country.

Climate. The rainfall, brought by the prevailing winds, occurs mostly between October and April; it is variable, averaging about 28 inches a year over most of the country. Although droughts are rare, their periodic occurrence is devastating. Temperatures in the lowlands vary from 90° F (32" C) in the summer to 20° F (−7° C) in the winter. In the highlands the temperature range is much wider, and below-zero readings are not unusual. Frost occurs widely in the winter, when the Maloti are usually snow-capped. Hail is a frequent summer hazard.

Vegetation. The grasslands of the highlands are mainly covered by *Themeda triandra.* Indigenous trees and shrubs have survived only in the more remote and sheltered valleys. The most common types are wild olives, wild garlic, wild willow, brushwood, thatching grass (*Hyparrhenia hirta*), hypoxis, and aloes.

Animal life. Wildlife is now almost extinct, except for occasional small antelopes, hares, and reptiles.

The landscape under human settlement. Although not permanently inhabited, the mountain grasslands found on the slopes of the high plateau as well as in the valleys provide excellent grazing for sheep and cattle, which are tended by herdsmen in isolated cattle posts. Some of the deep valleys, like the Senqunyane, produce good crops of



LESOTHO

wheat, peas, and beans. About 30 percent of the population live in the highlands; 20 percent live in the foothills, which good grazing and cultivation have made the most productive legion. Half the population live in the lowlands, which form a narrow corridor along the Caledon River, which averages only 25 miles in width.

The system of migratory labour

The Sotho (Basotho, Basuto) combine modernism and traditionalism to an unusual degree; this provides stability in a society that, possibly more than any other in existence, is disrupted by a permanent system of migratory labour. Traditional authority is still firmly exercised through a system of chieftaincy extending from the paramount chief (the king) and his court, down through senior chiefs and subchiefs, to headmen and subheadmen at the village level. Their authority now rests largely on the fact that they are responsible for the working and distribution of all land that belongs to the nation, with the king acting as trustee.

Social cohesion is strengthened by the persistence of clan and family loyalties. Families and clans still cluster together as units in the numerous small rural villages. There are no large towns in the country. The villages range in size from one large to four or five extended families, with an average of from 30 to 50 immediate families. The villages are often picturesque, offering fine views of the rocky highlands; on the plains they are often surrounded by aloes and trees, with the walls and doors of the houses frequently being covered with patterned designs. The villages themselves consist of clusters of circular or rectangular huts solidly built of turf, Kimberley brick (unburned clay), or dressed stone, mostly with thatched roofs; latterly, however, corrugated iron has come into vogue as a roofing material.

Initiation ceremonies

The average household usually has two or three huts, the larger one being used as a living and dining room and as the parents' bedroom; the smaller ones are used for kitchen and storage purposes and as sleeping quarters for the children. The hut of the chief, or headman, is usually in the centre of the village, flanked by that of the principal wife and ringed by those of the junior wives. The open court (the *lekhotla)* is in front of the chief's hut; besides it are the enclosures (kraals) for the cattle and stables for horses. Village life centres largely on the fields, the chief's court, the kraals, the school, the church, and the initiation lodge. Circumcision forms an integral part of the ritualized initiation ceremonies that train boys to take their place as full members of the family, clan, and nation—the three centres of social cohesion. Young boys still spend a large part of their lives as herdsmen, while women and young girls do much of the hard work in the fields, a practical necessity because the able men are usually absent, although they contrive to return home briefly for the plowing or the harvest.

Two distinctive features of social life are the people's love for horses and blankets. The small, sturdy Sotho pony is renowned for its sure-footedness in rough country; it is often the only means of rural transport. Because of the sharp variations in climate, both men and women invariably wear blankets, which they use as cloaks; a great deal of care is taken in choosing a blanket, which, especially for the men, is usually multicoloured. Men and women also wear the typical Sotho hat, which is woven from reed into conical shapes, with an unusual topknot.

Maseru, the capital, in the northwest on the banks of the Caledon River, is itself a small rural town with about 14,000 inhabitants, mostly civil servants, professional people, and traders. On most days of the week, however, it is a bustling little town crowded with people who are either from the surrounding lowlands, down from the mountains, or migratory workers passing to and from South Africa.

People and population. *Ethnic groups.* The Sotho comprise a cluster of tribes of the southern Sotho linguistic stock, who are united by a common loyalty to the royal house of Moshoeshoe (Moshesh). The group that formed the nucleus of the nation is that of the Kwena, who are made up of the Molibeli, Monaheng, Hlakwana, Kxwakxwa, and Fokeng tribes. They still regard themselves as the true nation and tend to look down on the other two main groups that were politically absorbed into their society but were not always culturally assimilated, although they speak the same language. The first of these groups is formed by the Natal (North) Nguni, who include the Phetla, Polane, and Phuti; they are largely indistinguishable from the Kwena. The second group comprises the Mahlape tribe of the Natal Nguni and the Cape (South) Nguni (Tembu).

There are about 1,000,000 Sotho (1969 census), 2,000 Europeans, 300 Asians, and 1,000 Coloureds (of mixed racial origin). The Europeans are mainly traders, businessmen, technicians, government officials, missionaries, and teachers, while the Asians are mainly traders.

Emigration

As the country is severely overpopulated, both temporary and permanent emigration has taken place. No exact figures exist for the number of Sotho working or living in South Africa. The 1966 Lesotho census showed that 97,000 men and 20,000 women were absent, while a South African census at the same time recorded about 130,000 males and 70,000 females who claimed they were born in Lesotho.

Religious groups. Christianity and traditional religions (which are based on a belief in ancestral spirits) co-exist uneasily in a country where the great majority of people are active members of Christian churches. Over 30 percent are Roman Catholics, and just under 40 percent are Protestants (mainly French Protestants, Anglicans, Baptists, and adherents of the Dutch Reformed Church).

Demography. About half the people are concentrated in just over one-quarter of the land. Although the average density of the country is only 87 per square mile, there are from 100 to 303 persons per square mile in the lowlands, as against an average of 34 per square mile in the highlands. The annual population growth is 3 percent.

Lesotho, Area and Population

	area		population	
	sq mi	sq km	1966 census	1972 estimate
Districts				
Berea	830	2,150	100,000	132,000

Economic links to South Africa

The national economy. Lesotho is basically a poor country with few natural resources; these are certainly insufficient to sustain even the present population. Lesotho's gross national product is only about $80,000,000. (The monetary unit is the South African rand; R 0.71 = $1 U.S.; R 1.71 = £1 sterling on December 1, 1970.) The condition of the country was well summed up in 1963 by the *Financial Mail* of Johannesburg, South Africa, as that of "a waif, sustained, not developed, by the South African economy." But its economy could not be sustained at all without such benefits as it derives from its neighbour, with which it forms part of a customs union, shares a single currency and an integrated communications system, besides depending wholly on it for the export of its surplus working population.

Agriculture. Only one-tenth of the land—about 750,000 acres—is suitable for arable agriculture; this amounts to about one acre per head of the resident population. Agriculture provides about two-thirds of the gross domestic product (GDP); it is devoted largely to subsistence crops. The main crops are maize (corn), sorghum, wheat, peas, beans, and barley. Crop yields are low. The large cattle herds have no significant commercial value; about 70 percent die annually from disease, exposure, malnutrition, or old age. The principal cash crops are wool and mohair.

Mining and industry. Geological surveys have so far shown little promise of mineral wealth, although small quantities of diamonds have been found; production is valued at about $1,600,000 a year. Other minerals discovered, such as iron ore, gypsum, quartz, and calcite (limestone chalk), are commercially uneconomic.

Secondary industry is of recent growth and is confined to such small-scale manufacturing as milling, brickmaking, and furniture making.

Tourism. Tourism is promising for a country that has justifiably been called the South African Switzerland. Modern hotels have been built, mountain roads and pony trails developed, and trout streams stocked with fish. There is a casino in Maseru.

Irrigation and lzydroelectricity. The country's most promising prospects for development lie in the harnessing of the rivers for irrigation and hydroelectric power. The Oxbow project for a dam to generate power in the Maloti mountains would produce over 350,000,000 kilowatt-hours of energy a year. The scheme, estimated to cost about $35,000,000, would benefit both Lesotho and South Africa, which has indicated interest in the project.

The Oxbow project

Trade. The economy runs on a heavy adverse balance of trade, importing in any normal year roughly five times more than it exports. Its budget and capital-aid deficits have, in the past, been made up by grants and loans from the United Kingdom (about $5,000,000 in 1970 to 1971 alone) and by remittances from migrants abroad. These amount to about $6,000,000 a year—an amount larger than the total exports, which total about $5,600,000.

The public sector. The government is the largest employer of labour in the country, over half its annual budget being made up of payments to its public employees. Its budget of about $8,000,000 has a deficit of almost 50 percent. Direct taxation produces almost $3,000,000, and $1,500,000 is provided by revenues from the customs agreement with South Africa.

The private sector. About 90 percent of all trade is controlled by the 72 members of the Chamber of Commerce, only two of whom are Sotho. Asians are not members. Two European firms control almost half of the wholesale trading outlets, which number about 140.

Taxation. Three forms of direct taxation are levied: a basic tax on all adult males; a graded tax on all income earners; and an income tax.

Transport. A single main road runs for 228 miles along the western and southern boundary. A mountain road from Maseru reaches into the interior. These two main arteries are served by short-distance feeder roads. Villages in the mountains are served by 1,600 miles of bridle paths.

A one-mile railway line links the capital to the South African transport network.

Although considerable use is made of light aircraft for passengers and for transporting mail and freight to the interior, only Maseru has a regular airport suitable for small commercial planes. There are 28 rough airstrips.

As mentioned earlier, ponies are much used in rural areas, and in mountainous areas they are often the only means of transport.

Administration and social conditions. *The governmental structure.* The country's constitution (suspended under the state of emergency in 1970) provides for a bicameral parliamentary system.

The National Assembly has 60 members, each elected to represent a single constituency; the elections are based on universal adult suffrage. The Senate's 33 members are nominated partly by the government and partly by the king. Bills must pass through both houses to become law and must be assented to by the king. There is also a College of Chiefs which deals with matters relating to the appointment and control of chiefs.

The constitution was suspended following the contested results of a general election in which the opposition claimed to have won a majority of the seats. The country has since been ruled by a cabinet which operates under a system of emergency regulations.

Defense and justice. There are no armed forces, but there are about 1,500 police and palamilitary personnel.

The legal system is based on Roman and Dutch law. There are magistrates' courts and a High Court. Appeals of certain cases of a constitutional nature may be appealed to the Privy Council in the United Kingdom.

Literacy

Education. The country has the highest literacy rate in Africa of about 80 percent. It has more girls than boys in school, due to the latter's employment as herdsboys. Although about 90 percent of all school-age children are in primary schools, less than 9 percent advance beyond the lower primary educational level, and less than 3 percent advance to secondary education. Most of the schools are run by the Christian churches, which receive over 80 percent of the cost of teachers' salaries from government subsidies. There are about 1,300 primary schools and 29 secondary schools; one agricultural school; and seven teacher-training colleges. The University of Botswana, Lesotho, and Swaziland is based at Roma, 22 miles from Maseru. Fewer than 30 percent of its students are Sotho. The university has an extension department.

Health. The country's healthy climate contributes largely to the comparatively low rate of sickness. The main incidence of ill health is the result of food-deficiency diseases, venereal disease, chronic rheumatism, infections of the respiratory tract, and dyspepsia. There are fewer than 20 hospitals, about half of which are operated by the government, and a number of clinics for maternity, child health, and venereal diseases, as well as a few health centres and mountain dispensaries. There are almost forty doctors in the country—about one doctor for every 22,820 people. Some teachers and corporate empolyees are paid by the state.

Employment. The country offers few opportunities for earning a salary. Out of approximately 20,000 people in employment outside the rural sector, 40 percent are government employees, 35 percent are employed by schools or missions, and 30 percent are employed in commerce and by cooperative societies.

Cultural life and institutions. Traditional institutions remain strong despite the modernization and politicizing of Sotho society. The paramount chief and the system of chieftaincy remain a strong focus of loyalty, especially since some of its more venal aspects were reformed in the 1960s; there still is, however, considerable criticism of the power of chiefs and headmen, especially of their manner of administering the distribution of land and of the proliferation of officeholders within the chieftaincy system. Historical traditions and the philosophy of the founder of the nation, Moshoeshoe I (who was born at the end of the 18th century and died in 1870), exercise a profound influence in sustaining the Sotho nation's sense of independence and national pride. There is a strong literary tradition, which has been stimulated by modem education. Folklore flourishes, both in oral and written forms.

Importance of the chieftains

The initiation schools continue to play an important role in the villages and are a source of keeping alive a sense of the traditional values of the clans and the nation.

Simple village crafts, such as the decoration of walls, woodwork, clay making, weaving, and basketwork, flourish. Choir singing is popular.

The press. There are no daily papers in the country. In normal times there are ten regular weekly or monthly publications. Under the emergency government, only one governmental bulletin and a few religious publications are available.

Broadcasting. A national broadcasting service is provided by a 10-kilowatt medium-wave transmitter and a 5-kilowatt shortwave transmitter, both located at Maseru. There is no television.

Prospects for the future. Losotho has poor prospects of ever being able to achieve true economic viability, since it has inadequate resources of its own, and its economy and communications are inextricably linked to South Africa. Its future depends upon the answer to the question of how, under these circumstances, it can best preserve the political independence of statehood, to which the Sotho are resolutely committed.

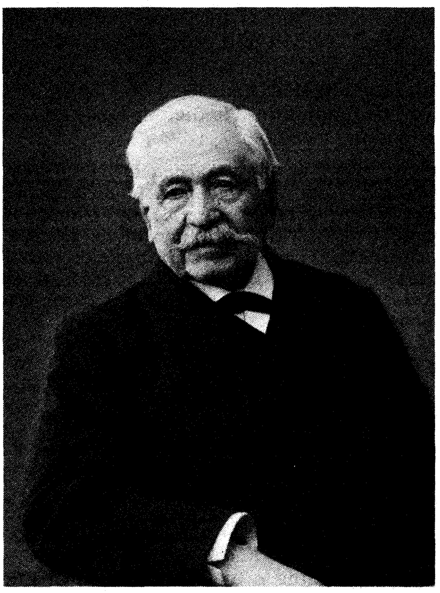
Lesseps, Ferdinand de

Diplomatic career

Ferdinand-Marie, vicomte de Lesseps, a French diplomat for 24 years, achieved lasting fame by realizing his dream of building a canal across the Isthmus of Suez, thus creating the shortest maritime route between Europe and the countries bordering the Indian and Pacific oceans. He was born at Versailles on November 19, 1805, of a family long distinguished in government service. Appointed assistant vice consul at Lisbon in 1825, he was sent to Tunis in 1828 and to Alexandria in 1832. At Alexandria the survey report of J.-M. Le Pkre, one of Napoleon's chief engineers, on the Isthmus of Suez, and his friendship with Muhammad ʿAlī, the Turkish viceroy of Egypt, and his son, Sa'id Pasha, led Lesseps to hope that he might one day finish the canal that Le Pkre had begun. For the time, however, he could not pursue his plans. From 1833 to 1837, Lesseps was consul at Cairo, where he gained distinction in combatting an outbreak of plague. Two years later he was transferred to Rotterdam. Subsequently he served at Málaga and at Barcelona, where he was promoted to consul general. From 1848 to 1849, after the proclamation of the Second Republic, he was minister of France at Madrid. In May 1849 he sent a mission to Rome from where Pope Pius IX had fled and where Mazzini had proclaimed the republic. This mission was ambiguous: it was a question of "placing a limit on the pretensions of Austria . . . of ending by arbitration . . . the differences which divided . . . the peninsula . . . ." Lesseps tried to reconcile the irreconcilables: the papacy and the republic. But at the end of May, when the French Legislative Assembly, conservative by nature, followed the Constituent Assembly, which held republican views, he was recalled, handed over to the Council of State, and censured. French troops re-established pontifical power in Rome. The diplomatic career of Lesseps was shattered. But in 1854, an invitation from Sa'id Pasha, newly appointed viceroy, or khedive, of Egypt, revived his ambitions. On November 30, 1854, Saʿīd Pasha signed the first act of concession authorizing Lesseps to pierce the isthmus of the Suez.



Lesseps.
Culver Pictures

Scheme for the canal

A first scheme, directed by Lesseps, was immediately drawn up by the surveyors Linant Bey and Mougel Bey (L.-M. Linant de Bellefonds and E. Mougel) providing for direct communication between the Mediterranean and Red sea; and, after being slightly modified, it was adopted by an international commission of engineers in 1856. Encouraged by this approval, Lesseps allowed no obstacles to retard the work, and he succeeded in rousing the French people to subscribe more than half the capital needed to form the company, which was organized in 1858. The first blow of the pickax was given by Lesseps at Port Said on April 25, 1859; and ten years later, on November 17, 1869, the Suez Canal was officially inaugurated by the Empress Eugénie who had been invited by the host of the celebrations, the khedive (viceroy), Ismāʿīl Pasha. In 1875 the British government, on the initiative of the prime minister, Benjamin Disraeli, purchased the khedive Ismāʿīl's Suez Canal shares and became the largest shareholder. Lesseps cooperated loyally with the British (in spite of the fact that they had earlier tried to block the building of the canal because of their suspicions of the French) and facilitated the transfer of ownership. Though he usually tried to keep out of politics, Lesseps stood as a Bonapartist candidate for a seat in the Chamber of Deputies at Marseille in 1869 but was defeated by Léon Gambetta, later one of the founders of the Third Republic.

In 1879, when the International Congress of Geographical Sciences met in Paris and voted in favour of the construction of a Panama canal, the 74-year-old Lesseps undertook to carry out the project. His despotic temper and stubbornness, however, made him fail to appreciate the difficulties of the task: at first he thought that it would be possible to pierce a canal without locks, even though the route was barred by the Culebra cut and by the torrential Chagres River. The task proved to be beyond the capacities of a private company, so that eventually, in 1889, the company that Lesseps had formed had to liquidate. After an official inquiry in 1892, the French government instituted the prosecution of the company's administrators; and in February 1893 Lesseps and his son Charles (1849–1923) were sentenced to five years' imprisonment. Only Charles, however, was imprisoned, and in June an appeals court reversed the decision. On the other hand, the fact that members of the government and parliamentarians were accused of having accepted bribes from the company made the Panama scandal a political affair as well as a financial one, with important repercussions in the history of the Third French Republic.

Lesseps was a member of the French Academy, of the Academy of Sciences, and of numerous scientific societies. He was also decorated with the grand cross of the

Legion of Honour and the Star of India and received the freedom of the City of London. His great gifts, unselfishness, and social charm made him everywhere respected, and the scandal that clouded his last years has done nothing to tarnish his reputation. He died at La Chenaie, near Guilly (Indre), on December 7, 1894.

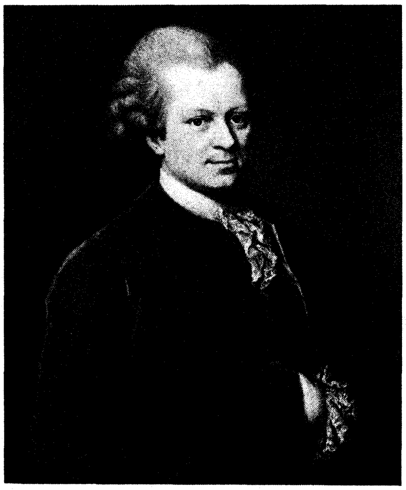
Lessing, Gotthold Ephraim

The first German dramatist of lasting importance, Gotthold Ephraim Lessing was also a social, dramatic, and religious critic and a writer on philosophy and aesthetics. His work is a plea for tolerance and humanity and everywhere reveals the two guiding principles of his own life — truth and reason.

By courtesy of the Gleimhaus, Halberstadt, East Germany



Lessing, oil painting by Georg May, 1768.
In the Gleirnhaus, Halberstadt, East Germany.

Lessing was born on January 22, 1729, at Kamenz, in Upper Lusatia, Saxony. His father, a highly respected theologian, was hard put to support his large family even though he occupied the position of *pastor primarius* (chief pastor). At the age of 12, Lessing, even then an avid reader, entered the famous *Fürstenschule* (Elector's school) of St. Afra, in Meissen. He was a gifted and eager student and acquired a good knowledge of Greek, Hebrew, and Latin. These were to stand him in good stead for his later work, while his admiration for the plays of the Latin dramatists Plautus and Terence fired him with the ambition to write comedies himself.

Early fascination with the theatre

Education and first dramatic works. In the autumn of 1746, Lessing entered the University of Leipzig as a student of theology. His real interests, however, lay toward literature, philosophy, and art. He also attended lectures in mathematics by A.G. Kastner, who was an epigrammatic poet of some renown and who may be considered as Lessing's first literary mentor. Lessing's cousin, the writer Christlob Mylius, and the dramatist Christian Felix Weisse introduced him to the lively social life of Leipzig, Germany's busy publishing capital and the site of a famous annual fair. Above all, he was fascinated by the theatre there, which had recently been revitalized by the work of a talented and energetic actress, Caroline Neuber. She had collaborated for many years with Johann Christoph Gottsched, an influential dramatic critic, moral philosopher, and educationalist (whom Lessing was later to attack for his narrow brand of rationalism). The "Neuberin" took an interest in the young poet and in 1748 successfully produced his comedy *Der junge Gelehrte* ("The Young Scholar"). In this, Damis, a merchant's son, a bigoted and self-centred young man, fancies that he deserves an academy prize for his verbose literary "masterpieces" and is so absorbed in them that he is quite unaware of the intrigues of marriage and inheritance taking place about him. The play is a delightful satire on a shallow know-it-all and ends with the audience laughing at the incurable arrogance of the vain and easily offended scholar. Lessing mocks his own bookishness in the play but is mainly concerned to criticize the middle class preoccupations of narrow-minded burghers and merchants, contrasting these characters with their much cleverer and warmer hearted servants. The other comedies belonging to this Leipzig period of 1747–49 (*Damon*, *Die alte Jungfer* ["The Old Maid"], *Der Misogyn* ["The Misogynist"], *Die Juden* ["The Jews"], *Der Freigeist* ["The Free Thinker"]) are witty commentaries on human weaknesses — bigotry, prejudice, nagging, fortune hunting, matchmaking, intrigue, hypocrisy, corruption, and frivolity. Set against this background are the virtuous men and women who are considerate and selfless, sensitive and helpful, forthright, and faithful in love. In *Die Judert* Lessing praised unappreciated nobility of mind and thus struck a blow for tolerance toward the Jews at a time when they were still confined to a ghetto life. Lessing had set himself the goal of becoming the German Molière: in these comedies he most interestingly begins to draw his characters as recognizable individuals, breaking away from the traditional dramatic "types" (although he was to create his finest comic individual only in his last comic masterpiece, *Minna von Barnhelm*).

Early work in Berlin

Early in 1748 Lessing's parents, who disapproved of his life in Leipzig, summoned him home. But he managed to win their consent to begin studying medicine and was soon allowed to return to Leipzig. He quickly found himself in difficulties because he had generously stood surety for some members of the Neuber company — although himself heavily in debt. When the company folded, he had no choice but to flee from Leipzig in order to avoid being arrested for debt. He eventually reached Berlin in 1748, where he hoped to find work as a journalist through his cousin Mylius, who was by this time an established editor. In the next four years he undertook a variety of jobs, mainly translating French and English historical and philosophical works into German. But he also began to make a name for himself through his witty criticism for the *Berlinische privilegirte* (later *Vossische*) *Zeitung*, on which he was book review editor, especially for his contributions to a monthly supplement, *Das Neueste aus dem Reicke des Witzes* ("The Latest from the World of Wit"). He also launched a periodical of his own, *Beiträge zur Historie und Aufnahme des Theaters* ("Contributions to the History and Improvement of the Theatre"). Despite its topical content, it did not long survive and had to be discontinued in 1750.

Rising reputation as dramatist and critic. After his flight from Leipzig, Lessing had first gone to Wittenberg, where he enrolled as a student of medicine. Now, from 1751 to 1752, Lessing went back there and took his degree. He then returned to Berlin, where he started another periodical, *Theatralische Bibliothek* ("Theatrical Library"), but this too had to be closed down after only four volumes were published (1754–58). The most significant event about this time, however, was the publication, in 1753–55, of a six-volume edition of his works. Apart from some witty epigrams, which Lessing called *Sinngedichte* ("mind poems") after those of the 17th-century poet Friedrich von Logau (whose epigrams he had earlier edited), the edition contained the most important of his Leipzig comedies. It also contained *Miss Sara Sampson*, which is the first major *bürgerliches Trauerspiel*, or domestic tragedy, in German literature. Middle class writers had long wanted to do away with the traditional class distinctions in literature, whereby heroic and tragic themes were played out by aristocratic figures, while middle class characters appeared only in comedy. Lessing was, in fact, not the first German writer to chal-

Attempt to create German middle class tragedy

lenge this tradition, but it is fair to say that his play marks the decisive break with the classical French drama that still dominated the German stage. *Miss Sara Sampson* was inspired by George Lillo's *London Merchant* (1731) and by the novels of Samuel Richardson—with their praise of middle class feminine virtue—and to a lesser degree, by the sentimental *comédie larmoyante* ("tearful comedy"), originated in France by the early 18th-century dramatist Pierre-Claude de La Chaussée. It is the first German play in which *bürgerlich* characters bear the full burden of a tragic fate, and it received its successful premiere at Frankfurt an der Oder in 1755. Its reflective prose skillfully lays bare the psychology of the situation —a conflict between the demands of virtue and the heart, between conscience and passion—and its characters are finely drawn. The plot centres on an innocent, sensitive heroine of a bourgeois family; she becomes the victim of Lady Marwood, her vampire-like rival in love, who disregards all restraints and inhibitions, and of Mellefont, a weak man who vacillates between the two women but finally atones for his guilt by his death.

Characteristic of Lessing's writings at this period are his *Rettungen* ("Vindications"), outstanding for their incisive style and clarity of argument. Here, in the spirit of the Age of Enlightenment—that was ruled by the conviction that right reasoning, rather than faith or revelation, would lead mankind to truth and happiness—he aimed to defend independent thinkers such as the Reformation-period writers Johannes Cochlaeus and Gerolamo Cardano, who had been unjustly slandered and persecuted. His scintillating and biting polemic *Vade Mecum für den Herrn Samuel Gotthold Lange* (1754) is a "vindication" of the poet Horace, directed against the carelessly corrupt translations of the arrogant scholar Lange, whose literary reputation was demolished by Lessing's attack. From this time, Lessing was justly feared as a literary adversary. His style increasingly became a finely honed weapon. But although he hit hard at those he considered incorrigible, he always fought for a cause and fought for truth, not victory.

The philosopher Moses Mendelssohn and the writer and publisher C.F. Nicolai stand out among his Berlin friends. With these men, Lessing conducted a truly epoch-making correspondence *(Briefwechsel über das Trauerspiel,* 1756–57) on the aesthetic of tragic drama. Tragedy, Lessing maintained, should not preach morality; it should arouse admiration and pity in the audience as evidence of their emotional involvement. Somewhat earlier, in the essay *Pope ein Metaphysiker!* (1755, "Pope a Metaphysician!"), he had joined forces with Mendelssohn to define the borders between philosophy and the theatre. At this time, Lessing also had many contacts with the poets Johann Wilhelm Ludwig Gleim and Karl Wilhelm Ramler, whose work he tended to overrate because of personal regard and friendship.

Between November 1755 and April 1758 Lessing was once again living at Leipzig, making brief excursions to Dresden, Halberstadt, Wolfenbüttel (where he was to live during the last years of his life), and Hamburg, there making the acquaintance of the poet Friedrich Gottlieb Klopstock. Lessing also planned to visit England with a young merchant, Gottfried Winkler, but they only got as far as Amsterdam when the outbreak of the Seven Years' War forced them to abandon the journey. In Leipzig Lessing became friendly with Ewald von Kleist, author of the poem *Der Frühling* (1749, "Springtime"). Kleist, a Prussian officer who fell in the Battle of Kunersdorf, was immortalized by Lessing as the character Major Tellheim in his comic masterpiece *Minna von Barnhelm.*

Friendship with the poet Ewald von Kleist

Lessing moved back to Berlin in May 1758 and remained until November 1760. There, besides writing occasionally for Nicolai's *Bibliothek der schönen Wissenschaften* ("Library of the Fine Arts"), he also contributed regularly, in 1759–60, to Nicolai's weekly, *Briefe, die neueste Literatur betreffend* ("Letters Concerning the Latest Literature"), writing a number of essays on contemporary literature. Here he praised the poems of Kleist as well as the *Kriegslieder von einem preussischen Grenadier* ("Battle Songs of a Prussian Grenadier") of his friend Gleim (whose unreflected patriotism, however, strikes most readers today as somewhat naïve). Lessing also stressed the importance of the poetry of Klopstock and C.M. Wieland, even while analyzing and criticizing their weaknesses. The central point of his essays, however, was a vigorous attack on the influential theatre critic J.C. Gottsched for his advocacy of a theatre modelled on French drama, especially that of the 17th-century tragedian Pierre Corneille. Lessing maintained that the courtly, mannered drama of France was alien to the German mentality. Instead, he demanded a truly national drama, belonging to the people, based on faithfulness to nature and reality. He urged German playwrights to take Shakespeare as their model. In the 17th *Literaturbrief* he published a stirring scene from his own fragmentary Faust drama. In this scene, Lessing sketches out a "Faust without evil" whose relentless spirit of inquiry is justified before God, notwithstanding his pact with the devil. He thus paved the way for his young contemporary Johann Wolfgang von Goethe and his great dramatic version of the Faust story.

In 1759 Lessing published some masterly prose fables, largely social criticism, and with them an essay on the fable form itself, in which he formulated the particular laws of the genre by analyzing its didactic and allegorical structure. At this time he was made an associate member of the Berlin Academy of Sciences; this was an unusual distinction to be bestowed on a free-lance writer. It did not, however, provide him with any economic security. In 1760 Lessing went to Breslau as secretary to General Tauentzien, a position in which he became familiar with the garrison life of Prussian officers. He later made good use of this knowledge in his play *Minna von Barnhelm.* He also studied philosophy and aesthetics in the Breslau libraries, the result being the great treatise *Laokoon: oder über die Grenzen der Malerei und Poesie* (1766, "Laocoon; or, On the Limits of Painting and Poetry"). Here he took issue with the contemporary art historian Johann Winckelmann, specifically over his interpretation of the "Laocoon," a famous *(c.* 1st-century-BC) sculpture of Hellenistic times, which shows the priest Laocoon and his sons as they are about to be killed by the serpents that hold them entwined. Winckelmann had admired above all the artistic control of suffering in the sculpture, and this provided the starting point for a discussion in which Lessing aimed to define the separate functions of painting and of poetry. He thought that whereas painting is bound to observe spatial proximity—and must, therefore, select and render the seminal and most expressive moment in a chain of events—poetry has the task of depicting an event organically and in its temporal sequence. The essence of poetry thus lies not in description but in the representation of the transitory, of movement. In his exposition Lessing displays a great understanding of Greek poetry without, however, recommending its imitation.

Lessing's definition of the separate functions of painting and poetry

The poetic fruit of his stay in Breslau was the play *Minna von Barnhelm* (1767), which marks the birth of classical German comedy. Goethe was to praise it for its contemporary relevance and for its central theme (the struggle between Prussia and Saxony in the Seven Years' War), which was an event of national significance. The central characters are a Prussian officer, Major Tellheim, and a young gentlewoman from Thuringia, Minna. The upright officer's conscientiousness and rigid interpretation of the code of honour has endangered his relationship with Minna; she, charming and spirited, takes matters into her own hands and, prompted by her heart's perceptions, resolutely overcomes the obstacles that war and occupation have placed in the way of their union. Clearheaded, and yet warmhearted, she resolves the conflict between the claims of conscience and those of happiness. Thus, in thinking and acting like true representatives of the Enlightenment, the two eventually behave like ordinary people and so bear witness to Lessing's concept of humanity. The two protagonists are supported by forcefully drawn secondary characters: the rough, adventure-seeking sergeant, the faithful manservant, the nosy innkeeper, the quick-witted lady's maid, the French gambler. Lessing's dialogue in this play enhances a lively dramatic action that can still hold an audience's attention.

Attempt to start a German national theatre

On returning to Berlin in 1765 he tried for the post of director of the royal library; but since he had quarrelled with Voltaire, who lived as a favourite at Frederick the Great's court, the King (who in any case thought little of German authors) rejected his application. Lessing then accepted the offer of some Hamburg merchants to act as adviser and critic in their privately funded venture of a national theatre. The project collapsed within a year, however, and Lessing recognized with some bitterness that the time for a German national theatre was not yet ripe, for the Germans did not then form a nation, either in the cultural or political meaning of the term. Even so, his reviews of over 50 performances were published, in the form of 104 brief essays on basic principles of the drama, under the title of *Hamburgisclze Dramaturgie* (1767–69). Here, too, Lessing argued against tragedy modelled on that of Corneille and Voltaire, although he praised the realism of the contemporary French writer Denis Diderot's descriptions of middle class life. Lessing interpreted Aristotle's famous and much-discussed concept of tragic catharsis (purging) as meaning the emotional release that follows tension generated in spectators who witness tragic events; he concludes that the sensations evoked by pity and fear should afterward exert a moral influence on the audience by being transformed into virtuous action. He also pleaded for acceptance of the principle of artistic unity in the drama. In 1768–69 he published *Briefe antiquarischen Inhalts* ("Letters of Antiquarian Content"), an attack on the pretentious learning and elitist attitudes of the Halle professor C.A. Klotz. Another result of this dispute was the perceptive essay *Wie die Alten den Tod gebildet,* in which Lessing contrasts the ugly medieval skeleton figure of death with the youthful spirit carrying a lowered torch, whom the Greeks thought of as the brother of sleep.

Final years at Wolfenbiittel. Being extremely poor, in 1770 Lessing had no choice but to accept the badly paid post of librarian at Wolfenbiittel, which he had earlier visited in 1766. This post was offered him by a German princeling, the dullish Duke of Brunswick. His years there were unhappy but rich in achievement. In 1771 he published "Zerstreute Anmerkungen uber das Epigramm" ("Scattered Observations on the Epigram"), in which he took up the cudgels on behalf of the Roman poet and epigrammatist Martial and also defended the artistic integrity of the epigram as a literary genre. In *Wolfenbiitteler Beiträge* ("Wolfenbiittel Contributions"), which appeared from 1773, he reported on discoveries he had made in the Wolfenbiittel library, bringing to light the late medieval fable poet Ulrich Boner. He also published extracts from the papers of the Hamburg biblical critic and scholar H.S. Reimarus, under the title of *Fragmente eines Ungenannten* (1774–77, "Fragments of an Unknown").

Controversy with the orthodox church

Theologians viewed this as a serious challenge to orthodoxy, even though Lessing himself had taken up a mediating position toward the radical theses of Reimarus, who had rejected the basic tenets of the Christian faith. Lessing went into battle against the orthodox clergy, involving himself in violent controversies with their leader, the chief pastor of Hamburg, J.M. Goeze. Against this rigid dogmatist, who was a man of almost pharisaical narrow-mindedness, Lessing launched some of his most cutting polemics, notably "Eine Parabel," "Axiomata," and "Anti-Goeze" (1778). In the equally militant pamphlet "Eine Duplik" ("A Rejoinder"), the subject of which is the Resurrection, he expounded his belief that the never-ending search for truth is more valuable than the certainty of having found it. *Ernst und Falk* (1778–SO), profound dialogues that plead for men to prove themselves humane in their everyday activities, had to be published anonymously, since the Duke had by this time forbidden Lessing to engage in any further polemic.

The tragedy *Emilia Galotti* had meanwhile been performed in 1772. Written in intense and incisive prose, this brilliantly constructed play deals with a conflict of conscience at the court of an Italian prince. Under the influence of the scheming courtier Marinelli, the prince, a shallow man of the world, abducts Emilia from her fiancé and her patrician parents. The girl, confused by the tumult of her own awakening sensuality, prefers death to dishonour; unable to do away with herself, she begs her father, Odoardo, to kill her. He is determined to save her from shame and stabs her with a dagger that the prince's own discarded mistress, in a fit of jealousy and enraged by the corruption of the court, had handed to him—intending that he should kill her faithless lover, the prince, for lusting after Emilia. But despite the fiery speeches that Lessing gives to Odoardo, the patrician cannot bring himself to raise the dagger against his own sovereign; instead of fighting against a social order that countenances such wantonness, he would rather kill his own innocent daughter. The timelessness of this play was demonstrated in Fritz Kortner's 1970 production in Vienna, where the play was brilliantly revealed as charged with contemporary force and significance.

Publication of *Nathan der Weise*

In 1779 appeared the "dramatic poem" in iambic verse *Nathan der Weise,* in which Lessing, according to his own statement, preaches once more from his old pulpit, the stage. It is a didactic play of a theological and philosophical nature, combining ethical profundity with many comic touches, and is a work of high poetic quality and dramatic tension. *Nathan der Weise* symbolizes the equality of three great religions in regard to their ethical basis, for the play celebrates man's true religion—love, acting without prejudice and devoted to the service of mankind. Among the representatives of the three religions—Islām (Saladin), Christian (the Templar), and Jewish (Nathan)—only the Jew, in whose character Lessing paid tribute to his old friend Moses Mendelssohn, lives up to the ideal of full humanity; he alone is capable of complete self-abnegation and has the courage to speak the truth even to the mighty. The fact that the main characters discover that they are related to one another serves to underscore their common membership in the larger family of mankind. Men whose religion guides them to a life of practical humanity are thus bound to each other by brotherly solidarity and mutual tolerance. Lessing maintains that God truly manifests himself in those deeds of charity, motivated by a sense of human responsibility, which man performs for his fellowman.

This conviction is also found in Lessing's last work, *Die Erziehung des Menschengeschlechts* (1780, *The Education of the Human Race),* a treatise that closely reflects the working of his mind and expresses his belief in the perfectibility of the human race. In the history of the world's various religions, Lessing saw a developing moral awareness that would, he believed, eventually attain the peak of moral freedom. After Lessing's death it became known that, in conversations with the Christian philosopher F.H. Jacobi, Lessing had expressed his belief in the pantheistic philosophy of Spinoza, after reading Goethe's poem "Prometheus." Thus he evidently made a decisive break even with the Deism of the Enlightenment, which did acknowledge a Creator. In *Die Erziehung des Menschengeschlechts,* mankind's salvation and the individual soul's eternal life do still beckon, but from an infinite distance, and the treatise closes with the question: "And what, then, am I in danger of missing? Is not all eternity mine?"

Thus the last decade of his life spent at Wolfenbiittel produced a rich harvest of philosophical and literary works. But his life there was otherwise full of tribulations. His health had begun to give way, and it was a lonely existence, with only a few trips to brighten the monotony. In 1775 he went to Vienna, where he was kindly received by the emperor Joseph II, and thence to Italy as companion to one of the Brunswick princes. Although he was there for nine months, the visit made little impression on him. Later, when visiting Mannheim in 1777, he tried to obtain a position at that city's theatre, but in vain. Also during this time (in 1776) he had finally been able to marry Eva Konig, the widow of a Hamburg merchant and a friend of long standing. But his happiness did not last; she died in 1778, giving birth to their only child. In a touching letter to a friend, Lessing wrote that "for once, I wanted as good a life as that which is granted to others; but I had to pay dearly for it." Eva's two children from her first marriage were a comfort to him, and he overcame his misery once again in order to defend his convictions in many critical and creative writings. Yet his last years were lonely and poor, and he died of a stroke on February 15, 1781, at the age of 52, in Braunschweig, and was there buried in a pauper's grave at public expense.

MAJOR WORKS

DRAMATIC WORKS: *Der junge Gelehrte* (produced 1748, printed 1754); *Damon* (written 1741–46); *Die alte Jungfer* (written 1746–48); *Der Misogyn* (written 1746–48); *Die Juden* (1749); *Der Freigeist* (1749); *Der Schatz* (1750); *Miss Sara Sampson* (1755); *Philotas* (1759); *Minna von Barnhelm oder das Soldatenglück* (1767); *Emilia Galotti* (1772); *Nathan der Weise* (1779).

OTHER WORKS: *Kleinigkeiten* (1751), poems and epigrams; *Ein Vade Mecum für den Herrn Samuel Gotthold Lange* (1754), criticism of Lange's translation of Horace; *Rettungen* (1754); *Fabeln* (1759); *Laokoon: oder über die Grenzen der Mahlerey und Poesie* (1766); *Hamburgische Dramaturgie* (1767–69), articles on the theory of drama; *Briefe antiquarischen Inhalts* (1768–69); *Wie die Alten den Tod gebildet* (1769); *Betengarius Turonensis* (1770); "Zerstreute Anmerkungen über das Epigramm" (1771); "Eine Paralbe," "Axiomata," and "Anti-Goeze" (1778), polemical writings directed against J.M. Goeze; *Ernst und Falk* (1778–80; *Lessing's Masonic Dialogues*, 1927); *Die Erziehung des Menschengeschlechts* (1780; *The Education of the Human Race*, 1858).

Many of Lessing's works have been translated, most of them during the 19th century. The most notable translations are *Selected Prose Works* and *The Dramatic Works*, ed. by E. Bell in "Bohn's Standard Library" (1819ff.); *Laocoon, Nathan the Wise*, and *Minna von Barnhelm* in "Everyman's Library" (1930 and 1959); *Theological Writings* (1956).

BIBLIOGRAPHY

Editions: (Miscellaneous publications): Sämmtliche Schriften, the first volumes that were published by Lessing during his lifetime until his death, ed. by his brother C.G. LESSING, J.J. ESCHENBURG, and C.F. NICOLAI, 31 vol. (1771–1825). *(Complete works): Lessings samtliche Schriften*, ed. by K. LACHMANN and F. MUNCKER, 23 vol. (1886–1924), remains the standard and most complete historical–critical edition; *Lessings Werke*, likewise a complete edition, ed. by J. PETERSEN and W. VON OLSHAUSEN, 25 vol. (1925–35). Selected works that are editorially sound throughout and that contain commentaries: *Gesammelte Werke*, ed. by P. RILLA, 10 vol. (1954–58), includes all the letters; *Lessings Werke*, ed. by G. WITKOWSKI, 7 vol. (1911); *Lessings Werke*, ed. by T. HOHLE, 5 vol. (1959 and 1964); *Lessings Briefe in einem Band*, ed. by H. GREINER-MAY (1967).

Biography: E. SCHMIDT, *Lessing: Geschichte seines Lebens und seiner Schriften*, 4th ed. rev. by F. SCHULTZ, 2 vol. (1923), the most complete biography written in the positivistic method; T.W. DANZEL and G.E. GUHRAUER, *Gotthold Ephrairn Lessing: Sein Leben und Seine Werke*, 2nd ed. rev. by W.V. MALTZAHN and R. BOXBERGER, 2 vol. (1880–81), a basic work, complementary to Schmidt-Schultz; H.B. GARLAND, *Lessing: The Founder of Modern German Literature*, 2nd ed. (1962), compressed and to the point; P. RILLA, *Lessing und sein Zeitalter* (1960), the first total presentation from the Marxist viewpoint; K.S. GUTHKE and H. SCHNEIDER, *Gotthold Ephraiin Lessing* (1967), a most important study.

Critical studies: F. MEHRING, *Die Lessing-legende*, 9th ed. (1926; abridged Eng. trans., *The Lessing Legend*, 1938), the first Marxist polemic appraisal of Lessing's alleged Prussianism; W. DILTHEY, "G.E. Lessing," in *Das Erlebnis und die Dichtung, Lessing, Goethe, Novallis, Hölderlin* (1906 and later editions), on the intellectual and philosophical–historical foundations; B.V. WIESE, *Lessing: Dichtung, Asthetik, Philosophie* (1931); A.M. WAGNER, *Lessing: Das Erwachen des deutschen Geistes* (1931); H. LEISEGANG, *Lessings Weltanschauung* (1931); O. MANN, *Lessing: Sein und Leistung*, 2nd ed. (1961); *Lessing Yearbook*, issued annually by the American Lessing Society since 1969.

(J.Mu.)

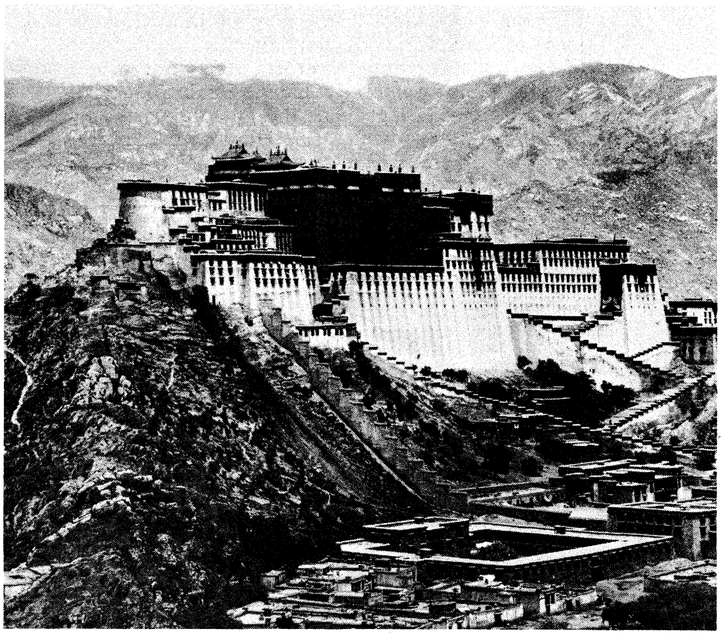
Lhasa

The former national capital of Tibet, Lhasa (La-sa in Pin-yin romanization) is the capital of the Tibetan Autonomous Region of the People's Republic of China. Perched high in the Tibetan Himalayas near the Skyid Chu (Skyid, or Happy, River; La-sa Ho in Chinese), a tributary of the Upper Brahmaputra, the city was long isolated from the outside world. It served as the national religious centre of Tibet, and much of its population was composed of Buddhist monks and laymen. The city has grown tremendously since the 1960s, and most of its estimated 400,000 inhabitants are now Chinese. Though its physical facilities have been improved under Chinese administration, most of Lhasa's Tibetan population has reportedly fled in the face of cultural and political persecution (for related articles see TIBET; BUDDHIST MYSTICISM).

History. Lhasa had been designated as the capital of Tibet by the 9th century AD. National power was decentralized following the assassination of the Tibetan king in 842, and Lhasa lost its position as the country's capital, though it gained in religious importance in succeeding centuries. In 1642 Lhasa was again the seat of the central government, a position it held into the 20th century. Although Lhasa and Tibet came under Chinese occupation in 1951, the city and the country remained under the Tibetan government until 1959, when direct Chinese administration was imposed. (For a more detailed discussion of history, see TIBET, HISTORY OF.)

The city site. Lhasa stands on a level valley plain at an altitude of 11,830 feet (3,606 metres) and is surrounded by dark and barren hills. The Skyid Chu flows through the valley on the south about a half mile from the city. The plain is fertile, though marshy in parts, and gardens scattered around the city are planted with fine trees. Lhasa is screened from view from the west by a lofty and narrow ridge with two high summits, between which is the main entrance to the city. The ridge to the north, called Potala Hill or Dmar-po Ri (Red Mountain), is crowned by the majestic buildings of the Potala, the winter palace of the Dalai Lamas. On the southern peak, called Lcagspo Ri (Iron Mountain), stands a monastic school devoted to the teaching of medicine. Gardens, groves, and open ground intervene between the ridge and the city for about one mile.

Ewing Galloway



The Potala Palace, former fortress of the Dalai Lamas, Lhasa.

The environment. The climate of Lhasa is generally dry, the city receiving only slightly more than 18 inches of precipitation annually. Humidity is low, and fog is practically nonexistent. The mean yearly temperature is approximately 49° F (9° C), with a January mean of 18° F and a July mean of 63" F.

Vegetation in the city includes weeping and Alpine willows, white and black poplars, junipers, elms, and thorn trees. There are fruit-bearing trees such as the peach, walnut, apple, pear, and apricot. Various vegetables are grown, and flowers include the rose, hollyhock, marigold, petunia, sweet pea, hydrangea, pansy, nasturtium, tiger lily, poppy, sunflower, carnation, zinnia, and gladiolus.

Domestic animals, such as the horse, mule, donkey, sheep, goat, yak, and cattle, are used for transportation, food, and clothing. Among the birds are the vulture, eagle, cuckoo, dove, owl, raven, crow, sparrow, lark, and hawk.

The city plan. The centre of the city is occupied by a four-story temple of Gtsug-lag-khang, considered to be the holiest in Tibet. Now converted by the Chinese into a guest house, it is ringed by an extensive mall, which held the main shopping area. A road leading west from the temple to the People's City Hall is lined with shops and is known as the New Market. In the western section of the city stands the former summer palace of the Dalai Lama—the Nor-bu-gling-ka (in Chinese, Na-pu-lin-k'a [Jewel Palace])—which is now the People's Pleasure Park.

The northwestern portion of the city is dominated by the imposing Potala Palace. At the foot of the palace stands a large exhibition hall built by the Chinese, military installations, and a prison. To the north of the palace is a lake, the temple of Klu-khang, and a large sports field, while between the palace and the city are located the People's Hospital, the Commerce Department, and an observatory. About four miles west of the city lies the monastery of 'Bras-spungs (Drepung; in Chinese, Che-pang), the largest in Tibet, which is now used as a military installation. The monastery of Se-ra (in Chinese, Se-la), the second largest in the country, lies about two miles north of the city and is now also used for military purposes.

Transportation. Before the Chinese occupation, the city was composed of narrow, unplanned streets lined with houses and shops. There was one wide road from the Nor-bu-gling-ka Palace to the Gtsug-lag-khang, by way of the Potala Palace. Since the 1960s new roads have been built, and an airport has been constructed near the city. A highway system now connects Lhasa with the major cities in the neighbouring Chinese provinces of Szechwan, Tsinghai, and the autonomous region of Sinkiang. The Skyid Chu has been bridged to accommodate motor vehicles, which were introduced by the Chinese. During the 1960s the mountain passes leading to India and the neighbouring Himalayan countries were sealed, and traffic was restricted within Tibet and between Tibet and China.

The population. Before the Chinese occupation, Lhasa had a permanent population of between 60,000 and 70,000 people from all areas of Tibet. The population was of homogeneous ethnic origin, and the Lhasa dialect of the Tibetan language was the national lingua franca. During the annual Smon-lam (Monlam) festival, the city population would swell to approximately 100,000 with Tibetan monks and pilgrims. The small groups of resident Chinese, Nepalese, and Indian and Chinese Musilms were concentrated in the mall area around the central temple.

Demographic changes

Since the 1960s the city has grown to more than 400,000 inhabitants, most of whom are Chinese civil servants and military personnel. Many of the city's inhabitants have gone to neighbouring countries, and the Chinese government has allegedly drafted most of the able-bodied men for forced labour on various construction projects. Lhasa is divided into eight administrative zones, and the small Tibetan population is restricted in movement from one zone to another.

Housing. Most houses in Lhasa were built of stone or brick; they were rectangular and topped with flat roofs. Buildings were whitewashed, and the doors and windows were outlined in black and often shaded with white canopies. Private buildings did not exceed three storys; the first story often served as a shop or stable. Every house had a Buddhist chapel or shrine, and prayer flags flew from every roof.

Economy. Before the Chinese occupation, the city's economy was based on the historic trade routes that converged on Lhasa from China, India, Nepal, and Bhutan. Except for handicrafts, the only industries were those of the ammunitions factory and mint, which were located between the city and the monastery of Se-ra. The Chinese administration has restricted trade to that with China and has established experimental farms outside the city. Small-scale industries include tanning and wool processing.

Administration and social conditions. Before the 1960s Lhasa served as the national capital of Tibet and the seat of its theocratic government. The city government was composed of both religious and secular civil servants.

Under Chinese administration Lhasa is the capital of the Tibetan Autonomous Region (*tsu-chih-ch'ü*) and also of the Lhasa Municipality (*shih*), which extends from beyond Na-mu Hu (Na-mu Lake), in the west, to Mo-t'o, in the east. The city is the seat of the autonomous region's revolutionary committee, which is headed jointly by the local Communist Party chief and Tibet's military commander.

Improved public utilities

Before the 1960s there was no water supply system in Lhasa, despite the proximity of the Skyid Chu. The only pipeline led to the central temple, and water for daily use was drawn from wells scattered around the city. Refuse was collected for use as fertilizer, and electricity, which was generated by hydroelectric power at Dokde to the north, was restricted to official use. The wealthy used kerosene and gas lamps and the poor, candles and oil lamps. The Chinese administration has apparently improved public utilities, and a large hydroelectric plant has been constructed on the Skyid Chu at Nachin, about 10 miles east of Lhasa.

Health facilities were updated with the operation of Lhasa's first hospital, which largely serves the Chinese community. Medical services were previously provided by the medical college and monasteries, and the government frequently ordered religious rites for the prevention of disease. The homeless, handicapped, and aged were housed and fed by the government. There were no fire-prevention services because Lhasa's houses were built of nonflammable materials. Police services were provided by the government for most of the year and by the religious community during the celebration of the Smon-lam festival.

The educational system, which was run largely by religious institutions, has been taken over by the Chinese government. There are now almost 40 primary and middle schools, and institutes of scientific research in agronomy and animal husbandry. Both the Tibetan and Chinese languages are taught.

Cultural differences with China

Cultural life. Cultural differences have perhaps been the greatest cause of strife between Lhasa's Tibetan population and its Chinese rulers. Buddhism had formerly formed the central core around which all of city life revolved, but the new government is attempting to eradicate it.

The weekly newspaper, the *Tibet Mirror*, which was published in India, and other Indian publications have all been banned, and all publications now arrive from China. Radio broadcasts in Tibetan and Chinese likewise are beamed only from China.

The city's various parks and open spaces are used for recreational purposes. Tibetans enjoy sports, and kite flying, horse racing, soccer, and wrestling were popular. Betting on sporting events was common, as was gambling with cards, dice, and Mah-Jongg (a game of Chinese origin, which is played with tiles); gambling is no longer allowed.

BIBLIOGRAPHY. The present situation and the conditions of the Tibetan people under the Chinese Communists are clearly given in KUNSANG PALJOR, *Tibet: The Undying Flame* (1970). Earlier descriptions of Lhasa are provided by S.C. DAS in *Journey to Lhasa and Central Tibet* (1902, reprinted 1970); LAURENCE A. WADDELL, *Lhasa and Its Mysteries* (1905); F. SPENCER CHAPMAN, *Lhasa: The Holy City* (1938); and GIUSEPPE TUCCI, *A Lhasa e oltre* (1950; Eng. trans., *To Lhasa and Beyond*, 1956).

(T.W.D.S.)

Liaoning

Liaoning (Liao-ning in Pin-yin romanization) is the southernmost of the three Chinese provinces, called by the Chinese the Northeast, that form the region of Manchuria. With an area of 58,300 square miles (151,000 square kilometres), Liaoning is bounded on the northeast by the province of Kirin, on the east by North Korea, on the south by the Yellow Sea, on the southwest by the province of Hopeh, and on the northwest by Inner Mongolian Autonomous Region. Its population was estimated at about 28,000,000 in 1968. The provincial capital is Mukden (Shen-yang).

The area, a region of early Chinese settlement in the Northeast, was known as Sheng-ching in Manchu times (1644 to 1911). The area was redefined in 1903 and named Feng-t'ien; in 1928 the boundaries were altered and it was renamed Liaoning. From 1947 to 1954 the territory was divided into a western province, Liao-hsi, and an eastern province, Liao-tung. In 1954, however, a northern zone was detached and it was re-established as a single province. It achieved its present form in 1956, when the former province of Jehol was partitioned and a portion added to Liaoning. Liaoning. Liao-hsi, and Liao-tung all take their names from the Liao Ho (Liao River). Precedents for the names go back to Han times.

Industrial importance

The economy of Liaoning is by far the strongest in the Northeast and is one of the strongest provincial economies in China. Liaoning is one of the country's principal industrial provinces, producing (with less than 4 percent of China's population and less than 2 percent of its area) about one-eighth of its total industrial production and 40 percent of its steel. One reason for the high level of development in Liaoning is the level of capitalization—very high by Chinese standards—which is based both on investments made under the People's government since 1949 and on important foreign investments made between 1896 and 1945, mainly by the Japanese. Equally, the high level of development in Liaoning cannot be separated from the province's wealth of readily accessible and varied resources, most of them still relatively unexploited at the beginning of the 20th century. Nor can either be separated from the growth of the Chinese population from a total (for the whole Northeast) of about 10,000,000 people in 1900 to more than 66,000,000 in 1968.

No part of contemporary Liaoning is densely populated by comparison with other parts of China where resources are strongly concentrated, and there is no reason to think that economic growth has yet approached its limits. (See MUKDEN; for an associated physical feature, see YALU RIVER; for historical aspects, see CHINA, HISTORY OF; and MANCHURIA, HISTORY OF.)

History. Most of the present Liaoning fell within the confines of the earliest Great Wall of China, built during the reign of the first emperor (221–209 BC), and hence formed part of China from early times. The environment and traditional Chinese civilization of the central plain in Liaoning continue into the North China Plain and into Shantung to the south. Chinese immigration from the south also has a long history, but, until the last years of the 19th century, it was on a modest scale. The traditional economy of Liaoning was one of Chinese peasant farm production in the plains; on the peripheries the economy was based in various places on herding, forestry, fishing, mining, and estate farming. Neither the aristocratic holders of the landed estates nor the people who depended on animals or on the products of the forests or rivers were generally Chinese; as elsewhere in the Northeast, they were of Mongol or Manchu stock.

Under the Ch'ing dynasty (1644–1911), whose own origins lay in the Manchu frontier aristocracy, official efforts were made to protect the Northeast from Chinese encroachment, except for the old Chinese-settled area in the Liao Valley. This policy was gradually abandoned, partly because of the pressure of Russian influence in the north.

Toward the end of the 19th century and on into the 20th, two intersecting forces together created a radically novel situation in Liaoning. One was foreign interference—Russian and, later, Japanese. The other was rapidly increasing Chinese immigration. These two forces resulted in the expansion of the economy of Liaoning at a wholly unprecedented rate.

Patterns of Chinese immigration

Immigrants travelled to Liaoning both by the Shan-hai-kuan land corridor in the southwest and from Shantung by sea to the Liaotung Peninsula in the east. The second group were the more numerous and have been the more successful, both because of the relative ease of travel by sea and because of the better opportunities for both work and settlement in Liao-tung. During the first half of the 20th century, during which time the population of the province rose to a size proportionate to its present figure, about two-thirds of the migrants travelled by sea. The population movement was based on seasonal migration for farm work, with about half of the migrants remaining in the Northeast after the harvests each year. Many strong Shantung communities grew up in Liao-tung, with traditions of mutual dependence and help.

The all-important South Manchurian Railway was constructed by the Russians between 1896 and 1903. This railway linked the new Liao-tung port of Dairen (now Ta-lien) with Ch'ang-ch'un, in Kirin Province, as well as with Harbin, in Heilungkiang Province, and with the then new Chinese Eastern Railway branch of the Trans-Siberian Railway. The South Manchurian Railway passed close to Mukden, replaced navigation on the Liao and much of the old cart transport, and bypassed the old port of Ying-k'ou. The foundations of the modern geography of Liaoning were laid by this railway. In 1907 the Russian railway, port, and territorial privileges were transferred to Japan at the conclusion of the Russo-Japanese War of 1904–05. From that time, Japan continually strengthened its hold on the economic life of Liaoning and the whole Northeast, partly through physical control but also through an active and successful policy of investment and economic expansion. From 1932 to 1945, Liaoning was part of the Japanese-dominated, "independent" state of Manchoukuo. Throughout this period, which included the Sino-Japanese War and World War II (1937 to 1945), Japanese policy aimed to develop the resources of Liaoning in a manner that would complement the economic strength of Japan. Heavy industry was particularly developed. Agriculture was in some degree diverted to soybeans and industrial crops, at the expense of grains. Engineering and light industries also developed but relatively weakly. The concentration on heavy industries represented a degree of imbalance that has been criticized; but, in the face of China's general lack of heavy industrial capacity, these installations have stood her in good stead since 1949.

The period of Japanese domination

Mukden fell to the Chinese Communists in 1948. The industrial installations of Liaoning had suffered heavily from war damage and from Soviet seizures of stockpiles and machinery. Industrial production in 1949 was only 28 percent of that of 1943. The People's government made the restoration of the Northeast one of its first priorities, and, by 1952, production had risen 28 percent above the previous peak of 1943.

After the defeat of the Japanese in 1945, the Soviet Union took over from Japan, and retained, residual rights to share with China the use of the naval base facilities at Lii-shun (Port Arthur) and some rights on the former South Manchurian Railway. These rights were all finally given up in 1955.

The landscape. Liaoning consists essentially of a central lowland, with Mukden at its centre, flanked by mountain masses to east and west. A southward extension of the eastern highlands forms the Liaotung Peninsula. There are four main topographical regions: the central plains, the Liaotung (Kwantung) Peninsula, the western highlands, and the eastern mountain zone.

The four main regions

Climate. The latitude of Mukden in central Liaoning is 42° N; mean temperatures there are January, 9° F (—13" C); April, 46° F (8" C); July, 76° F (24" C); October, 48° F (9° C).

Average annual precipitation is about 26 inches, three-quarters of it falling in the months of June, July, August, and September, and almost none during December, January, and February. At Mukden, there are about 160 to

180 frost-free days a year. The summer rainfall is often torrential; rainfall reliability is about 80 percent. Strong winds occur in spring.

Rainfall in Liaoning as a whole diminishes consistently from southeast to northwest. Everywhere the scarcity of spring precipitation tends to leave growing crops short of water.

Soils and animal life

The central plains. The central plains are the most important area in the province. Structurally, the depression that it occupies is continuous with that of the North China Plain, but, topographically, the Liaoning plains are erosional, rather than depositional, in character. The relief of the plain is undulating but low, and natural drainage is inadequate in many places, creating swamps, some of which have been redrained. Most of the landscape of the central plains is man-made, consisting of cultivated fields. Undeveloped areas include swamps and sand formations. The soils of the middle of the Liao lowland are of the calcareous alluvial type; those of the peripheries to east and west, of brown-forest types; those of the northern peripheries, red earths. The swamps have gley soils (having a sticky layer of clay under the waterlogged surface). Wild animals are scarce, apart from rodents. Locusts are the most important pest. The sea freezes at the coast in winter.

The Liaotung Peninsula. The Liaotung Peninsula is a rugged, mountainous area with a rocky coast. The usual height of the country is 1,000 to 1,500 feet above sea level. The rock types are very mixed, a fact that tends to create a complex and varied topography. Structurally, Liaotung represents a part of the same fold system as Shantung. The coastline is now experiencing submergence. Winters are milder than at Mukden. The January mean temperature at Dairen is 23° F (−5° C). There are about 200 frost-free days. The sea does not freeze at Dairen, though there is floating ice.

The soils of the peninsula, like the rock types and the topography, are very mixed and varied. Most of the best soils are of brown-forest type or of red or yellow loess (an unstratified wind-borne loamy deposit). There has been serious soil erosion, and skeletal soils occur on the steeper slopes. Generally speaking, soils are chemically neutral. The natural vegetation is not well preserved, because of the extent of cultivation and settlement. The forests that remain, mostly on the eastern sides of the hills, contain birch, lime, elm, and pine, together with typical Manchurian trees—oak, apple, and ash. On the western sides, trees are scarce. Wild animal life is now meagre, being almost limited to rodents.

The western highlands. Western Liaoning, fringing the northern shore of the Gulf of Liaotung (Po Hai) between Shan-hai-kuan and Chin-chou, is predominantly a highland area. These highlands comprise the broken and eroded fringe of the Mongolian plateau. They rise in Liaoning to general heights of about 1,500 feet. Toward the sea, the mountains have been intensely eroded by fast-flowing rivers, so that a complex mass of valleys and ridges has been formed. The section of these highlands that lies within Liaoning faces toward the southeast and usually receives adequate rainfall. Winter cold is moderated by the proximity of the sea. The frost-free period is about 200 days. The soils of the western highlands are brown earths in general, but there is great diversity, including thick loess deposits in some places. Vegetation is also very mixed and includes oaks, birches, pines, limes, and spruces. In former times, especially between 1911 and 1948, there was much indiscriminate cutting and thinning of the forests, not necessarily for permanent cultivation. Many areas now have scattered woodland where formerly thick forest stood. The animal life of the western highlands is impoverished by the extent of both forest clearance and human settlement; but it includes the wolf, fox, and marmot and some kinds of deer.

The eastern highlands. The eastern mountain zone lies to the east of Mukden. The least developed part of the province, it consists of a complex mountain mass, extending northward into Kirin Province, with elevations averaging about 1,500 feet. Average precipitation is plentiful, reaching 40 inches per annum in much of the area. There are only 120 to 140 frost-free days. Natural vegetation is predominantly a mixed coniferous and broad-leaf forest. Coniferous trees are mainly cedar, fir, and spruce species; deciduous trees include birch, oak, elm, ash, and walnut species. Soils are predominantly brown-forest types, slightly podzolized (with leached upper leaves), with podzolic–gley and other similar soils in ill-drained areas, often associated with peat.

Demography

Population. The population of Liaoning was officially recorded at 24,095,000 in 1957, the last year for which an official figure has been published. Because of changes in the area of the province since the previous census was taken in 1953, a direct projection of the present population from these figures is not possible. The natural increase of the population in Liaoning reached very high rates in the 1950s, probably reaching about 35 per thousand. Immigration contributed about 20 percent of population increase in the generation before 1957. Either or both of these sources of increase may have slackened since 1957. These figures, projected roughly to 1972, justify an estimate for population in Liaoning in that year of between 33,000,000 and 40,000,000 people, and probably about 35,000,000.

The urban population of the province was 42 percent of the total in 1958, the highest provincial figure of this kind in China; the figure was due, no doubt, to the high degree of industrialization in Liaoning and also to the relatively high capitalization of agriculture. In 1940, the corresponding figure was only about one-tenth. All the big towns are industrial. They include the following (populations for 1960 are given where available): Mukden or Shen-yang (earlier called Feng-t'ien or Sheng-ching), 2,400,000; (Lü-ta; comprises Lü-shun, formerly called Port Arthur, and Dairen, Ta-lien or Dalny), 1,500,000; Fu-shun, 1,000,000; An-shan 800,000. Other major towns are: Liao-yang, Pen-ch'i (Pen-hsi or Penki), Ch'ao-yang, Chin-chou (Chinchow), Ying-k'ou, and Tan-tung (Antung), all with populations below 500,000 in 1957. Some of the larger towns experienced spectacular growth in the earlier 1950s. Between 1948 and 1958, for example, the population of Mukden increased by 54 percent, while that of Fu-shun increased by 50 percent.

Population densities in Liaoning vary considerably. The highest densities (1957 figures), which occur between Mukden and the sea at Ying-k'ou, were upward of 780 per square mile. The usual figure in the developed areas with rail transport was about 520 per square mile. Thinly populated parts, such as the eastern mountains, had about 130 persons per square mile or less. The population-density figure for the whole province was 415 persons to the square mile—about the same as Hupeh to the south.

Ethnic composition and distribution

In Liaoning, 93 percent of the total population is recorded as Han Chinese. The bulk of the national minority population is Manchu, 70 percent, with 1,121,000 Manchu out of the total minority population of 1,600,000. The Manchus are located mainly in the Liao Valley and around Mukden, in the southeast around Tan-tung, and in the southwest around Chin-chou. The second significant minority is that of the Mongols, who are located toward the frontier of the Inner Mongolian Autonomous Region to the west. They number about 235,000. Broadly speaking, the Hui, or Chinese Muslim minority, follow the Manchus in their distribution. There are two autonomous *hsien* (administrative subdivisions representing minority nationalities). They are Fou-hsin (Fu-hsin) Mongol Autonomous Hsien, centred on the coal town of Fou-hsin; and Kharchin East Wing Mongol Autonomous Hsien, in the southwest. A small Korean minority is located near the Korean frontier.

Apart from the registered minority populations, many of the Chinese people of modern Liaoning have origins that are wholly or partly non-Chinese, usually Mongol or Manchu. Many of them are now totally assimilated into the Chinese sector of the population, both in terms of language and custom, as well as in terms of the adoption of contemporary Chinese life-styles.

Resources and economy. *Mining and industry.* Liaoning Province is rich in mineral resources, especially iron ore and coal. Most of the iron ores of Liaoning are concentrated in the triangle formed by the towns of Pen-ch'i, Hai-ch'eng, and Feng-ch'eng, all of which lie to the south of Mukden. These ores are generally easy of access, but their iron content is low—only about 20 to 35 percent; and their quartz content is high. Ores of better quality occur to the north of T'ieh-ling.

Mineral resources and mining

Coal is more widespread; its distribution partly overlaps that of iron. Coal is exploited in three main areas that may be said to radiate from Mukden: one to the north, including Fa-k'u and K'ang-p'ing; one to the east and southeast, including Fu-shun, Pen-ch'i, An-shan, and Tan-tung; and one to the west, extending as far as Ch'ao-yang and including Chang-wu, Fou-hsin, and Pei-p'iao. In 1957 Liaoning produced about 20 percent of China's coal output, although because of growth elsewhere, this proportion is likely to have fallen rather than risen, since that time. The coal reserves of Liaoning form less than 4 percent of national reserves. More than 80 percent of the coal reserve is of bituminous quality, with some anthracite in the southeastern section.

Fu-shun and Fou-hsin have two of the most important collieries in China. Both were exploited under the Japanese but have been expanded since the Communists came to power. Both use opencast (strip-mining) methods. Apart from its use as fuel and in smelting, coal is used in Liaoning to produce synthetic petroleum. Petroleum is also produced from oil shale, which occurs in the Fu-shun area and at Ch'ao-yang, generally overlying coal seams.

Rich reserves of manganese ore occur in the Ch'ao-yang region of western Liaoning and in the southeast. In the eastern mountain area, there are substantial deposits of copper, lead, and zinc; smaller similar deposits also occur in the Chin-chou area in the west, together with an important deposit of molybdenum. Important concentrations of magnesium ore are found at the southern corner of the central plain, at Ying-k'ou and Ying-k'ou-hsien. There are also reserves of other minerals, including bauxite and gold. Sea salt is produced for use in food and in the chemical industry.

Heavy industry

During the first five-year plan of the People's government (1953 to 1957), capital investment in Liaoning was about one-seventh of that in the whole of China. The bulk of this and subsequent investment appears to have taken place in heavy industry, and especially in the industrial network centred on the An-shan iron and steel complex, which forms the industrial heart of Liaoning. In heavy industrial production, Liaoning ranks first among the provinces of China, producing, in addition to steel, over one-third of China's cement and crude oil and about one-fifth of its electrical power.

Apart from iron and steel, the industries of Liaoning include nonferrous-metal processing; machinery manufacture, including electrical, agricultural, mining, and transport machinery, and machine tools; textiles, including both cotton and silk; foodstuffs; paper; and cement. Some hydroelectricity is generated at the Shui-feng (Sup'ung) plant, on the Yalu River, and at the Ta-huo-fang plant, to the east of Fu-shun.

About 75 percent of Liaoning's industrial production by gross value in 1957 came from five cities: Mukden, An-shan, Dairen, Fu-shun, and Pen-ch'i.

An-shan

An-shan is China's principal steel centre. There are abundant local iron-ore resources and supplies of manganese and other metals. Coal is brought there from Fu-shun and Fu-hsin. The first blast furnace (1919) was Japanese, but An-shan has had a long history of smelting from Han times onward. After 1949, An-shan was restored and reconstructed, partly with Soviet aid, under the first five-year plan. It became a principal industrial centre for China, as well as one of the principal suppliers of producer goods within a wide technological spectrum: 5,000 steel products are now manufactured at An-shan. Equipment and trained men have also been supplied by An-shan to other steel centres in China, such as Wu-han. Taken as a whole, An-shan is the biggest single enterprise in industrial investment ever established in China. In 1958 it produced 40 percent of the Chinese iron and steel output. A number of other iron and steel works in Liaoning have been drawn into complementary relationship with An-shan; these are located at Pen-ch'i, Fu-shun, Dairen, Chilin, and T'ung-hua.

Mukden has a wide and varied range of industries, including electricity, metallurgy, machinery and machine tools, chemicals, and building materials; light industries manufacture textiles and paper among other things. Fu-shun is part of the Mukden complex; but its industries. which include artificial petroleum, are all based upon coal. Pen-ch'i, lying to the southeast of Mukden, is another important iron and steel centre, and also manufactures cement.

Dairen lies near the tip of the Liaotung Peninsula and, in the Yellow Sea, is of obvious strategic importance. It has the best harbour in the Northeast. In the Japanese period, Dairen was developed as a port for trans-shipment, servicing, and repairs, and the foundations were laid for the development of its modern engineering industries, including shipbuilding and locomotive production. Chemical industries form the second big industrial grouping in Dairen. There are also a steel mill, an oil refinery and textile mills, together with a food-processing industry and a fishery industry.

Western Liaoning, centred on Chin-chou, is less advanced than the Mukden–An-shan area, or Dairen; but it has valuable mineral resources and some industries. The minerals include coal, oil shale, manganese, and rare metals, for which Chin-chou forms a centre. Coal is mined, particularly at Fou-hsin and Pei-p'iao. Petroleum and other synthetic products are made at Chin-chou and Chin-hsi. There are also cotton and paper mills. Since 1949, industry in Chin-chou has expanded, with emphasis on heavier types of manufacturing.

Eastern Liaoning is also less advanced. In this area, there are important mineral and timber resources. The chief commercial products, apart from farming products, are nonferrous metals, lumber, paper, and wild (tussah) silk. Tan-tung is the chief port of the area, as well as the chief centre for silk reeling, paper, and other light industries such as chemicals.

Agriculture. Agricultural advance in Liaoning has been less spectacular than industrial development. There are several reasons for this. Investment has always been much heavier in industry than in farming. The province's inheritance from the Japanese phase was much less valuable in agriculture than in industry. Liaoning also suffers from both natural calamities such as spring droughts, and, at least until 1958, from backward cultivation methods in many places that resulted in low yields. Exceptional opportunities for employment in industry also tend to deprive agriculture of much of the best labour, in spite of policies designed to prevent this. Yet, in much of Liaoning, topography and soils, and even climate, are quite favourable to agriculture, and the degree of farm mechanization is very high by Chinese standards; Liaoning has more tractors than any other province. One-third of the area of the province is under cultivation, and, of this amount, 60 percent lies on the central plains. The average area of cultivated land per farming family in 1957 was almost four acres. About 15 percent of the cultivated area is used for industrial crops or for export crops like apples; the rest is used for grain crops, vegetables, and soybeans. Liaoning is, nevertheless, a food-deficit province. It must depend partly on food from Kirin and Heilungkiang to the north and partly on imported grain.

Agricultural problems

The summer in Liaoning is not long. In few places, consequently, are two crops per year produced. Corn (maize) and kaoliang (grain sorghum) are the principal crops, followed by soybeans—which are used both as a food and as an industrial crop—and by millet and rice, cotton, and vegetables. Higher yielding corn and rice, formerly grown mainly in the east and the southeast, have tended to supplant millet and kaoliang in the plains. Industrial demand for cotton is very high and competes with the demand for surplus-grain production to feed the industrial workers. The central plain is the best farming area, growing kaoliang, corn, and wheat, with soybeans and vegetables. In the Liaotung Peninsula, with its shorter winter, there is a diversified agriculture, with less grain growing. Three-quarters of the total Chinese output of apples comes from this area; much of the apple crop is exported. Vegetable farming is important, with some double-cropping.

Western Liaoning grows millet and kaoliang as staple crops. Apple growing has been successfully practiced since 1949. In the eastern region, less than 20 percent of the land is cultivated. Rice, sweet potatoes, and corn are characteristic of this area, together with tobacco and the forest products of the mountains. The chestnut-leaved oak feeds the tussah silkworm. The forests support commercial lumber exploitation, but the supply of mature trees is limited, due to previous overexploitation, and the output of lumber is low.

Livestock raising is of minor importance. There are some 8,000,000 head of domestic animals in Liaoning, half of which are pigs. Pigs are bred mainly in the south and central parts, and in the west other animals are raised.

Transportation. The rail transportation facilities of Liaoning are the best in China, and the tonnage transported is also the highest for any province (about one-fifth of the total). The backbone of the transportation system is the Ch'ang-ch'un-Dairen railway (formerly called the South Manchurian Railway), which passes through Mukden and which was double-tracked in 1954. Railroads in Liaoning total (1963) 1,920 miles. Rail traffic primarily comprises either industrial freight or food products in bulk.

Highways in the province are extensive, amounting to about 15,000 miles, but many are of poor quality; the total length of good roads is probably about the same as that of railroads. About 70 percent of the goods transported by road are carried in carts by animals in the traditional style.

Shipping

Navigation, by sea or river, carries less than 1 percent of the internal traffic of Liaoning, but sea navigation is of great importance for transport to other parts of China. Dairen is the greatest port, handling 70 percent of traffic, followed by Ying-k'ou.

Administration and political development. At least until 1958, the Northeast in general and Liaoning in particular stood in the forefront of development in mainland China. The Communists came to power in the Northeast in 1948, and land reform took place here earlier than elsewhere. Communist experiments in economic planning and the accounting systems were also first in the Northeast. For a few administrative purposes, Liaoning has been granted exceptional treatment; for instance, in 1958 the province was grouped with Peking, Shanghai, and Tientsin in respect to revenue provisions. Industrial investment in Liaoning was particularly heavy.

BIBLIOGRAPHY. Material on Liaoning appears in most indexes and bibliographies under "Manchuria." There is very little literature specifically on Liaoning.

SUN CHING-CHIH (ed.), *Economic Geography of Northeast China* (1962; orig. pub. in Chinese, 1959), contains a long chapter on Liaoning. Because of its relatively recent date, and its origin in mainland China as one of a series of standard regional texts, this work carries special authority from the standpoint of information. E.M. MURZAYEV, USSR *Survey of Northeastern China* (1965; orig. pub. in Russian, 1955), is a formal physical geography; O. LATTIMORE, *Manchuria: Cradle of Conflict*, rev. ed. (1935), a wide-ranging and perceptive study of the northeast in historic and modern times. K.C. SUN and R.W. HUENEMENN, *The Economic Development of Manchuria in the First Half of the Twentieth Century* (1969), is a narrower and more technical historical study that utilizes Japanese materials.

(F.A.L.)

Liberalism

Liberalism does not lend itself to easy definition. A major difficulty is that, with some exceptions, liberals have shunned dogma, preferring generally a pragmatic to a doctrinaire approach to social problems. Another, which has been a prolific source of misunderstanding, has been liberals' own frequently opposing views concerning the scope of government. The confusion thus engendered is sometimes compounded by a tendency to identify liberalism exclusively with its 18th- and 19th-century variant, or with the program of this or that liberal party, in a formulation that has on occasion led many to announce the "decline" or "end" of liberalism and to compose obituaries that have been quite misleading. Through the centuries liberalism has changed drastically in content, but it has maintained a constant form. Those who note the first and neglect the second understandably find the term confusing and its application inconsistent.

HISTORICAL BACKGROUND

Liberalism is the culmination of a development that goes back to the Hebrew prophets, the teachings of the pre-Socratic philosophers, and the Sermon on the Mount, from all of which there emerged a sense of the importance of human individuality, a liberation of the individual from complete subservience to the group, and a relaxation of the tight hold of custom, law, and authority.

Throughout much of his history, man as an individual has been submerged in his group. His emancipation as an individual can be understood as a unique achievement of Western culture, perhaps its very hallmark. If this be so, then the emergence of liberalism was, in an important sense, inseparable from Western man's quest for freedom; for liberalism, in the broadest sense, seeks to protect the individual from arbitrary external restraints that prevent the full realization of his potentialities.

Mercantilism and the rise of the middle class

Medieval society did not provide a soil in which the first seeds of liberalism might easily germinate. The Middle Ages produced a society of status in which the rights and responsibilities of the individual were determined by his place in a stratified, hierarchically ordered system. Such a closed, authoritarian order, however grandiose in outline and noble in aspiration, was bound to place great stress upon acquiescence and conformity. As new needs and interests, generated by the slow commercialization and urbanization of Europe, gained strength, the medieval system was modified to accommodate the ambitions of national rulers and the requirements of an expanding industry and commerce. The ensuing policies and arrangements came to be known as mercantilism, a policy of state intervention that, in theory at least, might be extended to regulation of the most minute details of economic life (*cf.* Eli Heckscher, ***Mercantilism***, 1935). However, as such intervention came more and more to serve established interests and to inhibit enterprise, it was challenged by the members of the newly emerging middle class. The challenge took the form of revolt, first against the Universal Church, and later against mercantilist states, presided over by absolute monarchs. The former manifested itself in the Protestant Reformation and the quest of Calvinists and Calvinist sects for freedom of conscience; the latter in the great revolutions that rocked England and France in the 17th and 18th centuries, notably the Glorious Revolution of 1688, the French Revolution a century later, and the successful revolt of England's American colonies. Classical liberalism as an articulated creed is a product of those great collisions.

The fortunes of liberalism differ with the historical conditions in each country—with the strength of the crown, the élan of the aristocracy, the pace of industrialization, and the circumstances of national unification. Thus, by contrast with England, the character of liberalism in France reflected the decadence of its nobility and the absolutism of the Bourbons. The failure of liberalism in Germany in the 19th century was attributable in great part to the dominant role of a militarized and Lutheran Prussia and the reactionary influence of Austria. The advent of liberalism in Italy was delayed by the armies of Austria and of Louis Napoleon and the opposition of the Vatican. Whatever the variations, the liberal impact on authoritarianism reverberated throughout Europe and its dominions, voiced by a Kossuth in Hungary, a Mazzini in Italy, a Thorbecke in the Netherlands, a Bolivar in South America. For a moment even Russia, in 1905 and again between March and November in 1917, heard the echo and, had there been a sufficiently numerous middle class to listen, the course of modern history would no doubt have been changed.

ECONOMIC AND POLITICAL FOUNDATIONS

The authors of the liberal creed vary widely, even in the countries in which liberalism was cradled. But their agreements sufficiently exceed their differences to permit their being included in the same tradition—a tradition whose main manifestations are economic and political. That the classical liberals, perhaps more perceptively than their successors, regarded these as only abstractly separable is indicated in the very title of their science—political economy.

"Private vices, public benefits"

The economics of the "free" market. On the economic side 18th- and 19th-century liberalism based itself on the sovereignty of the market and the "natural harmony of interests." On this view, if individuals are left free to pursue their self-interest in an exchange economy based upon a division of labour, the welfare of the group as a whole will necessarily be enhanced. Classical liberal economists describe a self-adjusting market mechanism free from all teleological influences. While moral goals are invoked and ethical criteria presupposed in passing ultimate judgment on the system, they play no part in determining the sequence of events within it. The one propelling force is the selfishness of the individual, which becomes harnessed to the public good because in an exchange economy he must serve others in order to serve himself. It is only in a *free* market, however, that this happy consequence can ensue; any other arrangement must lead to regimentation, exploitation, and economic stagnation. The most celebrated formulation of this doctrine is to be found in Adam Smith's *Wealth of Nations:*

> He generally, indeed, neither intends to promote the public interest, nor knows how much he is promoting it. . . . by directing. . . industry in such a manner as its produce may be of the greatest value, he intends only his own gain, and he is in this, as in many other cases, led by an invisible hand to promote an end which was no part of his intention. Nor is it always the worse for the society that it was no part of it. By pursuing his own interest he frequently promotes that of the society more effectually than when he really intends to promote it. I have never known much good done by those who affected to trade for the public good. It is an affectation, indeed, not very common among merchants, and very few words need be employed in dissuading them from it.

The same thought had been expressed more tersely by Bernard de Mandeville (*c.* 1670–1733) in the phrase, "private vices publick benefits." A poet (Pope) said it best:

> Thus God and Nature link'd the gen'ral frame,
> And bade Self-love and Social be the same.

Every economic system must be concerned with at least two basic problems: first, arrangement must somehow be made for determining *what* shall be produced—*i.e.*, how "scarce means" shall be allocated—and, second, there must be some way of apportioning what is produced. In a controlled economy this is accomplished by a planning agency acting at the behest of the government. In the economy envisaged by the classical economists of the 18th and 19th centuries, and those conservative economists who today may be called neoclassicists, this is accomplished in the free market through the price mechanism. In such a market the theoretically free choices of individual buyers and sellers determine how the resources of society (labour, goods, capital) shall be employed. These choices manifest themselves in bids and offers that in their totality determine the price at which a commodity will sell. Theoretically, when the demand for a commodity is great, prices will rise, making it profitable for producers to increase the supply; as supply approximates demand, prices will tend to fall until producers divert productive resources to other uses. In this way the closest possible coincidence is said to be achieved between what is wanted and what is produced. Moreover, in the distribution of the wealth thereby produced, the system is asserted to assure a reward in proportion to merit. The assumption is that in a freely competitive economy in which no one is barred by status from engaging in economic activity, the income received from such activity is a fair measure of its value to society.

Man—the rational economic animal

Presupposed in the foregoing is a conception of man as an economic animal rationally engaged in minimizing costs and maximizing gains (wages, profit, interest). Egoistic and hedonistic assumptions about human nature, which were taken for granted, led easily to an emphasis on man as a forward-looking and end-seeking creature. "When matters of such importance as pain and pleasure are at stake . . . who is there that does not calculate," Bentham asked. In Pope's descriptive couplet, although

> Self-love, the spring of motion, acts the soul;
> Reason's comparing balance rules the whole.

If, as the Enlightenment liberals assumed, "reason's comparing balance" rarely fails man in any of his activities (Bentham went so far as to construct an entire theory of penology based on the assumption that even would-be lawbreakers carefully balance the pleasure to be derived from their contemplated crime against the pain of punishment), it could be affirmed *a fortiori* that they would also meticulously balance utilities against costs at the marketplace. Since rational men best know their own interest, it must follow that interference by agencies of government could only diminish that "greatest happiness of the greatest number" that the followers of Bentham claimed to desire.

Assumed also by the classical creed is a conception of the consumer as sovereign, decreeing by his purchases how the resources of society shall be allocated. No one has celebrated this coronation of the consumer more eloquently than Ludwig von Mises in his *Omnipotent Government:*

> Within the market society the working of the price mechanism makes the consumers supreme. They determine through the prices they pay and through the amount of their purchases both the quantity and quality of production. They determine directly the prices of consumers' goods, and thereby indirectly the price of all material factors of production and the wages of all hands employed.
>
> . . . In that endless rotating mechanism [i.e., a market society] the entrepreneurs and capitalists are the servants of the consumers. The consumers are the masters, to whose whims the entrepreneurs and capitalists must adjust their investments and methods of production. The market chooses the entrepreneurs and the capitalists and removes them as soon as they prove failures. The market is a democracy in which every penny gives a right to vote and where voting is repeated every day.

The justification of private property

Implied by the logic of this economic creed is a functional justification of private property, often buttressed, to be sure, by a doctrine of natural right to shield manifestly functionless claims to property. John Locke's *Two Treatises of Government* (1690) pointed the way by defining property as "whatsoever . . . [man] hath mixed his labour with. . . . " Adam Smith found that "The property which every man has in his own labour. . . is the original foundation of all property. . . ." And Bentham noted that "It is this right that has overcome the natural aversion to labour. . . ." Since acquisitiveness and indolence were regarded as inborn and ineradicable human traits, security of property had to be preserved if incentive was not to be destroyed and the producton of goods discouraged. Both French revolutionaries and English gentry could be rallied to such a defense of property; and the American Constitution as well as the French Declaration of the Rights of Man and of the Citizen, both of them liberal testaments, charge government with basic responsibility for its protection.

The role of government. On the political side the guiding principle of historical liberalism has been an undeviating insistence on limiting the power of government. Inspired by the need to remove the state from destructive interference with the economic life of the community, the principle degenerated, under the influence of men like Herbert Spencer, into a doctrinaire form of antistatism. Spencer would even forbid government, either local or national, to assume responsibility for the paving, lighting, and sanitation of cities. Even the less doctrinaire Bentham's sole advice to the state was to "Be quiet," and Edmund Burke—who in this context must be reckoned a liberal—declared that "It is in the power of the state to prevent much evil; it can do very little positive good. . . ." Thomas Paine, eloquent pamphleteer for the American Revolution (of which Burke approved), wrote in his *Common Sense* that "Government, even in its best state, is but a necessary evil . . . ," and generations of Americans almost ritualistically repeated Thomas Jefferson's advice that that government is best that governs least.

The prevailing view was perhaps best spelled out in Adam Smith's enumeration of government functions. Smith assigned the "sovereign" three tasks: to protect the group from outside violence; to protect individual members of society from the injustices or oppressions of their fellow citizens; and, finally, to erect and maintain "those public institutions and those public works, which, though they may be in the highest degree advantageous to a great society, are however of such a nature, that the profit could never repay the expense to any individual, or small number of individuals. . . ." An agenda more faithful to Adam Smith's intent would provide a central place for the enforcement of contracts, without which voluntary individual arrangements could hardly replace government fiat in the conduct of economic affairs.

In general, liberals believed that government must not do for the individual what he is able to do for himself. Legislation like Britain's Ten Hours Act (1847), which limited the labour of women and children to 58 hours a week, was denounced by the English jurist A.V. Dicey as late as 1905 as socialistic. Criticizing the Adulteration of Food or Drink Act and the Sale of Food and Drugs Act of 1899, he contended that such laws safeguard individuals from mistakes "which often may be avoided by a man's own care and sagacity" and therefore "rest upon the idea . . . that the State is a better judge than a man himself of his own interest . . ." (*Law and Public Opinion in England,* 2nd ed.; 1914; pp. 237–238; 263–264). Such views were even more prevalent in the United States.

Separation of powers. The institutional devices by means of which liberals sought to limit government to the exercise of its proper functions were numerous: federalism (though not in France and Britain), bicameralism, the separation of powers. The last of these, that is, the distribution of power among such functionally differentiated agencies of government as the legislature, the executive, and the judiciary, and the system of checks and balances by which it was accomplished, was given its classic embodiment in the U.S. Constitution and its political justification in that brilliant apology for the Constitution *The Federalist* (1787–88), by Hamilton, Madison, and Jay. Montesauieu had already formulated such a doctrine in his famous De *l'esprit des loix* (1748; Eng. trans., *The Spirit of Laws,* 1750), receiving the idea from Locke, who had not developed it fully.

Such a separation of powers could have been achieved, of course, through a "mixed constitution," that is, by having a monarch, a hereditary chamber, and an elected assembly share in power with some appropriate differentiation of function. The Greek historian Polybius hailed such a mixed government as the glory of the Roman constitution, and Blackstone (misled perhaps by Montesquieu) in his famous *Commentaries on the Laws of England* (1765–69) extolled its embodiment in the constitution of England, as Burke was to do later with greater eloquence. But it was precisely despotic kings and functionless aristocrats (more functionless in France than in England) who thwarted the interests and ambitions of the middle class, which turned, therefore, to the principle of majoritarianism.

Liberal conflicts of interest. The greatest check on government is, of course, the threat of dismissal by its constituents. But in determining the crucial question of who the constituents are to be, classical liberalism fell victim to an ambivalence, torn between the great emancipating tendencies generated by the revolutions with which it was associated, and middle class fears that democracy would undermine private property. Most 18th- and 19th-century liberal spokesmen feared popular sovereignty and for a long time suffrage was limited to property owners. In Britain even the important Reform Act of 1867 did not completely abolish property qualifications. France, for her part, bore revolutionaries but suckled reactionaries: although the Revolution of 1789 proclaimed the ideal of universal manhood suffrage and the Revolution of 1830 reaffirmed it, there were no more than some 200,000 qualified voters in a population of about 30,000,000 during the reign of Louis-Philippe, "citizen king" installed by the ascendant bourgeoisie in 1830. And, in the United States, Jefferson's brave language in the Declaration of Independence notwithstanding, it was not until 1860 that universal white male suffrage prevailed.

Although by the time of the Revolution he had changed his opinion, Benjamin Franklin spoke for the Whig liberalism of the Founding Fathers when he observed that "as to those who have not landed property the allowing them to vote is an impropriety." John Adams in his famous *Defense of the Constitutions of Government of the United States of America* (1787) was more explicit, finding that, if the majority were to control all branches of government, "Debts would be abolished first; taxes laid heavy on the rich, and not at all on others; and at last a downright equal division of everything be demanded and voted." Thomas Babington Macaulay spoke for English Whigs when he found universal suffrage "incompatible, not with this or that form of government, but with all forms of government." French statesmen like François Guizot (1787–1874) and Louis Adolphe Thiers (1797–1877) expressed similar sentiments and on the rest of the continent universal suffrage was for the most part a remote ideal until the turn of this century.

The fear
of majority
tyranny

Objections to democracy were not limited to misgivings about the fate of private property. Many liberals genuinely feared the potentialities for tyranny latent in democracy. If the will of the majority is to be supreme, everyone will be at its mercy. Benjamin Constant (1767–1830), noted French diplomat, expressed a general concern when he observed that from the point of view of the individual it makes no difference whether he is tyrannized by a single despot or by the totality of individuals composing his society; he is oppressed just the same. Indeed the latter could well be worse: tyrannicide might rescue him from an individual oppressor and, in any event, others would commiserate with him; whereas if oppressed by a large majority, he would have no comparable recourse or comfort.

Despite such misgivings, the voices of Thomas Paine and Jefferson, of Rousseau and de Tocqueville, and of the English philosophical radicals led by Bentham and James and John Stuart Mill finally prevailed among the liberal philosophers. But the democratic principle that they espoused had first to be reconciled with the liberal requirement that power be limited. The problem was to accomplish this in a manner consistent with the democratic ideal, that is, without doing violence to the majoritarian principle and in conformity with Bentham's dictum that each person is to count as one and no one as more than one. How, since hereditary elites were discredited, could the power of a majority be checked without giving greater voice to property owners or some other kind of "natural" elite?

The liberal formula. The essence of the liberal solution is twofold. It lies partly in making the decision of any given majority subject to the concurrence of other majorities distributed over a period of time. The majority that elects a president of the United States, for example, is different from the majority that two years before elected one-third of the Senate and two years later elects another third. Likewise two-thirds of the senators are elected by a majority other than the majority by which members of the House of Representatives are elected. These groups, in turn, are checked by the Constitution, which was approved and later amended by majorities no longer alive. While an act of Britain's Parliament is forthwith a part of the British constitution, Parliament before acting on a highly controversial issue of great concern to the country will seek a mandate from the people, that is to say, a majority other than the majority that elected it. Thus, the "people" to be consulted in a liberal democracy, if they are not quite that partnership envisaged by Burke ". . . between those who are living, those who are dead, and those who are to be born," are not either, except in a revolutionary crisis, a "momentary aggregation" whose sovereign will may be ascertained by a plebiscite. Burke's characterization of democracy as "the vulgar practice of the hour" may well apply to those spontaneous assemblies of the people to which Rousseau would assign plenary power; it can be denied that it applies to the mainstream version of liberal democracy that is essentially *constitutional* democracy, that is to say, democracy in which the power of a current majority is checked by the verdicts of majorities that preceded it.

The second part of the solution is related more directly to the initial inspiration of liberalism, its basic commitment to the autonomy and integrity of the individual, which the limitation of power is, after all, intended to preserve. In the liberal understanding, the individual is not only a citizen who shares a social compact with his fellows; he is a person and, as such, he possesses rights that the state may not invade. Even as a citizen, he must, if majoritarianism is to be meaningful, possess such rights. Majorities do not form in a vacuum. Unless a majority verdict is some miraculous coincidence or spontaneous merger of individual judgments—which it is not—it can come about only if individuals are free to some extent to formulate and express and exchange their views. This involves, beyond the right to speak and write freely, the freedom to associate and organize and, above all, freedom from fear of reprisal. But the individual has rights apart from his role as citizen. These are rights that secure his personal safety and hence his protection from arbitrary arrest and punishment. And beyond these are those rights that preserve large areas of *privacy.* In a liberal democracy there are affairs that do not concern the state, even if the state's interest in them reflects the will of an overwhelming majority. Such affairs may range from the worship of God, to works of art, to how parents raise their children. And for the liberals of the 18th and 19th centuries they included, above all, most of those activities in which individuals engage in production and trade.

Classical liberals differed in their interpretation of individual rights—whether to understand them as "natural" (Locke) and therefore "inalienable" and "indefeasible," to justify them as functional (Bentham) or traditional (Burke). But eloquent and persuasive declarations affirming such rights were embodied in the English Bill of Rights of 1689, the American Declaration of Independence and Constitution, the French Declaration of the Rights of Man and of the Citizen of 1789, and the basic documents of nations throughout the world that later used these as their models. Freedom thereby became more than the right to make a fractional contribution in an intermittent mandate to government; it designated the right of men to live their own lives.

The problems of the dispossessed

Rhetoric and reality rarely coincide. Liberals were not usually troubled over the small numbers by whom, in fact, such freedom was enjoyed, and the masses were still too inarticulate to remind them. In the dawn of the Industrial Revolution, the blessings of liberty must have seemed remote to millions of brutally exploited factory workers huddled together in the slums of their dreary cities. Liberals have been accused of concentrating exclusively on the property right to the neglect of such abuses, and in general, few liberals paused to ponder how the freedom they cherished would be used, and it did not occur to them, as it has to a later generation of libertarians, that such freedom brings with it a heavy burden of choice and decision. Finally, in their concern for the individual, liberals depicted him too simply as an isolated monad. and society as a collection of such monads, failing to reckon with the myriad social relationships through which individuals achieve identity.

ACHIEVEMENT AND FAILURE

In historical perspective it can be seen that the complex of forces, of which classical liberalism was the rationalization, wrought great changes. The feudal system was destroyed. Capitalism replaced the static society of the Middle Ages. A functionless aristocracy was deprived of its privileges. Tyrants were challenged and curbed. The middle class was left free to employ its energies in expanding the means of production and vastly increasing the wealth of society. Representative government came into its own. As they set about limiting the sovereign power, liberals converted the ideal of constitutional government into a reality, and they developed a doctrine of individual rights, including the right to worship freely, the right of a free press, of free speech, and of free assembly, which lies at the heart of modern democracy. J.S. Mill's essay *On Liberty* (1859) is justly celebrated as one of the great testimonials to civil liberties.

However, vast economic changes, first in Great Britain and later in the United States, led increasingly at the turn of this century to disenchantment with the principal economic basis for liberalism—the ideal of a market economy. (This ideal had never evoked comparable loyalties on the continent of Europe.) The advent on a large scale of absentee ownership made it increasingly difficult to invoke a functional justification for many forms of private property. Multitudes whose real bargaining power fell far short of what it was in theory—especially those seeking work—did not actually enjoy the "free choices" postulated by the economists. Economic man's "pecuniary sagacity" (Veblen) fell far short of the idealizations of textbook writers; and modern psychology suggests that he is at least as much a creature of impulse, habit, and custom as he is a rational calculator with his eye on the main chance. The often impenetrable complexity of goods offered on the market in an economy where transactions are no longer simple affairs of horse-trading, not to mention the mendacity of much advertising, seemed to make the consumer more a subject than a sovereign. Reality failed to approximate the state of free competition envisaged by the classical economists. Orthodox liberal economists have accordingly referred with increasing frequency to "frictions" and "exceptions" and have employed qualifications ("in the long run"; "other things being equal") to save their generalizations. The result has been an abstract science that a new generation of liberals and multitudes of socialists came to regard as having only limited relevance to the real world.

Concentration of wealth and irrational economies

Worst of all, according to its critics, the profit system concentrated vast wealth in relatively few hands, with several decisively adverse consequences. First, great masses of people failed to benefit from the wealth flowing from mines and mills and lived under impoverished conditions that became increasingly anomalous in an affluent society. Second, since those who alone could consume the output of a vastly expanded productive system lacked the purchasing power, the system, after other markets were glutted, endemically failed to realize its productive potentialities and recurrently came to a near halt in periods of stagnation that have come to be called "depressions." Finally, those who owned the means of production, or their managers, were endowed with vast power that could be used to overwhelm the individual as surely as the power of a 17th-century despot, thanks to the device of incorporation on a scale far beyond the simple requirements of efficiency and economy in production. In short, the near atrophy of government achieved in the 19th century had left a vacuum that private interests readily filled. Businesses were effectively organized and some of them used their power to influence and control government, to manipulate an inchoate electorate, to limit competition, and to obstruct substantive social reform. Some of the same forces that had once released the productive energies of Western society now restrained them; some of the very energies that had demolished the power of despots now nourished a new despotism. Such, at any rate, was the verdict of 20th-century liberals and such were the conditions that led them to oppose private collectivism by supporting a positive role for government and encouraging the formation of power centres outside business and government.

CONTEMPORARY LIBERALISM

The contemporary variant of liberalism is even more amorphous than the classical. There are no "fathers" such as John Locke or Adam Smith. In Germany and the Scandinavian countries where socialists, even though they trace their ancestry to Marx, are overwhelmingly revisionist, it is difficult to distinguish between their program and programs elsewhere designated as liberal. British socialism never embraced Marx and, as the Labour Party grows less doctrinaire, it is increasingly difficult to distinguish it from the Liberal Party, which largely accounts for the decline of the latter. U.S. liberal social legislation since the crash of 1929 has been notably formless. But even so, the outlines of contemporary liberalism are fairly discernible.

Critique of the market. Cognizant of the real achievements of the profit system, liberals do not seek its abolition, only its modification and control. They find no fixed line laid up in heaven eternally dividing the private and the public sectors of the economy; the determination, they contend, must be by reference to what works. The spectre of regimentation in completely planned economies and the dangers of bureaucracy even in mixed economies deter them from jettisoning the market and substituting an omnicompetent state. On the other hand—and this is a basic difference between classical (or neoclassical) and contemporary liberalism—most liberals now believe that the dispensations of the market, as it has in fact operated, must be supplemented and corrected in substantive ways. They hold that the rewards dispensed by the market are too crude a measure of the contribution many or most people make to society, and that the needs of those who lack opportunity or are physically handicapped are ignored. They contend that enormous social costs incurred in production are not reflected in market prices, and that resources are used wastefully. Not least, liberals charge that the market biasses the allocation of human and physical resources in the direction of satisfying superficial wants (for oversized motor cars in annual models, changing fashions in attire, and unnecessary gadgets), while basic needs (for schools, housing, rapid public transit, sewage treatment plants) go unmet. Finally, although liberals believe that prices, wages, and profits should continue to be subject to negotiation among the interested parties and responsive to conventional market pressures, they insist that price–wage–profit decisions affecting *the economy* as a *whole* must be reconciled with public policy.

The liberal program. To achieve a juster distribution of rewards, liberals have relied on two major strategies. First, they have promoted the organization of workers and consumers to improve their power to bargain with employer-producers. Such a redistribution of power has had political as well as economic consequences, making possible a party system in which at least one party is responsive to the interests of wage earners and consumers. Second, enlisting the political support of the economically deprived, liberals have evolved the so-called welfare state, with its panoply of social services "from the cradle to the grave."

Foundations of the welfare state

Social legislation, beginning with free public education and workmen's accident insurance, now includes support for all who are physically and mentally handicapped, programs of old-age, unemployment, and health insurance, minimum-wage laws, and—for the most part still in the blueprint stage—guaranteed annual incomes. Such legislation is most comprehensive in the Scandinavian countries and, among countries with mature economies, possibly least comprehensive in the United States where social legislation at the federal level was virtually ignored until passage of the Social Security Act of 1935.

Liberals have been less successful in correcting what they regard as an irrational schedule of priorities by using the taxing powers of government to obtain greater allocations for the public sector of the economy. They have been least successful, at any rate in the United States, in persuading the business community and labour unions to accept government participation in pricing and wage decisions.

Initially, the quest for these objectives was viewed as requiring a redistribution of wealth to be achieved by steeply graduated income and death (inheritance) taxes—a program likely, if it were to become confiscatory, to evoke the unlimited resistance of high income groups. Increasingly, as modern technology promised mature economies miracles of abundance, attention shifted to the institutional failures that kept such economies from fully realizing their productive potentialities, especially during periods of mass unemployment and depression. The culmination of this effort was the White Paper on Employment Policy produced by Britain's wartime coalition government and, in the United States, the Employment Act of 1946, which goes well beyond the British, declaring it to be "the continuing policy and responsibility of the Federal Government to use all practicable means . . . to promote maximum employment, production, and purchasing power." Thereafter the old rhetoric about "sharing the wealth" gave way to concentration on growth rates as liberals, inspired by J.M. Keynes' General Theory of Employment, Interest and Money, urged the use of fiscal policy—*i.e.*, use of the government's power to borrow, tax, and spend—not merely to counter contractions of the business cycle but to encourage expansion of the economy. Here, clearly, was a program less disruptive of class harmony and the basic consensus essential to a democracy than the old Robin Hood method of "taking from the rich and giving to the poor."

Industrialism reconsidered

In the 1960s the emphasis of liberals again shifted as it became more and more evident that expanding production is not an unmixed blessing. The litany is now a familiar one. The same industry that produces our wealth pollutes our rivers, lakes, and atmosphere. Its gleaming artifacts become mountains of junk and it menaces the ecological balance of nature. It concentrates millions in drab cities that, in the United States at least, are being evacuated by those who can afford to escape to the suburbs. The result is a daily movement of traffic, choking the highways, poisoning the air, jangling the nerves. The inventory could be extended indefinitely. Much of the "wealth" produced by industry hardly justifies such consequences.

Some criticism goes deeper. It is urged that, quite apart from its disastrous impact on the environment, modem technology deracinates man, depriving him of his sense of identity, chaining him to a treadmill, trapping him in a depersonalized, regimented, over-organized society. The voice of the romanticist, denouncing preoccupation with production as a bourgeois aberration or an archaic Protestant ethic and urging a return to the relaxed, simple life, is once again heard. That voice is often found persuasive, it so happens, by a new generation of youthful intellectuals and vagabonds.

Most liberals contend that environmental disruption is not a necessary consequence of expanding industry but of a failure to subordinate the quest for quick profits to the requirements of intelligent planning. The "fallacy of romantic regression," as the American psychologist Kenneth Keniston has called it, is also rejected. Nevertheless, there is increased respect for Freud's reminder in *Das Unbehagen* in der *Kultur* (Eng. trans. Civilization and Its Discontents, 1930) that "power over nature is not the only precondition of human happiness," and more and more concern is expressed for the "quality" of life. However, Freud went on to observe that, if happiness requires more than power over nature, this "is no ground for inferring that technical progress is worthless from the standpoint of happiness." Mainstream liberals have agreed.

THE FUTURE OF LIBERALISM

At present the traditional coalition on which liberals have relied is in disrepair in many countries. Ethnic minorities have become confused and divided by the separatist creed of their more militant leaders; the academic community is traumatized and in a state of turmoil; and labour unions lack a good deal of their old dynamism; even the once engagé artist has been lost to aestheticism and esotericism. The increasing polarization between right and left finds the liberals attacked on both flanks, but the appearance of beleaguerment may well be deceptive. Much of the liberal program has in fact become public policy. When, in the 1930s, Pres. Franklin D. Roosevelt established the National Resources Planning Board, it was called un-American by conservatives, its budget was slashed, and it was finally abolished. Today, although most conservatives might resist liberal proposals to establish a council on national goals, they would no doubt support a national agency to plan the use of natural resources. Despite appearances, Western society could be on the eve of less, rather than more, polarization.

All of this suggests a new source of strength for liberalism epitomized in what has been called the "end of ideology." Whether the movement of Western capitalist nations toward mixed economies and the Soviet Union's flirtation with the profit motive is indicative of such a trend need not be explored here. But, clearly, both socialists and conservatives in western Europe (and the British Commonwealth) are much less prone to apply pre-established dogma to new problems. This is equally true of Conservatives and Labourites in Britain. And, except for the far right and left, there is a growing tendency in the United States to reject doctrinaire approaches to social problems. Ideology may not be dead, but it appears to be in decline. If the result is a pragmatic, experimental temper in which old principles are adjusted to new needs and dissent is not identified with disloyalty, this is very much in the liberal mood.

Changing policies, enduring values

The expansion of government power and responsibility sought by liberals today is clearly opposed to the contraction of government power and responsibility sought by liberals yesterday. The content of liberalism varies with varying conditions: liberals may one day challenge and another day cherish the church; in one age they may seek less government intervention in economic affairs, in another age more; they have been hospitable to the interests and ambitions of the business community, under changed circumstances they may be hostile; for decades they have preached the virtues of labour unions, they may one day consider their vices. But in every case the inspiration is the same: a hostility to concentrations of power that threaten the freedom of the individual and prevent him from realizing his potentialities; a willingness to re-examine and reconstruct social institutions in the light of new needs. This willingness, tempered by aversion to sudden, cataclysmic change, is what sets the liberal off from the radical, who often ignores its hazards. Also the very eagerness constantly to entertain and encourage useful change distinguishes the liberal from the conservative. If the content of liberalism varies, the above listed characteristics constitute its distinctive and enduring form.

The 18th-century French philosopher Condorcet could write that "human perfectibility is in reality indefinite" and that "the progress of this perfectibility, henceforth independent of any power that might wish to stop it, has no other limit than the duration of the globe upon which nature has placed us." Another French philosopher of the Enlightenment, Helvétius, wrote that "to be happy and to be powerful is only a matter of perfecting the science of education." In his ***Autobiography***, John Stuart Mill, reminiscing about the elder Mill, writes:

> So complete was my father's reliance on the influence of reason over the minds of mankind, whenever it is allowed to reach them, that he felt as if all would be gained if the whole population were taught to read, if all sorts of opinions were allowed to be addressed to them by word and in writing, and if by means of the suffrage they could nominate a legislature to give effect to the opinions they adopted. He thought that when the legislature no longer represented a class interest, it would aim at the general interest, honestly and with adequate wisdom . . .

Commenting on the faith of the mid-19th century, Henry Adams noted: "Education was divine, and man needed only a correct knowledge of facts to reach perfection . . ."

Sobered by the tragic events of this century and informed by new psychological insights into man's biasses and perversities, a chastened and far more sophisticated liberalism no longer shares the naive confidence of most classical liberals in man's rationality and perfectibility and in the inevitability of progress. Most of today's liberals are more likely to heed those who warn that human nature is ineradicably flawed than heed those who hope that man may be persuaded to apply the scientific method to the solution of social problems and thereby find contentment. There is a strong suspicion that if man had no serious social problems he would invent them. Nevertheless, the strong commitment of liberals to social reform suggests a persistent optimism and a belief that man can control his fate and build a better world. To this extent the Heavenly City of the Philosophers still beckons them.

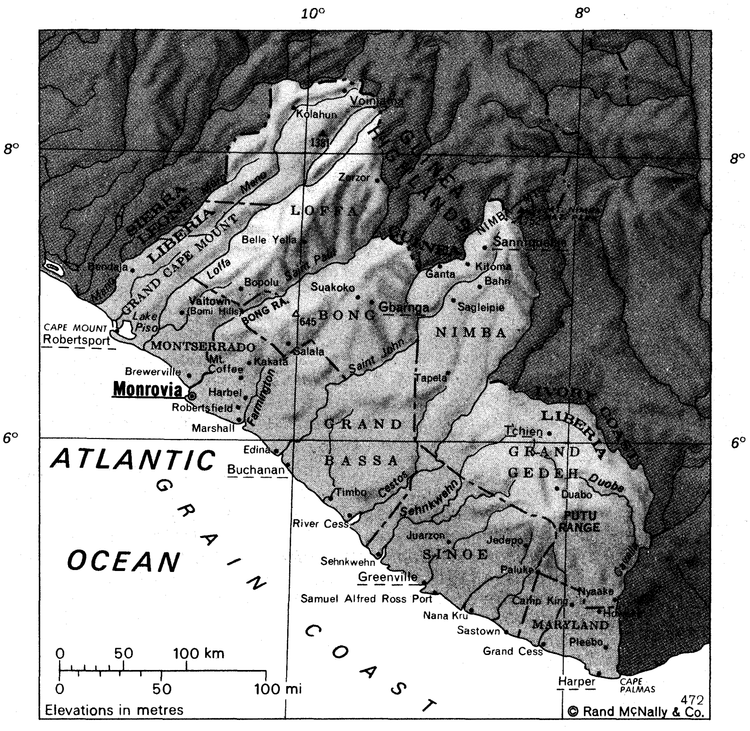
Liberia

The oldest republic on the African continent, and the only black African state never to have been subjected to colonial rule, Liberia is situated on the West African coast in the tropical rain forest region. It has an area of about 43,000 square miles (111,400 square kilometres) and a population of about 1,500,000. It is bounded by Guinea to the north, Sierra Leone to the northwest, the Ivory Coast to the east, and the Atlantic Ocean to the south and west. The capital is the port city of Monrovia (population about 100,000).

Formerly relying heavily upon its rubber production, Liberia, since World War II, has also become a major producer of iron ore. Liberia has preserved a traditional friendship with the United States, which, during the 19th



LIBERIA

century, played a role in the country's foundation; Liberia's currency is the United States dollar, with Liberian coins being used in smaller denominations. Under the presidency of William V.S. Tubman (1944–71), an Open Door economic policy encouraged Western investment. Liberia is a founding member of the United Nations as well as of the Organization of African Unity (OAU).

THE LANDSCAPE

Physical features

Physiography. *Relief.* Liberia has a somewhat complex relief, and its physical features are not uniform. The coastal terrain, which is 350 miles long and which varies from 15 to 25 miles in width, is sandy, low, and interspersed with lagoons and swamps, as well as with occasional rocky promontories. Behind this region is rolling hill country. Farther inland there occurs a thin strip of steep scarps and hills, about 20 miles wide, and trending northeast to southwest. This is followed by a relatively flat highland about 1,500 to 2,000 feet in height, cut into hills and valleys by erosion. Finally, farthest from the coast, in the northwest and centre, is a mountainous region of which one of the most striking features is Mt. Nimba, at the Guinea–Liberian border, which rises to a height of 4,500 feet (1,372 metres) on the Liberian side and which contains rich deposits of iron ore. The Mano and Morro rivers form the northwestern boundary of the country, and the Cavalla River forms the eastern boundary. Apart from these, there are five major rivers, all of which drain into the Atlantic Ocean—the Lofa, St. Paul, Farmington, St. John, and Cestos rivers. The rapids on the St. Paul River, 17 miles northeast of the capital, have been harnessed as a source of hydroelectric power.

Rocks and soils. Liberia forms part of the Precambrian Shield, an ancient crystalline rock formation 2,700,000,000 to 3,400,000,000 years old, composed of granite, schist (a coarse-grained rock containing mica), and gneiss (another coarse-grained rock, in which bands of granular minerals alternate with bands of schistose minerals). The shield underlies the entire African continent and lies exposed over about one-third of its surface. Specimen granitic rocks from western Liberia have been found to be between 2,500,000,000 and 3,600,000,000 years old. In Liberia, the shield has been subjected to intense folding and faulting; it is interspersed with iron-bearing formations known as itabirites. Along the coast lie beds of sandstone, while intrusive rocks crop out, forming such promontories as Cape Mount, which is 1.050 feet (320 metres) high, Cape Mesurado, and Cape Palmas. Monrovia, the capital city, stands on a ridge of diabase, a basaltic (dark-coloured, fine-grained) rock, about four to six miles (six to nine kilometres) long and one to two miles wide. Diabase and gabbro (a dark-coloured, coarse-grained igneous rock) occur in the interior of the country where, as a result of geological eruptions, they have intruded into fissures in the older rock in long and narrow masses.

The soil is an evenly disposed bed of laterites (rust-red aluminum and iron oxides), which have been eroded and repeatedly leached as a result of heavy rainfall. Because of its thin top soil it is more suited to the growth of tree crops than of food crops.

Temperature and rainfall

Climate. The climate, especially on the coast, is warm and humid all year round. It is dominated by a dry season from November to April, and by a wet season from May to October. A minor "middle dry" season occurs from mid-July to August. The dusty and dry desert winds, known as the harmattan, which blow from the Sahara to the coast in December, also influence the climate. Temperatures range between 65° and 85° F (18" to 29° C). The greatest amount of rainfall, 205 inches (5,200 millimetres) occurs on the Cape Mount Promontory; rainfall diminishes inland to about 70 inches (1,775 millimetres) on the central plateau. The interior has hot but pleasant days and cool nights during the dry season.

Vegetation. Liberia has year-round evergreen vegetation. Its tropical rain forest contains some trees that attain heights of 200 feet (61 metres). Many trees are of commercial value, but natural stands of a single species are rare, thus preventing easy exploitation by the lumber industry. Forestry operations are therefore concentrated on scattered species. Lumber is put to a variety of uses. Termite-resistant woods, such as red ironwood, camwood, and whismore (a large tree resembling mahogany, but tougher), are used for construction, while several African mahoganies are used for cabinet and veneer woods. Farmers, in order to practice crop rotation, cut or burn 50,000 acres (20,000 hectares) of often valuable forest trees each year. As a countermeasure, a Forest Conservation Act was passed in 1953. Other trees of value are rubber, cocoa, coffee, and the raffia palm.

Animal life. Liberia's tropical rain forest is not conducive to an abundant animal life. The monkey, chimpanzee, some species of small antelope, and various rodents are to be found. There is also a pygmy hippopotamus and several species of anteater. Elephants, bush cows (short horned buffaloes), and leopards are present, but gradually disappearing. There are many reptiles and at least eight poisonous snakes, among them the black cobra and the causus viper, or night adder. Three types of crocodiles have been identified. Scorpions and lizards are numerous, and there are several unique species of bats and birds. Fish are also numerous. Pond-fish culture is being encouraged.

The landscape under settlement. There are more than 2,000 villages, the majority of which are concentrated in Bong County in central Liberia, Lofa County in the northwest, and in the coastal county of Montserrado. Different architectural styles are used by different tribes. The huts in the villages of the Vai people, for example, are both round and rectangular and are handsomely decorated with clay and geometric designs. Traditional activities in the villages include farming, hunting, and fishing, although weaving and carving are also practiced.

Monrovia

The capital of Liberia, Monrovia, founded in 1822, is situated on the left bank of the St. Paul River. Standing on the ridge formed by Cape Mesurado, it commands an imposing view of the Atlantic Ocean. The city proper, although not precisely defined, occupies an area of about one square mile, while its outlying districts and suburbs occupy another four square miles. The population of Monrovia is about 100,000. The old style of architecture that once characterized it, reminiscent of that of the southern United States before 1860, is now fast disappearing, giving way to contemporary styles of housing. Monrovia was founded by Liberian settlers from the United States after an earlier attempt to settle near Sierra Leone had failed. It is the political, administrative, and industrial centre of Liberia. All of the tribes of Liberia are represented in its population, as also are other groups, including refugees, African nationals from other countries, and Europeans. Elsewhere, some mining towns have been built in rural areas since World War II.

People and population. The group most closely associated with the founding of the Liberian state were Negroes from the New World, known historically as Americo-Liberians. Most of them migrated to Liberia between 1820 and 1865, during and immediately after the suppression of the transatlantic slave trade. Other Negroes from the Americas have since then continued to migrate intermittently. Out of Liberia's population of about 1,500,000, however, they number fewer than 50,000. The government is still controlled by this group, although a unification and integration policy that encourages equal opportunities for all citizens, tribal and nontribal, is slowly effacing divisions.

The African tribes may be classified into three linguistic groups, the Mande, the Kru, and the Atlantic (West Atlantic) groups. The Mande are themselves divided into two groups, the Mande-tan (so named because the number ten is *tan* in their language), called the Nuclear Mande by anthropologists, who are located not only in northwest Liberia but also in Senegal, Mali, Guinea, and Sierra Leone; and the Mande-fu (so named because the number ten is *fu* in their language), known to anthropology as the Peripheral Mande. Prominent among the Mande-tan are the Malinke (Mandingo). The Mande-fu group, who inhabit the northern and central region of Liberia, include the Loko, Gbande, Gio, Kpelle, Toma (also known as Buzi or Loma) Mano, Mende, and Vai tribes. The Kru include the Bassa, De, Grebo, and Kru tribes of the coast, and the Kran Padebu, Sapo, Sikon, and other tribes occupying the interior and southern half of the country. The Atlantic group includes the Gola, Kissi, and other tribes in the north. Traditionally, different tribes have shown a preference for different shapes of huts, the Mande, for example, preferring round dwellings with conical thatched roofs, while the Kru prefer rectangular houses. Architectural borrowings have, however, occurred in both directions. The Vai are renowned for having invented an alphabet in the 19th century; during World War II this alphabet was borrowed and improved on by the Germans, who, having acquired knowledge of it from German traders in the Cape Mount area, used it for a code. The De, Kpelle, Mano, Mende, and Vai, among others, have secret societies known as the Poro school, for men, and the Sande school, for women. These institutions exercise educational, political, legal, and religious functions. In effect, only the Bassa, Kru, and Malinke are reputed not to have had Poro in the past. The Kru tribes are organized by age sets, or generations; long distinguished by militarism, they opposed the Liberian government in Monrovia until the 1930s.

Tribal dwellings

Liberia, Area and Population

	area*		population

*Area figures given purportedly represent land area, although some inland water appears to be included. Second total is generally accepted total area of Liberia. †All area and population figures for the commonwealth district of Monrovia are included in Montserrado County. ‡Figures do not add to total given because of rounding.
Source: Official government figures.

There is no adequate reporting of births and mortality rates. In 1969 only 12,000 births and fewer than 2,000 deaths were reported. Immigration from other West African countries and elsewhere has occurred in recent years. No immigrants were admitted in 1969. Emigration, especially among the population under 45, appears to be increasing.

Population distribution is markedly uneven, amounting to less than the national average of 40 persons per square mile in many areas. There is a concentration of about 100,000 per square mile in the capital and about 6,000 per square mile in mining centres. This uneven distribution is expected to continue as settlement follows the siting of industries, resulting in either permanent or seasonal migration from rural areas.

The national economy. Liberia's buoyant economy has been attributed to the Open Door Policy, which encourages foreign investment, promulgated by the Tubman administration. Government expenditure increased from barely $1,000,000 on the eve of World War II to $60,000,000 in 1970. Liberia's rapid rate of growth has been second only to that of Japan in recent years. The fact that Liberia's currency is based on the dollar has, however, placed it in an isolated economic zone. Liberia is not a member of any major African economic or free-trade bloc, although it is a member of a not-fully-operative free-trade grouping to which Sierra Leone, Guinea, and the Ivory Coast also belong. It is also not a member of any international trade grouping.

Iron ore production

Liberia is the leading producer of iron ore on the African continent and is one of the principal exporters of iron ore in the world. The registration of foreign shipping under a Liberian "flag of convenience" has established Liberia as the foremost nation in terms of registered shipping tonnage. Liberia nevertheless remains a primarily agricultural and underdeveloped country.

The country is, however, rich in natural resources, although the distribution of wealth after production is uneven. The coastal districts receive a far greater share of economic benefits than the hinterland, after which the county capitals are the next beneficiaries.

Mineral resources. Since 1951 Liberia has been a producer of rich iron ore. Reserves amounted to 20,000,000 tons of magnetite (magnetic iron ore) and hematite (the principal iron ore), containing 66 percent of pure iron, in the Bomi Hills; 100,000,000 tons of red and black itabirites (iron-bearing formations), with an iron content of 55 percent, 50 miles away from Monrovia at Mano River; between 200,000,000 and 250,000,000 tons of poorer ores, with an average iron content of 38 percent, in the Bong Range; and 300,000,000 tons of ore, with a content of from 60 to 70 percent of iron, in the Nimba Range in northeastern Liberia. Other reserves exist at Kitoma Mountain, south of the Nimba range; in the Wologizi range in northwest Liberia, and in the Putu range in eastern Liberia. Other minerals including diamonds, gold, cyanite (a silicate of aluminum, with thin bladelike crystals), and barite, while there are possible oil reserves off the coast.

Biological resources. About half of the land area is suitable for cultivation. It is estimated that 2,000,000 acres (800,000 hectares) at a time can be devoted to growing food crops, and a further 5,000,000 acres (2,000,000 hectares) of low land can produce either tree crops or food crops, while yet another 5,000,000 acres on rolling or hilly terrain is suited to growing tree crops. The climate favours rubber production. The rain forest type of vegetation is unsuitable for the raising of livestock but produces fine hardwood timber, especially in the east of the country, but also in the centre and in the west.

Agriculture, forestry, and fishing. Both rice and cassava, the principal food crops, are cultivated. More than 500,000 acres (200,000 hectares) are planted with these crops each year; after use the land is left to lie fallow for a decade or more, so that altogether more than 10,000,000 acres (4,000,000 hectares) are in periodic use. About 200,000 tons of rice are produced annually, but this is insufficient to meet the growing demand. The deficit is sometimes met by imports of rice from the United States and Egypt. Taiwanese rice experts are practicing experimental farming in order to increase production, and rice strains from the Philippines and Sri Lanka (Ceylon) have been introduced.

Rubber production

Rubber is the main cash crop. In 1926 the Firestone Tire and Rubber Company of the United States obtained the concession of up to 1,000,000 acres (400,000 hectares) for rubber cultivation. The concession consists of two estates—a large estate at Harbel in Montserrado County, 15 miles (24 kilometres) inland, and a small estate near the Ivory Coast frontier. More than 80,000 acres (30,000 hectares) are in production on these sites alone, apart from additional acreage elsewhere, which is either in use by other U.S. concerns, notably the B.F. Goodrich Company, or by the 4,000 Liberian rubber farmers, who occupy about 130,000 acres (50,000 hectares). Altogether over 250,000 acres (100,000 hectares) of rubber trees are under cultivation. Coffee, both of the robusta variety and of the local variety known as liberica, is also grown, as are cocoa, kola nuts, palm oil, palm kernels, sugar cane, peanuts (groundnuts), and cotton. Cattle, goats, pigs, and poultry are also raised. Although between 1,000,000 and 1,500,000 cubic feet (28,000 and 42,000 cubic metres) of timber are produced a year, exploitation of the forest resources is difficult, chiefly because of the scarcity of good roads and shortage of labour.

Kru and Fanti fishermen, the latter from Ghana, have traditionally been the suppliers of fish to coastal areas; two Liberian fishing companies now supplement these tribal fishing activities. Inland fish-breeding ponds have been introduced in order to provide a source of protein.

The Nimba Range deposits

Mining. To export the iron ores, iron interests have built special railroads. The Bomi Hills mine, which is American-operated, is linked to the port of Monrovia by a narrow-gauge railroad 43 miles (69 kilometres) long. A further 49-mile (79-kilometre) length of line connects the Mano River workings to the Bomi Hills. The Bong Range mine, which is operated by a German company, is linked to Monrovia by a 50-mile (80-kilometre) standard-gauge line. The Nimba Range reserves, which constitute one of the largest and richest iron ore deposits in the world, are operated by the Liberian American-Swedish Minerals Company (LAMCO) in conjunction with the Bethlehem Steel Corporation of the United States. The reserves have almost no overburden (other material covering the deposits), impurities are insignificant, and the ore can be used untreated. It is exported from the port of Buchanan, to which the ores are sent via a 168-mile (270-kilometre) standard-gauge railroad.

Manufacturing. The number of manufacturing enterprises has increased, particularly since 1960. Most of them serve the local market. Near the port of Monrovia there is a petroleum refinery as well as a cement plant. Other industries include an explosives factory, to supply the iron mines, and plants engaged in tire retreading, paint manufacturing, tuna processing, milk reconstituting, and manufacturing pharmaceuticals. Bricks, tiles, cement blocks, lumber and furniture, soap, and footwear are also manufactured, and there are several distilleries.

Energy. Power is provided by public and private installations, which are either hydroelectric or employ petroleum. Altogether they have a total capacity of over 250,000,000 kilowatts. The rubber-growing and iron-mining enterprises generate their own power. A hydroelectric plant at Mt. Coffee on the St. Paul River, which supplies power to Monrovia and to adjacent districts, has a 102,000-kilowatt capacity.

Financial services. Financial services are provided by eight banks, of which six are foreign. These are the Bank of Monrovia (an affiliate of the First National City Bank of New York), the International Trust Company of Liberia, the Chase Manhattan Bank, the Union National Bank (Liberia), Inc., the Bank of Liberia, Inc. (under Liberian management), the Commercial Bank of Liberia, the Liberian Trading and Development Bank Ltd. (Tradevco), and the government-owned Liberian Bank for Industrial Development and Investment, which provides medium- and long-term loans to private firms. There are also two credit corporations—the Liberian Agricultural Credit Corporation and the Liberian Development Corporation. Several Lebanese merchants provide short-term loans.

Foreign trade. Liberia enjoys a favourable balance of trade; its trade surplus reached a record amount of over $80,000,000 in 1969. Rubber and iron ore account for almost 90 percent of the value of all exports. Imports include machinery and transport equipment, food, beverages and tobacco, miscellaneous manufactured goods, mineral fuels, lubricants, and chemicals. The United States is the principal trading partner, followed by West Germany.

The Open Door Policy

Taxation. The tax structure is designed to attract foreign companies and capital to the country. Under the terms of the Open Door Policy, as operated since World War II, 80-year leases for tracts of undeveloped land may be obtained, and the flow of capital and dividends from the country is not restricted. Imports of machinery for industries are exempt from customs duty. A graduated income tax is applicable both to individuals and to corporations. Corporate incomes of more than $50,000 are taxed at a rate of 25 percent.

Trade unions. The two principal industrial unions are the Labor Congress of Liberia and the Congress of Industrial Organizations (CIO). Under the Labor Code, enacted in 1963, labour disputes are to be submitted to the government-established Labor Practices Review Board before a strike can be called.

Economic policies. The Open Door economic policy, which encourages foreign investment, has already been referred to. In addition, an Operation Production Policy aims at making Liberia self-sufficient in the production of staple food crops and at raising living standards in rural communities.

Problems and prospects. While Liberia has experienced little difficulty in obtaining international loans because of its abundant mineral resources, a substantial percentage of government revenue is allocated to reducing outstanding debt. An austerity program was proclaimed in the early 1960s in order to hasten the rate at which the national debt is liquidated. The reported location of further minerals resources, including the possibility of oil in the shallow waters off Monrovia, plus the existence of the further iron ore deposits at Mt. Kitoma, Wologizi Range, and Putu Range have led to the expectation that the economy will continue to expand.

Transportation. There is no national transportation network. Nearly all transport facilities are controlled by private enterprise; Liberian National Airways is an exception. There are about 4,200 miles of roads, of which about 325 miles are paved.

Four ports—Monrovia, Greenville, Harper, and Buchanan—serve Liberia's 350-mile coastline. The free port of Monrovia, the principal commercial port, with a draft of 35 feet (11 metres), can accommodate eight ships at a time. It also has facilities for transshipping iron ore and liquid latex. Nimba Range iron ore is shipped from Buchanan, while the port at Greenville and also a partially sheltered pier at Harper used by coastal craft are used primarily for the shipment of rubber and forest products. A fifth port, Robertsport, is planned for the export of iron ore.

Roberts International Airport is 27 miles from Monrovia, with which it is connected by road. It is used by 12 airlines and has a runway 9,000 feet (2,745 metresj long. In 1968 Pan American World Airways, in agreement with the Liberian government, took over the management of all airfields and is engaged in improving James Spriggs Payne Airfield at Monrovia to meet international standards.

A telecommunications network links Monrovia and 21 other towns by microwave relays for telephone and telegraph. There are automatic telephones in Monrovia, and several larger towns have manual exchanges.

Tourism is promoted by the government. There are several hotels and motels in Monrovia and its vicinity. Beaches provide popular recreation.

Administration and social conditions. Liberia has a republican form of government patterned after that of the United States and divided into legislative, executive, and judicial branches. The legislature is bicameral. The Senate has 18 members representing the nine counties, and the House of Representatives has 52 members representing the four territories and nine counties. Senators are erected for a six-year period and members of the House for four years. The president and vice president are elected for eight-year terms and may be re-elected for additional four-year terms. County superintendents, appointed by the president, manage county affairs, while district commissioners and tribal chiefs administer local affairs in the hinterland.

Political, cultural, and economic factors long separated the descendants of the original Liberian immigrants, also known as Arnerico-Liberians, or settlers, from the African tribal populations. In 1944 a national unification program was launched to speed the integration of the two groups, and in 1964 the old division between coastal and hinterland rule was abolished. In addition to the original five coastal counties of Grand Cape Mount, Montserrado, Grand Bassa, Sinoe, and Maryland, and the four territories (tribal enclaves) of Marshall, River Cess, Sastown, and Kru Coast, four new hinterland counties—Grand Gedeh, Nimba, Bong, and Lofa—were created. Tribal peoples are allowed, as far as possible, to govern themselves according to customary law.

National unification program

The constitution provides for a Supreme Court and for one chief justice assisted by four associate justices, all of whom are appointed by the president and who serve during good behaviour (*i.e.*, so long as they uphold the constitution to the satisfaction of the president). Subordinate courts established by legislative enactment serve the nine counties.

All citizens are entitled to vote. Since the creation of the four inland counties, tribal members have begun to participate in politics. Liberian politics, which, during the early years, took the form of a two-party system representing a conflict of interest between mulatto and black, has since 1878 been controlled by the True Whig Party, which is black-dominated and characterized by strong executive control. The Reformation Party (formed in 1951) and the Independent True Whig Party (formed in 1954) were both banned by the National Legislature in 1955.

Defense. The Liberian National Guard, numbering 3,200, is maintained at various strategic points. The militia, a voluntary body of officers and men numbering about 10,000, constitutes the reserve force. There is a small coast guard fleet of patrol cutters. A constabulary force of about 1,000 men and women comprises the national police force. These services are administered and controlled by the departments of justice and national defense.

Education. Formerly supplied mostly by Christian missions, educational services were greatly expanded by the government after 1945. The budget for national education was about $6,000,000 in 1970. Total enrollment at all levels was 150,000 by 1970. Since 1939 education has been legally compulsory for children between the ages of 6 and 16. By 1970, however, only about three out of ten children of school age were receiving education. Education is usually free at the primary level, although in the interior, but not in Monrovia, books must be bought. There are three vocational schools—the Booker Washington Agricultural and Industrial Institute at Kakata, which is a government school, and two more that are concession-operated. Advanced training is provided at the University of Liberia at Monrovia, at Cuttington College and Divinity School at Suakoko (Episcopalian), and at Maryland College of Our Lady of Fatima at Harper (Roman Catholic). Tubman University, was preparing to open in Harper. A medical school, the Monrovia Torrino Medical College, trains paramedical students. Liberian students abroad, amounting to nearly 500 in any given year, receive advanced training under a government foreign scholarship program. Grants from the United Nations enable Liberia to attract teachers from Europe and the United States to assist in the teaching of economics, science, and mathematics, in addition to which the government also sponsors the employment of foreign teachers. The United Nations supported the government's national literacy program, and ten of the major tribal languages have now been written down. Middle-level education has been adapted to the needs of the economy. Six years of primary school education are followed by three of middle school and three of high school education. In 1968 Liberia became an associate member of the West African Examinations Council so as to provide an international yardstick for measuring the quality of its education.

Vocational schools, colleges, and universities

Health and welfare. Conditions remain poor, although much progress has been made in providing better health facilities. The incidence of malaria is close to 100 percent, and that of leprosy 2 percent. Yaws is no longer a serious problem, following a control program carried out by the World Health Organization, but tuberculosis has been difficult to eradicate. Dysentery, malaria, and diarrhea continue to be the most important causes of infant mortality. Influenza, hernias, and intestinal worms, as well as trypanosomiasis (sleeping sickness), schistosomiasis (a parasitic disease), and elephantiasis (a skin disease in which the skin resembles an elephant's hide) are also prevalent. Most modem homes are screened against malaria mosquitoes, tsetse flies, and other dangerous insects. The government conducts inoculation campaigns to combat smallpox and yellow fever, and mobile units employ insecticides, usually DDT (dichloro-diphenyltrichloroethane), against malaria-carrying mosquitoes and other insects.

Major diseases

The government, foreign Christian missions, and concessions together sponsor 31 hospitals, of which the most modem are the 250-bed John F. Kennedy Memorial Hospital in Monrovia, sponsored by the U.S. Agency for International Development, the Roman Catholic Hospital at Monrovia, and Phebe Hospital in Bong County, all of which have nursing and medical schools attached to them. There are 143 clinics, some specializing in the problems of the blind and the aged, and others specializing in tuberculosis, sleeping sickness, and leprosy.

The Department of Public Works supervises low-cost housing projects and is also responsible for city planning and zoning. Housing is expensive, and most building equipment is imported. On the outskirts of Monrovia, tribal communities exist side by side with modern communities. Most of the people in these districts are squatters who are liable to be vacated from empty town lots by the authorities.

Living conditions. Living conditions throughout Liberia, while poor, are improving. Increasingly the hinterland farmers are growing such cash crops as rubber, coffee, and palm produce, as well as subsistence crops. The money economy is consequently gradually expanding throughout the interior. Some 80,000 men and women are employed on the various plantations and in iron-mining enterprises. There is a standard 48-hour working week in industry and a 40-hour week in most government departments. A wage law establishes the minimum unskilled industrial wage at 15 cents an hour and the minimum unskilled agricultural wage at 8 cents an hour. Many of the concessions provide family housing, as well as free medical and educational facilities, and provide partially subsidized rice, fish, and palm oil to their employees.

Social conditions. Intermarriage and economic progress have both been important factors in breaking down social divisions in Liberia. Mines and plantations are distributed throughout the country and have contributed to the slow trend toward a more equitable distribution of income. Particularly in the coastal districts, government jobs, foreign businesses, and local markets also provide greater opportunities for economic and social advancement. Economic and social divisions are more keenly felt betweeen the coastal and rural areas because the cash economy has only recently spread inland. Transportation, communications, and commerce, however, all serve slowly to lessen differences.

Cultural life and institutions. In the dance halls of Monrovia and in towns elsewhere, both Western and African music and dancing styles are in vogue. In rural areas, African musicians and drummers use traditional rhythms at weddings, burials, and feasts, as well as at the graduation ceremonies of boys and girls from the Poro and Sande schools.

Musical festivals and dramas are staged several times a year at Cuttington College and the University of Liberia, which are also visited by foreign drama and ballet troupes.

Several institutions instruct young men and women in the legends, traditions, songs, arts, and crafts of African culture. The government encourages the preservation and promotion of African culture through such agencies as the National Cultural Center, which exhibits house styles representing Liberia's 16 different tribal cultures. The sculpture of masks, representing both humans and animals, is an artistic pursuit that is also related to the social structure of some tribes.

There are two daily newspapers and one biweekly paper, ***The Liberian Age,*** which is government-owned. There are several radio stations, including the government-owned ELBC station, ELWA (a religious broadcasting station for Africa), and a Voice of America station. There are also some concession-operated newspapers and radio stations. There is also a television station (ELTV), although relatively few receiving sets are as yet available. In addition to western television programs, locally produced programs are shown for several hours each week.

Prospects. The Open Door Policy has been the capstone of the nation's economic growth since the 1940s. No other national policy has, since the foundation of the Liberian state, exerted such an influence upon the economy as well as upon the course of political, cultural, and social development. As a result, life in Liberia has undergone a transformation in less than three decades. Unless the unpredictable should occur, the prospect—particularly since further mineral discoveries have been made—is for continued economic growth. With the passage of time and the increased pace of modernization, the old division between the coastal regions and the interior may be expected slowly to be eroded.

Library

The word library, which in English refers to a collection of books gathered for purposes of reading, study, or reference (and which derives from the Latin *liber*, "a book"), has a long history, occurring in a prose translation of the Roman philosopher Boethius' ***Consolation of Philosophy*** that Geoffrey Chaucer made in about 1374. The word *librairie* in French (and its counterpart in other Romance languages) does not have the same meaning, being used to denote a bookshop or, by extension, a publisher; the word used in many other countries to signify a collection of books, public or private, is derived from a Latinized Greek word, ***bibliotheca:*** hence *bibliothèque* in French, ***biblioteca*** in Italian and Spanish, *Bibliothek* in German, ***biblioteka*** in Russian. In Japanese the word is *tosho-shitsu.* The use of the word library to denote a building, room, or set of rooms in which a collection of books is contained also has a lengthy history, which goes back to the 15th century.

The basic function of all libraries is to preserve material by collection, but they have come to serve many other purposes as well. The material they stock now often includes films, slides, phonograph records, and tapes, as well as books and manuscripts. Thus, by housing readily available information and the means of its convenient transmission to students and others and by providing a source of instructive and creative reading, viewing, and listening for the general public of all ages, libraries play a major role in modern social organization. The following article deals with the development of libraries from earliest times and describes the functions of different kinds of libraries; it outlines some of the principles of planning involved in library architecture and concludes with an explanation of some problems faced by libraries in a technological age. The detailed operations of libraries and library procedures are dealt with in the article LIBRARY SCIENCE.

HISTORICAL PERSPECTIVES

The ancient world. In earliest times there was no distinction between a record room (or archive) and a library, and in this sense libraries can be said to have existed for almost as long as records have been kept. A temple in the Babylonian town of Nippur, dating from the first half of the 3rd millennium BC, was found to have a number of rooms filled with clay tablets, suggesting a well-stocked archive or library. Similar collections of Assyrian clay tablets of the 2nd millennium BC were found at Tell el-Amarna in Egypt. Ashurbanipal (668–627 BC), the last of the great kings of Assyria, maintained an archive of some 25,000 tablets, comprising transcripts and texts systematically collected from temples throughout his kingdom. The majority carry his name, and some state that the king had "edited" them and caused them to be collected in his palace at Nineveh.

Ashurbanipal's library

Greece and Alexandria. The idea of book collecting, however, and hence of libraries as they are now understood had its origin in the classical world. Most of the larger Greek temples seem to have possessed libraries, even in quite early times; many certainly had archive repositories. The tragic playwright Euripides was known as a private collector of books, but the first important institutional libraries came in Athens during the 4th century BC with the great schools of philosophy. The Stoics, having no property, had no library; the schools of Plato and of the Epicureans did possess libraries, whose influence lasted for many centuries. But the most famous collection was that of the Peripatetic school, founded by Aristotle and systematically organized by him with the intention of facilitating scientific research. Aristotle's library went to his successor and heir, Theophrastus. After that it was owned by Apellicon of Teos, from whom it was claimed as war booty by Sulla, when he conquered Athens in 84 BC, and taken back by him to Rome (where the orator Cicero, one of Rome's great book lovers, enjoyed its use).

Aristotle's library is said by Strabo, a traveller and historian of the late 1st century BC, to have formed the model for that established at Alexandria, which became the greatest in antiquity. It was planned by Ptolemy I Soter (died 283 BC) and brought into being by his son Ptolemy II Philadelphus (308–246 BC) with the collaboration of Demetrius of Phalerum, their advisor. The founders of this library apparently aimed to collect the whole body of Greek literature in the best available copies, arranged in systematic order so as to form the basis of published commentaries. Its collections of papyrus and vellum scrolls are said to have numbered hundreds of thousands. Situated in a temple of the Muses called the Mouseion, it was staffed by many famous Greek writers and scholars, who included the grammarian and poet Callimachus (died 240 BC), Eratosthenes (died c. 194 BC), the philosopher Aristophanes of Byzantium (died c. 180 BC), and Aristarchus of Samothrace (died 145 BC), the foremost critical scholar of antiquity.

Pergamum. In Asia Minor, a library rivalling that of Alexandria was set up at Pergamum during the reigns of Attalus I (died 197 BC) and Eumenes II (died 159 ac). Parchment (charta pergamena) was said to have been developed there in order to counteract the decision of Ptolemy Philadelphus to forbid the export of papyrus from Egypt, thereby impeding the copying of books for its library. The library was bequeathed with the whole of the kingdom of Pergamum to the Roman people in 133 BC, and Plutarch records a rumour that Antony gave its 200,000 volumes to Cleopatra, to become part of the Alexandrian library.

Rome. There were many private libraries in classical Rome, including that of Cicero. Indeed, it became highly fashionable to own a library, judging from the strictures of the moralizing statesman Seneca and the spiteful jibes by the poet Lucian on the uncultured "book clown." Excavations at both Rome and Herculaneum have revealed what were undoubtedly library rooms in private houses, one at Herculaneum being fitted with bookcases around the walls. A Roman statesman and general, Lucullus, who became known as the richest man in the ancient world, famous for his luxurious way of life, acquired as part of his war booty an enormous library, which he generously put at the disposal of those who were interested. His biographer, Plutarch, speaks appreciatively of the quality of his book collection, and Cicero tells of an episode when he visited the library to borrow a book to find his friend, Cato, already ensconced there surrounded by books of the Stoic philosophy.

The library planned by Julius Caesar

Julius Caesar planned the creation of a public library and entrusted the implementation of his plans to an outstanding scholar and writer, Marcus Terentius Varro (died 27 BC), also the author of a treatise on libraries, De bibliothecis (which has not survived). Caesar died before his plans were carried out, but a public library was built within five years by the literary patron Asinius Pollio (died AD 4). Describing its foundation in his Natural History, Pliny coins a striking phrase which has application to libraries generally: *ingenia* hominum *rem publicam* fecit ("He made men's talents a public possession"). Libraries were also set up by Tiberius, Vespasian, Trajan, and many of the later emperors; the Bibliotheca Ulpia, which was established by Trajan in about AD 100 and continued until the 5th century, was also the Public Record Office of Rome.

The Imperial library at Byzantium, set up by Constantine the Great in the 4th century, was an important centre for Christian literature; but it also played a part in the preservation of the literature of Greece and Rome. In the 5th century, when the Roman Empire was being destroyed by the onslaught of Germanic barbarian incursions, libraries both public and private went up in flames or were left to decay. Fragments of the cultural heritage of Greece and Rome were, however, preserved in churches and monasteries, from which later blossomed the culture of the Renaissance.

Destruction of ancient libraries

Middle Ages and Renaissance. Role of the monasteries. As monastic communities were set up (from as early as the 2nd century AD) books were found to be essential to the spiritual life. The rule laid down for observance by several monastic orders enjoined the use of books: that of the Benedictine Order, especially, recognized the importance of reading and study, making mention of a "library" and its use under the supervision of a precentor, one of whose duties was to issue the books and make an annual check of them. Scriptoria, the places where manuscripts were copied out, were a common feature of the monasteries—again, especially in those of the Benedictine Order, where there was a strict obligation to preserve manuscripts by copying them. Many—Monte Cassino (529) and Bobbio (614) in Italy; Luxeuil (c. 550) in France; Reichenau (724), Fulda (744), and Corvey (822) in Germany; Canterbury (597), Wearmouth (674), and Jarrow (681) in England—became famous for the production of copies. Rules were laid down for the use of books, and curses invoked against any person who made off with them. Books were, however, lent to other monasteries and even to the secular public against security. In this sense, the monasteries to some extent performed the function of public libraries.

Contents of monastic libraries

The contents of these monastic libraries consisted chiefly of the Scriptures, the writings of the early Church Fathers and commentaries on them, chronicles, histories such as Bede's Ecclesiastical History of the English Peoples, the philosophical writings of St. Thomas Aquinas and Roger Bacon, and possibly some secular literature represented by the Roman poets Virgil and Horace and the orator Cicero. After the universities were founded in the 13th century, monkish students, on returning to their monasteries, deposited in the libraries there the lecture notes they had made on Aristotle and Plato, on law and medicine, and so forth, and in this way expanded their contents.

The new learning. The libraries of the newly founded universities—along with those of the monasteries—were the main centres for the study of books until the late Middle Ages; books were expensive and beyond the means of all but a few wealthy people. The 13th, 14th, and 15th centuries, however, saw the development of private book collections. Philip the Good, duke of Burgundy, Louis IX, and Charles V (who may be looked upon as the founder of what is now called the Bibliothèque Nationale in Paris) were great collectors, as were also such princes of the church as Richard de Bury, bishop of Durham (died 1345), who wrote a famous book in praise of books, *Philobiblon* (first printed in Cologne, 1473). But new cultural factors—including the growth of commerce, the new learning of the Renaissance (that was based on newly discovered classical texts), the invention of printing, and a substantial expansion of lay literacy—widened the circle of book collectors to include wealthy merchants whose libraries contained books of law and medicine, herbals, books of hours, and other devotional works. Italian humanists, such as Petrarch, searched for and copied manuscripts of classical writings to establish their scholarly libraries. Niccolo Niccoli (librarian to Cosimo de Medici, a wealthy Florentine patron of the arts), and Gian Francesco Poggio Bracciolini were two scholars who inherited Petrarch's enthusiasms and ransacked Europe and the Near East for manuscripts of the writers of Greece and Rome. Notable collections of books were made outside Italy, too (though Florence remained the centre of the rising book trade): by Diane de Poitiers, mistress of Henry II of France; by Jean Grolier, a high French official and diplomat, who was a great patron of bookbinders; by John Tiptoft, earl of Worcester; by Henry VII and Henry VIII of England and by many others.

Renaissance public libraries

Petrarch had wished to bequeath his collection to the municipality of Venice as a public library, but his intention was not realized. Cosimo de' Medici, however, set up, on the basis of Niccolo Niccoli's library, the Biblioteca Marciana in Florence, in the convent of San Marco. The rich library of Lorenzo the Magnificent, grandson of Cosimo and an even greater patron of learning and the arts, also became a public library. It was opened in 1571 in a fine building designed by Michelangelo and still exists as the Biblioteca Laurenziana (though in 1808 it was amalgamated with the Marciana to form the Biblioteca Medicea-Laurenziana). Many other princely libraries were formed at this time, including that of Matthias I Corvinus of Hungary. Like the Medicis, Corvinus employed agents to purchase manuscripts in the Levant, and he was also a customer of a well-known Florentine dealer in manuscripts, Vespasiano da Bisticci. Corvinus' library was destroyed when the Turks overran his capital of Buda in 1526 (a few books that survived are in the Austrian National Library at Vienna). The library of the Escorial in Madrid, founded in 1557, was based on the collections of Philip II. The Vatican library also dates its foundation from this time, the real founder of the collections as they are today having been Pope Nicholas V (reigned 1447–55), who dispatched agents to Germany, England, and Greece in search of manuscripts; Sixtus IV (reigned 1471–84) reassembled the Vatican collection in its present location.

Effects of the Reformation and religious wars. In England the end of the monastic libraries came in 1536–40 when the religious houses were suppressed by Henry VIII and their treasures dispersed. No organized steps were taken to preserve their libraries: it seems likely that a few—though only a very small proportion of the whole—were taken for the Royal Library. Even more wholesale destruction came in 1550: Henry VIII and Edward VI aligned with the "new learning" of the humanists; and university, church, and school libraries were purged of books embodying the "old learning" of the Middle Ages. The losses were incalculable. A change of attitude came about with Elizabeth's reign when those in authority realized that the kind of books that had been dispersed would form useful propaganda for the government's policy; the archbishop of Canterbury, Matthew Parker, and the Queen's principal secretary, Robert Cecil, took the lead in seeking out and acquiring the scattered manuscripts. Many other collectors were also active, including Sir Robert Bruce Cotton and Sir Thomas Bodley. As a result, some considerable portion of the libraries that had been scattered at the suppression was, by 1660, reassembled in collections—Parker's eventually went to Corpus Christi College at Cambridge; Cotton's to the British Museum; and the Bodley's to form the Bodleian Library at Oxford—where they remain to this day.

Elsewhere in Europe, the period of the Reformation also saw many of the contents of monastic libraries destroyed, especially in Germany and the northern countries. The Reformation leader Martin Luther, however, did himself passionately believe in the value of libraries, and in a letter of 1524 to all German towns he insisted that neither pains nor money should be spared in setting up libraries, or book houses, particularly in the larger towns. As a consequence, many town libraries in Germany, including those at Hamburg (1529) and Augsburg (1537), date from this time. These, and the libraries of the newly created universities (such as Konigsberg, Jena, and Marburg), were partly, at any rate, built up on the basis of the old monastic collections. In Denmark, similarly, some books from the churches and monasteries were incorporated with the new university library, though many were destroyed.

Libraries in Germany suffered severely in the Thirty Years' War. The Bibliotheca Palatina at the University of Heidelberg, for example, which had been founded in 1386, was taken as the spoil of war by Maximilian I of Bavaria, who offered it to Pope Gregory XV in 1623; and Gustavus Adolphus sent whole libraries to Sweden, most of them to swell the library of the University of Uppsala, which he had founded in 1620. The collections of the Royal Library in Stockholm were similarly enriched by the war booty that fell to Sweden during the reigns of Queen Christina and Charles X.

In France, Italy, Southern Germany, and Austria, where the Catholic faith remained unshaken, the old libraries remained and were supplemented by new ones set up, for educational purposes, by the Society of Jesus (the Jesuits).

17th and 18th centuries: the great national libraries. A notable feature of the 17th and 18th centuries was a widespread enthusiasm for book collecting, sometimes out of ostentation, but often the result of genuine scholarship. Several fine private collections were assembled, many of which were eventually to become the core of today's great national and state libraries—for this was also the period that saw new national and university collections springing up all over Europe. There were, of course, other developments. In England there was established a number of parish libraries, attached to churches and chiefly intended for the use of the clergy (one of the earliest, at Grantham in Lincolnshire, was set up as early as 1598, and some of its original chained books are still to be seen there). They were sometimes the result of lay donation: a Manchester merchant, Humphrey Chetham, left money in 1653 for the foundation of parish libraries in Bolton and Manchester and also for the establishment of a town library in Manchester (which still exists, housed in its original bookcases, in its original building). Later, in the 18th century, especially in England and America (though also elsewhere in Europe), there was a great vogue for the circulating and "subscription" libraries—book clubs that provided an agreeable reference service and lending collections for their members and had much influence on the formation of popular literary taste, especially in fiction.

Parish, town, and subscription libraries

"Opening of the Manchester Free Library," engraving by an unknown artist, from The *Illustrated* London News, 1852.

Library planning. 'The private libraries of powerful and influential collectors such as Cardinal Mazarin in France were so large that a new approach to library organization was needed. The Escorial library in Madrid, erected in 1584, had been the first to do away with book bays on the medieval pattern and to arrange its collection in cases lining the walls. The old practice of chaining books to their cases was gradually abandoned; and the change to the present arrangement of standing them, spines facing outward, began in France, probably with the library of the historian Jacques-Auguste de Thou (died 1617). Mazarin's library was in the charge of Gabriel Naudé, who produced the first modern treatise on library economy, ***Advis pour dresser une*** *Bibliothèque* (1627). This work had great influence on the collectors and scholars of the Restoration period: widely translated, it marked the transition to the age of modern library practice. One of its first fruits, the library of the diarist Samuel Pepys, organized with meticulous care and beautifully housed, is still at Magdalene College, Cambridge. Naudé's concept of a scholarly library, systematically arranged, displaying the whole-of recorded knowledge and open to all scholars without fear or favour, took root. It was above all absorbed by the philosopher Gottfried Wilhelm Leibniz (died 1716), the greatest librarian of his age, who conceived the idea of a national bibliographical organization that would provide the scholar with easy access to all that had been written on his subject. He realized that scientific progress above all depends on ease of communication between scholars and that the purpose of great libraries and museums is to provide and keep open the channels of communication.

Emergence of national collections. The boundaries of knowledge were expanding rapidly during the 17th and 18th centuries, especially in the field of historical studies and philosophy, resulting in a vast outpouring of books that went to swell the libraries of private collectors. The lawyer, historian, and councillor of state Jacques-Auguste de Thou was in charge of the Bibliothkque du Roi (founded by Charles V and largely reorganized during the 15th century by Louis XII). Mazarin's library was scattered when he was compelled to leave France during the movement known as the Fronde, but it was reassembled when he returned to power in 1661. Rehoused in a new building, it was opened to the public in 1691 and remained one of France's great libraries until after the French Revolution when it was incorporated with other collections (including the Bibliothkque du Roi) to form the Bibliothkque Nationale, today one of the world's great libraries. August, duke of Brunswick, established a library in 1604 that later became the Herzog August Bibliothek at Wolfenbiittel, one of the finest libraries in Europe (Leibniz was its librarian from 1690–1716). A library assembled by the elector Friedrich Wilhelm of Brandenburg was founded in 1659 and later became the Prussian State Library. The collections of the English book collectors, Sir Hans Sloane, Sir Robert Cotton, and Edward and Robert Harley, earls of Oxford, formed the basis of the British Museum collection, founded in 1753, which from the start was regarded as the national library; it was further enlarged by the addition in 1757 of the Royal Library, containing books collected by the kings of England from Edward IV to George II.

The great national collections

The effects of the French Revolution. The anti-clerical movement on the continent of Europe that found expression in revolution sealed the fate of many monastic and church libraries: those in France, for example, were expropriated in 1789; in Germany in 1803; in Spain in 1835. The dispersal of books was, however, better organized than that of the English monasteries under Henry VIII. In France they were collected in the main towns of the *départements* in what were called *dépots littéraires.* In 1792 the same fate befell the collections of aristocratic families, and these, too, were added to the *dépots.* The enormous accumulations caused problems, and many books were lost, but the plan of coordinating library resources throughout the country was carried out. The Bibliothèque Nationale received some 300,000 volumes; and new libraries were set up in many important provincial cities. Napoleon's successful campaigns in Europe also brought acquisitions, in the form of war booty, to the Bibliothkque Nationale, but these turned out to be only temporary; most of the books were returned after the treaty of Vienna in 1815. In Germany the Bavarian State Library was greatly enriched by the contents of over 150 confiscated libraries, and many of the provincial libraries were similarly enlarged. In Austria, as a result of confiscations, Studienbibliotheken (study libraries) were set up at Linz, Klagenfurt, and Salzburg, the university libraries at Graz and Innsbruck were substantially enlarged, and many valuable acquisitions accrued to the Hofbibliothek in Vienna.

19th- and 20th-century developments. The 19th century saw a significant awakening. Libraries had grown in size, but their growth had been haphazard; administration had become weak, standards of service almost nonexistent; funds for acquisition were inadequate, the post of librarian was looked on as a part-time one, cataloging was in arrears and lacked proper method.

The university library at Gottingen was a notable exception. Johann Gesner, the first librarian, working in close association with the curator of the University, G.A. von Miinchhausen, and proceeding on the principles laid down by Leibniz, made strenuous efforts to cover all departments of learning; the library provided good catalogs of carefully selected literature and was available to all as liberally as possible. The next director, C.G. Heyne, enthusiastically followed the same principles, with the result that Gottingen became the best organized library in the world.

The revolution in library administration

By the middle of the century new conceptions of the purpose and scope of learned libraries were everywhere taking shape. Within a few years the picture of library service had been transformed, and a leading figure in this development was Antonio (afterward Sir Anthony) Panizzi, a political refugee from Italy who began working for the British Museum in 1831 and was its principal librarian in 1856–66. From the start he revolutionized library administration, demonstrating that the books in a library should match its declared objectives and showing what these objectives should be in the case of a great national library. He perceived the importance of a good catalog and to this end elaborated a complete code of rules for catalogers. He also saw the potentiality of libraries in a modern community as instruments of study and research, available to all, and showed how—by his planning of the British Museum reading room and its accompanying bookstacks—this potential might be realized. His ideas have dominated library thought in the field of scholarly—or, as they are now called, research—libraries up to the present day, and may have achieved their major expression so far in the Library of Congress in Washington, D.C.

By the middle of the 19th century the idea had been accepted that libraries might be provided by local authorities at public expense. This proved a significant stage in the development of library provision. Panizzi had stated that he wanted the facilities of a great library to be available to poor students so that they could indulge their "learned curiosity"; now, in 1840, an Act of Parliament was passed in England enabling local councils to levy a rate for the provision of free library facilities. From the first tentative beginnings there has been continuous growth in the providing of reading services and in the use that is made of them by the public. Libraries now provide not only books and periodicals but also many audio-visual materials; in some cases also they provide facilities for lectures and dramatic performances and art exhibitions and are able even to lend works of art for use at home. Such developments in the public libraries are commonest in the United Kingdom, the United States, and the Scandinavian countries. Elsewhere, the large town libraries in Europe have always been regarded as public libraries; and, since the 18th century, local libraries and reading groups have provided, to some extent, popular instructional reading. But so far there has been no comparable vitality and spirit of social purpose.

Library services in the age of specialization

The 20th century has added a new dimension to library services, as well as a new range. Developments in scientific and industrial research, with a consequent vast increase in the publication, on a worldwide basis, of specialized information—mostly in the form of periodicals—have led to a demand for rapid and easy access to wide ranges of periodical literature and an information service that could furnish references and bibliographies on specific subjects. In the applied sciences especially, books are no longer regarded as the main repositories of knowledge; existing research libraries, with their large reserves of books but comparatively deficient stock of modern scientific periodicals, with their traditional practices and administrative routines, were, generally speaking, unable to satisfy the new demands and in some quarters were looked upon as backward, out of touch with contemporary needs. An important result has been the growth of special libraries, often connected with commercial enterprises or specialized professional bodies and financed by them. These libraries have had a significant influence on the kind of service now offered in research libraries and also on the public libraries.

KINDS OF LIBRARIES

Library services available throughout the world vary so much in detail from country to country that it is impossible to present anything but the most general picture of their activities. Nevertheless, they follow a broad but discernible pattern that has evolved over the years.

Aims of a national library

National libraries. In most countries there is a national or state library or group of libraries maintained by national resources, usually bearing responsibility for publishing a national bibliography and for maintaining a national bibliographical information centre. National libraries strive principally to collect and to preserve the nation's literature, though they try to be as international in the range of their collections as possible.

Most national libraries receive, by legal right, one free copy of each book and periodical printed in the country. Certain other libraries throughout the world share this privilege, though many of them receive their legal (or copyright) deposit only upon request.

The Bibliothèque Nationale in Paris, the British Museum in London, the Library of Congress in Washington, D.C., and the Lenin Library in Moscow are the most famous and possibly the most important national libraries in the Western world. Their importance springs from the quality, size, and range of their collections, which are comprehensive in scope and attempt to maintain their comprehensiveness. This latter they achieve with diminishing success in view of the vastly increased number of publications that daily appear throughout the world and the difficulty of ensuring adequate representation of publications issued in the developing countries.

Bibliothèque Nationale. The Bibliothkque Nationale was before the Revolution known as the Bibliothkque du Roi and owes its origin (as is indicated above) to Charles V. It was the recipient during the 15th and 16th centuries of a number of important collections of manuscripts; in 1617, under the librarianship of the great collector J.A. de Thou, its right to legal deposit was reaffirmed and continued to be rigidly enforced. In the first quarter of the 18th century four of the library's departments (of Prints, Coins, Printed Books, and Manuscripts) were created; it was opened to the public in 1735. Enormous additions accrued to the library as a result of the French Revolution and the confiscation of aristocratic and church private collections. The catalog of the library on cards was completed under the librarianship (1874–1905) of Léopold Delisle, and in 1897 he made a start to the task of compiling a printed catalog in volume form. This is still incomplete (209 volumes had appeared by 1971). The library has 6,500,000 volumes of printed books; 180,000 volumes of manuscripts; and over 5,000,000 prints.

Unique character of the British Museum

The British Museum Library. The British Museum is unique in that it combines a great museum of antiquities with a great comprehensive library. It was founded in 1753 by the acceptance of the bequest of the collections of Sir Hans Sloane, physician to King George II and president of the Royal Society. The library was built up on the basis of two other important collections, that of Sir Robert Cotton and that of Edward and Robert Harley, earls of Oxford; to these were added the Royal Library, given by George II in 1757. With this collection came also the right to legal deposit of one copy of every book published in the British Isles; this right is most rigorously enforced. These four basic collections were notably enlarged during the first century of the library's history by the addition of many private collections, including the libraries of King George III (1823) and of Sir Thomas Grenville (1846). Sir Anthony Panizzi, as already indicated, reorganized the library and gave it its present modern shape; he was also responsible for its printed catalog, made between 1880 and 1905; a new edition was published between 1961 and 1966 in 263 volumes. Like the Bibliothkque Nationale, the British Museum Library is exceptionally rich in early printed books and manuscripts, of which there are a number of catalogs. It has continued to receive significant collections of valuable manuscripts and printed material; it has very fine collections of music and maps. The collections amount to 8,500,000 volumes of printed books; there are over 150,000 manuscripts. Prints and drawings, of which there are very large collections, are maintained in a separate department of the museum, as are the coins and medals.

Library of Congress. The United States' Library of Congress, located in Washington, D.C., is the largest of the national libraries and its collection of modern books is particularly extensive. It was founded in 1800 but lost many of its books by fire during a bombardment of the Capitol in 1814. These losses were to some extent made good by the purchase of Thomas Jefferson's library shortly thereafter. The library remained a strictly congressional library for many years, but as the collections were notably enlarged by purchases and by additions under the copyright acts, the library became and remained—in effect, although not in law—the national library of the United States. Library of Congress catalog cards were first printed for the use of subscribing libraries in 1902 (in the first year there were 212 subscribers; they are now used by many thousands of American libraries and institutions), a service initiated by Herbert Putnam, librarian from 1899 to 1939. In 1927 the library began printing the *National Union Catalog,* representing the stock of some 2,500 libraries, which has now reached the formidable size of 18,000,000 entries and is currently being printed in volume form. The library has collections totalling over 15,000,000 volumes and pamphlets, 29,000,000 pieces of manuscript, 176,000 prints and drawings, and 3,000,000 photographic negatives and slides. Further services to scholarship include the publication of several specialist catalogs.

National Union Catalog

Lenin Library. The State V.I. Lenin Library in Moscow, the national library of the Soviet Union, is to all intents a recent creation, founded after the Revolution of 1917 as a national library to replace the old Imperial Library in Leningrad. It is already one of the largest libraries in the world. It receives copies of all new publications issued in the Soviet Union, and its collections are given as 25,000,000 volumes of printed books and 2,500,000 manuscripts.

Other national collections. Besides these four great national libraries, there are many others with important collections and very long histories. The Bibliothkque Royale Albert I, in Brussels, founded in 1837 on the basis of the library of the dukes of Burgundy, is the national library of Belgium and the centre of the country's library network; it maintains a regular lending service with the university libraries and with the large town library of Antwerp. The Dutch Royal Library in The Hague was founded in 1798 and it, too, is the centre of a well-developed interlibrary loan system. Italy, because of its historical development as a series of city-states, has a number of national libraries, the chief being the Biblioteca Nazionale Centrale Vittorio Emanuele II in Rome, founded in 1875 and possessing more than 2,000,000 volumes, and the historically richer Biblioteca Nazionale Centrale at Florence, founded in 1747, with over 4,000,000 volumes. Other Italian national libraries are at Milan, Naples, Palermo, Turin, and Venice. Germany was equally remarkable before World War II both for the importance of its state or provincial libraries and for the lack of a recognized national library. The former Preussische Staatsbibliothek was permitted to assume this role in 1919; after World War II, under the name Deutsche Staatsbibliothek, it became the national library of East Germany with a collection numbering 3,000,000 volumes. West Germany has no national library as such, the functions of such a library being performed by the Deutsche Bibliothek in Frankfurt and the Staatsbibliothek Preussischer Kulturbesitz in Marburg and West Berlin. The National Library of Austria, founded by the Emperor Maximilian I in 1493, has rich collections—notably of manuscripts from the Austrian monasteries and from the library of Matthias Corvinus, dispersed after the capture of his capital, Buda, by the Turks in 1526. The National Library of Australia in Canberra is a comparatively new creation, having been formally created by legislation in 1960. It had, however, a long preparation for its role by its association with the Commonwealth Parliamentary Library. It is responsible for the *Australian National Bibliography* and has built up significant collections and played a large part in cooperative library developments. It has occupied since 1968 a fine new building on the shores of Lake Burley Griffin.

National libraries in Asia

At least 25 nations in Asia have national libraries, some of them—including the National Library of Peking, the National Diet Library in Tokyo, and the Jewish National and University Library in Jerusalem—with holdings of more than 2,000,000 volumes. The National Library of India (formerly the Imperial Library) in Calcutta, founded 1903, has over 1,000,000 volumes. Each of the countries of Central and South America has its own national library: that of Argentina is located in Buenos Aires, that of Mexico in Mexico City, and that of Brazil in Rio de Janeiro, this being by far the largest. In the developing countries of Africa the creation of national libraries is still largely a dream, though many of them, by setting up national library services, have taken a useful step toward realizing it.

University libraries. Like the national libraries, university libraries are in the main general in scope. Some of them, notably Harvard University Library at Boston and the Bodleian Library at Oxford, compare with the greatest national libraries in their collections' quality and range. Harvard is by far the largest university library in the world, rivalling in size both the British Museum and the Bibliothkque Nationale. Its collections have been conscientiously built up, since its foundation in 1638, by a succession of eminent librarians, and it now has outstanding collections in English and foreign literature, law, economics, Slavonica, and Orientalia. The director of the library has under his control nearly 100 specialist and separate departmental libraries. The Bodleian Library owes its foundation, in 1602 on the site of a former library, to Sir Thomas Bodley, a successful diplomat and bibliophile. Bodley was able to attract many benefactions to the library and was successful in concluding an agreement with the Stationers' Company in London whereby they deposited a copy on request of every new book published, a privilege which has been confirmed up to the present by successive Copyright Deposit Acts. The Bodleian is in process of reorganization as a federation of dependent libraries, including the Radcliffe Science Library, the Indian Institute Library, the Law Library, and others.

Many other university libraries, especially in the United States, have very large general collections, in some cases numbering upwards of 3,000,000 volumes, notably at Berkeley, California, Chicago, Los Angeles, and Princeton; they often have fine special collections. The same is true of the libraries belonging to many academies in Eastern Europe, notably the Academy of Sciences in Leningrad, which was founded in 1714 and was greatly enlarged after the 1917 Revolution.

Public Libraries. Public libraries play an indispensable role in the life of the community: they promote the reading of literature among grown-ups, adolescents, and children; they provide familiar information and reference centres, where the modern citizen can secure reliable and disinterested advice on practical matters and where he is helped to get his bearings in the complexities of modern community life.

Role of public libraries

From modest beginnings in the middle years of the 19th century, public libraries now provide well-stocked reference libraries and wide-ranging loan services based on systems of branch libraries. They are further supplemented by travelling libraries, which serve outlying districts. Special facilities are provided for the old and the disabled, and in many cases library services are organized for local schools, hospitals, and jails. The services provided vary in proportion to the size of the municipality or the area covered. In the case of very large municipalities, library provision may be on a considerable scale, including a reference library, which has many of the features associated with large research libraries. The New York Public Library, for example, has rich collections in many research fields; and Boston Public Library, the first of the great city public libraries in the United States (and the first to be supported by direct public taxation), has had from the first a twofold character as a library for scholarly research as well as for general reading. In the United Kingdom, the first tax-supported public libraries were set up in 1850; 120 years later, they provided a highly significant part of the country's total national library service. The importance of public library activities has been recognized in many countries by legislation designed to ensure that good library services are available to all without charge.

In many cases, public libraries build up collections that relate to local interests, often providing information for local industry and commerce. It is becoming more and more usual for public libraries to provide, for home loan: music scores, phonograph records, and, in some countries--notably in Sweden and the United Kingdom—original works of art for use, against a deposit, in the home.

Not all countries provide public library services of an equally high standard, but there has everywhere been a tendency to recognize their value and to improve services where they exist or to introduce them where they do not. Public librarians work strenuously, through such organizations as the International Federation of Library Associations, for such developments.

Special libraries. The national, university, and public libraries mentioned above form the backbone of the general library system in a country, looking after the needs of scholars and the general public. They are supplemented by libraries established to meet the highly specialized requirements of professional or business groups. These special libraries spring from the need felt in science and industry for better control of bibliographical information and greater efficiency in its communication and use than was possible in libraries of the traditional kind. Special libraries form an important element in a country's planned library system, whether directly, as in the case of the National Library of Medicine and the Library of the Department of Agriculture in the United States, or indirectly, as in the National Reference Library of Science and Invention in the British Museum, and in other parts of large reference libraries (the map and music libraries in the national libraries, for example, or the specialist libraries in the Harvard University and the Bodleian complexes). The libraries of specialist colleges and universities are, naturally, themselves special libraries.

Functions and services of specialist libraries

Special libraries are often attached to official institutions such as government departments, hospitals, museums, and the like. For the most part, however, they come into being to meet specific needs in commercial and industrial organizations. They are planned on strictly practical lines, with activities and collections carefully controlled in size and scope, though they may be and often are large and wide-ranging in their activities; they cooperate widely with other libraries. They are largely concerned with communicating information to specialist users, in response to, or preferably in anticipation of, their needs. They have therefore been much concerned with the theoretical investigation of information techniques, including the use of computers. Their activities have led to a critical reappraisal of library practices and have thus greatly benefitted library work in general.

School libraries. In countries in which public library legislation exists, public library services are often available to school libraries. Technical procedures, such as book purchase and processing, are carried out by the local library; the books are then sent to the school ready to be put onto its library shelves. This is the case in Denmark, for example. There is similarly close cooperation in other European countries, notably Germany, Sweden, and the United Kingdom. The service thus made available is paralleled in the United States by commercial cataloging services; in the U.S.S.R. it is performed by the All-Union Book Chamber, which prepares bibliographical descriptions and distributes them to all the school libraries of the country. The importance of school libraries is widely accepted on both sides of the Atlantic; teachers have too little time to spare for running the libraries properly, and so it is becoming more common for full-time professional librarians to be appointed.

Private libraries. The libraries owned by private individuals are as varied in their range of interest as the individuals who collected them, and so they do not lend themselves to generalized treatment. The phrase private library is anyway unfortunate because it gives little idea of the public importance such libraries may have. The private collector is often able to collect in depth on a subject to a degree usually impossible for a public institution; being known to booksellers and other collectors, he is given early information about books that will be of interest to him and that will fit into his collection; he can give close attention to the condition of the books he buys. In these ways he adds greatly to the sum of bibliographical knowledge (especially if he makes his collection available to scholars).

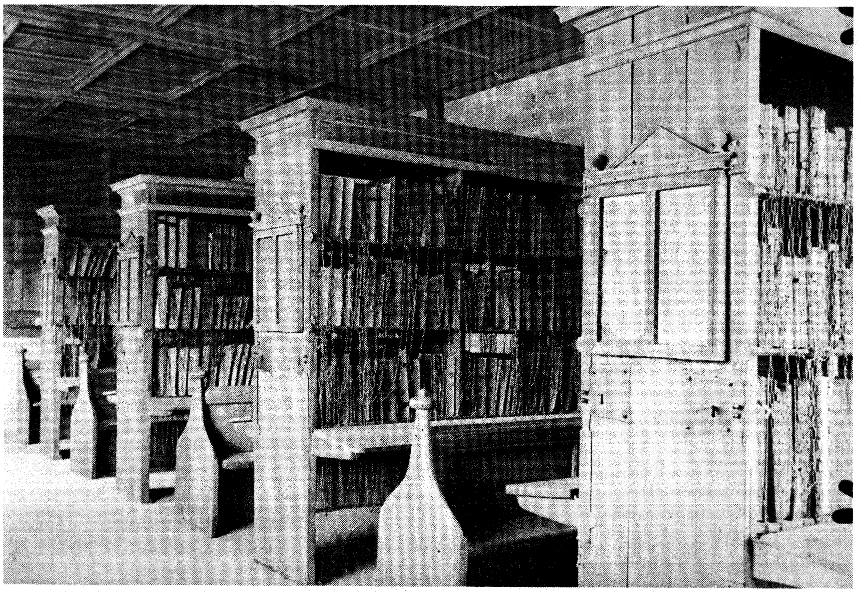
Henry Clay Folger, for example, collected no fewer than 70 copies of one book—the first collected edition of Shakespeare's plays. (In 1932 he opened the Folger Shakespeare Library in Washington, D.C., which had been built to house his collection.) As a result of the uninhibited nature of his collecting he added greatly to the sum of knowledge about the printing of Shakespeare's plays and about 17th-century printing in general. Collectors of private libraries may confer another inestimable benefit upon their fellows by leaving their collections to public institutions or by founding a library bearing their name. This practice has been common in recent years in the United States, where such names as Henry E. Huntington, John Carter Brown, William L. Clements, Pierpont Morgan, Henry Clay Folger, to mention but a few, are held in high esteem by scholars. They were following a tradition which had long been established in Europe, where notable private libraries (such as those of the Medici, Mazarin, and George III) have greatly enriched public institutions.

Subscription libraries. Part public, part private, these libraries enjoyed much popularity from the late 17th to the 19th centuries. Many of them were set up by associations of scholarly professional groups for the benefit of academies, colleges, and institutions; but their membership was also open to the general public. Some of them are still in existence: perhaps the most famous are the Library Company of Philadelphia, founded by Benjamin Franklin in 1731; the Boston Athenaeum, founded in 1807; and the London Library, opened largely at the instance of Thomas Carlyle in 1841, which today has a wide-ranging collection of over 500,000 volumes for loan to its members in their homes.

Famous subscription libraries

During the 19th century, the great size of many subscription libraries enabled them to wield much influence over publishers and authors: Mudie's Library, for instance, established in London in 1842, would account for the sale of as much as 75 percent of a popular novel's edition. Nevertheless, these libraries were for the most part unable to survive, and the service they gave is now largely provided by the free public libraries.

Archives. Archives are created in the course of conducting business activities of a public or private body; they are natural accumulations of documentary material. Originally, such records were not distinguished from library materials and were preserved in the same places as other manuscripts, right up until the mid-15th century and the invention of printing. The importance nowadays accorded to public records in an organized society has been recognized as one outcome of the French Revolution, when for the first time an independent national system of archive administration was set up, for whose preservation and maintenance the state was responsible and to which there was public access.



Chained library at Hereford Cathedral, England.

The science of archive administration embraces the study of records management, records appraisal, accessioning and arrangement, archival buildings and storage facilities, preservation and rehabilitation, and reference services, including exhibition and publication. Academic courses offering instruction in archive work are available in many parts of the world in universities and schools of library science.

While the administration of archives shares with libraries the basic obligation to collect, to preserve, and to make available, it has to employ different principles and management techniques. Libraries might be described as collecting agencies, whereas archival institutions are receiving agencies: they do not select—their function is to preserve documents as organic bodies of documentation. They must respect the integrity of these bodies of documents and maintain as far as possible the order in which they were created. And, of course, the documents need catalogs and finding aids, or guides.

Distinction between public and private archives

A distinction has to be drawn between public and private archives. Every state, broadly speaking, now recognizes the need to preserve its own official records and is expected to maintain a system of archive administration, which has the function of collecting them, preserving them, and making them publicly available after the appropriate lapse of time. Among the best known are the Archives Nationales in France, the U.S. National Archives, and the British Public Record Office. Nonofficial archives—the records of the day-to-day activities of an institution or a business—are now recognized as having great value for socio-economic history, and they are frequently sought by libraries for their historical value and preserved in manuscript and similar collections. It is the practice for many institutions such as universities, professional and commercial organizations, and ecclesiastical establishments, to set up their own archive departments.

LIBRARY ARCHITECTURE

Function and design. The basic function of a library building is to house the library's collections, to provide adequate space for staff administration and procedures, and to offer acceptable accommodation in which the collections can be used. The form given to the library is undoubtedly of great importance, but its success will in the long run be measured by its ability to meet the basic functional requirements. These requirements have to be interpreted differently according to the objectives and needs of different types of library, whether large research, university, public, or special.

In planning a research or university library, due regard to the following considerations is essential: (1) The space set aside for the collections must not only be adequate for immediate needs but also allow for planned growth over a reasonable period of time. (2) Adequate provision should be made to ensure the preservation and safety of the collections, such as proper temperature and humidity control, air conditioning, and a building plan calculated to provide security against misuse. (3) Provision should be made for the convenience and comfort of the readers and of the library staff, including the avoidance of unnecessary and time-wasting movement within the building.

The same strictures apply, on the whole, to the planning of other kinds of libraries. A good public library would pay more attention to providing an attractive exterior, a convenient layout, and pleasing conditions for users so that they can "browse" at leisure and discuss their reading and information requirements comfortably with the staff employed for that purpose. The functional emphasis in a special library would be on ease and speed of consultation.

Essential collaboration between architect and librarian

The final form to be aimed at in all these cases is a library building both functionally and architecturally distinguished. This a first-class architect can accomplish, but he is unlikely to do so unless he understands the institution he is working for and its objectives and has a satisfactory program to work to. Hence, the closest collaboration is essential between librarian and architect, the former supplying as complete a brief as possible (after careful discussion with library colleagues) and the latter endeavouring to understand the librarian's brief and interpret it in building terms. Difficulties and misconceptions are removed by close and constant discussion. Cooperation of this kind has become normal practice only in recent years; indeed, it is only in recent years that the concept of a fully documented brief prepared by the librarian has been accepted or even understood by architects and librarians alike. In the early days, libraries were often associated with temples; and it is still common to look upon a library as a central feature in a municipal or university complex, hence the temptation to erect a "prestigious" building, which may and often does subordinate function to appearance.

Historical developments. The clay-tablet rooms in the temple at Nippur in Babylonia may be looked upon as functionally designed for their purpose, as was an "archive room" excavated at Herculaneum; and, in the cloister of the early monasteries, the *armarium*, or book cupboard, was appropriately placed for its purpose in the well-lighted cloister. Monastery and cathedral libraries of the later medieval period employed the chained library stall system and were eminently functional in their form. Each consisted of a long room that ran the length of the building, usually on the first upper floor, lighted on both sides with rows of windows. Between the windows and at right angles to the walls were rows of back-to-back presses, with two or three fixed shelves on each side and with desks attached to the presses at the level of the lowest shelf; the books were chained to a long bar running the width of the presses by chains just long enough to enable them to lie open on the desk. When not in use, the books, usually at the time bulky folios and quartos, stood on the shelves, with their front edges facing outward so that the chains, which were normally attached to the front edge of the upper or lower cover, should not damage the binding of the other books on the shelves. A centre gangway ran the length of the room between the presses; and in the alcoves formed by the presses there were fixed benches for readers, who were thus able to get at the books on the desks and have enough light from the windows to read by.

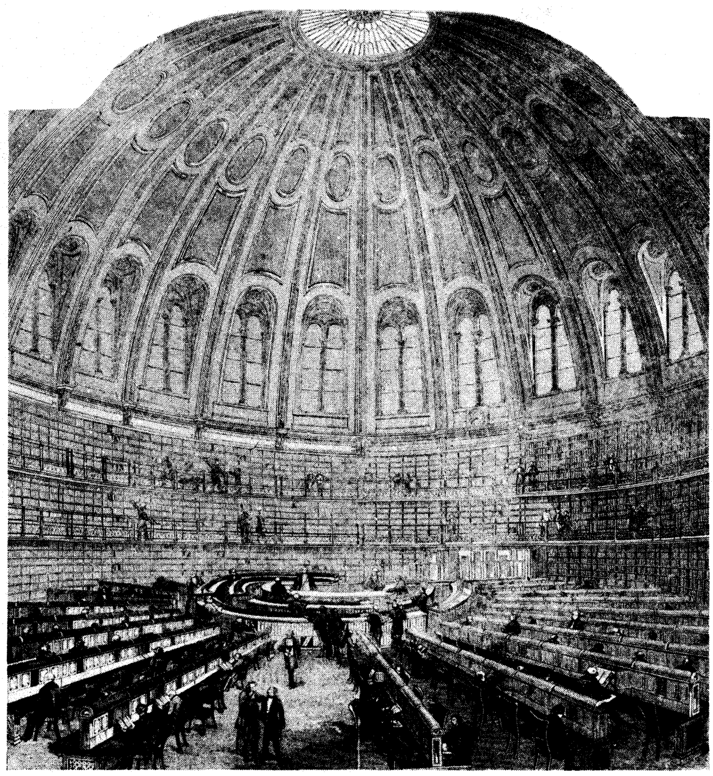
17th and 18th centuries. The "long room" was retained even in 17th- and 18th-century libraries, a reminder of the older system. The abandonment of chaining, however, coupled with a change in the pattern of publication—marked by increasing cheapness and greater numbers of publications, particularly in smaller sizes—made possible the adoption of wall shelving. Wall shelving, in turn, made possible the greater use of the height of a building—the higher the walls, the greater the number of books that could be shelved; besides this, the disappearance of chains made it possible for books to be taken away from the shelves for reading, and seats could be disposed as desired; the walls thus left unencumbered with desks and benches could be experimented with, and the main floor area could be left empty or provide an elegant setting for statuary or exhibits of other kinds, such as coin cabinets. Sometimes spaciousness and display were more highly prized than convenience for study. An example of this mood is to be found in the Prunksaal in the Austrian National Library in Vienna, erected in 1723–26 after a plan by Johann Fischer von Erlach, which consists of a magnificent Baroque hall, decorated with marble Corinthian columns; a statue of Charles VI stands in the middle and other statues of princes of the empire are placed along the walls. A number of the libraries in the Oxford and Cambridge colleges—the Wren Library at Trinity College, Cambridge, and that at Christ Church, Oxford—also provide excellent examples. Perhaps the last great flourish of library design of this kind was the King's Library in the British Museum, built between 1823 and 1826 to house the library of King George III, acquired by the museum in 1823. It consists of a room 300 feet (about 100 metres) in length with a gallery; the walls are lined with book shelves from floor to ceiling.

Wall shelving

British Museum reading room. A complete innovation in functional planning was made with the celebrated reading room in the British Museum. By the middle of the 19th century, readers were too numerous for the space provided for them in the existing reading rooms. In 1854 Antonio Panizzi, its principal librarian, by a brilliant application of the "engineering age" to library construction, planned a bookstack in cast iron with exterior enclosing walls and widely spaced brick piers, to hold some 1,500,000 volumes; it was designed to surround and support a huge, circular reading room whose radiating rows of reading desks with places for 450 readers naturally followed the circular plan, facilitating supervision, and whose walls provided space for an open access general reference library of 25,000 volumes. The "iron library," which provided an extensive library in close proximity to the reading area, reduced the risk of fire and demonstrated immense saving of space by eliminating brick supports and substituting metal. Modern stack construction has greatly improved on it, substituting steel for cast iron and generally economizing on space; but the basic plan of this stack was followed in subsequent stacks.

Bookstacks and reading rooms

The modern period. Panizzi's creation focussed attention once more on functionalism in library planning. From that time up to World War II, the design of libraries was conditioned largely by architects' interpretation of the functions to be performed by the library, and their buildings rarely gave any indication of what was actually performed within them. General style tended toward the monumental, as befitted (so it seemed to them) a building devoted to noble and scholarly pursuits. The librarian had little say—indeed, as a rule probably had little to say--on the design of the building, except to indicate the proportion of space to be allotted to bookstacks, reading rooms, and administrative quarters.



British Museum Reading Room. designed by Antonio (later Sir Anthony) Panizzi, 1854. Illustration by Sydney Smirke, from The Illustrated London News. 1857.

A specific part of the building was set aside for bookstacks, and, not surprisingly in view of the constant growth in library collections, the stack frequently came to be designed as a tower. Reading rooms were treated as separate architectural units, in many cases, related neither in proportion nor access, to the bookstacks. Finally, the space provided for administrative purposes and the routine library procedures (such as control and recording of acquisitions, cataloging, binding, and so on) was frequently planned without properly appreciating the importance of a relationship between bookstacks, reading rooms, and public. Fixed function planning produced buildings with little possibility of the flexible use of space and as a rule with only limited, if any, possibility of expansion. Much frustration was caused to the librarian, who had to put up with (and provide) light and heat for unnecessarily high reading rooms, spacious corridors and, sometimes, monumental halls and staircases. The reader was expected to climb unnecessary stairs and to walk long distances from entrance to reading room and often from the catalog and the reference shelves back to his reading place.

Access to the stacks by readers was rarely provided in the large research libraries (nor is it always desirable that it should be). Public libraries, however, though they too were often housed in monumental buildings, found it possible to introduce open access to their stock of books very early on (in England during the 1890s). Open access made bookstacks with high shelves impracticable for readers, and it encouraged the use of classified arrangement of books so that readers could easily locate the subjects and the volumes of special interest to them.

A remarkable change of attitude toward the design and construction of library buildings took place following

World War II. It is of considerable interest for the history of libraries and their development to consider what the reasons for this change may have been. Scientists, technologists, and others had, during the war, needed precise information, speedily supplied; there was undoubtedly much dissatisfaction with the traditional library services and hence a more critical attitude toward libraries and their characteristic features. Afterward, the needs of users and their convenience were given greater consideration and more careful regard. There were also many more people using libraries—more students in a greater number of universities and colleges and more members of the general public looking to libraries for information, instruction, and recreation. Significant improvements in building techniques, moreover, made new building designs and methods possible, whereas very many new libraries were needed, partly because of the interruption of building during the war, partly because many libraries in Europe and other parts of the world had been destroyed or damaged. The old kinds of library, with their monumental and inflexible structure, were no longer acceptable.

The modular system of building

The new look at library design, thus prompted, has been further encouraged by development of the modular system of building. In the modular building, the basic floor area is divided into equal rectangles defined by structural columns at the corners, which are the only weight-bearing structures within the building. Subdivisions of these areas can be created by non-weight-bearing walls, bookstacks, and freestanding furniture; it follows, in theory, that nothing within the building is fixed and immovable except the columns (and of course stairways, elevators, heating facilities, ducts, and plumbing) so that the use made of an area can be extended or modified at will.

Erik Uluots

Interior of the library in Växjö, Sweden, building and furniture designed by Erik Uluots. completed 1985.

The value of such a building needs no emphasizing. The modular method may, however, have a restrictive effect on the architect. It is likely to be most effective if it is used in a basically rectangular building. There is thus a real danger that library buildings designed on this basis may be commonplace or even downright ugly.

An eye to the future. If one of the major requirements of library architecture, maximum flexibility, has been provided by the use of the modular system, there are nonetheless many other matters which still have to be seriously considered by the library planner. It is commonly held that, on present showing, research library collections are doubling in size every 16 to 20 years—even the largest national libraries are increasing at this rate. Such an increase can hardly be supported indefinitely, so librarians (and the bodies to which they are responsible) even now are being urged to plan their strategy to deal with the problem. Demands for reading places also continue to grow, and it is likely that society will require sympathetic responses to this and other demands, including longer hours of opening and more convenient and comfortable reading and study conditions.

CONTEMPORARY LIBRARY SCIENCE

The libraries mentioned above are, for the most part, splendidly maintained and a source of pride to the institutions or public bodies that administer them. But it would be idle to pretend that research libraries, in particular, do not face great problems as their number proliferates: how to maintain comprehensiveness and balance in the collections, given the enormous increase in book production both from traditional sources and from new publishing centres; how to cope with local, fluctuating demands for collections in depth to meet important projects; how to solve the difficulty of increased pressure on funds and space; even, at times, how to avoid internecine rivalry for the possession of certain items or groups of items as they become available.

Experimental solutions to library problems. *Interorganization cooperation.* The problems listed above are insistent problems—common to libraries everywhere—and they are not being ignored. If convincing solutions to them have not yet been found, many expedients are at least under investigation and experimentation. There is first the rationalization of collection, by means of acquisitions schemes such as the Farmington Plan in the United States and the Scandia Plan in the Scandinavian countries, whereby individual libraries agree voluntarily to cover, in as much depth as possible, certain subjects or subject fields without abrogating their right to continue collecting in any other subject for which they may have special responsibility (a similar system is in practice in West Germany, under the aegis of the Deutsche Forschungsgemeinschaft); there is also the use of cooperative centres for the acquisition and preservation of out-of-the-way books, as the Center for Research Libraries (formerly the Midwest Inter-library Center, Chicago); the use of joint storage for little used material; centralized or cooperative cataloging, with the ultimate aim of making cataloging an internationally shared activity, the catalog entries being provided from central sources in each country; the introduction of the practice of printing a catalog entry in every book as it is published; the formation of networks or consortia to establish computer-aided technical-processing centres. While these experiments hold out much promise, it is by no means clear whether they are sufficiently far-reaching or whether they get to the root of the problem. Neither is it certain that institutions will be willing to contemplate any diminution of their cherished independence of policy and action. Some much more drastic replanning—and perhaps some fundamental rethinking of library activities, especially in very large libraries—may be necessary before solutions to these difficult problems appear.

Substitution of microform copies

Microforms. It seems advisable to many that the expansion now typical of almost every library should be limited as far as possible so that only selected libraries, such as national collections, by reason of their special place in the community, should continue to collect and preserve comprehensively. There are, however, certain expedients that may provide temporary alleviation of the problems associated with growth. One of the most heavily canvassed is the substitution of microform copies of library material instead of original volumes. Such copies take the form of microfilm or the extension of that concept of the microfiche, or film card. This is a promising expedient but one that so far has suffered from many disadvantages: the cost of microfilming has been high, though the expense can properly be weighed against the saving in the cost of valuable library space; the devices for reading microforms for the most part have been clumsy and inconvenient and possibly trying to the reader forced to use them over long periods. In many cases, particularly when rare and valuable books are involved, when scholars may need to examine closely the details of printing, paper, layout, and the like, microforms may be unreliable or misleading. Much research is under way to remove or reduce these disadvantages, especially as many libraries are likely to be forced—either because copies of the originals can no longer be found or because of limitations of space—to use microforms.

Space-saving techniques. Another way of economizing on space is to use "compact shelving": briefly, this means that standard stack ranges, mounted on rails with ball-bearing wheels, can be pushed tightly together, thus adding very substantially to the amount of storage available in any given area. The disadvantages are high cost, the need for extremely strong floor construction, and diminished availability to the reader.

Projected developments. The introduction of devices such as these will inevitably have a major impact both on design and on library procedures, as will also the mechanical and data-processing devices that are more and more frequently being employed. All of these will inevitably play a major part in future library services, particularly the circulation systems, interlibrary cataloging, and information retrieval. Facilities for storing and using audio-visual aids, motion-picture films, tapes, and computer tapes will all have to be provided in the libraries of the future.

Librarianship is clearly at a time of great potential development. Above all, there is a need for reappraisal and fundamental rethinking regarding the place of libraries in the community. The traditional independence that libraries have always enjoyed may have to be modified because of a need for cooperation; for example, standard procedures may have to win a more general acceptance. The advent of automation, which may help the librarian to exploit the material under his care more effectively than is possible by traditional methods, might well have a decisive influence here.

It is important that libraries should hasten to make these modifications themselves rather than, by delaying, have more drastic changes forced upon them. For it is an indication of the contemporary reaction to the difficulty and complexity of library problems that they are beginning to be dealt with nationally rather than locally. Although many libraries and librarians place great confidence in local initiative and distrust the effects of enforced uniformity and centralism, the economics and the technology of the modern world suggest that local support and initiative cannot solve the problems alone. In many countries there is a national ministry with responsibility for libraries, with a system of inspectors to ensure uniformity of services and achievements. Such systems exist already in the countries of Eastern Europe, and France and Italy have long had their directorates of libraries. Norway has recently joined the ranks, but with a National Library Advisory Service (Biblioteks tjenesten) that can apparently allow scope for initiative and independent action. In the United Kingdom, steps are being taken to set up a National Library Authority but so far with control only over the strictly national libraries.

Library systems and procedures in advanced countries inevitably influence those in the developing countries, and in most of the contacts between representatives of the two there has been an assumption that what works well in the advanced countries will work equally well for the others. Many now recognize that this may be a mistaken assumption, and it may be more desirable that such public educational institutions as libraries should endeavour to embody and reflect local cultural patterns. International library associations, including the International Federation of Library Associations (IFLA) and the International Federation for Documentation (FID), with active members in all parts of the world, are playing an increasingly important role in providing a meeting place for nationals of many countries, including those in course of development, where such problems can be discussed.

Despite the attention paid to research in librarianship, little study has been devoted to the deeper implications of the current library situation, and it may well be that it is too early and the complexities too involved for it to be possible for a librarian to take a dispassionate view of his profession, however desirable an objective reappraisal may be. Library literature is plentiful and good on the practical problems of library work, but it would appear that librarians seem for the most part to be too heavily engaged in the day-to-day activities and in the routine tasks of administration to be able to devote much time to the study of their profession. Work on the history of libraries generally tends to be similarly descriptive but deficient in studies in depth—for which there is ample raw material. The best work has been done on the early history of libraries by, for example, John Willis Clark (***The Care of Books,*** 1900) and F. Wormald and C.E. Wright (***The English Library before 1700, 1958***). The library associations, of which there are very many throughout the world covering the work of libraries of different kinds, seem to be similarly preoccupied in the discussion of current professional problems.

BIBLIOGRAPHY. The literature of libraries is very large, but of uneven quality.

Encyclopaedias: There are numerous encyclopaedias; the most authoritative of these is probably by FRITZ MILKAU (in German), but this consists of a series of studies on individual aspects of libraries and librarianship and is not so convenient to consult as those alphabetically arranged by topics. A. KENT and H. LANCOUR (eds.), ***Encyclopedia of Library and Information Science,*** vol. 1–3 (1968–70); C. LOEFFLER and J. KIRCHNER (eds.), ***Lexikon des gesamten Buchwesens,*** 3 vol. (1935–37); ***Nordisk Leksikon for Bogvaesen,*** 2 vol. (1949–57); FRITZ MILKAU (ed.), ***Handbuch der Bibliothekswissenschaft,*** 2nd ed., 3 vol. (1950–57); J. KIRCHNER, ***Lexikon des Buchwesens,*** 4 vol. (1952–56), vol. 3 and 4 plates only; SVEND DAHL (ed.), ***Nordisk Håndbok i Bibliotekskundskap,*** 3 vol. (1957–60); THOMAS LANDAU (ed.), ***Encyclopaedia of Librarianship,*** 3rd ed. (1966); H. KUNZE and G. RUCKL, ***Lexikon des Bibliothekswesens*** (1969).

Periodicals: Among the wide range of library journals, the ***Journal of Documentation*** (quarterly) is authoritative in its field, and the following are widely respected as important sources of information on library matters in general: ***Journal of Librarianship, Library Quarterly, Library Trends, Libri, Unesco Bulletin for Libraries, Zentralblatt fur Bibliothekswesen, College and Research Libraries, School Librarian, Special Libraries. (Abstract journals)*: *Library Literature*** and ***Library Science Abstracts.***

Guides to libraries: Among guides to libraries, the ***World of Learning*** (annual), gives factual information about libraries of all kinds, in all parts of the world. The following are useful guides to the range of library and bibliographical services in the various countries with which they deal. ROBERT B. DOWNS, ***American Library Resources: A Bibliographical Guide*** (1951); GISELA VON BUSSE and H. ERNESTUS, ***Das Bibliothekswesen der Bundesrepublik Deutschland*** (1968); G. OTTERVIK and S. MOHLENBROCK, ***Bibliotek i Sverige*** (1964); PAUL L. HORECKY, ***Libraries and Bibliographical Centres in the Soviet Union*** (1959).

Techniques of librarianship: The emphasis formerly placed on the techniques of librarianship in such valuable works as MARGARET HUTCHINS, ***Introduction to Reference Work*** (1944); and MARGARET MANN, ***Introduction to Cataloguing and the Classification of Books,*** 2nd ed. (1943), is being supplemented by attention to the functions of libraries as in the following: R.R. SHAW (ed.), ***The State of the Library Art,*** 5 vol. (1960–61); RONALD STAVELEY ***et al., Introduction to Subject Study*** (1967); MAURICE F. TAUBER ***et al., Technical Services in Libraries*** (1954); E.E. WILLIAMS, ***Farmington Plan Handbook*** (1961); LOUIS R. WILSON and MAURICE F. TAUBER. ***The University Library: The Organization, Administration and Functions of Academic Libraries,*** 2nd ed. (1956).

Types of libraries: A.J.K. ESDAILE, ***National Libraries of the World,*** 2nd ed., 2 vol. (1957), is a purely descriptive account, but in general, books on types of libraries show a concern for function rather than description. UNESCO, ***National Libraries: Their Problems and Prospects*** (1960); HERMAN H. FUSSLER and J.L. SIMON, ***Patterns in the Use of Books in Large Research Libraries*** (1961); W.A. MUNFORD, ***Penny Rate: Aspects of British Public Library History, 1850–1950*** (1951); WILFRED ASHWORTH (ed.), ***Handbook of Special Librarianship and Information Work,*** 2nd ed. (1962); GUY R. LYLE, ***The Administration of the College Library,*** 3rd ed. (1961); C.A. STOTT, ***School Libraries: A Short Manual,*** 2nd ed. (1955); MARY P. DOUGLAS, ***The Teacher-Librarian's Handbook,*** 2nd ed. (1949).

History of libraries: The history of libraries, apart from descriptive histories of separate libraries, which is too bulky to mention here, has not in general attracted the scholarly attention it deserves. The following, however, demonstrate what can be done by scholarly treatment. J.W. CLARK, *The Care of Books*, 2nd ed. (1902); R. IRWIN, *The English Library* (1966); N.R. KER, *Medieval Libraries of Great Britain: A List of Surviving Books* (1941); C.B. OLDMAN, *et al.*, *English Libraries 1800–1850* (1958); JAMES W. THOMPSON, *The Medieval Library* (1939, reprinted 1957); FRANCIS WORMALD and C.E. WRIGHT, *The English Library Before 1700* (1958).

Library education: Library education has a wide literature. A useful survey of the subject is given in LARRY E. BONE (ed.), *Library Education: An International Survey* (1968).

Automation: The importance of automation in libraries is shown by a growing body of literature on the subject. ROBERT M. HAYES and J. BECKER, *Handbook of Data Processing for Libraries* (1970); and R.T. KIMBER, *Automation in Libraries* (1968), give an overall picture. HENRIETTE D. AVRAM, *The Marc Pilot Project* (1968), describes the important development by the Library of Congress in the use of automation to provide comprehensive bibliographic control.

Architecture and buildings: The universal acceptance of the importance of libraries in the community, and the growth in the size of research libraries, has resulted in great attention to library buildings and the creation of many new library buildings, and as a consequence in a number of outstanding contributions to the literature of the subject, notably: ANTHONY THOMPSON, *Library Buildings of Britain and Europe* (1963); RALPH E. ELLSWORTH, *Planning the College and University Library Building* (1960); KEYES D. METCALF, *Planning Academic and Research Library Buildings* (1965); H.R. GALVIN and M. VAN BUREN, *The Small Public Library Building* (1958); J.L. WHEELER and A.M. GITHENS, *The American Public Library Building* (1941).

Archives: The comparatively recent development of archive administration on a scientific basis is being supported by a growing literature, of which the following are significant: H. JENKINSON, *A Manual of Archive Administration*, 2nd ed. (1937); L.J. REDLAND and F.W. STEER, *Local Records: Their Nature and Care* (1953); T.R. SCHELLENBERG, *Modern Archives: Principles and Techniques* (1956) and *The Management of Archives* (1965); E. POSNER, *American State Archives* (1964).

(F.C.F.)

Library Science

Library science is the discipline that encompasses all aspects of library operation. It did not become an identifiable discipline, nor did librarianship begin to emerge as a profession, until the latter half of the 19th century. Although libraries have existed since ancient times, they were previously related to religious or educational institutions, and their direction had been merely one of the duties of members of the organization.

The first modern work on library science, the *Advis pour dresser une Bibliothèque* (1627; "Advice on Establishing a Library"), was prepared by Gabriel Naudé, who was appointed by Cardinal Mazarin to run the Bibliothèque Mazarine in Paris. Translated into English in 1661, this source must have had a considerable influence on the wealthy collectors and scholars of the Restoration period. Further identification of the principles of operation and creation of codes of practice began to occur with the creation of the royal libraries in the 18th century. A significant advance in librarianship occurred in the British Museum under the direction of Sir Anthony Panizzi, whose rules for creation of the catalog of that library have had a most important influence on library practices until today.

Library economy was the designation first used for the subject and continued to be used, particularly in Great Britain, into the 20th century. The term library science was current in the United States by the middle of the 19th century and has persisted despite objections from time to time that the field cannot qualify as a science.

More recently, two other fields of study related to library science have evolved: documentation and information science. The scope of these subjects has not been clearly defined; some use them interchangeably with each other, while others consider them two distinct subjects. Documentation deals with the creation, reproduction, analysis, and retrieval of documents. Information science, usually considered to be somewhat broader in conception, is concerned with the entire information-transfer process, whether through the medium of recorded documents or otherwise. To some, however, information science is identified with the electronic transmission of signals and is closely related to information theory. To others, information science is synonymous with computer science. In any event, library science is closely related to both information science and documentation and is making increasing use of the concepts being developed by them.

Related fields: documentation and information science

The librarian's work encompasses the collection, organization, and making available of the records of all human activity. To achieve these ends, thousands of libraries have developed to serve more or less homogeneous groups on the basis of subject, interest, age, or geographic distribution. The materials acquired may consist of books and booklike documents, art in all media, phonograph records, motion pictures, models, and even data in digital form. Although the book represents the most numerous category of documents, the proportion of other forms is increasing as a result of the technological changes of the 20th century.

Despite the fact that the totality of the library's contacts with users numbers high into the millions, it is not an institution of mass communication. With few exceptions, each loan or consultation of a document is in response to the individual needs and desires of one person. The uses to which such consultations are put may run from the most casual entertainment to the most serious research, but it is the emphasis on satisfying the needs of the individual at the time of his own choosing and in private that differentiates libraries from museums, theatres, or classrooms. (See also LIBRARY; INFORMATION PROCESSING.)

TECHNICAL SERVICES

Acquisition. *Selection policy.* The clientele of each library influences the materials to be acquired, the organization of that material, and the policies to be followed in making it available. The contents of libraries serving apparently similar constituencies are quite varied. Because there are tens of millions of books to choose from, it is obvious that many will not be found in even the largest libraries. In two university libraries of the same size, more than half of the contents of one library will be different from those of the other.

Because facilities and budgets do not permit acquisition of all materials published, each library must follow some selection policy. Authorities recommend that a formal selection policy be adopted in a library, but in practice the policy is more likely to be implicit than explicit. Each library limits its acquisitions on the basis of assumed or demonstrated needs of its users. A college or university library will usually exclude all elementary or secondary school textbooks; a public library will not buy material in an exotic foreign language; an elementary school library will not consider scientific-research reports. From these obvious limitations each library naturally progresses to finer definitions of categories of material to be acquired and the depth of coverage; thus, one library may collect only a representative group of materials on the archaeology of Crete, while another will seek to obtain every book, journal, or report on the subject in every language.

Limitations of acquisitions

Problems in development of a selection policy are relatively simple in libraries of institutions with clearly focussed and narrowly defined missions. As these limits are broadened and the focus becomes less clear, conflict between various interests and points of view appear and reach their peak in the public library. Because the public library serves the entire spectrum of interests of a large population, it has endured a continuing struggle between satisfaction of popular demands for recreational reading and the more diverse demands of intellectually elite minorities. This often results in a contest between entertainment and education or between best sellers and quality books.

Censorship. This same lack of agreement on the primary goals of the public library make it a fruitful ground for controversy or censorship in the selection of materials. Because of concern for children, the school library is an equally sensitive area.

Pressures on libraries to prohibit, restrict, or label certain materials arise from various sources: individuals; social, religious, political, or ad hoc organizations; public officials; governing boards; and even on occasion members of the library staff. Many examples of library censorship exist, among them the rigid government control of German libraries during Nazi rule, when books by Jewish and Communist writers were banned.

At times it becomes difficult to identify a practice as censorship or as selection policy. In recent years in the United States, there have been accusations of censorship against the library by minorities who feel that the selection policy has systematically excluded material of interest to or in support of the minority point of view; these objections have included claims that books on the Afro-American contribution to the culture have been ignored or that books with a conservative point of view have been rejected. Concern with the problem of censorship led the American Library Association to adopt a library bill of rights in 1939, which was last amended in 1967. This document stresses the right of access to all points of view, rejects the notion that books should be excluded because of the race, nationality, or beliefs of its author, and states that libraries should resist both private and official censors.

Censorship and library bill of rights

Evaluation procedures. Few libraries are in a position to examine any significant portion of books to be acquired. More commonly, dependence must be on selection and reviewing media. The American Library Association, for example, publishes the *Booklist and Subscription Books Bulletin,* which includes short reviews of books that may be appropriate for a small library. It also publishes *Choice,* which has short, unsigned reviews of books considered appropriate for college libraries. Several commercially published library periodicals contain reviews of current books.

In addition, libraries utilize literary periodicals and book-review sections of newspapers, such as the London *Times Literary Supplement* and the *New York Times Book Review.* Many scholarly journals review books in the scope of the journal, but these are far less current and are often delayed from six months to two years after the original publication date of the book reviewed.

Bibliographic verification. Many books are purchased without benefit of review, because of either the delay in reviewing or the inadequacy of reviewing media to cover all books. Often acquisition is based upon the reputation of the author or of the publisher. Newer books may be requested as a result of publisher announcements; older books may be requested in response to inclusion in a bibliography or citation in some other work.

In many cases it is necessary to verify the authorship, publisher, place of publication, edition, date of publication, or the price. At times it is even necessary to establish the existence of the book. Tools used in this process include national bibliographies published in many countries, such as the *British National Bibliography* and the *Japanese National Bibliography,* published at frequent intervals. There is no national bibliography in the United States, but the *National Union Catalog,* published by the Library of Congress, serves the same purpose fairly well. A number of commercial lists of current books, known as trade bibliographies, are published in various countries. In the United States these include the *Cumulative Book Index,* which lists each month new books reported by author, title, and subject.

National and trade bibliographies

Sources of purchase. Libraries obtain current books from the publisher, through a retail book store, or through a jobber or wholesaler who specializes in library business. Periodical subscriptions may be obtained either directly from the publisher or from subscription jobbers or agents.

Libraries acquiring foreign materials seldom attempt to deal directly with publishers. They have a choice of using a native jobber who specializes in importing books or of using a jobber in each country who specializes in export business. There are advantages in each type of arrangement, depending in part on the volume of purchasing being done in the country.

Since the 1960s there has been an expansion of approval-order plans, particularly among larger academic libraries. Various jobbers have developed plans by which a library will be supplied automatically with all current books that fit the specifications of a profile that the library has supplied; the books may be returned within a specified period of time if not wanted. Advocates of these programs point to the increased speed in receipt of material; opponents cite the tendency to take everything and thus to fill shelves with material of questionable value.

Every library must also acquire older material not available from the publisher or through normal trade channels, either as replacement or because it was missed at the time of publication. The antiquarian book trade is a complex of independent dealers who handle secondhand or rare books, often specializing by subject or some other characteristic. Finding the book needed often involves advertising in one of the periodicals devoted to the antiquarian book market.

Gifts and exchanges of books

Other sources of supply. Gifts and exchanges are supplementary sources of library materials. Gifts by individuals to libraries may on occasion be the only source of acquisition. Many of the outstanding scholarly collections resulted from the philanthropy of a book collector; numerous weak and struggling libraries could not exist without the gifts of ordinary books from numerous small donors. Exchange of materials between libraries further enhances their collections; arrangements may exist between libraries for the regular exchange of publications of the institutions of which they are a part. Universities and learned societies have extensive exchange relations throughout the world.

A number of organizations conduct programs for piece by piece exchange of unwanted duplicates. This traffic includes books but concentrates most on single volumes or issues of periodicals. Establishment of such operations was proposed in the 19th century. In the United States, for example, the American Library Association, the American Association of Law Libraries, and the Medical Library Association each conduct exchanges.

Cataloging. Cataloging and classification, although associated, are two distinct operations, and each can be utilized in a library without the other. Cataloging consists of listing the bibliographic items that make up a library, usually by author, by title, by subject, or by a combination thereof. Classification consists of assigning each item to a specific class, which in most systems is subdivided by subject. The call number is the notation of the specific class to which the book is assigned, with additional symbols to identify the specific book. Books are generally arranged by number when they are placed on shelves, although some libraries, especially in Germany and Austria, still arrange books by order of acquisition and by size (when access to bookshelves is restricted).

Book and card catalogs. Cataloging is far older than classification, and catalogs have been in existence for many centuries. The earliest catalogs were manuscripts, themselves in book form. Manuscript book catalogs exist today in some of the most important libraries of the world; *e.g.,* the Bodleian Library of Oxford University. Various methods were used to interpolate new entries as they were added to the catalog.

Early catalogs

The first important French catalog was made in 1622 for the collection that was to become the Bibliothèque Nationale. Another catalog was prepared in 1684, arranged into 23 classes, each designated by one or more letters (this is still in use). During the 19th century the practice of libraries printing their catalogs in book form became rather common. Pressure by the trustees of the British Museum in 1834 for a printed catalog was the impetus for creation of Panizzi's cataloging code of 1839. Although this project met nearly insuperable obstacles, two editions have been published: 1881–1900 and 1931–66. In the United States the Library of Congress Catalog was first printed in book form in 1942–46, and cumulative supplements have followed regularly.

The card catalog was the product of the small group of library pioneers in the 1870s; in the United States it existed almost to the exclusion of other forms, while in other countries with long library histories book-form catalogs continued in use despite the preponderance of card catalogs. The Library of Congress has printed cards for its catalogs since 1898 and has sold cards to other libraries since 1901. The impetus for the card catalog was the difficulty in incorporating new entries into the book-form catalogs and the near impossibility of updating in a single alphabet the various copies of the printed book catalog. But in time disadvantages of the card catalog became apparent; it became difficult, particularly in catalogs containing several million cards, for the user to find the materials needed in sections that have many subdivisions, such as "Shakespeare" or the "Union of Soviet Socialist Republics."

The electronic computer, with its capacity for manipulating large stores of data rapidly, has been studied as a possible tool to eliminate the difficulties of book catalogs. There have been numerous experimental uses of the computer to create book catalogs, but in only a few instances have they replaced card catalogs. Experimentation continues, and there is the possibility that both the book and card catalogs may be replaced eventually by an electronic catalog that can be projected, one item at a time as requested, on a cathode-ray-tube screen.

Arrangement of entries in library catalogs is usually alphabetical by word rather than letter by letter. When author, title, and subject entries are all filed in the same sequence, the result is a dictionary catalog. When the author and title entries are filed in one sequence and subject cards in another, the result is called a divided catalog. The subject section of the catalog may be arranged according to the classification scheme used in the library rather than alphabetically by the indexing terms used. Such an arrangement results in a classed catalog.

Types of catalogs

Cataloging codes. Whenever a library consists of more than a few thousand volumes, the complexities of cataloging reach such proportions that a formal set of cataloging rules must be established. Cataloging codes have existed since at least the 16th century. One code that has exerted strong influence on modern libraries was that developed for the British Museum by Sir Anthony Panizzi. A direct lineal descendant was the Anglo-American rules of 1908, which was the standard for the English-speaking world for 40 years. In 1949, in an effort to simplify cataloging, new American rules were published. These modifications were never completely satisfactory, and a concerted attempt was made to create a new code that would restore uniformity to cataloging practices in all English-speaking countries and at the same time approach agreement with the practices in Europe that were based upon the Prussian Instructions, a set of cataloging rules for the Preussische Staatsbibliothek (now the Deutsche Staatsbibliothek) that had long served as a model for libraries in German-speaking areas and influenced practices in countries using other Germanic languages. The new Anglo-American code adopted in 1967 achieved some but not all objectives of its promoters.

Subject cataloging is the procedure that bridges cataloging and classification. Traditional subject cataloging consists of assigning one or more subject headings to represent the content of the book. These headings are selected from an approved list of terms, such as the Library of Congress ***Subject Headings Used in the Dictionary Catalogs of the Library of Congress*** (eighth edition). Provision is made for cross-references from unused terms and from one term to a related one. A catalog containing these entries is known as a syndetic catalog.

Classification. Systematic classifications of knowledge, influenced by Aristotle, Bacon, and other philosophers, have been utilized in libraries for many years. In China, which has a library tradition dating back to the 6th century BC, a system of classification using four categories (classics, history, philosophy, belles lettres) was employed but has been modified under the influence of the modern Universal Decimal and Library of Congress systems. The pioneers of classification by subject were the booksellers and bibliographers, including a group in the 18th century known as "the Paris booksellers," and the Swiss doctor Conrad Gesner, who published a classified list of 20,000 scholarly books, the ***Pandectarum sive partitionurn universalium***, in 1548. France has produced many classified bibliographies, notably the ***Manuel du libraire*** of J.C. Brunet in 1810.

Widespread interest in classification developed in the latter half of the 19th century, a period of great growth of libraries and the expanding concept of open stacks. The Americans Melvil Dewey and Charles Cutter and other librarians developed systems soon after 1870. The organization of the American Library Association in 1876, followed very shortly by the Library Association in Great Britain, made possible formal discussion and propagation of interest in the subject.

Development of classificatory systems

Classification systems may be categorized as enumerative or as facetted. Enumerative systems set forth major subjects and various levels of subdivisions in a linear fashion. Facetted systems attempt to represent more than one logical relationship through the representation of a number of facets of a subject by combining segments of the system. The most well-known facetted systems are the Universal Decimal Classification, originally an adaptation of the Dewey Decimal Classification, and the Colon Classification (so-called for its use of the colon to represent facets), developed by the Indian librarian S.R. Ranganathan.

Dewey Decimal Classification. The most widely used classification system is that developed by Melvil Dewey in 1873 for Amherst College. It is used in far more libraries in the United States than all other systems combined and is employed throughout Europe, Asia, and Africa, as well as Latin America. Editions and modifications have been published in many languages; there have been 18 editions of the standard version and nine editions of an abridged edition used in schools and other small libraries. Taking its name from the decimal notation used, the system uses 999 major numbers, but additional classes can be created almost without limit by the generation of decimal subdivisions. An example from the schedule for chemistry shows how numbers are subdivided:

540	chemistry and allied sciences
541	physical and theoretical chemistry
541.2	theoretical chemistry
541.3	physical chemistry
541.34	solutions
541.35	photochemistry
542	laboratories, apparatus, equipment.

Another feature of the Dewey system is the mnemonics used for certain types of subdivisions. Thus, many subjects can be subdivided geographically by the use of the historical-geographical number as decimals:

900	general geography and history
970	history of North America
973	history of the United States.

Combining with the art schedule, the number for history of art in the United States is obtained:

700	the arts
709	history of art
709.73	history of art in the United States.

Library of Congress Classification. In the United States another widely used system is that developed by the Library of Congress. It was first published in outline in 1904 and since then has been continually expanded and revised. It is spreading rapidly in the United States, particularly in college and university libraries. By 1970 an estimated 400 libraries were using this system. The Library of Congress Classification owes much to Charles A. Cutter, whose Expansive Classification was originated almost simultaneously with Dewey's Decimal Classification. Pragmatic in approach, it is planned as a classification of books rather than of knowledge, and its allocations of space for expansion are more nearly in proportion to the publication rates than those of the Dewey system.

Popularity of Library of Congress system in the U.S.

Universal Decimal Classification. The Universal Decimal Classification was first published in French in 1905; it has since been expanded in great detail by the Fédération Internationale de Documentation and published in many languages. The wider subject divisions are similar to those of the Dewey Decimal Classification, but the detail has diverged considerably. Any two class numbers in the scheme can be linked by a colon to form a more specific subject. Thus, 621.785 "heat treatment" may be combined with 669.14 "steel" to form 621.785: 669.14 "heat treatment of steel."

The combination of classes in this way leads to long class numbers, inconvenient for the spines of books and catalog cards. The founders of the Universal Decimal Classification, Paul Otlet and Henri Lafontaine, realized that shorter numbers could be obtained if the subdivisions of a main class were sorted into homogeneous groups, such that combinations would often occur among groups but rarely within groups. Terms from each group can be combined with a shortened class number.

SERVICES TO USERS

Reference services. Reference service consists of providing personal assistance to individual library users in pursuit of information: it requires the recognition by the library that such assistance-is necessary in fulfilling its duties, and that a specific administrative organization of qualified personnel must be provided. The emergence of reference service as a major aspect of librarianship is rather recent in comparison to the acquisition, organization, and custody of library materials. The term did not appear until about 1890, although recognition of the need for aid to readers had been emerging for several decades.

As first envisaged in Europe and the United States, reference service was to be rendered to the uninitiated user largely through assistance with the bibliographic apparatus of library operation. The most austere or conservative approach to reader assistance was found in the college and university libraries. Scholars were presumed not to need help, and librarians were considered incapable of rendering assistance to them. Public libraries were frequently more generous in assistance, but, until the end of the 19th century, the reference librarian was considered essentially a guide or at best a teacher.

The liberal approach to reference service

The so-called liberal approach to reference service arose in special libraries, such as those serving industrial corporations or specialized government agencies. The point of view emphasized the information dispensing function of the library and recognized such services as literature searches, preparation of abstracts, evaluations of sources, and the dispensing of information orally. The advocates of this approach did not turn their backs upon the teaching function of reference service but included preparation of reading lists as appropriate activites. In most parts of the world, current practices in most libraries fall somewhere between these extremes.

Within the older conception of reader assistance, the services of libraries have been extended to the more sophisticated and scholarly users, as well as novices. Subject specialization in reference work, with departments devoted to such areas as business, art, science and technology, and history, staffed by librarians with advanced knowledge of the subject, have become commonplace in larger libraries of all types.

Preparation and dissemination of bibliographies on topics of timely interest are a standard facet of library service. Sometimes the local bibliographic endeavours are supplementary to published guides and become part of the apparatus that the reference librarian uses.

In the organization of libraries, certain books needed frequently for consultation are usually set apart and held for use within the library. At one time reference librarians tended to look upon these reference collections as their chief concern, but, as the conception of reference service has broadened, they have come to rely upon the entire resources of the library and even beyond. Currently, reference departments frequently administer extensive interlibrary-loan programs and photocopying services.

Instruction in use of the library. In schools and colleges there is need for more extensive instruction in use of the library than can economically be rendered through regular reference services. Various forms of classroom or group instruction are found.

Public libraries seldom have formal meetings for instruction, relying instead upon information desks and the regular reference desk. Like college and university libraries, they sometimes have handbooks of library information for free distribution to patrons.

Attempts to create an ideal system for recording loans

Charging systems. Because the number of loans made in a large library may run into millions each year, the system for recording them should be economical for both the library and the borrower, as well as effective in providing the essential information. For the last century, librarians have sought the ideal system that would answer the questions: where is a particular book? when is it due? what books does a borrower have? In addition, the system should provide statistical data for improvement of book acquisition and retention policies and similar management functions.

After much experimentation, two widely used systems had evolved by the early 20th century. The Newark System, developed by the Newark (New Jersey) Public Library, was adopted almost universally by U.S. public libraries and is also used in other countries. A card with call number, author, title, and other identifying data was kept in a pocket on the inside cover of a volume. Each time the book was issued, the identification of the borrower and the date the book was due were entered on the card. The cards were filed by call number or by author and title and placed behind a date guide. This file provided an effective control on the prompt return of books. At the time of registration, each borrower was issued a borrower's card, on which the essentials of each loan transaction were recorded; thus, the number of books allowed to a borrower could be controlled, fines could be collected, and delinquent borrowers could be refused further loans. Discovering the location of a book was more difficult, because at least 12 separate date files were to be consulted.

The second system that was widely used in college and university libraries in the United States and other countries was similar, except there were two cards. One was filed by date as in the Newark System; the other was interfiled in a master file by call number. College libraries seldom limited borrowers to a fixed number of books, so that the borrower card was rarely used.

Dissatisfaction with the Newark System began to be manifest about 1925. The first new development was the book-charging machine, which was used to imprint the borrower's registration number, using an embossed plate attached to the borrower's card. The next significant change in public-library systems was the use of the transaction card, of which there are two basic versions. In the Photocharger system, a camera placed at the circulation desk is used to photograph the borrower's identification card, the book identification (the book card or its equivalent pasted inside the cover), and a numbered transaction card as the record of a loan. The transaction card, on which the due date has been stamped, is inserted in the book pocket. Because the transaction cards are used consecutively, the file arrangement is purely chronological. This system has the advantages of accuracy and economy but makes impossible the location of a book on loan, imposes a single loan period, and makes renewal difficult. The audio-charge is similar, except that the elements of the record are recorded on magnetic tape or disk.

Computer-based circulation systems

The transaction system was not accepted by United States college libraries because of the loss of information considered essential to service. Instead, they moved in the direction of punched cards and, eventually, computers. The systems developed were considerably more expensive than those utilized in public libraries, but they approached the ideal system sought by librarians in the 19th century. When increased enrollments led colleges in the United States to issue identification cards, it was relatively simple to adapt them to data-collection devices used in conjunction with computers. The combined data of borrower's identification and book identification plus date and time of the transaction are recorded in a punched card or on a magnetic tape or disk. Although relatively expensive, the system is economical of borrower time, eliminates all filing and most of the work of removing records from the file, and provides answers to all of the basic questions asked of a charge file. Statistical data are generated automatically for more effective management.

Library extension. The public-library movement has been characterized in most countries by a missionary zeal to extend the benefits of library service to ever-increasing numbers of people. This extension has been achieved by the establishment of libraries to serve rural areas and smaller cities, by building branches in larger cities, by the use of bookmobiles, and by the use of the postal services to deliver books.

In metropolitan areas the public library may maintain widely dispersed branches, so that most potential users can have ready access to them. The branch undertakes to stock the most frequently used books for adults and for children, to provide basic reference services, and to bring the resources of the central library to the neighbourhood user by interbranch loans or by referral to it. In very large libraries there are regional branches that serve to augment the resources of the neighbourhood branches.

Bookmobiles serve to bring the library even closer to the entire constituency. In the United States they were first used in rural areas but more recently have been employed in cities as well. They are also used in many other areas of the world, including the British Isles and Australia. The bookmobile is a specially constructed van mounted on a truck chassis and equipped with book shelves. Stocked with a collection of materials selected to meet the various interests of users in the route to be served, it may make two or more stops in a day at shopping centres, schools, parks, or village squares. Only limited reference service can be rendered directly, but the bookmobile librarian may take questions or requests for specific books back to the central library. The information may be sent by mail directly to the requester's home or delivered on the next return of the bookmobile.

In several countries "outreach programs" have been developed that do not rely on the user's walking into the branch or bookmobile. Participating libraries have active programs of making specialized and personalized library service available to patients in hospitals, to the elderly, and to the handicapped. Programs aimed at segments of society that have not used books in the past are also being tried, particularly in urban areas.

Interlibrary cooperation. Cooperation between libraries in provision of better services assumes many forms. Basic to all 'programs is the sharing of resources, but there are also programs for cooperative acquisition, cataloging, and storage of materials at both the local and the international level. Interlibrary loan is an essential part of the cooperative effort.

Inter-library loans

By 1926 the practice of interlibrary lending had become common enough in the United States that a national interlibrary loan code was adopted to clarify and standardize policies and procedures. Revised several times, this code restricts lending to serious scholarship. Local and regional arrangements are more generous and may make any materials available to serve any user. Developments in photocopying have altered lending practice through the provision of facsimile copies of short articles in lieu of the loan of bound volumes of periodicals, but this practice is somewhat limited by copyright. At the local level, the sharing of resources may include mutual honouring of library cards issued by the participating libraries. Thus, the residents of neighbouring towns may visit and borrow freely from any local public library, or the students of one college may use the library of another.

In the Latin American countries, several important projects for library cooperation are in progress, including the use of cooperative cataloging and union catalogs, as well as interlibrary loans.

Union catalogs and cooperative processing. One of the chief obstacles to effective interlibrary loan service is knowledge of the location of material. Cooperative efforts have been devoted to creation of union catalogs of the cooperating libraries. The first national union catalog to begin publication was the ***Deutscher Gesamtkatalog*** (1931–39), which was to include the books held by the major German libraries. Only 14 volumes covering A through Beethoven had been published when the project was suspended in 1939.

The ***National Union Catalog*** at the United States Library of Congress includes reports from several hundred participating libraries in every state. The catalog was originally in card form and was consulted by letter or telephone call to the Library of Congress. From 1956, additions to the catalog have been printed in book form in annual and later in five-year editions. The pre-1956 catalog is in process of publication and is said to be the largest work ever published; when completed it will have 610 volumes. This national catalog does not represent the holdings of smaller libraries, however, so that there exist many local and regional union catalogs.

The ***Union List of Serials*** provides information on the specific volume holdings of periodicals and other serial publications in the major participating libraries of the United States. Likewise, numerous local and state lists augment the information in the national list.

Coopera-tive processing centres

Other nations also have or are preparing union catalogs, among them Brazil and Italy. The activities of libraries in creating bibliographic guides to library resources for interlibrary loans has corollaries in cooperative processing centres that purchase or catalog materials or both for the participating libraries. The earliest of these centres were established by groups of small public libraries in which each individual library was too small to support an efficient operation alone. With the development of computer technology, the concept has spread to larger libraries and to wider geographic areas. The Ohio College Library Center, for example, which serves most of the colleges of Ohio, provides various services, including the creation of sets of catalog cards by the computer, consultation of the common catalog via computer terminals in each library, and insertion of new catalog data through these same terminals.

Cooperative acquisition. Because libraries have recognized the impossibility of even the most affluent to be sufficient alone, efforts at cooperative acquisition have been made at the local and national levels. In most cases the participating libraries assume major responsibility for collecting material on specified subjects, leaving the other libraries free to ignore these areas or to acquire only those items specifically in demand. The best known cooperative-acquisition program in the United States is the Farmington Plan, which aims to assure that at least one copy of every book of research value published anywhere in the world is acquired by a library in the United States. These materials are recorded in the ***National Union Catalog*** and are available for loan to any library. The program began operation in 1948 for three countries and has been expanded to include most of the world's book production.

Yet another type of cooperative-acquisition project is the Center for Research Libraries in Chicago, which acquires and houses materials that are available to its member libraries. Originally conceived as a cooperative storage centre to which members might transfer little-used materials, recent emphasis has been on original acquisition by the centre of important material for which a single copy will meet the demands of a large clientele. Supported by membership fees, it has members throughout the United States and Canada.

BUILDINGS AND STORAGE

Library buildings in the 19th and early 20th centuries, even the smaller ones, tended to be monumental in design, following the pattern of the British Museum. They usually contained a high-ceilinged reading room, often on the second floor, and a multitier steel bookstack. After World War II, new library buildings tended to emphasize functional rather than aesthetic considerations.

Post-World War II library architecture

With the development of the fluorescent light and the adoption of air conditioning, the need for high ceilings was eliminated. Library buildings began to be created with ceilings from eight to nine feet (about 2½ metres) in height throughout, and the multitier bookstack was often abandoned in favour of movable shelving. Thus, it became possible to utilize any area as a bookstack, reading room, or office. The flexibility increased the potential for growth and change in libraries that had been limited by the architectural features of older buildings, but the buildings tended to become austere, rectangular boxes. After several years the value of architectural aesthetics was recognized, and more recent buildings have sought to retain the flexibility, while restoring architectural beauty.

The changes in buildings have been related to changes in the philosophy of library organization. At one time, the major portion of the book stock was closed to the public. In large libraries the multitier stack was an efficient method of storage. But over the years the concept of free and open access to the books by all users gained more acceptance. Closely related to the idea of open stacks was the subject-divisional organization of services to readers. As with open access to books, this movement to place reference and other assistance to readers near the books they needed began in the public library and spread into university libraries. Under these influences, the distinction between reading rooms and stacks tended to disappear, and the architectural differentiation was inappropriate.

Experimentation and development in increasing the efficiency of the library building led to the creation of compact stacks with a considerably greater shelving capacity than traditional stacks. There are three basic types, all of which reduce the amount of space devoted to aisles. One has sections of shelves mounted on hinges; a second system places the books on pullout drawer-type shelves, which again are made accessible by temporarily blocking the aisle. The third type has a number of ranges of stack on tracks with space for a single aisle between them.

Automatic shelving and reshelving

A recent development, not yet widely used, is a shelving system by which books may be called for and reshelved automatically; it is most efficient if installed in new buildings specifically constructed to its specifications. In this system books are placed in containers of uniform size, the number in each container determined by the size and shape of each book. Because there can be no browsing among the shelves, arrangement is most efficient if based on size rather than on subject.

DEVELOPMENTS IN DOCUMENTATION

Information centres. A proliferation of publications in many technical fields, particularly those affected by government research grants, has led to the need for assistance beyond that traditionally provided in library-reference services. While libraries, as a matter of both economic necessity and basic philosophy, attempted to guide the reader to the materials he desired without influencing his own evaluation of them, information centres undertake to analyze, evaluate, select, and even on occasion to synthesize answers to questions by users.

These centres may but need not be part of a regularly constituted library and may rely upon human sources as well as documents in providing their answers. Some are operated or supported by governments. Such centres are set up to serve a narrowly defined, highly specialized field. An example is the Japanese Information Centre of Science and Technology, established in Tokyo in 1957 to collect, store, and retrieve information from foreign and domestic sources. The information received is classified according to the Universal Decimal Classification, and there are mechanical devices for information retrieval. The centre undertakes on request bibliographical and documentation research work and translations from Japanese into English and from the foreign language into Japanese. It also services microfilms. In the United States the Defense Documentation Center (DDC), which originated as the Armed Services Technical Information Agency, the Educational Resources Information Center (ERIC), a loosely coordinated group of more specialized clearinghouses, and the National Technical Information Service are well-known governmental centres. The work of these agencies is coordinated by a presidential Committee on Scientific and Technical Information (COSATI).

Services of information centres

Information centres vary in the services rendered and the clientele served, but they all publish guides to report literature, provide microform reproductions of the more significant fugitive publications, and do computerized searches of the literature in response to user requests. They generally publish abstracts of significant literature and often publish exhaustive reviews of the entire literature of the subject. These publications are made available on a regular basis to all potential users of the centre. Some maintain systems for selective dissemination of information (SDI), based upon the use of computers in the indexing functions, that provide timely notification to Individual users of new publications appearing to fall in their particular fields of interest.

Information centres rely heavily upon newer techniques in documentation, including computers, telecommunication, and microform reproduction. Centres that provide specific answers to individual questions often utilize computerized search techniques.

A few centres have completely automated the inquiry and response to a limited number of frequently asked questions. In a centre devoted to heart disease and stroke, for example, several hundred questions have been recorded on audio tape and are kept up to date. The user can call the centre by telephone, specifying the question by dialing the appropriate numbers, and then listen to a response. If more information is needed, he merely gives his name and address, which is recorded, and the information is provided after a search of the appropriate literature; photocopies of appropriate articles are sent to the user.

Microphotography. Microphotography was originally used in libraries to reproduce unique or rare items not otherwise obtainable, such as manuscripts or early books; material on paper subject to deterioration, such as newspapers; and bulky, little-used materials. More recently, original publication has occurred in microform.

A microform may be defined as a document in reduced format, such that the text cannot be read with the naked eye. There are essentially four types of microforms. Microfilm is the oldest and most widely known. Consisting of a cellulose acetate base to which a silver-bromide emulsion has been applied, it is exposed, developed, and fixed using standard photographic processes.

Microcards were conceived by Fremont Rider, a U.S. editor and publisher, who in his concern for the inexorable expansion of libraries proposed to reproduce the text of a book on a card of the dimensions used in catalogs. A brief catalog entry appears at the top of the card in normal size; from 60 to 80 pages of an average-sized book are reproduced on the lower portion of the card, with additional cards used as needed. The Microcard is a contact photographic print from a master negative. The similar microprint card is produced by photolithography, using a high-gloss paper and special drying inks. The microfiche is similar to the Microcard in format, except that it is on a transparent cellulose base, created as a positive contact print from a master negative. Microfiche was used in Europe for some time before it took hold in the United States.

Uses of microforms for varying types of publications

Although there is competition between each of the forms, each remains dominant in specific areas. The ribbon microfilm is most frequently used for newspaper reproduction. Microfilm is economical for very small editions; in fact, editions of one copy are most common. Microfiche and Microcard are most convenient for small publications that can be reproduced on a single fiche or card.

Most commercial publication in microform consists of massive collections of material representing a subject, a period of time, an outstanding library collection, or a geographic area, rather than single bibliographic items. In many cases the library must acquire the entire collection, and, when individual pieces are for sale, the prices are appreciably higher. Frequently some form of bibliographic guide for a project is provided, so that the library does not need to catalog the individual items.

Care of and conditions for microforms

Microforms, if properly developed and treated, will last as long as rag paper, but the conditions (*i.e.*, temperature and humidity) under which they must be stored are somewhat more rigorous than those required for paper. They must be protected from dust and chemical pollutants in the air. Except for archival master negatives, ideal conditions usually exist in recently constructed air-conditioned libraries.

The successful use of microforms depends upon the availability of devices for reading them. Each requires a separate type of machine. Efforts to build a satisfactory multiple-form reader have had only limited success. Because of the range of reduction ratios used in original photographing and the varying size of the originals, readers capable of handling all microform reproductions are bulky and expensive. Models of readers have been developed by which the user needing a specific image for intensive use may make an enlarged print automatically. These readers are even more expensive, however, and by some processes the cost of the print is high. Most libraries with large microform collections have enlargement facilities that can provide the prints more economically.

There continues to be user resistance to microforms. Whether this results from physiological or psychological causes, users complain of eyestrain, inconvenience in locating and consulting a specific page, and limitation of availability. The user will accept microforms if he must use the material and there is no alternative, but because of this resistance there is little likelihood that microforms will replace the extensively used lending-book collections.

Library automation. The introduction of data-processing equipment and procedures into library operation began about 1935 in the United States. The University of Texas Library introduced a circulation system using punched cards; the Boston Public Library made use of punched-card methods to analyze certain aspects of acquisition at about the same time. An experimental, highly advanced circulation system was installed at the Montclair, New Jersey, Public Library in 1941. Although there were some expressions of interest elsewhere, adoption was slow.

Computer problems

Various factors impeded the adoption of computer-based techniques: ignorance and fear of machines; limitation of character sets to capital letters, numbers, and a few punctuation marks; costs of conversion and operation. By the 1960s, however, enthusiasm for library automation was worldwide; unfortunately, performance did not always approach expectations. Computer specialists not familiar with library problems underestimated the complexity of them and promised too much; interested librarians had too much faith in computer magic. The result often was systems that were inadequate or that cost more than estimated. By the end of the decade, reality began to approach expectation, but only a small fraction of library operation was computer based.

Data processing. Interest in computers in libraries has been at two distinct levels: at the data-processing level, which includes the automation of operating records, and at the level of retrieving the intellectual contents of the library. There is a basic connection between the two that was not recognized at first. It is essential to conceive of the library as an information system, the chief components of which involve acquisition procedures and attendant fiscal operations, the inventory-control functions, including circulation records, and the bibliographic subsystem that includes creation and maintenance of catalogs and indexes for effective utilization of the library's contents. There is also the management function itself; the information about the other functions and operations is used in making management decisions.

Use of computers for retrieval

Information retrieval. Most of the attempts to utilize computers that originated in libraries were concerned with implementing an acquisition system or a record system for lending books or the creation of catalog cards. The projects at the information retrieval level were generated primarily in research settings, funded by grants from government and private sources. Project MAC at Massachusetts Institute of Technology, one of the most acclaimed, is a general purpose information retrieval system in which a number of users can simultaneously make inquiries via remote terminals. Its importance lies in the demonstration of the potentialities of the computer as an information storage and retrieval device. The Medlars project of the National Library of Medicine in the United States was originally directed toward the mechanization of publishing of Index *Medicus,* but outside interest in it has focussed more on its potential for mechanized retrieval of medical information.

Although entering the field of library automation somewhat later, the United States Library of Congress has assumed national leadership in the field. A study by a panel of experts published in 1964 reported the feasibility of automation of its bibliographic processes and envisaged access to its contents through computer consoles rather than through extensive card and book-form catalogs. The Marc project (Machine-Readable Cataloging) that followed established and tested a standard format for exchange of bibliographic information in machine-readable form. Tapes containing a significant portion of the cataloging output of the library are available for purchase by subscription and form the basis of a number of regional cooperative processing centres.

Interest in mechanized information retrieval has led to research in new indexing techniques. New classification systems, thesaurus construction, statistical analysis of language to create abstracts automatically, and improvements in concordances are examples of the variety of subjects studied. The most widely used technique for indexing by computer, although not the most sophisticated, is the KWIC, or Key-Word-In-Context, index. In most cases it is simply a permuted title index, with the remainder of the title surrounding it—in context.

There have been predictions that the computer revolution in information handling will eventually result in magnetic, electronic, and microform stores of information that can be retrieved and viewed from cathode-ray-tube screens in the office or the home, and that the traditional library with its bookstacks and reading rooms will be obsolete. A more realistic appraisal is that computers will be extensively used to create tools for utilization of the library's collections, and that only a small segment of the informational content will be under complete computer control. The reasons will be more economic than technological; the cost of information storage in a computer probably will remain many times the cost of storage in book form on library shelves.

Attempts to automate classification

Automatic classification research. Advances in information-processing technology have brought attempts to automate the process of classification. As pointed out previously, a library classification system is a scheme for organizing a collection of documents into groups, so that related subject matter is brought together in a systematic fashion. Establishing clearly demarcated groups or categories can reduce to reasonable proportions the number of items to be scanned by a user. If the process is to be automated, the principle for determining class membership by subject area must be stated in terms that a computer can process. Computers cannot understand ideas per se. The ideas in documents, however, are expressed in words, and computers can process and compare words, as well as numbers. Documents on different subjects will use different sets of words to express ideas. It follows, therefore, that documents can be ordered into classes on the basis of similarity or differences in vocabulary. This is the basic principle on which automated-document classification rests. Research in automated classification includes activities in two areas: (1) automated methods of deriving a classification system and (2) automated methods of classifying documents. One can set out to automate the role of the classificationist—the one who designs the classification schedule and determines the number and kinds of categories that will be used.

There are a number of mathematical techniques that enable the analysis of a document collection into a number of subjects. One commonly begins by characterizing each document as a list of content-word terms and then continues by comparing each document with every other one in the collection on the basis of the words they share in common. Subsets are thus obtained. Each subset is a category within the classification scheme. Initial studies indicate that these automatically produced categories are reasonably descriptive of the document collection and similar to the manually derived categories.

Automatic determination of the subject of a document

The second aspect of classification research deals with the specification of mathematical procedures for computing the probability of a document belonging to a designated category—to automate the job of the classifier. The aim is to be able to determine automatically the subject content of a document and thus classify it into its proper, pre-established category. The procedures used are based upon word-content similarity.

Numerous techniques have enabled researchers to achieve a certain measure of success in automatically classifying documents. The diversity indicates that no one method is clearly superior to all the others, and no one method has achieved a full measure of success.

LIBRARY EDUCATION

Library associations. The development of library services and the rapid growth of public libraries in Britain and the United States in the second half of the 19th century led to a natural desire of librarians to unite in the furtherance of their aims. The American Library Association (ALA) was founded in Philadelphia in 1876 and the Library Association of the United Kingdom in London in 1877. The ALA is the largest of the national library associations. Its object is to promote library service and librarianship in the United States and throughout the world. The Library Association of the United Kingdom, renamed the Library Association (LA) in 1896, was granted a royal charter in 1898. In 1962 the LA was reorganized and became fully professional.

After the formation of these library associations, numerous others were set up in countries all over the world. Worldwide interchange of ideas occurs through the International Federation of Library Associations (IFLA), which was founded in 1929 and meets annually. It sponsors research projects of international interest aimed at unifying the principles of library science. Independent regional library organizations include the Asian Federation of Library Associations (1957) and the Inter-American Bibliographical and Library Association (1930).

The International Federation of Documentation (FID) was founded in 1895 as the Institut International de Bibliographie. Its chief project was a universal card catalog of the world's great libraries, of which about 14,500,000 cards had been compiled in Brussels by 1934; little progress, however, has been made since then. The Institut became a federation in 1938; after its first postwar congress (16th, Paris, 1946) it devoted itself to problems of documentation, classification (especially the Universal Decimal Classification), document reproduction, information services, and, later, mechanical and electronic storage and retrieval of information. In this specialized field, the International Federation for Information Processing (IFIP) was founded in 1959. IFLA and FID cooperate closely with the International Organization for Standardization (ISO) in promoting the international standardization of bibliographical references, abbreviations of titles of periodicals, and transliteration.

UNESCO's interests in library science

The work begun by the International Institute of Intellectual Co-operation set up by the League of Nations was in part revived by UNESCO after World War II. UNESCO began with four main objects: improvement of bibliographical services, promotion of public libraries, promotion of international conventions facilitating the free flow of all forms of information, and development of the international exchange of publications. Although the program developed to suit changing conditions, changes flowed logically from one or more of the original aims. Thus, the improvement of bibliographical services led to the establishment of national libraries and bibliographical centres; development of bibliography and documentation in education, the natural and social sciences, and specialized subject fields; cooperation with ISO and FID in international bibliographical standardization; encouragement of national copyright laws; and improvements in cataloging. In this special field the work is coordinated by the UNESCO International Advisory Committee on Bibliography, Documentation and Terminology, a group of experts meeting regularly under various titles since 1953.

Training. In Great Britain, the Library Association is the recognized professional examining body. Training is undertaken at ten full-time schools of librarianship (one year for graduates; two years for nongraduates). There are also postgraduate diploma courses (one year) at the University of London School of Librarianship and Archives and at Sheffield, Strathclyde (Glasgow), and Queen's (Belfast) universities. There are university schools in Canada, Australia, New Zealand, India, Pakistan, Ceylon, Ghana, Nigeria, and Malaysia, and several university schools in South Africa.

Training of librarians in the U.S.

In the United States, there are one- and two-year postgraduate courses at university library schools. These and the schools in Canada are accredited by the American Library Association. The master's degree indicates professional status. The first formal education for librarianship occurred with the establishment of the School of Library Service by Melvil Dewey at Columbia University in 1887. In 1926 the Graduate Library School was established at The University of Chicago to provide education beyond the first professional degree, offering a Ph.D. degree in library science. Since 1950, the number of doctoral programs in the United States has increased. In addition, the emergence of information science as an identifiable discipline has brought a new dimension into curricula of library schools, the newer ones being designated as Schools of Library and Information Science.

In France there is an advanced school at the Bibliotheque Nationale, and the École Nationale des Chartes issues a diploma in archive work. In Germany and Sweden academic librarians and public librarians are trained in separate schools. Switzerland has a library school at Geneva. In The Netherlands training is controlled by the Central Association for Public Libraries. Norway, Denmark, and Finland each have a library school and professional certification. In Spain the Department of Archives, Libraries, and Museums holds courses to train librarians; a school at Barcelona trains public librarians.

The Soviet Union has a highly developed training system of government-controlled schools. In Poland examinations are controlled by the Ministry of Education. There are library schools in Czechoslovakia and Hungary, where qualifications are regulated by law. Turkey, Israel, Iran, Thailand, the Arab Republic of Egypt, Senegal, the Philippines, Taiwan, and Japan have library schools. In Latin America there are schools in Argentina, Brazil, Chile, Colombia (including the Interamerican Library School at Medellin), Cuba, Mexico, Peru, Uruguay, and Venezuela. Successive regional seminars on library development held by UNESCO in Asia, Africa, and Latin America have consistently urged governments to increase training facilities.

APPLICATIONS OF LIBRARY SCIENCE TO DIFFERENT TYPES OF LIBRARIES

National libraries. Most countries have national libraries at the apex of their library systems. In some cases the library is part of the executive department of the government, but in others the library that serves the legislature is also the national library (*e.g.*, the National Diet Library of Japan). In some instances (*e.g.*, that of Norway), the library of the national university serves also as the national library.

Functions of national libraries

Despite wide variations in organization and control, certain functions are usually performed. In most cases the national library is the recipient of copies of all copyrighted publications. This fact facilitates the publication by the library of comprehensive bibliographies of current book production and allows it to serve as a centre for cataloging services for other libraries within the country. In addition, it provides the mechanism for more effective interlibrary cooperation. The national library assumes direction of, or at least a leadership role in, extension of library services to the entire population. Examples of this are the provision of materials for the blind and the use of the library's resources for extensive interlibrary loans.

In some countries, including the United States, there is no single national library. The Library of Congress, which serves many of the functions of a national library, is legally only the library for the Congress. Its national role is shared with the National Library of Medicine, which was originally the library of the Surgeon General of the Army, and the National Agricultural Library, which was formerly the library of the Department of Agriculture. The functions of the national library in the United States*are shared by the state libraries.

In the Soviet Union, four great libraries—the State V.I. Lenin Library of the U.S.S.R., the State Public Scientific and Technical Library, the Central Library of Agricultural Science, and the State Central Scientific Medical Library—act as administrative centres. Thus, they advise individual libraries on acquisitions, as well as on cataloging, technical processes, and readers' services.

University libraries. University libraries share with national libraries the responsibility for supporting most of the research in a country. They continue to support the archival functions that characterized libraries in ancient and medieval times while making their resources more widely available to users than in the past. Development of comprehensive collections in areas of primary interest rather than uniform coverage of all fields characterizes university library operation.

In the United States, the phenomenal growth of university enrollment in the mid-20th century made it necessary for libraries to alter their organization in order to render adequate service to both undergraduates and research-oriented faculty and graduate students. Two trends have been apparent: the creation of separate undergraduate libraries and the increase in specialized subject libraries.

The responsibility for selection of materials has shifted markedly from faculty to the library staff. In most cases there is a joint responsibility with the faculty library committee, of which the library director is usually a member and serves in an advisory capacity on policy. Reasons for the increased responsibility for the library staff include a significant improvement in the educational qualifications of librarians, the emphasis on research, with its consequent pressures on the faculty, and the great increase in rates of book publication.

Adoption of Library of Congress system in university libraries

There has also been a trend in the United States toward use of the Library of Congress Classification instead of the Dewey Decimal Classification. Among the reasons for this shift, which began about 1930, is the belief that the Library of Congress system better reflects the disciplinary distinctions in a university. There is also an economic advantage in using without change the cataloging and classification information available through the printed catalog cards that the Library of Congress distributes.

School libraries. When the newer media—motion pictures, slides, sound recordings-came into existence they were adopted for use in elementary and secondary education sooner than in colleges and universities. In the United States, there arose a new group of audiovisual specialists who operated almost entirely independently of the library. Recently, however, there has been a movement for reuniting the two aspects of essentially the same function under the name of Instructional Materials Center. These centres may include individual study booths for listening to records of all types and for watching motion pictures as well as for reading books.

Role of the public library

Public libraries. The objectives of the public library are not limited by those of the parent institution; its policies are determined largely by its governing board, and the staff has far greater responsibility for its direction and activities than is the case in other types of libraries. Yet there have been more difficulties in defining the role of the public library. Is its primary function to serve as an educational institution? Or is its chief purpose provision of recreational reading? The pursuit of meaningful social values without becoming an active participant in community conflict has been of continuing concern. Public libraries generally consider their role to be more than the passive lending of books to those who walk in. Many provide meeting rooms for use by community groups. Libraries frequently sponsor lectures and forums, show educational motion pictures, and may actively participate in adult education programs.

Learned society libraries and special libraries. Scholarly libraries maintained by private bodies such as professional and learned societies usually specialize in one subject, and often have the finest collections in their specialty. Examples include the Royal Society of London and the Zoological Society of London. An increasingly popular modern variation of this type of library is the establishment of an academy of sciences, a network of research institutes covering most fields of learning. Particularly in socialist countries, these academies may be created and at least partly supported by the government. The libraries of learned societies and academies in the United States do not have an importance comparable to those in Europe. Prototypes of learned society libraries in the United States are those of the National Academy of Sciences and the American Antiquarian Society, which have national impact. There are also many regional and state scientific and historical societies that maintain significant libraries. Some of the scholarly functions of European societies are served by privately endowed libraries, such as the Newberry and the John Crerar libraries in Chicago, the Henry E. Huntington Library in San Marino, California, the Folger Shakespeare Library in Washington, D.C., and the Linda Hall Library in Kansas City, Missouri. In general, these libraries do not lend materials to individuals, but make their resources and services available to other libraries and to scholars through various means, including photocopying.

The term special library is at best ambiguous and is applied to libraries undertaking to serve only a limited subject interest; it may be the library of a corporation, a government department, or a division of a university. Special libraries are closely related to, and are often indistinguishable from, information centres. They tend to be nonconventional in their practices, creating, for example, their own rules for cataloging and classification.

BIBLIOGRAPHY. Although originally published in 1933, PIERCE BUTLER, *An Introduction to Library Science* (1961), remains one of the best explications of library science as an intellectual discipline. Another book that delves more deeply into the philosophical aspects of libraries is JESSE H. SHERA, *Libraries and the Organization of Knowledge* (1965). PAUL S. DUNKIN, *Cataloging U.S.A.* (1969), discusses technical aspects of library operation, but undertakes to emphasize the rationale of library cataloging practice. The Dewey Decimal Classification system is widely known and generally understood by library users, but JOHN P. IMMROTH, *A Guide to Library of Congress Classification* (1968), provides one of the first discussions of that system in depth. A good textbook on library selection and acquisition procedures may be found in MARY DUNCAN CARTER and WALLACE J. BONK, *Building Library Collections,* 3rd ed. (1969). The conflicting philosophies of library reference service are brought into focus in D.J. FOSKETT, *Information Service in Libraries,* 2nd ed. (1967); and in the somewhat older historical study of SAMUEL ROTHSTEIN, *The Development of Reference Services Through Academic Traditions, Public Library Practice, and Special Librarianship* (1955). A non-technical treatment of libraries and the newer technology may be found in PAUL WASSERMAN, *The Librarian and the Machine* (1964). Two influential books on library administration are JOSEPH L. WHEELER and HERBERT GOLDHOR, *Practical Administration of Public Libraries* (1962); and Louis R. WILSON and MAURICE F. TAUBER, *The University Library,* 2nd ed. (1956).

(R.H.Pa.)

Libya

The Libyan Arab Republic (in Arabic, al-Jumhūrīyah al-'Arabiyah al-Libiyah) is an independent Socialist republic of North Africa. It is bounded by the Mediterranean Sea on the north, Egypt on the east, The Sudan on the southeast, Niger and Chad on the south, and Tunisia and Algeria on the west. Largely composed of the Sahara, it covers an area of 675,200 square miles (1,748,700 square kilometres) and is one-fourth the size of the conterminous United States and almost twice the size of

Egypt The early 1970s population of about 2,084,000 was concentrated along the coast, where the de facto capital, Tripoli (Ṭarābulus), and Benghazi (Benghāzī), the de jure capital, are located.

Before the discovery of oil in the 1950s, Libya was poor in natural resources and severely limited by the climatic conditions of the Sahara. The country was almost entirely dependent upon foreign aid and the import of commodities necessary to the maintenance of the economy. Petroleum dramatically changed the economy, and Libya became one of the richest countries of the Middle East and Africa. Both the monarchy and the military government that took power in 1969 have been sensitive to the problems of dependence upon a single natural resource. The government has attempted to develop agriculture and industry with its vast oil revenues. It has also established a welfare state, which provides free medical care and education to all. For history, see NORTH AFRICA, HISTORY OF.

THE LANDSCAPE

Relief features. Libya is composed of basement rocks of Precambrian age (from 570,000,000 to 4,600,000,000 years old) that are overlain with marine and windborne deposits. There is also evidence of ancient volcanic activity. The major physical features are the Jabal Nafiisah (Arabic *jabal*, "mountains") and the associated Gefara plain in the northwest, al-Jabal al-Akhdar in the northeast, and the Saharan plateau. The Gefara plain covers about 10,000 square miles of Libya's northwestern corner. It rises from sea level at the coast to about 1,000 feet at the foothills of the Jabal Nafiisah. Composed of coastal cliffs, sand dunes, salt marshes, and steppe, the plain contains most of Libya's population and its largest city—Tripoli. The Jabal Nafiisah is a limestone massif that stretches for about 212 miles from west to east between the Gefara and the Sahara; it reaches altitudes of between 2,000 and 3,000 feet.

In the country's northeastern corner, al-Jabal al-Akhdar stretches for about 100 miles along the coast between al-Marj and Darnah. The limestone mountains rise steeply and stretch about 20 miles inland, attaining altitudes between 2,000 and 3,000 feet.

The desert and the plateaus

The Saharan plateau covers about 99 percent of Libya, making it truly a desert land. The sand-covered undulating plateau surface is broken by several physical features, including the al-Harūj al-Aswad, the al-Ḥammādah al-Ḥamrā', and the Tibesti mountains. Al-Harūj al-Aswad is a hilly basaltic plateau, which covers about 15,400 square miles in central Libya. It rises to about 2,600 feet and is crowned by volcanic peaks. The region is covered with angular stone fragments and boulders.

Al-Ḥammādah al-Ḥamrā' is a rocky plateau that lies behind the Jabal Nafiisah and covers an area of about 19,000 square miles. It contains bare rock outcrops and rises to 2,700 feet. An arm of the Tibesti stretches northward from the main massif in Chad. Picco Bette rises to 7,500 feet (2,286 metres) on the Libya–Chad border.

Drainage and soils. There are no perennial rivers. The numerous wadis (dry riverbeds) are filled by flash floods during the rains and quickly dry up or are reduced to a trickle. There is, however, extensive underground percolation (seepage) of water, and the numerous oases are watered by wells and springs that are fed by the underground water table. Along the coastal strip there are several salt lakes, or *sabkhah*s, formed by the ponding and evaporation of water behind coastal dunes, the capillary movement of water from the underground water table, or the collection of water where percolation is restricted. Principal salt lakes are those of Tāwurghā', Zuwārah, and the Banghāzī Plain.

On the western coast the gray-brown soils are highly saline. In the east, the soils of the Barce plain are light and fertile. The result of decomposition of limestone deposits, they contain potash and phosphoric acid. The rest of the country is covered by wind-eroded sand or stony desert.

Climate. The climate over most of the country is that of the hot, arid Sahara, but it is moderated along the coastal littoral by the Mediterranean Sea. The maritime influence is greater in winter, while the Saharan influence is stronger in summer. The large daily range of temperatures is especially notable in the Sahara; it is modified along the littoral, where the sea cools during the day and warms by night. Coastal cloud cover moderates winter coastal temperatures by limiting insolation (the delivery of direct solar radiation) by day and by acting as an insulator at night.

The warmest months are July and August, when Benghazi experiences average monthly temperatures of 72° to 85° F (22° to 29° C) and Tripoli has average temperatures of 62° to 86° F (17° to 30° C). The coolest months are January and February; Benghazi has winter monthly temperatures of 50° to 63° F (10° to 17° C) and Tripoli has 47° to 61° F (8° to 16° C). Al-‘Azīzīyah on the Gefara has recorded temperatures of about 136° F (58° C).

The effect of the *ghibli* wind

The amount of annual precipitation declines, and its variability increases, inland from the coast. Benghazi receives an annual average rainfall of 10 inches, and Tripoli receives 15 inches. In the maritime zone, however, the periodic high incidences of rainless periods in a year are sufficient to cause drought. In the Sahara, 200 consecutive rainless days in a year have been recorded in various areas, and the world's highest degree of aridity occurs at Sabhā. The dry climate is exacerbated by the ghibli, a hot, arid wind that blows from the south several times a year. It is preceded by a short lull in the prevailing winds, which is followed by the full force of the *ghibli*. The wind carries large quantities of sand dust, which turn the sky red and reduce visibility to less than 20 yards. The heat of the wind is increased by a rapid drop of relative humidity, which can fall from 80 to 10 percent within hours.

Vegetation and animal life. In years of good rainfall the northern plains are covered with herbaceous vegetation and annual grasses; the most noticeable of plants are the asphodel (an herb of the lily family) and jubule. The northern area of al-Jabal al-Akhdar—where the influence of the Mediterranean is most apparent—supports low and relatively dense forest (or macchia), in which the main trees are the juniper and lentisk. Annual plants are abundant and include species such as brome grass, canary grass, bluegrass, and rye grass. The forest becomes more scattered and stunted south of the mountain crest, and annual plants are less frequent. The Jabal Nafūsah has less plant life, and the natural vegetation of grassland lies between barren hills.

When rainfall is less than six inches, semidesert conditions prevail, and vegetation is sparse; isolated plants grow in generally barren pockets. The species most commonly found are saltwort (a plant used in making soda ash) and spurge flax (a shrubby plant), while goosefoot (an herb), wormwood (a woody herb), and asphodel also are widespread. Annual grasses grow in the rainy season, and leguminous plants appear in years of good rainfall. Although rainfall is extremely low in the true desert zone and the vegetation cover is scant, some of the plants of the semi-arid region penetrate into the occasional wadi (periodic river) valley, and date palms are grown in the southern oases.

Wild animals include desert rodents, such as the desert hare and the jerboa; hyenas; foxes, such as the fennec and the red fox; jackals; skunks; gazelles; and wildcats. The poisonous adder and krait are among the reptiles that inhabit the scattered oases and water holes. Insects are common; and the interior is crossed by migrating locusts, birds, and butterflies. Native birds include the wild ringdove, the partridge, the lark, and the prairie hen. Eagles, hawks, and vultures are common.

Tripolitania, Cyrenaica, and Fezzan

Traditional regions. The three former provinces of Tripolitania in the west, Cyrenaica in the east, and Fezzan in the southwest are coincident with Libya's traditional regions. There are deep geographical differences between the three areas, the centres of population of which are separated by hundreds of miles of barren and inhospitable country.

Economic and environmental factors accentuate strong feelings of provincial attachment. In Tripolitania (Arabic

Tariibulus), the vast majority of the population is engaged in commercial farming based on irrigation; plots of land are generally held in individual ownership and are often small. On the Jabal Nafūsah, where water is less readily available, a sophisticated agrarian system, based on olive- and fruit-tree cultivation and associated livestock raising, has evolved. In Cyrenaica (Arabic Barqah), however, the traditional economy was based on nomadic and semi-nomadic pastoralism. Arable farming has largely been an adjunct of the pastoral system, with shifting dry-land cultivation rarely entailing sedentary farming. Land ownership is no longer exclusively tribal, but the system of tenancy contrasts sharply with that of ownership in the west. In the Fezzan (Arabic Fazzān), isolated irrigated farming at the oases represents a third traditional economic system.

Cultural differences between the provinces are also important. Tribal affiliations among the Arab groups are to smaller rather than larger units. The population of the west is far more cosmopolitan than that of the east and includes a higher proportion of people with Berber, Negro, and Turkish origins. Although Tripolitania came to uneasy terms with the Italian colonial regime, Cyrenaica was the scene of constant fighting and disruption; the commercial, administrative, and cultural impact of the Italians was therefore more appreciable in the west. Cyrenaica was profoundly affected by the teachings of the 19th-century Sanūsīyah, an Islāmic brotherhood, which had little influence in the west and south.

The landscape under human settlement. The most significant mode of life practiced in rural Libya is that of the sedentary cultivator. In the traditional oases most farmers rely on irrigation, and water is raised from shallow wells either by the animal-powered *dalū* (a goatskin bag drawn by rope over a pulley) or, increasingly, by electric or diesel pumps. Landholdings in the oases are small and fragmented; the average five or seven acres per farm are generally divided into three or four separate units. On the coastal lowlands farmers normally live on their land and often have rights to graze stock and undertake shifting grain cultivation. In both the east and the west, Arab farmers occupy large, formerly European estates, in which individual units range from 12 to 600 acres, and operations are conducted at a high technical level.

Nomadism is mainly a feature of the unirrigated region?, particularly al-Jabal al-Akhdar and its surrounding area in Cyrenaica. Nomadic groups subsist primarily on their holdings of sheep, goats, and camels but also participate in the shifting cultivation of cereals. In the east, the Bedouins move south as soon as pasture appears and remain there until the ephemeral grasslands die and necessitate the return to the northern hill lands.

The village was originally an alien institution to Libya's tribal organization. Since the first Turkish occupation in the 16th century, towns and villages were developed mainly as military posts or administrative centres by occupying powers. Many village sites have been occupied for centuries; smaller settlements often began as collecting centres for the nomadic tribes during their summer residence in the oases or hill pastures. Berbers in the west, however, are thought to have retained a more or less continuous thread of settlement in their fortified nucleated villages in the western Jabal Nafūsah. In the southern oases, the villages served both as defense posts for the scattered communities and as watering and provisioning points on the trans-Saharan caravan routes.

Urban settlement

Modern development has led to the expansion of villages into large towns and has fostered a movement of the rural population from the land to the centres of settlement. Villages now reflect a purely indigenous expression, and, except in isolated parts of the east, they are integrated into Libyan social and economic life.

The two main cities of Tripoli and Benghazi have expanded to the exclusion of virtually all others. The surrounding extensive garden suburbs, such as al-Fuwayhāt to the southeast of Benghazi and Giorgimpopoli to the west of Tripoli, are a collection of colourful and luxurious villas inhabited by the more wealthy nationals and aliens. Many old buildings have been replaced with new hotels, apartment blocks and offices. Shanty towns are also found near the two cities; and, although low-income housing is under construction, these areas present problems of sanitation and water supply.

Tripoli is the main port, and Tripoli and Benghazi together handle most of the country's maritime trade. Tripoli handles the bulk of the imports, particularly those associated with the oil industry and the booming trade in consumer goods. Tobruk (Tubruq), the third most important port, is located in a remote area of sparse population. There are many other lesser ports.

PEOPLE AND POPULATION

The tribe (qabilah) is the basis of the social order in Libya, and eight out of every nine persons reside in tribal domains. Tribal organization has persisted in spite of three centuries of successive occupation by Turkish, Karamanli, Italian, and British forces.

Population groups. The Berbers were the major original element in the population. Most Arab chroniclers divide them into two main groups, whose branches indigenous to Libya are the Luata, the Nefusa, and the Adassa. The Berbers lived in coastal oases and practiced sedentary agriculture. Most of them have been assimilated into Arab society except in the Jabal Nafūsah region, Awjilah, Hūn, Socra, and Zuwārah. The 50,000 Berbers speak their own Hamitic language but have adopted the Arabic alphabet. Many are bilingual in Berber and Arabic.

Origins of the Arab population

The first influence of the Arabs was felt during the invasions of the 7th century. The initial Arab incursion into Berber lands was essentially military and had little effect upon the composition of the population. The Banū Hilāl invasion of 1049 and succeeding attacks of the Banū Sulaym in the 11th century, however, were paramount factors in the ethnic character of the population. By the 20th century, about 97 percent of Libya's inhabitants were Arabic-speaking Muslims of mixed Arab and Berber descent.

The Banū Sulaym were composed of four main groups —the Banū Hebib, the Auf, the Debbab, and the Zegb. The Hebib settled in Cyrenaica, while the others went into Tripolitania. After the establishment of tribal groups, Libya underwent a period of disorder and tribal feuding, which was augmented by the incursion of other Arab adventurers from Egypt. Toward the close of the period of anarchy, the Debbab group took control of much of Tripolitania.

Several other social groups exist alongside the tribal unit. They are the Sharifs (holy tribes), who came originally from Fezzan; the marabouts (dervishes who are credited with supernatural powers), who infiltrated from Sakiet el-Hamra in Morocco; and the Koulouglis, who are descended from the Janissaries (elite Turkish soldiers). The Sharifs constitute a religious hierarchy that claims direct descent from Muhammad. Their blood relationship with the prophet gives them a powerful standing in Muslim society, where they are looked upon as holy men with divine powers of foresight. Extensive tracts of land are found under Sharif control in all the oases of western Libya.

Marabout tribes are descended from holy men who also claimed relation to Muhammad. Infiltration of marabouts from Algeria, Tunisia, and Spain began in the 14th century and continued intermittently for several centuries. The true marabouts founded their religious devotions upon an ascetic life manifested in their existence as hermits. In areas where their teachings and way of life made them acceptable to the local inhabitants, they settled and founded tribes pledged to the pure way of life.

Minority population groups

The 35,000 Koulougis are descendants of Janissaries, Berbers, and Christian slaves. Since Turkish times they have served as a secretarial class in several areas and are often concentrated in and around villages and towns. They speak Arabic and practice Islām.

The trans-Saharan trade in slaves, which continued during Turkish times, left a pronounced black element in many of the tribes, especially in the western littoral. There are about 35,000 blacks, most of whom live in Tripolitania and the Fezzan. Their languages are those of the central Sahara and the eastern Sudan; most also speak Arabic and have adopted Islām. Before World War II there were about 30,000 Jews in Libya, but their numbers have declined to little more than 6,000. It has been suggested that the Jewish peoples are descended from colonies that existed before the Hilālian invasion. They specialize in trade, commerce, and handicrafts and are concentrated in Tripoli and other urban centres.

Small groups of Tuareg tribesmen are found in the southwest, especially at Ghudiimis and Ghāt oases. Traditionally nomadic, they are gradually assuming a sedentary life style. Isolated Teda (Tebu) communities of the southeast are gravitating toward the north and al-Kufrah oasis in search of employment. The former Italian and Greek populations have declined to negligible proportions since 1969.

Demography. In 1972, Libya had a population estimated to be just over 2,084,000. The high rate of natural increase of 3.5 percent annually is well above the regional average. The crude birth rate is 43 births per 1,000 population, and the crude death late is 9 per 1,000. There are considerable regional variations, and isolated areas of the interior have high rates of infant mortality of about 300 deaths for 1,000 live births.

Libya, Area and Population

	area		population

Source: Official government figures.

Before the 1960s there was substantial emigration of Libyans to Tunisia and Egypt in search of employment. Recent economic changes have tended to reverse the permanent flow of Libyans abroad. Temporary emigration for health, commercial, and educational purposes has become common, but the major flow is that of expatriate Libyans returning from Tunisia and Chad. In the late 1960s there was a slightly higher rate of immigration than of emigration.

Libya is one of the most urbanized countries of the Near and Middle East. Over one-fourth of the population live in cities with a population of more than 100,000; more than one-half reside in centres of more than 5,000 inhabitants; and one-third is to be found in towns of more than 2,000. Possibly the outstanding feature of the urban situation is the concentration of two-thirds of the urban dwellers in Tripoli city proper (380,000) and Benghazi (279,000). Urbanization has been achieved at a rate of growth of 25 percent between 1954 and 1966 and at an accelerated rate since then. It has taken place within limited bounds; with the exceptions of al-Baydii' and al-Marj, no new settlements of stature have emerged. Most of the new urban settlers are of rural origin, and rural population densities are static or are in decline.

Besides Tripoli and Benghazi, there are 12 large towns. In the west Gharyiin, al-Khums, Misrātah, Tājūrā', Siiq al-Jum'ah, Zanziir, and Zāwiyah are the major centres of more than 5,000 inhabitants. In the east Ajdābiyah, al-Marj, al-Bayḍā', Darnah, and Tobruk are of the same rank.

Demographic trends

The population was expected to continue to grow at a rate of 3.5 percent or more through the 1970s as birth rates remain steady and infant survival is more assured. Mortality rates are also likely to continue to show rapid decrease. Movement from rural areas to the cities seems certain to be a feature of the 1970s. The major losses will probably occur in isolated areas such as the Fezzan and the western Jabal Nafiisah rather than in the more developed areas of northern Libya. Given political stability and positive governmental support for agriculture, farming will remain an important occupation for many Libyans. It is foreseen, however, that Tripoli and Benghazi will further enhance their primacy.

THE NATIONAL ECONOMY

Natural resources. Petroleum is Libya's most important mineral resource. First discovered in 1956 near the Algerian border, it has since been located mainly in the Surt Basin. The major oil fields are Zalṭan, Amal, and Intisar A in Banghiizi *muḥāfaẓah* (governorate); Dahra field in Misrātah *muḥāfaẓah;* and Sarir field in Darnah *muḥāfaẓah.* Deposits have been located near Ghudiimis on the western border, Marziiq in the southwest, and al-Kufrah oasis in the southeast. In 1971 proven oil reserves totalled 28,000,000,000 barrels. Libyan crude oil is low in sulfur content and therefore causes less corrosion and less pollution than most crude oils. The deposits are associated with natural gas.

There are important deposits of natron (hydrated sodium carbonate) in the Fezzan and of potash in the Surt Desert near Mariidah. The iron ore in the Fezzan is low in iron content, and development is hampered by the field's distance from the coast. Marine salt is produced in Tripolitania, where there are also small deposits of gypsum, manganese, and lignite coal. Sulfur has been found in the Surt Desert, and there are scattered deposits of chalk, limestone, and marble.

The arid climate supports few biological resources except for the grasslands of al-Jabal al-Akhdar and the Jabal Nafūsah, which are valuable for grazing. There are no hydroelectric resources, and oil represents the only domestic means of producing thermal electricity.

Sources of national income. Agricultural production has declined since the 1960s because of the exodus from rural areas to the cities. The oil industry has attracted a large amount of labor from the farms, and foodstuffs are increasingly imported. Cereals are the major crops throughout the country. Barley is the chief cereal grown because it adapts well to different climates and soils. Wheat is grown primarily on the eastern and western plateaus, and sorghum is raised in the Fezzan. Olive plantations were introduced by the Italians on the Gefara and on the Jabal Nafiisah, and there are smaller olive patches in the east. Orchards of almonds, citrus fruit, apricots, and figs occur on small and large farms and on small, crowded plots in the oases. Dates are the principal crop of the southern oases. Grapes, broad beans, and peanuts are also grown. Tobacco is raised in Tripolitania.

Animal husbandry is important in Cyrenaica, where the herds are raised on communal grazing lands. Livestock includes sheep, goats, cattle, camels, horses, mules, and donkeys. Animals are raised for their milk, meat, and hides or for their services as a means of transportation. Cattle often serve as draft animals. A small amount of milk is produced commercially, and commercial poultry farms are developing around the larger cities.

Before the 1950s, the only wooded area in Libya was the region of scrub brush on al-Jabal al-Akhdar. Since then, the government has launched a massive afforestation program. Between 1957 and 1964, 27,000,000 acacia, eucalyptus, cypress, cedar, and pine trees were planted in Tripolitania.

There is little demand in Libya for fish, and most fishing is carried out off the Tripolitanian coast by Libyan, Tunisian, Greek, and Maltese fishermen. The catch includes tuna, sardines, and red mullet. Sponge beds are also important. The sponges are harvested mainly by Greeks who are licensed by the Libyan government.

The oil industry

Libya constitutes the oil-bearing region most convenient to western Europe. By 1970 oil accounted for over 99 percent of the country's export earnings and over 80 percent of the government's planned expenditures. Petroleum, however, is a diminishing resource, and Libya has a dangerous dependence upon the industry.

Almost the entire oil industry is held by foreign companies. Unlike other oil-producing nations, Libya has not concentrated on one or two large companies but has licensed more than 40 concessionaries, mainly from the United States, the United Kingdom, and West Germany. Profits are divided equally between Libya and the oil companies, and taxes are paid on the posted price for oil. Competition is high and companies are encouraged to engage in development projects as part of their bids for concessions. If oil is discovered, some companies have offered to pay extra royalties, build refineries and petrochemical plants, sponsor agricultural development, and furnish scholarships to Libyan students.

The first pipeline was constructed from the Zalṭan field to Mars2 al-Burayqā' in 1961. Since then two lines have been built from Dahra to as-Sidar and to Ra's al-Uniif, and other pipelines connect the Tobruk field to Marsā al-Hariqah and the Intisar A field to az-Zuwaytinah. A natural-gas pipeline runs parallel to the oil pipeline from Zalṭan. The gas liquefaction plant at Marsā al-Burayqā' is the world's largest.

Libya produced more than 152,000,000 tons of oil in 1971 and is the seventh largest producer of oil after the United States, the Soviet Union, Saudi Arabia, Iran, Venezuela and Kuwait. Sales to Europe have been enhanced by the closure of the Suez Canal after the Arab-Israeli War of 1967. About 2 percent of the Libyan labour force is employed by the oil industry, along with about 4,000 aliens. It has been estimated that the industry will not be able to employ more than 5 percent of Libya's work force, even when fully developed.

Mining of other mineral resources is little developed. Natron is mined, and marine salt is produced in substantial quantities. Concessions have been granted for the exploitation of iron ore and potash, but mining had not begun by the early 1970s. Gypsum, limestone, chalk, and marble are quarried for the construction industry.

Industrial development

Industrial development is hampered by the lack of skilled labour, the limited domestic market, the poor transport system, and inadequate water and natural resources. Most factories are located in Tripoli and Benghazi and are managed by Arabs. The industrial work force is small: more than 90 percent of the factories employ fewer than 100 persons, and more than 50 percent employ fewer than 10. Most factories are engaged in the manufacture of processed food, beverages, and leather. The small textile industry is almost totally dependent upon imported raw materials. There are also oil-related industries, which produce steel drums, tanks, pipe fittings, ahd housing and office buildings.

The government also contributes to manufacturing. The Libyan Tobacco Monopoly processes all tobacco and controls its import and export. There are also government monopolies for salt and esparto grass. Other ventures include the production of processed food, leather, gypsum, rugs, and mineral water.

The production of electricity for public consumption is a government monopoly. There are also private plants, such as the 25,000-kilowatt facility built by an oil company at Marsā al-Burayqah. In 1971 the total installed capacity was about 300,000 kilowatts, more than half of which was located in the west. All electric plants are powered by oil.

Financial services are headed by the Bank of Libya, which supervises the banking system, regulates credit and interest policies, and promotes the transformation of foreign banks into Libyan institutions. The Industrial and Real Estate Bank extends credit to private and governmental operations and the National Agricultural Bank gives credit and guidance to cooperatives and farmers. There are also four foreign commercial banks from the United Kingdom, Italy, and Jordan.

Foreign trade

Since 1963 Libya has enjoyed a favourable balance of trade. Almost all of its exports are represented by oil, but agricultural products and hides and skins are also exported. Major customers for Libya's products are Italy, West Germany, the United Kingdom, France, and The Netherlands. Imports consist of equipment for the oil and construction industries, farm machinery, consumer goods, and agricultural products. Most imports are purchased from Italy, the United States, the United Kingdom, West Germany, and France.

Management of the economy. The Libyan economy may be characterized as one of foreign and private initiative and cautious government control. The administration has maintained control of the concessions granted to the foreign-dominated oil industry but, apart from British Petroleum (nationalized in 1972), has resisted nationalization. It has attempted to promote private industrial and agricultural development since 1966 by the granting of interest-free loans. The shortage of capital and technical knowledge in the private sector, however, has prompted the government to enter directly into industrial endeavours.

Rapidly growing oil revenues are the main source of the government's income. Other revenues are import duties, direct taxes, and profits from government monopolies. The income tax law promulgated in 1969 includes fixed-percentage qualitative taxes and progressive income taxes on individuals and corporations.

Trade unions are weak, and their membership is small. Labour regulations are put forth by the government. In practice, most labour disputes are handled directly between the employees and the owners, but larger problems are mediated by the government.

Unions are organized by craft and by industry; the strongest organizations are the two oil workers' unions. There are three labour federations—the National Federation of Trade Unions, the Professional Workers Federation. and the Federation of Trade Unions. Their 37,000 members are largely skilled and semiskilled workers.

Economic policies and problems

Economic policy emphasizes the development of the economic infrastructure and industry. There is increased government participation in such activities as the construction of roads, schools, housing, and ports. The development of Libyan-owned enterprises is promoted to combat the influence of the foreign-owned oil companies. It is possible that government trading corporations will be established in partnership with foreign capital.

The greatest economic problem is the shortage of skilled labour. Educational and training facilities must be expanded and the towns must be developed so as to stem the migration of workers from the rural areas to the cities. Because of the influx of money from oil, inflation has increased since the 1960s. Prices for food, housing, and services have been continually rising. To curb inflation, Libya needs more workers rather than more money.

Transportation. There is a total of more than 8,900 miles of roads, of which almost 3,800 miles are paved. The main artery is the 1,100-mile coastal highway between the borders of Tunisia and Egypt, which has branch roads to the coastal towns. The Sabhā road runs from the coastal highway at al-Qaddāḥīyah south and southwest to Ghāt near the Algerian border. There are several roads between the coast and the major oil fields, and a road is planned to run south from Sabhā to the borders of Chad and Niger. The two railroads that served Tripoli and Benghazi were closed in the 1960s, and no new lines are planned.

Tripoli and Benghazi are the main seaports; they handle all imports and exports except crude oil. Petroleum is shipped from as-Sidar and Marsā al-Burayqah. Misrātah, Zuwārah, and al-Khums are to be developed as fishing ports, and Darnah and Tobruk are also being improved. The two international airports are Tripoli International Airport and Banīnah outside of Benghazi. Domestic airfields include those at Sabhā, al-Bayḍā', Ghudāmis, and Ghāt. The Libyan Arab Airlines and foreign airlines operate domestic flights and services to Europe, Egypt, Lebanon, and Tunisia. There are also domestic flights operated by the oil companies.

ADMINISTRATION AND SOCIAL CONDITIONS

The government. In September 1969 the monarchy of Idris I was overthrown and the constitution suspended in a military coup d'etat. Since then, the country has been governed by the 12-member Revolutionary Command Council and by Col. Muammar al-Qaddafi, who is head of the Council, prime minister, minister of defense, and commander in chief of the armed forces. The Council appoints the 16-member Cabinet; there is no legislature.

Local government

The country is divided into the ten *muḥāfaẓāt* (governorates) of Ṭarābulus, Banghāzī, Sabhā, al-Bayḍā', Gharyān, Misrātah, az-Zāwiyah, al-Khums, Darnah, and al-Khalij (Surt, Ajdābiyah, and al-Kufrah oases). Each district is headed by a governor (*muḥāfiẓ*), who is appointed by the Revolutionary Command Council and is responsible for the administration of local services and utilities, security, and the supervision and control of municipalities in his district. The governor is assisted by a local council that is composed of the directors of the departments representing the 9 central ministries, 18 elected members, and 4 members chosen from the local communities of the Arab Socialist Union. The councils participate in development planning, which is conceived and supervised by the central ministries.

The *muḥāfaẓāt* are divided into about 30 *baladiynt,* which are further broken down into the smallest administrative units, or *maḥallāt.* Each tribe is headed by a sheikh or an imam (religious leader). One of the major functions of the regional administrative system is to increase national identification with Libya.

Both men and women have the right to vote, but there have been no elections since 1969. There were no political parties until the formation of the Arab Socialist Union in 1971.

The judiciary is officially independent from the government. It consists of two codes of justice and court systems for traditional Islāmic law (Shari'ah) and secular law. In practice the Shari'ah courts handle civil matters, whereas the courts of first instance and courts of appeal of the secular system deal with criminal matters. The Supreme Court serves as a final court of appeal for both systems and has the power of judicial review. Judges are appointed for life but must retire at 65 years of age.

The armed forces

The armed forces consist of a 20,000 man army, a 2,000 man navy, and a 3,000-man air force. Since 1969, the armed forces have been controlled by Colonel Qaddafi and a coterie of young officers and have played an increasingly political role in government.

The 11,000-man police force, the Security Force, is divided into ten regional divisions. They are responsible for the maintenance of law and order and assistance in criminal investigation.

Social conditions. Public education is free and primary education is compulsory for both boys and girls. Arabic is the language of instruction at all levels. The few private schools are attended largely by aliens. About 85 percent of the school-age population attends classes.

The school system is composed of a six-year primary level, a three-year intermediate and vocational level, and a three-year secondary and advanced vocational level. There are also about 100 Qur'ānic schools, which are financed by the government.

Higher education is offered by the secular state institutions of the University of Libya. Advanced religious training is obtained at a branch of the university at al-Bayḍā'. Libyan students also study abroad in Egypt, Europe, and the United States.

In order to increase the literacy rate from its present low level of 30 percent, the government has also sponsored an adult educational program.

The chief health problems are tuberculosis, trachoma, and schistosomiasis (a parasitic infestation of the liver or intestines). The incidence of malaria has declined, but gastroenteritis and tetanus remain major diseases.

Medical and hospital care and medicines are free. The country has a total capacity of one hospital bed for every 260 persons. Most care is available in hospitals as there are few outpatient or specialized-care facilities. Facilities are adequate only in Tripoli and Benghazi, but there are a number of health centres in rural areas.

Most medical personnel are aliens, and the training of Libyan women as nurses is hampered by religious custom. In 1971 there was only one doctor for every 692 persons.

Welfare programs

The National Social Insurance Institute operates social security programs. Workers covered by government insurance programs receive medical examinations and treatment, maternity benefits, and dental care. There are also old-age pensions and payments for incapacity or death as a result of work-related accidents.

Housing facilities range from the Bedouin tent to the luxury apartment. About half the population occupies Mediterranean-style row houses in the towns and cities, while another 43,000 persons live in single homes or apartments. The oil economy has exaggerated the growth of slums and shanty towns in the urban areas.

A minimum wage was established by the government in 1967 and revised in 1969, but wages vary greatly. Rates are generally lower in the rural areas than in the cities, and skilled workers may earn 600 percent more than unskilled labourers. The per capita income, however, has risen from an equivalent of U.S. $100 annually to $1,979 in 1971.

Life styles in both town and village are strongly influenced by tribal affiliations and the close identity with the family. The universal group in the tribal system is the *bayt* (tribal subgroup), which may include three or four generations within its organization. All of the families of a tribe claim direct descent from a single ancestor, usually the descendant of the founder of the larger tribe. Organization is patriarchal; the eldest or most influential male is invested with supreme authority in the conduct of all affairs that relate to other similar groups. The extended family remains important even in the largest urban areas, and it is not uncommon for the eldest male to collect all earnings of the family and to allocate funds irrespective of the individual contributions made. In this situation, social contacts take place within the family context, and marriage is often arranged by the senior male.

There are also economic divisions of the population. In 1969, 10 percent of the population received more than half of the national income. The elite controlled the country through its economic advantage and family influence.

CULTURAL LIFE

Libyan culture centres on folk art and traditions, which are highly influenced by Islām. The traditional arts of weaving, embroidery, metal engraving and leatherwork rarely depict people or animals because of the Islāmic prohibition against such representation. The dominant geometric and arabesque designs are best presented in the stucco and tiles of the Karamanli and Gurgi mosques of Tripoli. Surviving traditions are represented by festivals, horse races, and folk dances. Musical styles are basically Arabic and rely upon improvisation and embellishment of melody; major musical instruments are the cane pipe and drums. Nonreligious literature has developed largely since the 1960s; it is nationalistic in character but reveals Egyptian influences. The arts are supported by the government through the Ministry of Information, the Ministry of Education and National Guidance, and the al-Fikr Society, a group of intellectuals and professionals. Government subsidies are essential because national awareness of the fine arts and folklore is weak and needs encouragement.

Cultural institutions

Libraries include the Government Library and the Archives in Tripoli, the Public Library in Benghazi, the university libraries, and those of the United States and Egyptian cultural centres in Tripoli. The Department of Antiquities is responsible for the Archaeological Museum, the Leptis Magna Museum of Antiquities, the Natural History Museum, and the Sabratha Museum of Antiquities, all in former Tripolitania, and the archaeological sites of Ptolemais and Appolonia in Cyrenaica. The Sabhā Museum contains exhibits of ancient remains of the former Fezzan region.

Although the press is officially independent, there is considerable governmental control. The six daily newspapers, six weekly newspapers, and seven magazines published in 1971 were all printed in Arabic. All were printed in Tripoli or Benghazi; one newspaper and six magazines were owned by the government and the rest were independent.

Broadcasting is owned and controlled by the government. Radio Libya has two radio stations at Tripoli and one each at Benghazi and al-Bayḍā'. Programs are broadcast in Arabic, English, and French and include cultural programs and literacy lessons for adults. The television stations in Tripoli, Benghazi, and Sabhā broadcast in Arabic and English for three hours daily.

Prospects for the future. At the time of independence in 1951, Libya was considered to be one of the poorest countries in the world, with few known natural resources, a difficult natural environment, and a population that was small, poor, and illiterate. This unpromising picture was dramatically changed with the discovery of oil; since 1963 oil revenues have provided a new source of capital for economic and social development. The main problem of the oil boom is how best to use the large sums of money available to promote the well-being of the nation as a whole.

Only a minority of the population can expect to earn its living directly through the oil and related industries. Other sources of livelihood must be developed to provide employment and income for the majority, whose needs will not automatically be met by the growth of oil production. The government has devoted large sums of money to the development of agriculture and to the raising of livestock, which are the traditional mainstays of the Libyan economy. It is believed that—with good administration, better education, and increased capital investment—a much larger production can be obtained from the land, and that good opportunities exist for the development of fisheries and tourism.

Lichen

Lichens, associations of fungi and algae, are among the most remarkable and successful examples of mutualism, a type of symbiosis, to be found in nature. Often confused with mosses, lichens appear to be single plants. Under a microscope, however, the association is seen to consist of millions of cells of algae (called the phycobiont) woven into a matrix formed of the filaments of the fungus (called the mycobiont). Approximately 15,000 different kinds of lichens, some of which provide forage for reindeer and products for man, have been described. Some lichens are leafy and form beautiful rosettes on rocks and tree trunks; others are filamentous and drape the branches of trees, sometimes reaching a length of nine feet. At the opposite extreme are those smaller than a pinhead and seen only with a magnifying lens. Lichens grow on almost any type of surface; bark, soil, rocks, and stones are common habitats. Glass, leaves, sun-bleached animal skulls, and the backs of certain weevils are unusual but not unknown habitats.

GENERAL FEATURES

Moisture requirements

Distribution. Almost all areas of the world contain lichens. They are especially prominent in bleak, harsh regions where few plants can survive. They grow farther north and farther south and higher on mountains than most plants. The body of a lichen, called a thallus, has one of several characteristic growth forms (crustose, foliose, or fruticose—see below). Each form has a different moisture requirement for growth and a favoured means for obtaining the moisture it needs. The relationship between growth and moisture requirement separates growth forms according to environmental habitats. Crustose thalli, which resemble a crust closely attached to a surface, are drought resistant and well adapted to dry climates. They prevail in deserts, Arctic and alpine regions, and ice-free parts of Antarctica. Foliose, or leafy, thalli grow best in areas of frequent rainfall; two foliose lichens, ***Hydrothyria venosa*** and ***Dermatocarpon fluviatile,*** grow on rocks in freshwater streams of North America. Fruticose (stalked) thalli and filamentous forms prefer to utilize water in vapour form and are prevalent in humid, foggy areas such as seacoasts and mountainous regions of the tropics. When growth conditions are optimal, lichens, despite their slow growth rates, cover extensive areas. Reindeer pastures in the far north consist of dense mats of ***Cladonia*** and ***Stereocaulon,*** and trees in the mountains or along seacoasts may become blanketed with ***Alectoria*** and ***Usnea.*** Few lichens grow near cities and industrial areas because of the extreme dryness and prevailing air pollution of these regions. Notable exceptions exist, however; and in England ***Lecanora conizaeoides*** actually is confined to areas of high pollution, apparently a product of the industrial age.

An example of the versatility of lichens is ***Verrucaria serpuloides,*** which is continuously submerged in the cold coastal waters of Antarctica. Other marine species of ***Verrucaria*** form black crusts on coastal boulders in intertidal zones. Some lichens inhabit the world's driest deserts, where they grow mostly underground, obtaining light and moisture through a window-like opening on the surface of the earth. A small group of desert lichens, not firmly attached, are distributed freely by wind. One such wandering lichen, *Lecanora esculenta,* is reputed to be the manna that in ancient days fell from the skies and served as a food source for man and his domestic animals.

Types. Although basidiomycetous fungi form only a few unions with algae, one well-known basidiolichen, *Cora pavonia,* is widely distributed in the tropics and has the blue-green alga *Scytonema* as the phycobiont. Several species of another basidiomycete (*Omphalina*) commonly form lichen unions with the green alga *Coccomyxa* in northern and alpine regions. The majority of mycobionts are placed in a single group of Ascomycetes called the Lecanorales, which are characterized by an open, often button-shaped fruit called an apothecium. The remaining mycobionts are distributed among various fungal groups —*e.g.*, Sphaeriales, Caliciales, Myrangiales, Pleosporales, and Hysteriales. Although there are various types of phycobionts, most of them also belong to a single group; *i.e.*, half the lichen associations contain species of *Trebouxia,* a single-celled green alga. Representatives of **26** genera of algae participate in lichen associations; 17 are green algae, eight are blue-green, and one is yellow-green. *Coccomyxa* and *Trentepohlia* are common green phycobionts; the latter, along with *Phycopeltis,* is especially prevalent in tropical lichens. Among the blue-greens, *Nostoc* and *Scytonema* are common phycobionts.

IMPORTANCE

Man has used lichens as food, as medicine, and in dyes. A versatile lichen of economic importance, *Cetraria islandica,* commonly called Iceland moss, is still being used widely by man more than **230** years after it was first prescribed for coughs and chest ailments. Nutritious and easily digested, Iceland moss sometimes is used either as an appetite stimulant or as a foodstuff in reducing diets; it has also been mixed with bread. Iceland moss also has been used to treat diabetes, nephritis, and catarrh. Lichens have little medical value. A compound (usnic acid) present in many lichens is processed in several countries as a drug for treating superficial wounds and infections. Although many lichen compounds have the ability to inhibit or destroy bacteria, molds, and viruses, lichens have not yet been used extensively to produce antibiotics.

Lichens as dye sources

Lichens are well known as dye sources. Dyes derived from them have an affinity for wool and silk and are formed by decomposition of certain lichen acids and conversion of the products. One of the best known lichen dyes is orchil, which has a purple or red-violet colour. Orchil-producing lichens include species of *Ochrolechia, Roccella,* and *Umbilicaria.* Litmus, formed from orchil, is widely used as an acid-base indicator. Synthetic coal-tar dyes, however, have replaced lichen dyes in the textile industry, and usage of orchil now is limited to its use as a food-colouring agent and an acid-base indicator. A few lichens (*e.g., Evernia prunastri*) are used in the manufacture of perfumes.

Caribou and reindeer depend on lichens for two-thirds of their food supply. In northern Canada, an acre of land undisturbed by animals for **120** years or more may contain **560** pounds of lichens; some forage lichens that form extensive mats on the ground are *Cladonia alpestris, C. mitis, C. rangiferina,* and *C. sylvatica.* Arboreal lichens such as *Alectoria, Evernia,* and *Usnea* also are valuable as forage. An acre of mature black spruce trees in northern Canada, for example, may contain over **600** pounds of lichens on branches within ten feet of the ground. Extensive consumption of lichens by animals in northern regions poses a problem, however, because lichens can absorb and retain many compounds. In addition to harmless minerals that accumulate in the thallus, radioactive derivatives of strontium and cesium also are retained in high concentrations. These isotopes, ingested by caribou and reindeer feeding on radioactive lichens, may reach dangerous levels in man when the animals are eaten by Eskimos and other human inhabitants of northern regions.

Although it has been said that lichens break down rocks and build soil on which other plants can grow, there is little evidence to support this idea. Lichen acids can extract metals from rocks, but the extent of this chemical weathering is limited. Windblown dust and soil that accumulate beneath lichen thalli growing on rocks probably have contributed to the idea that lichens are soil formers.

NATURAL HISTORY

Fungal–algal recombinations

Propagation and reproduction. Although the fungal symbionts of many lichens have fruiting structures on or within their thalli and may release numerous spores that develop into fungi, indirect evidence suggests that natural unions of fungi and algae occur only rarely among some lichen groups, if indeed they occur at all. Frequent occurrence of such unions should result in extensive genetic variability among lichen species, since fungal spores are genetically diverse, In addition, free-living algal populations, capable of serving as phycobionts, should be readily available. Evidence indicates, however, that neither condition exists in nature. Many variations that occur among lichens are induced by environmental factors affecting similar populations. In addition, free-living, potential phycobionts are not widely distributed; *e.g.*, despite repeated searches, free-living populations of *Trebouxia* have not been found. This paradox, an abundance of fungal spores and a lack of algae capable of forming associations, implies that the countless spores produced by lichen fungi are functionless, at least so far as propagation of the association is concerned. Some phycobionts —*i.e.*, species of *Nostoc* and *Trentpohlia*—*can* exist as free-living populations, so that natural reassociations could occur in a few lichens.

Some lichens have solved or bypassed the problem of recombination. In a few lichens (*e.g., Endocarpon, Staurothele*) algae grow among the tissues of a fruiting body and are discharged along with fungal spores; such phycobionts are called hymenial algae. When the spores germinate, the algal cells multiply and gradually form lichens with the fungus. Other lichens form structures, especially soredia, that are effective in distributing the association. A soredium, consisting of one or several algal cells enveloped by threadlike fungal filaments, or hyphae, may develop into a thallus under suitable conditions. Lichens without soredia may propagate by fragmentation of their thalli. Many lichens develop small thalloid extensions, called isidia, that also may serve in asexual propagation if broken off from the thallus.

In addition to these mechanisms for propagation, the individual symbionts have various methods of reproduction. Ascolichens—*i.e.*, lichens in which the mycobiont is an ascomycete—for example, form fruits (ascocarps) similar to those of free-living ascomycetes, except that the mycobiont's fruits are capable of producing spores for a longer period of time. The algal symbiont within the lichen thallus reproduces by the same methods as its free-living counterpart.

Symbiotic interactions. Most lichen phycobionts are penetrated to varying degrees by specialized fungal struc-

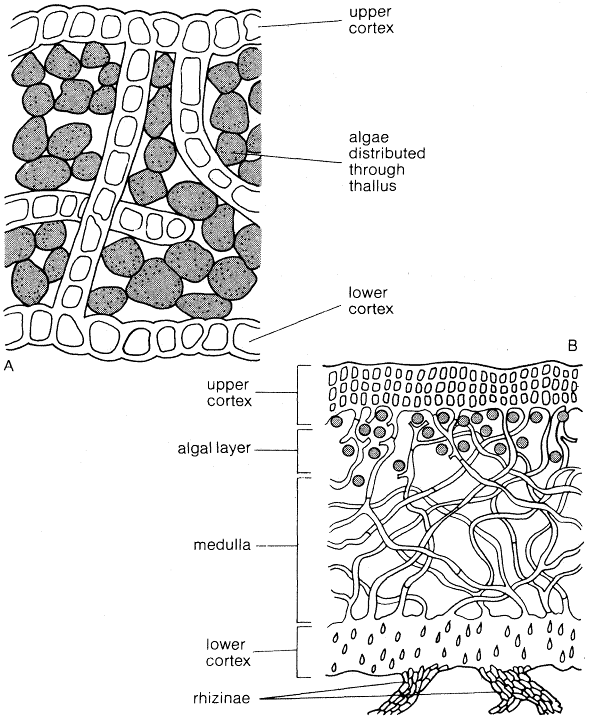

Figure 1: Distinctions based on distribution of algal cells: (A) homoiomerous thallus; (B) heteromerous thallus.

tures called haustoria. *Trebouxia* lichens have an interesting pattern, one in which deeply penetrating haustoria are prevalent in associations lacking a high degree of thalloid organization. On the other hand, superficial haustoria prevail among forms with highly developed thalli. *Lecanora* and *Lecidea,* for example, have individual algal cells with as many as five haustoria that may extend to the cell centre. *Alectoria* and *Cladonia* have haustoria that do not penetrate far beyond the algal cell wall. A few phycobionts, such as *Coccomyxa* and *Stichococcus,* which are not penetrated by haustoria, have thin-walled cells that are pressed close to fungal hyphae.

Although deeply embedded in an algal cell, a haustorium remains separated from the cell by walls and membranes; the haustorium wall is thinner than that of the usual fungal hypha. The contents of the algal cell appear to remain intact around the haustorium; in some lichens, however, a region containing many vesicle-like cavities occurs between the contents of the algal cell and the tip of the haustorium. Although the outer wall of *Trebouxia* is ruptured by the haustorium, the inner wall is more flexible, folding inward to accommodate the haustorium.

Carbohydrate flow

The flow of nutrients and metabolites between the symbionts is the basic foundation of the symbiotic system. A simple carbohydrate formed in the algal layer eventually is excreted, taken up by the mycobiont, and transformed into a different carbohydrate. Each phycobiont excretes a specific carbohydrate; *i.e.*, the mobile carbohydrate in *Nostoc* and other blue-green algae is a simple sugar, glucose. Green phycobionts excrete another type of carbohydrate known as sugar alcohols; *i.e., Trebouxia, Myrmecia,* and *Coccomyxa* excrete ribitol; *Hyalococcus,* sorbitol; and *Trentepohlia,* erythritol. The mobile carbohydrate formed by the phycobiont is taken up by the mycobiont and converted to mannitol, a sugar alcohol commonly found as a storage product in fungi. Smaller amounts of another sugar alcohol, arabitol, also may be produced. The release of carbohydrate by the phycobiont and its conversion by the mycobiont occur rapidly. In *Peltigera polydactyla,* for example, glucose forms and is released by the phycobiont within a minute, and mannitol is found in the mycobiont after two minutes. Whether or not the fungus influences the release of carbohydrate by the alga is not yet known with certainty, but carbohydrate excretion by the alga decreases rapidly if it is separated from the fungus.

Other symbiotic relationships

Carbohydrate transfer is only one aspect of the symbiotic interaction in lichens. The alga may provide the fungus with vitamins, especially biotin and thiamine, important because most lichen fungi that are grown in the absence of algae have vitamin deficiencies. The alga also may contribute a substance that causes structural changes in the fungus since it forms the typical lichen thallus only in association with an alga. One contribution of the fungus to the symbiosis concerns absorption of water vapour from the air; the process is so effective that, at high levels of air humidity, the phycobionts of some lichens photosynthesize at near-maximum rates. The upper region of a thallus provides shade for the underlying algae, some of which (*e.g., Trebouxia)* are sensitive to strong light. In addition, the upper region may contain pigments or crystals that further reduce light intensity and act as filters, absorbing certain wavelengths of light.

Lichens synthesize a variety of unique organic compounds that tend to accumulate within the thallus; many of these substances are coloured and are responsible for the red, yellow, or orange colour of lichens. Although these compounds have been assumed to be products of the symbiosis (*i.e.,* neither symbiont could produce them alone), certain mycobionts grown in the absence of algae form the same compounds that are found in the symbiosis. The role of lichen substances in the symbiosis has not yet been clarified. They might be waste products with no function, or, since some of the substances are effective chelating agents (*i.e.*, capable of binding metal atoms), they might extract minerals, thus making them available to the symbiosis. Other possible roles of lichen substances may be to increase the ability of compounds to penetrate the membranes of the algal cells, to stimulate algal metabolism, or to prevent the growth of decomposing organisms in the thallus.

FORM AND FUNCTION

Thalloid types. *Homoiomerous thallus.* A lichen thallus or composite body has one of two basic structures. In a homoiomerous thallus, the algal cells, distributed throughout the structure, are more numerous than those of the fungus. The phycobiont is a blue-green alga whose filaments are embedded in a matrix. In *Collema,* the mycobiont has a few of the threadlike filaments called hyphae growing between the algal filaments; in *Leptogium,* however, the mycobiont forms regions known as the upper and lower cortex.

Heteromerous thallus. The most common type of thallus, a heteromerous thallus, has four distinct layers, three of which are formed by the fungus and one by the alga. The fungal layers are called upper cortex, medulla, and lower cortex. The upper cortex consists of either a few layers of tightly packed cells or hyphae that may contain pigments. A cuticle may cover the cortex. The lower cortex, similar in structure to the upper cortex, participates in the formation of attachment structures called rhizines. The medulla, located below the algal layer, is the widest layer of a heteromerous thallus. It has a cottony appearance and consists of interlaced hyphae. The loose

nature of the medulla not only provides it with numerous air spaces but also allows it to hold large amounts of water.

The algal layer, about three times as wide as a cortex, consists of tightly packed algal cells enveloped by fungal hyphae from the medulla. The algal layer is not uniform in width; localized growth results in ridges or humps, some of which extend upward into the cortex or downward into the medulla. In addition to a primary phycobiont, some lichens also have a secondary one. *Lobaria*, Nephroma, and *Solorina* have a blue-green secondary phycobiont; the primary one is always green. The secondary phycobiont is found within the thallus either in clusters or as a distinct, uninterrupted layer directly below the primary alga. In some lichens, a gall-like structure called a cephalodium results from the association of the fungus with a secondary blue-green phycobiont.

Growth forms

A heteromerous thallus may have a stalked (fruticose), crustlike (crustose), or a leafy (foliose) form. Although these growth forms have considerable taxonomic significance, they are not inflexible structures, and many transitional types exist. It is not known, moreover, which growth form is primitive, which is advanced. Fruticose lichens, which usually arise from a primary thallus of a different growth form (*i.e.*, cmstose, foliose), may be shrubby, pendulous, or consist of upright stalks. The fruticose form usually consists of two thalloid types: the primary thallus is crustlike or lobed; the secondary thalli, which originate from the crust or lobes of the primary thallus, consists of stalks that may be simple, cup-shaped, intricately branched, and capped with brown or red fruiting bodies called apothecia. Fruticose forms such as *Usnea* may have elongated stalks with a central solid core that provides strength and elasticity to the thallus.

The crustose thallus is in such intimate contact with the surface to which it is attached that it usually cannot be removed intact. Some crustose lichens grow beneath the surface of bark or rock so that only their fruiting structures penetrate the surface. Crustose lichens may have a hypothallus—*i.e.*, an algal-free mat of hyphae extending beyond the margin of the regular thallus. Cmstose form varies: granular types such as Lepmria, for example, have no organized thalloid structure; but some Lecanora species have highly organized thalli, with lobes that resemble foliose lichens lacking a lower cortex.

The foliose forms are flat, leaflike, and loosely attached to a surface. The largest known lichens have a foliose form; species of Sticta may attain a diameter of several feet. Other common foliose genera include Cetraria, *Parmelia*, *Peltigera*, and Plzyscia. Umbilicaria, called the common rock tripe, differs from other foliose forms in its mode of attachment in that its platelike thallus attaches at the centre to a rock surface.

Specialized thalloid structures. *Rhizines, cilia, and pores.* Rhizines, hairlike growths that anchor the thallus to a surface, consist of bands of hyphae that originate in the medulla and lower cortex. Especially prevalent in foliose lichens, rhizines may be scattered over, or localized on, the under surface of the lichen. The tip of a rhizine may contain a sticky substance that increases its adhesive capability. Rhizines are not involved in the uptake of water or minerals to the lichen.

Cilia, long hairlike projections with no known function, originate from cortical hyphae on margins of a thallus or apothecium. Cyphellae are well-defined pores that facilitate gas exchange in the lower surface of some foliose lichens such as *Sticta.* Pseudocyphellae, less well-defined, irregular pores usually filled with a granular material, have a function similar to that of cyphellae.

Ceplzalodia. Cephalodia, gall-like structures connected to the main thallus, contain an algal type, usually a blue-green, different from that in the main thallus. A cephalodium develops when a foreign alga comes in contact with the thallus and stimulates the mycobiont to form a mass of tissue around it. Cephalodia have characteristic forms; *e.g., Peltigera aphthosa* has numerous disk-shaped cephalodia containing *Nostoc,* while *Stereocaulon* has saclike cephalodia containing either *Scytonema* or *Stigonerna.*

Soredia and isidia. Soredia (Figure 2A) are powdery masses that result from outgrowths of algae through cracks and pores in the upper cortex. A single soredium consists of one to several algal cells and the fungal hyphae accompanying them. Soredia, common in foliose and fruticose lichens but rare in crustose lichens, may be scattered over the thallus or limited to clumps called soralia. Soralia vary in size, shape, and thalloid position in different species—*e.g.,* elongated furrows on thalloid ridges of *Parmelia sulcata,* swollen knobs on the marginal lobes of *Hypogymnia physodes.* Powdery soredia are found on the stalks of many species of *Cladonia,* while the thallus of *Lepraria* consists entirely of soredia. Prolonged periods of moisture stimulate growth of the phycobiont in some lichens, resulting in increased soredial production.

Soralia

Isidia (Figure 2B) are similar to soredia in origin and reaction to moisture, but they differ from soredia in that the algae do not grow through the upper cortex. Instead, the algae extend the cortex into small knobs whose tissues are continuous with the tissues of the main thallus. Thalli of *Parrnelia furfuraccu* in moist localities are covered with isidia.

Fruticose lichen.
Alectoria sarmentosa, a northern forest lichen sensitive to warm temperatures.

Fruiting bodies and spores. The complex fruiting bodies (ascocarps) of lichen fungi are of several types. The factors that induce fruiting in lichens have not yet been established with certainty. Button-like fruiting bodies called apothecia (Figure 2C) are found on the upper surface or sides of Lecanorales thalli. Some thalli are covered with apothecia, while others may have few or none. An apothecium contains a spore-bearing tissue called the hymenium, which consists of saclike bodies (asci) containing spores (ascospores). Interspersed between the asci are sterile hyphae, called paraphyses, whose ends frequently are enlarged to form a hymenial surface layer (epithecium). The asci and paraphyses originate from a layer of fungal tissue called the hypothecium, which extends along the sides of the hymenium to form an apothecial margin—*e.g.,* as in *Lecidea.* Below the hypothecium may be another layer that is part of the thallus and contains algae. This layer may envelop the apothecial margin —*e.g.,* as in *Lecanora.*

Lichen fungi belonging to the Sphaeriales have a flask-shaped fruiting body called a perithecium, which has an outer margin, usually black in colour, and a tiny pore called an ostiole. Lichen fungi of the Hysteriales have a thick-walled narrow fruiting body. In the Caliciales, the asci disintegrate prematurely, and the mass of spores and paraphyses is called a mazaedium.

Ascospores of lichen fungi are of many sizes and shapes; *e.g., Pertusaria* has one or two large spores in one ascus; *Acarospora* may have several hundred small spores per ascus. An ascospore generally has one nucleus but may be single-celled or multicellular, brown or colourless; the *Pertusaria* spore, however, is a single cell containing 200 nuclei. Another type of fungal spore may be what are sometimes called spermatia (male fungal sex cells) or pycnidiospores; it is not yet certain that these structures can germinate and develop into a fungal colony. Few lichen fungi produce conidia, a type of asexual spore common among ascomycetes.

Separation and growth of symbionts. A phycobiont may be isolated from a lichen thallus by several techniques. If a thallus is fragmented in water, individual algal cells can be freed of visible debris and placed onto a nutrient agar. A visible colony will usually develop from such cells within two weeks. An easier isolation technique is to crumble a dry thallus over the surface of a mineral agar and to incubate the small fragments in the presence of light; the phycobiont grows faster than the fungus. Isolation of blue-green phycobionts is more complex because bacteria commonly are found in their gelatinous sheaths.

A mycobiont may be isolated either from spores or from pieces of hyphae. The hyphal isolation technique, best applied to foliose and fruticose lichens, involves separation and transfer of pieces of the medulla to a suitable growth medium. Both alga and fungus may be grown by isolating algal cells that have large fragments of fungus attached to them.

Culture methods

The growth or culture methods for lichen symbionts are similar to those used for other micro-organisms. The behaviour and requirements of many lichen fungi and algae, however, are unique. Most of the symbionts grow slowly, and the best growth is obtained on complex media rich in nutrients. Unlike other green algae, which require minerals alone for growth, *Trebouxia* grows well only if provided with a medium of sugar, organic nitrogen, and minerals. The phycobiont synthesizes nutrients both for itself and its fungal partner: *Trebouxia,* for example, can fix carbon by photosynthesis almost as well as other green algae; but ribitol, the photosynthetic product that accumulates, is incorporated so slowly into algal growth substances that it accumulates, begins to leak out of the cells, and is absorbed and converted to mannitol by the fungus.

A lichen develops only if the symbionts are forced into the union by stress conditions—*e.g.,* periodic drying or nutrient deficiency. Successful synthesis has been accomplished with *Cladonia cristatella* and *Endocarpon pusillum.* With *C. cristatella* the synthesis occurs in two phases, development of thalloid lobes and formation of fruiting bodies. The first occurs only after an interaction of the two symbionts; the second occurs in separate cultures of the mycobiont, but the fruiting bodies are immature and lack spores. The synthesis of *E. pusillurn,* on the other hand, represents the first complete synthesis of a lichen. The fungal and algal symbionts, isolated and grown separately, are mixed on a soil surface. Thallus lobes and mature fruits form within four months; in addition, spores from the fruiting bodies germinate.

Effects of drying

Factors that influence metabolic activity. *Water content.* The metabolic activity of lichens is greatly influenced by the water content of the thallus. The rate of photosynthesis may be greatest when the amount of water in the thallus is from 65 to 90 percent of the maximum. During drying conditions, the photosynthetic rate decreases and, below 30 percent is no longer measurable. Although respiration also decreases rapidly below 80 percent water content, it persists at low rates even when the thallus is air-dried. Since lichens have no mechanisms for water retention or uptake from the surface to which they are attached, they very quickly lose the water vapour they absorb from the air. The rapid drying of lichens is a protective device; *i.e.*, a moisture-free lichen is more resistant to temperature and light extremes than is a wet one. Frequent drying and wetting of a thallus is one of the reasons lichens have a slow growth rate. Studies have revealed that the phycobiont *Trebouxia* stores two products. If the lichen is dry, large numbers of fat-containing droplets are found within pyrenoid, or storage, structures in the algal cells. When the lichen is kept moist for several days, starch granules appear in addition to the fat droplets. Since starch is the usual storage product in green algae, fat may be a product that has evolved from the symbiosis with fungi. Both the natural habitats of lichens and the relatively short daily period of time during which adequate water balance exists indicate that fats may represent a product whose function is to provide a large amount of energy in a small period of time and possibly supply enough water to maintain the metabolic machinery of the symbionts.

Temperature and light. Maximum photosynthesis in lichens takes place at temperatures of 15° to 20° C. More light is needed in the spring and summer than in the winter. The photosynthetic apparatus of lichens is remarkably resistant to cold temperatures. Even at temperatures below 0° C, many lichens can absorb and fix considerable amounts of carbon dioxide. Respiration is much less at low temperatures so that, in nature, the winter months may be the most productive ones for lichens.

Crustose lichens grow less than one millimetre per year, while fruticose and foliose forms increase in size at a rate of a few centimetres a year. Thalli of some arctic crustose lichens such as *Rhizocarpon* and *Lecidea* may be 4,500 years old. In temperate regions, however, changes in a lichen community occur more rapidly. Lichens, which are sensitive to small changes in climate, appear or disappear from an area depending on climatic changes. Lichens may form thalli and fruits within two to eight years after growth on a new surface has begun.

EVOLUTION

Trebouxia lichens

The fossil record of lichens is inconclusive. It has not yet been established with certainty when and how these associations evolved, although lichens must have evolved more recently than their components and probably arose independently from different groups of fungi and algae. It seems, moreover, that the ability to form lichens can spread to new groups of fungi and algae. Interesting lichens, in terms of evolution, are *Trebouxia* lichens. It has been postulated that *Trebouxia* is a genus that originated as a result of an association with fungi. Its ancestor may have been a type of alga commonly found in soil. Two groups of *Trebouxia* are recognized; one group (I) occurs in *Cladonia* and related lichens, while the other group (II) is found in foliose and in many crustose forms. Certain features of group I *Trebouxia*, similar to features found in free-living soil algae, may reflect those of the ancestral type. On this basis, *Cladonia* and its related forms would have given rise to lichens with Group II *Trebouxia*. This hypothesis is contrary to the usually accepted idea that fruticose lichens represent the most advanced type.

Foliose lichen.
A species of Pseudocyphellaria showing fruiting bodies.

CLASSIFICATION

Distinguishing taxonomic features. The taxonomy of lichens is based mainly upon the character of the fungal symbiont. The primary taxonomic features involve details of the fruiting bodies such as type of ascocarp, size and nature of spores, and height of the hymenium. Secondary taxonomic characters include details of the external structure of the thallus—*i.e.*, colour; width of lobes; presence, absence, shape, size, and location of isidia, soredia, cyphellae, psuedocyphellae, cephalodia, cilia, and rhizines.

Other secondary characters include internal structural details of the thallus—*i.e.*, thickness of the cortex, type of algal symbiont, nature of the chemical substances found in the thallus. Geographical distribution and the type of growth surface also are factors in taxonomic evaluation. In some cases, a grouping of secondary features has been considered sufficient to give species rank to a lichen.

Annotated classification. The following abridged classification is adapted from one published by M.E. Hale in 1967.

PHYLUM ASCOMYCOTA (sac **fungi)**

Class Ascomycetes

Sexual spores contained within asci.

Subclass Ascomycetidae

Asci mainly unitunicate (one wall), arranged in a hymenium with unbranched paraphyses.

Order Lecanorales. Fruiting bodies of the apothecium type.

Family Acarosporaceae. Thallus crustose or scalelike; numerous minute spores in an ascus; on rocks in Arctic and temperate regions; *Acarospora* apothecia sunk in thallus; *Biatorella* thalli may be embedded in rock substrate.

Family Cladoniaceae. Two types of thalli; primary thallus crustose or scalelike; secondary thallus fruticose; on rocks, soil, and rotted wood in Arctic and temperate regions; *Baeomyces roseus*, pink apothecia on small stalks, common on roadside soil banks; *Cladonia,* a commonly collected type of lichen.

Family Collemataceae. Thallus gelatinous when wet; phycobiont blue-green; Arctic and temperate regions; on soil, rocks, and trees in moist locations; *Collema,* thallus black or dark brown, dull; *Leptogium,* thallus slate-blue, shiny.

Family Graphidaceae. Thallus crustose; apothecium elongated with narrow slitlike opening; on trees, predominantly in tropical and subtropical regions; *Graphis,* called "script lichen" because clusters of apothecia resemble hieroglyphic writing.

Family Lecanoraceae. Lichen family second only to Lecideceae in number; crustose, sometimes scalelike; apothecium with a thallus rim; on trees and rocks in Arctic and temperate regions; *Lecanora,* over 1,000 species.

Family Lecideaceae. Largest lichen family; thallus crustose; apothecia lack thallus rim; on rocks and trees in Arctic and temperate regions; *Lecidea,* over 1,000 species, simple spores; *Bacidia,* elongated, multicellular spores.

Family Parmeliaceae. Thallus foliose or subfruticose, well developed; on rocks and trees in Arctic, temperate, and tropical regions; *Parmelia,* largest genus of foliose lichens, common on deciduous trees in southeastern United States, apothecia on thallus surface; *Cetraria,* common on conifers in cold regions, apothecia on thallus margin.

Family Peltigeraceae. Thallus foliose, often with gall-like structures (cephalodia); on soil, mosses, and trees in Arctic and temperate regions; *Peltigera,* common in damp woods, large, thick thalli; *Hydrothyria venosa,* aquatic form in streams at high elevations.

Family Physciaceae. Thallus crustose or foliose; spores brown; on trees and rocks, Arctic to tropical; *Physcia,* small, ash-white thalli commonly rosette-shaped; *Buellia*, small, inconspicuous crustose thallus.

Family Stictaceae. Thallus foliose; includes some of the largest known lichens; both cyphellae and pseudocyphellae pore types common; on trees in temperate and tropical regions; highly developed in Southern Hemisphere; *Lobaria pulmonaria*, "lungwort lichen"; *Sticta*, with thalli up to several feet in diameter in Southern Hemisphere.

Family Teloschisfaceae. Thallus yellow or orange, crustose, foliose, or fruticose; on trees and rocks in Arctic and temperate regions; *Xanthoria parietina*, common along seashores; *Caloplaca elegans*, one of the most colourful lichens.

Family Unzbilicariaceae. Thallus foliose, attached to rocks at a single point (umbilicus); Arctic and temperate regions; *Umbilicaria*, "rock tripes."

Family Usneaceae. Thallus fruticose, sometimes pendulous to great lengths; on bark and rocks in Arctic and temperate regions; *Usnea*, "old-man's beard"; *Letharia vulpina*, covers branches of trees in mountains of western U.S.

Order Sphaeriales. Fruiting bodies of perithecium type.

Family Pyrenulaceae. Thallus crustose; mostly on trees in tropical areas; *Pyrenula*, thallus inconspicuous, often immersed within growth surface.

Family Strigulaceae. Thallus crustose; tropical; *Strigula*, often parasitic on leaves.

Family Verrucariaceae. Thallus crustose or scalelike; on rocks, trees, and soil; Arctic and temperate regions; many freshwater and marine species; *Verrucaria*, forms black crusts on rocks along seashores; *Endocarpon*, fruits contain algal cells that are discharged along with spores.

Order Caliciales. Fruiting bodies of the mazaedium type (asci disintegrate at maturity).

Family Caliciaceae. Thallus crustose, poorly developed; fruits on slender stalks, resembling tiny nails; on bark and soil in temperate regions; *Calicium, Coniocybe.*

Family Opegraphaceae. Thallus crustose; on trees and soil in temperate regions; highly developed in Southern Hemisphere; *Sphaerophorus*, shrubby thallus with branched, intertangled stalks.

Subclass Loculoascomycetidae

Asci bitunicate (two walls) an arranged with branched paraphyses in an ascostroma.

Order Myrangiales. Ascostroma poorly differentiated; asci distributed irregularly.

Family Arthoniaceae. Thallus crustose, poorly formed, embedded in trees in temperate and tropical regions; *Arthonia*, widely distributed.

Order Pleosporales. Ascostroma well differentiated, resemble perithecia; asci distributed in regular fashion.

Family Arthopyreniaceae. Thallus crustose; on trees and rocks; primarily tropical; *Arthopyrerzia*, smooth, whitish thalli partly within growth surface.

Order Hysteriales. Ascostroma well differentiated, resemble apothecia or are elongated and irregular.

Family Opegraphaceae. Thallus crustose; on trees and rocks in temperate and tropical regions; *Opegrapha*, "script lichen" similar to *Graphis* (family Graphidaceae).

Family Roccellaceae. Thallus crustose or fruticose; on rocks and trees in tropical and subtropical regions; *Roccella*, fruticose thalli, common in dry, coastal areas of eastern Pacific, Africa, and the Mediterranean.

Class Basidiomycetes

Sexual spores borne on basidia; *Cora*, on soil and trees in tropical regions; *Omphalina*, on soil in Arctic and mountainous regions.

Class Fungi Imperfecti

Sexual spores absent; *Lepraria*, granular, mealy thallus of irregular form; common on rocks and soil in moist, shaded areas.

Critical appraisal. Lichens are a biological group lacking formal status in the taxonomic framework of living organisms. Although the mycobiont and phycobiont have Latin names, the product of their interaction, a lichen, does not. Earlier names given to lichens as a whole now are considered names for the fungus alone. Classification of lichens is difficult and remains controversial. Part of the problem is that the taxonomy of lichens was established before their dual nature was recognized; *i.e.*, the association was treated as a single entity. Another difficulty encountered in lichen classification is inherent in the field of taxonomy—*i.e.*, whether or not taxonomic systems should reflect the natural phylogeny of living organisms or conveniently identify them. In a system designed for convenience, it is advantageous to consider the association as one unit.

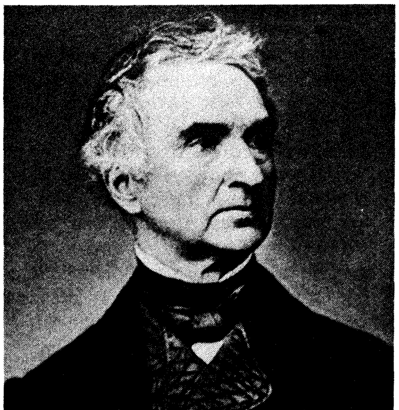
Liebig, Justus von

Justus von Liebig, German chemist, made many important contributions to the early systematization of organic chemistry, to the application of chemistry to biology (biochemistry), to chemical education, and to the basic principles of agricultural chemistry. He was born at Darmstadt on May 12, 1803. After studying pharmacy for a short time he followed his ambition to become a chemist by entering the University of Bonn to study with a leading chemist of the day, Karl Wilhelm Gottlob Kastner.

Education

When Kastner moved to the University of Erlangen, Liebig accompanied him and received his doctorate there in 1822. He then received a grant from the Hessian government to study in Paris. Through the influence of Alexander von Humboldt he was able to work in the private laboratory of Joseph-Louis Gay-Lussac.

By courtesy of the Gesellschaft Liebig-Museum, Giessen, West Germany



Liebig, photograph by F. Hanfstaengl, 1868.

In 1824 he joined the faculty of the University of Giessen, where he became a full professor in 1826. At Giessen he established the first laboratory in which the methods of chemical research were taught systematically to young chemists. The laboratory soon became world famous, and students from all over Europe came to study with him. Among them were many of the notable chemists of the following generation, including August Wilhelm von Hofmann, Sir Edward Frankland, F.A. Kekule von Stradonitz, and Charles-Adolphe Wurtz. Liebig's laboratory set the pattern for chemical education that came to prevail in Germany and was in large part responsible for the great development of German chemistry later in the 19th century. In 1845 he was made a baron, and in 1852 he became professor of chemistry at the University of Munich, where he remained until his death in Munich on April 18, 1873.

Development of radical theory

Liebig was an active worker in many fields of inorganic and organic chemistry, but certain of his studies stand out because of their great significance in the later development of chemistry. His early studies on the isomerism of cyanic and fulminic acids made a great impression on his contemporaries and led him into the field of organic chemistry. Through his work in organic chemistry, he became acquainted with another outstanding chemist, Friedrich Wohler. His friendship with Wohler lasted a lifetime, and the two men collaborated in several investigations. The most important of these was the study of bitter almond oil (benzaldehyde), in which the same chemical group was found to pass unchanged through a great variety of reactions. Such a group was called a radical, and the radical theory that Liebig did much to develop was the first major attempt at systematization in organic chemistry.

Liebig's studies in organic chemistry were greatly aided by the simple method he developed for the analytical determination of carbon and hydrogen. He also developed a method for the analytical determination of halogens, published important work on polybasic organic acids, and did much to support the hydrogen theory of acids. He popularized, but did not invent, the Liebig condenser, still used in many laboratory distillations.

After 1838 Liebig's interest shifted from pure organic chemistry to the chemistry of plants and animals. He made a large number of analyses of tissues and body fluids and carried out a study of the nitrogenous products of the animal organism. A by-product of this investigation was the Liebig extract of beef. He then became greatly interested in agricultural problems and in 1840 published *Organic Chemistry in Its Application to Agriculture and Physiology*. This book exerted very great influence on practical agriculturalists. He rejected the old theory that humus supplied plants with food and showed that plants took carbon dioxide, water, and ammonia from the air and soil. He advocated the use of mineral fertilizers to supply other elements that might become depleted in soils.

In his later years Liebig's reputation became so great that he was regarded as the final authority in chemical matters. He never hesitated to express his sometimes rather rigid views. As a result he was often involved in scientific controversies in which he was not always in the right. Much of his work was published in the journal that he founded in 1832, the *Annalen der Pharmacie*, which ultimately became the *Annalen der Chemie*, one of the major chemical journals.

After he accepted the professorship at Munich, Liebig gradually lost his enthusiasm for laboratory work. He soon refused to accept new students and devoted himself more and more to literary activities. In these, aside from his frequent polemics, he was occupied in stressing the broader applications of chemistry to human life.

BIBLIOGRAPHY. Most of the biographies of Liebig have been written in German. The earliest English account is A.W. VON HOFMANN, *The Life Work of Liebig in Experimental and Philosophic Chemistry* (1875). A good account is by F. HABER in E. FARBER, *Great Chemists* (1961). The work of Liebig and its results are treated in *Liebig and After Liebig*, ed. by F.R. MOULTON (1942). An excellent picture of Liebig's relations with his contemporaries is H. VON DECHEND (ed.), *Justus von Liebig in eigenen Zeugnissen und Solchen seiner Zeitgenossen*, 2nd ed. (1963).

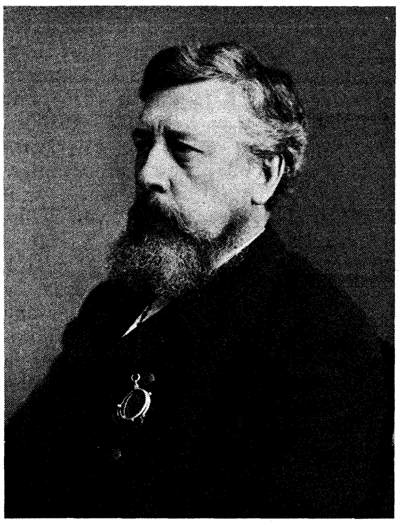
(H.M.L.)

Liebknecht, Wilhelm and Karl

Between the German revolutions of 1848–49 and 1918–19 Wilhelm and Karl Liebknecht, father and son and prominent German Socialists, successively provided much of the leadership to the Marxian wing of the German Socialist movement, which was characterized by a collectivist, internationalist, antimilitary, and anti-war tradition. The revolutions of 1848–49 in Germany and elsewhere in Europe marked the beginning of Wilhelm Liebknecht's active espousal of Socialism. The German Revolution of 1918, which claimed the life of Karl Liebknecht, closed a period in which father and son significantly shaped the nature and destiny of German Socialism.

Wilhelm. Wilhelm Liebknecht was born at Giessen in Hesse, on March 29, 1826. He was still a child when his father died, but he was brought up comfortably. He attended the universities of Giessen, Marburg, and Berlin and developed an interest in French Socialist thinking, formulated in the early 1830s by Henri Saint-Simon, Charles Fourier, and Pierre-Joseph Proudhon. Dissatisfied with his life in Germany, he planned to emigrate to the United States when he was in his 20s. Instead, he accepted an invitation to teach at a Swiss elementary school, where for the first time he came in close contact with the working classes. He then decided to study law and be called to the bar in Switzerland.

Archiv fur Kunst und Geschichte



Wilhelm Liebknecht, c. 1890.

This was in 1847. On February 23, 1848, revolution erupted in Paris. He arrived too late to become involved and returned to Germany, where he participated in several revolutionary insurrections that failed. During an attempt to fan the fading revolutionary embers in Baden, he was captured and held prisoner for eight months. In 1849, after his release, he returned to Switzerland.

Years with Marx

Liebknecht's stay in Switzerland was short, for the Austrian and Prussian governments, fearful of his growing influence among the Swiss workers, succeeded in having him expelled from Geneva. In 1849 he went to England, where he remained for 13 years. In London he joined the Communist League, working closely with Karl Marx and Friedrich Engels and supporting himself as London correspondent for the *Augsburger allgemeine Zeitung* ("Augsburg Gazette"). In 1862 the Prussian government granted him amnesty; he returned to Berlin and became a writer for the *Norddeutsche allgemeine Zeitung* ("North German Gazette"), soon becoming an influential Socialist. But Otto von Bismarck, who had become minister president (prime minister) in 1862, resented Liebknecht's influence among the working classes and, failing to gain his support, had him expelled from Prussia in 1865.

In Leipzig, where he moved, Liebknecht joined the floundering Allgemeiner Deutscher Arbeiterverein (General German Workers' Association), founded by the Socialist leader Ferdinand Lassalle in 1863. He also formed a friendship with August Bebel, a woodturner, who on his travels as a journeyman had become familiar with the poverty of the masses throughout Germany. Liebknecht, the writer, and Bebel, the orator and practical politician, complemented one another and together they provided the leadership for German Socialism for the remainder of the century. In Leipzig, Liebknecht worked hard to win new recruits for the cause and continued his efforts to educate the masses through the *Demokratisches Wochenblatt.* In 1867 the workers elected Liebknecht to the North German Reichstag, where he opposed Lassalle's advocacy of a "paternalistic" state socialism. In 1869, at a congress at Eisenach, Liebknecht and Bebel organized the Sozialdemokratische Arbeiterpartei (Social Democratic Labour Party) and affiliated it with the First International (International Workingmen's Association) headquartered in London.

The outbreak of the Franco-Prussian War in 1870 put Liebknecht's devotion to international Socialism to a practical test. His failure to vote for war credits and his writings against the war and the government resulted in his conviction on charges of "treasonable intentions" in 1872. He was sentenced to two years' confinement in the fortress of Hubertusburg, along with Bebel, who was similarly charged.

The Prussian military victory in 1871 did nothing to abate the Socialists' growing strength in the Reichstag, and Liebknecht continued to be a thorn in Bismarck's side. Bismarck's determination to repress the Socialists brought about the merger of the Lassalleans and Liebknechtians as the Sozialistische Arbeiterpartei Deutschlands (Socialist Labour Party) at Gotha in 1875. The Gotha Program, a compromise between the positions of the two parties—although criticized by Marx for its call for government-aided productive organizations—remained the charter of German Socialism until the adoption of the Erfurt Program in 1891, which discarded the state-aid provisions of the Gotha Congress and pledged the party to a Marxist program. Bismarck won his battle to repress the Socialists in 1878 when the Reichstag adopted the Anti-Socialist Law that, among other things, forbade the publication of Socialist literature. Until the legislation against the party expired in 1890, Liebknecht did double duty by establishing an office in Leipzig to aid victims of the law and devoting his writing talents to the preparation of scholarly books and pamphlets.

Socialist leader

Notwithstanding a dozen years of repression, the party continued to grow significantly. When the law expired in 1890, it was obvious that Liebknecht's tactic of education, not conspiracy, had been productive. When the liberated party met at Erfurt in 1891, it adopted a charter embodying the 19th century's fullest expression of Social Democratic ideas. Thereafter, the party was known as the German Social Democratic Party (SPD). Liebknecht became one of its leading spokesmen, primarily as a writer for *Vorwarts,* the party's most prominent newspaper, founded in 1890. It was his gift as a writer, giving expression to his belief in the education of the masses, that made him a great leader of German Social Democracy, which was perhaps the most important political development in Europe between the Franco-Prussian War and World War I. Liebknecht died in Berlin on August 7,1900.

Karl. On August 13, 1871, while Wilhelm was in prison awaiting trial, his son, Karl, was born in Leipzig. Karl grew up during the years when the Anti-Socialist Law was in force against his father's party. Lacking the means for professional study, Karl independently studied nature, poetry, art, and music. Later, with financial help from the party, he studied law and political economy, first at Leipzig and then at Berlin, where he earned his doctor's degree. He planned to devote his career to the defense of Marxism.

After serving with the Imperial Pioneer Guards in Potsdam during 1893–94 and subsequently as a junior barrister in Westphalia, he returned to Berlin in 1898. In 1900, the year of his father's death, he married his first wife, Julie Paradies, by whom he had three children. She died ten years later, and in 1912 he married Sophia Ryss, a woman of Russian birth who had graduated from the University of Heidelberg.

Lawyer and revolutionary

In 1904, at a trial at Konigsberg, he defended propertyless peasants accused of infiltrating Socialist propaganda from East Prussia into tsarist Russia. His defense of the accused was primarily an apology for Social Democracy and provided him with a platform for his attacks against militarism. The key to the fight against militarism, he maintained, was the education of youth. Encouraged by the Russian Revolution of 1905, he worked among the youth, criticizing the "Moloch of Militarism," which he promised to fight "to the last drop of blood." In 1907 he played a principal role in the establishment of the International Union of Socialist Youth Organizations in Stuttgart. His publication of *Militarismus und Antimilitarismus* in the same year earned him a jail sentence of 18 months in Glatz, Silesia. While still in prison, he won a seat in the Prussian Landtag, and in 1912 he entered the Reichstag as the chief spokesman against the government and against the growing movement within the Social Democratic Party to revise its Marxist doctrine.

Karl **Liebknecht,** 1913.
Interfoto-Friedrich Rauch, Munich

During World War I Karl Liebknecht became a leading figure in the development of opposition movements to the wartime government. He was the first in the Reichstag to vote against the war credits and spoke out publicly, as early as January 1915, for the transformation of the national war into a civil or class war. The government conscripted him as a noncombatant but furloughed him to fulfill his duties as a deputy in the Reichstag and the Prussian Assembly. He served on the Düna sector of the Russian front, felling trees, peeling potatoes, and burying the rotting corpses of the dead, until he suffered physical collapse in October 1915. In 1916 he was expelled from the SPD for opposing the party's leadership. The ouster brought him into close alliance with another revolutionary personality, Rosa Luxemburg. Together, they provided the leadership for illegal opposition to the war through the subversive Spartacusbund, which disseminated through its network of confidential underground agents various kinds of revolutionary propaganda. Liebknecht edited the famous illegal "Spartacus Letters," the "official" organ of the Spartakusbund.

Ouster from Social Democratic Party

On May 1, 1916, Liebknecht participated in a May Day demonstration in Berlin and called for the overthrow of the government and an end to the war. The Spartakusbund continued its propaganda activity in the spirit of Liebknecht after the government tried and imprisoned him for his May Day activities. In prison he worked as a shoemaker, heartened by evidence of German disintegration on the military and domestic fronts. In October 1918 the climate in Germany had become more revolutionary and Liebknecht was granted an amnesty by the government of Prince Max of Baden.

Liebknecht entered the maelstrom of the German revolutionary period with great expectations. The Russian Soviet government celebrated his release from prison by a dinner for him at its embassy in Berlin. He planned to develop, through the Spartakusbund, a German revolution after the Soviet pattern. While the SPD, under the leadership of Friedrich Ebert, channelled the revolution along moderate lines, Liebknecht harangued the masses to win support for a "real" revolution. He played a leading role in the formation of the German Communist Party (KPD), which attempted without success to organize the radical elements. A series of bloody clashes between the provisional government formed by Ebert after the downfall of the monarchy and the extreme radicals culminated in the January 1919 *Putsch* in which Liebknecht resorted to force, a tactic both he and his father had strongly opposed. His use of force stimulated the growth of the counterrevolution, and both he and Rosa Luxemburg were among its first victims. On January 15, 1919, they were shot to death by counterrevolutionary volunteers on the pretext of attempted escape while under arrest. Their deaths paved the way for Soviet influence in the KPD, which, in turn, provided a stimulant for the growth of German political reaction.

BIBLIOGRAPHY. Sympathetic biographies of the Liebknechts were written in German by their contemporaries. KURT EISNER, *Wilhelm Liebknecht, sein Leben und Wirken* (1900), is the most available reference, written by a left-wing Socialist and journalist. HARRY SCHUMANN, *Karl Liebknecht*, rev. ed. (1923), renders a good profile of Liebknecht as a person; K.W. MEYER, *Karl Liebknecht: Man Without a Country* (1957), the only recent and English-language biography, stresses his political activities.

(K.W.M.)

Liechtenstein

The tiny Principality of Liechtenstein is one of the smallest states of Europe. Nestled between Switzerland and Austria, it covers 62 square miles (160 square kilometres), an area just smaller than Washington, D.C. The total population of about 22,000 is slightly smaller than that of Lugano, Switzerland. The national capital is at Vaduz.

Throughout most of its history, Liechtenstein has been a quiet, rural corner of the world that was largely unaffected by its European neighbours. After World War II, however, the country underwent a remarkably rapid period of industrialization, which has transformed the economy but which has not as yet been attended by environmental pollution or social dislocation.

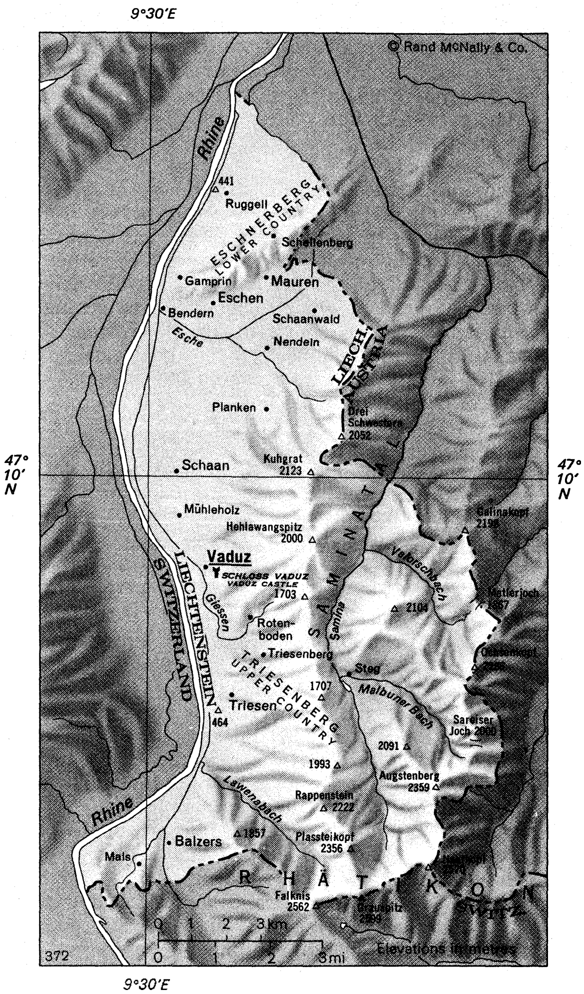
The landscape. *Relief and climate.* The eastern two-thirds of the country is composed of the rugged foothills of the Rhatikon Massif, part of the central Alps. The mountains rise to altitudes between 5,900 and 8,600 feet. Their lower slopes are clothed by evergreen forests and alpine flowers, while their bare peaks are blanketed by snow. The mountains contain three major valleys and are drained by the Samina River. The western section of the country is occupied by the Rhine River floodplain. This, together with the valley of the Ill River, forms a triangular lowland widening northward. The river valley was once marshy, but a drainage channel built in the 1930s has made its rich soils highly suitable for agriculture.

The climate is mild and is greatly affected by the warm southerly wind known as the foehn. The annual totals of rainfall and snowfall range, according to location, between 36 and 45 inches. In winter the temperature rarely falls below 5° F (−15° C), while in summer the average temperature varies from 68° to 82° F (20° to 28° C). These conditions allow for the cultivation of grapes and maize (corn), unusual in a mountainous area.

Vegetation and animal life. Small though it is, Liechtenstein has a remarkable variety of vegetation. Water milfoil and mare's-tail as well as reeds, bulrush, bird's eye primrose, and orchids can be found. The forests comprise a mixed woodland with copper beeches, common and Norway maple, sycamore, lime, elm, and ash. As to the animal life, Liechtenstein is rich in red deer, roe deer, chamois, hare, marmot, blackcock, pheasant, hazel grouse, partridge, fox, badger, marten, polecat, stoat, weasel, and others.

Ancient lordships

Traditional regions. The Rhine plain has always been the focus of settlement. For centuries, the valley was occupied by two independent lordships of the Holy Roman Empire, Vaduz and Schellenberg. Although they were united under the princes of Liechtenstein in 1719, they are still recognized as unique regions—the Upper Country and the Lower Country—and they form separate electoral districts.



LIECHTENSTEIN

The population. *Ethnic origins.* The Liechtensteiners are descended from the Alemanni tribe that came into the region after AD 500. Although the official language is German, the population still speaks an Alemanni dialect containing local variations in pronunciation and vocabulary. The Walsers, descendants of immigrants from the Swiss canton of Valais, settled in Triesenberg at the end of the 13th century and continue to speak a particularly distinctive form of the language. Over 90 percent of the population is Roman Catholic.

Demography. The total population numbered 21,350 at the census of 1970. To the south, the more industrial Upper Country contains the communes of Vaduz, Balzers, Triesen, Triesenberg, Schaan, and Planken. The Lower Country, on the north, is divided into the communes of Eschen, Mauren, Gamprin, Ruggell, and Schel-

Liechtenstein, Area and Population

	area		population	
	sq mi	sq km	1960 census	1970 census
Gemeinden (communes)				
Balzers	7.58	19.62	2,115	2,704
Eschen	3.99	10.33	1,571	2,114
Gamprin	2.37	6.14	434	660
Mauren	2.88	7.45	1,536	2,055
Planken	2.05	5.30	122	177
Ruggell	2.85	7.37	783	866
Schaan	10.37	26.85	3,022	3,890
Schellenberg	1.37	3.55	444	513
Triesen	10.17	26.35	1,789	2,637
Triesenberg	11.49	29.77	1,414	1,813
Vaduz	6.67	17.28	3,398	3,921
Total Liechtenstein	61.78*	160.01	16,628	21,350

*Converted area figures do not add to total given because of rounding.

lenberg. As a result of postwar industrialization, there has been a movement of people to the larger communes *(Gemeinden)*. The most populous communes are Vaduz, the administrative and commercial centre, and Schaan, the principal industrial community. The birthrate is 1.95 percent of the population and the mortality rate a low 0.78 percent.

The economy. Liechtenstein has no natural resources, and virtually all raw materials, including wood, have to be imported. Industrialization, therefore, has as yet been free of the pollution problems suffered by other developed areas. All of the principality's 10,400 acres of forest are protected in order to maintain the ecology of the mountain slopes and to guard against erosion. There is no heavy industry, and the small manufacturing concerns—the largest employs about 1,000 workers—are spread throughout the country.

Of the working population, about 46 percent are employed in industry and trades; 15 percent in construction; 6 percent in agriculture; 25 percent in commerce, banking, transportation, and the hotel industry; and 8 percent in other occupations.

Growth of industry

The burgeoning industrial economy has been borne on a larger European economic expansion. Total exports rose from 15,200,000 Swiss francs (SFr. 4.373=$1 U.S.; SFr. 10.495=£1 sterling, on December 1, 1970) in 1950 to more than SFr. 400,000,000 in 1972. Production includes metalworking, pharmaceuticals, food processing, and the manufacture of consumer goods.

In 1921 Liechtenstein adopted Swiss currency, and in 1924 it joined the Swiss customs union. By the early 1970s, over half of the exports went to the European Free Trade Area (including Switzerland and Finland) and a third to the European Economic Community.

Despite the small and declining percentage of the population engaged in agriculture, production rose by the 1970s to exceed SFr. 5,000,000. Farming units have been increasing in size, and the largest concerns concentrate on stock breeding and dairying. Maize (corn) and potatoes are traditional crops, but the production of cereals and vegetables is steadily increasing. Vineyards are few and are split into small units. The Alpine slopes are used for grazing during the three summer months.

Tourism

Tourism is sponsored by the government and generated an annual income in the 1970s exceeding SFr. 15,000,000. Most visitors come from the surrounding European countries and centre their activities around Vaduz. The registration of foreign firms in Liechtenstein provides a source of tax income.

There is a network of excellent roads connecting the country with its neighbours. The railway, part of the Paris–Vienna express route, passes through the northern sections of the country. There is no airport.

Administration and social conditions. *Government structure.* Liechtenstein is a constitutional principality in which governmental power derives from both the prince and the populace. Succession to the throne is hereditary through the male line and is determined by the regulations of the princely house. The constitution of 1921 provides for a unicameral Landtag, or parliament, composed of 15 members who are elected for four-year terms. The government consists of a chief and deputy chief of government and three councillors who are appointed by the prince, on proposition of the Landtag, for four-year terms. Through a civil-service staff of about 250, the government is responsible for all administrative matters. The 11 *Gemeinden* (communes) are governed autonomously—but under government supervision—by mayors and city councils, elected every three years.

Politics. The franchise, of secret and direct ballot, extends to all male citizens over 20 years of age. The citizenry is also guaranteed the right to referendum (submission of legislation to a popular vote), plebiscite (popular choice of a type of government or a ruler), and initiative (popular proposal of legislation). Political activity is channelled through a multi-party system. In 1970 the Patriotic Union (formerly People's) Party won its first majority in 32 years.

Justice. The judiciary is fully independent. There are two administrative courts—the Administrative Tribunal and the State Tribunal—that hear appeals against governmental decisions and decrees, as well as complaints concerning the violation of civil rights. In matters of civil law, original jurisdiction is exercised by the Lower Courts. Criminal cases originate in the Lower Courts for petty offenses, the assize court for misdemeanours, the criminal court for felonies, or the juvenile court. Both civil and criminal cases can be appealed to the High Court and the Supreme Court of Justice. The government maintains a 33-man police force, but the standing army was abolished in 1868.

Social services. Matters of public health are in the hands of a committee of public health, the standing executive watchdog authority, which is headed by a state medical officer. Liechtenstein's small, 30-bed hospital and two maternity wards are supplemented by the excellent neighbouring Swiss facilities, to which the principality contributes support. Social security is sustained by a variety of compulsory insurance schemes to which citizens contribute between the ages of 20 and 65. The financing of these comprehensive plans is shared by employers, employees, and the government, the last also assuming any deficits.

Education is supervised by the National Board of Education. The school system consists of eight-year primary schools, three-year secondary schools, a vocational school, an eight-year grammar school, a five-year commercial high school, a music school, and a technical college offering evening courses. There is also a five-year commerical high school for girls, run by a religious order. All citizens over the age of seven are literate.

Cultural life and institutions. The five-member Advisory Council for Culture and Youth was established by the government in 1964. Its major functions include the encouragement of artistic activity and the promotion of works by Liechtenstein artists.

Art collections and museums

The world-famous art collections of the princes of Liechtenstein, exhibited in the newly enlarged Englanderhaus in the centre of Vaduz, include outstanding works of the Flemish painters Rubens, Van Dyck, Brueghel, and Teniers, as well as of the Dutch painters Ostade, Steen, Rembrandt, Ruisdael, Cuyp, Hobbema, and van de Velde. The State Art Collection, opened in 1969, includes paintings by Frans Hals, Van Dyck, and Jan van Goyen and a modern-art section with graphic art by Picasso, Braque, Barlach, Max Beckmann, Goya, Gustave Klimt, Kokoschka, and Alberto Giacometti.

The Liechtenstein Postal Museum (founded in 1930) exhibits a large stock of stamps, including national issues since 1912 and stamps received since 1921 as a result of Liechtenstein's membership in the Universal Postal Union. The Liechtenstein National Museum in Vaduz houses primarily early and Roman artifacts, but it also contains a collection tracing the history of the arts in Liechtenstein and another collection devoted to the principality's folklore. The Liechtenstein National Library was established in 1961 as a public foundation.

Future prospects. As Liechtenstein continues to develop its industries, it is increasingly faced with certain attendant problems. Its citizens are moving to urban areas, and the rural calm that was so highly prized is beginning to be threatened. The consolidation of agricultural holdings and the expansion of towns increased the value of land, and speculation has become a serious problem. Although industrial pollution is not yet a real threat, the government is alert to such dangers and is guarding against them.

Life

The profusion of life on earth has been studied in great detail, and a number of general principles have been revealed. Foremost among them is the principle of evolution by natural selection — the stepwise adaptation of organisms to their environment with increasing precision by small random mutations, or changes, in their hereditary material — which is the feature that distinguishes living from non-living matter. This article treats first the varieties of definitions of life and then covers, in some detail, the similarities and differences among organisms on earth. It deals with the problem of the origin of life on earth and concludes with a consideration of the possibility of life beyond the earth.

This article is divided into the following sections:

DEFINITIONS OF LIFE

What is known about life

A great deal is known about life. Anatomists and taxonomists have studied the forms and relations of more than a million separate species of plants and animals. Physiologists have investigated the gross functioning of organisms. Biochemists have probed the biological interactions of the organic molecules that make up life on our planet. Molecular biologists have uncovered the very molecules responsible for reproduction and for the passage of hereditary information from generation to generation, a subject that geneticists had previously studied without going to the molecular level. Ecologists have inquired into the relations between organisms and their environments, ethologists the behaviour of animals and plants, embryologists the development of complex organisms from a single cell, evolutionary biologists the emergence of organisms from pre-existing forms over geological time. Yet despite the enormous fund of information that each of these biological specialties has provided, it is a remarkable fact that no general agreement exists on what it is that is being studied. There is no generally accepted definition of life. In fact, there is a certain clearly discernible tendency for each biological specialty to define life in its own terms. The average person also tends to think of life in his own terms. For example, the man in the street, if asked about life on other planets, will often picture life of a distinctly human sort. Many individuals believe that insects are not animals, because by "animals" they mean "mammals." Man tends to define in terms of the familiar. But the fundamental truths may not be familiar. Of the following definitions, the first two are in terms familiar in everyday life; the next three are based on more abstract concepts and theoretical frameworks.

Physiological. For many years a physiological definition of life was popular. Life was defined as any system capable of performing a number of such functions as eating, metabolizing, excreting, breathing, moving, growing, reproducing, and being responsive to external stimuli. But many such properties are either present in machines that nobody is willing to call alive, or absent from organisms that everybody is willing to call alive. An automobile, for example, can be said to eat, metabolize, excrete, breathe, move, and be responsive to external stimuli. And a visitor from another planet, judging from the enormous numbers of automobiles on the earth and the way in which cities and landscapes have been designed for the special benefit of motorcars, might well believe that automobiles are not only alive but are the dominant life form on the planet. Man, however, professes to know better. On the other hand, some bacteria do not breathe at all but instead live out their days by altering the oxidation state of sulfur.

Metabolic. The metabolic definition is still popular with many biologists. It describes a living system as an object with a definite boundary, continually exchanging some of its materials with its surroundings, but without altering its general properties, at least over some period of time. But again there are exceptions. There are seeds and spores that remain, so far as is known, perfectly dormant and totally without metabolic activity at low temperatures for hundreds, perhaps thousands, of years but that can revive perfectly well upon being subjected to more clement conditions. A flame, such as that of a candle in a closed room, will have a perfectly defined shape with fixed boundary and will be maintained by the combination of its organic waxes with molecular oxygen, producing carbon dioxide and water. A similar chemical reaction, incidentally, is fundamental to most animal life on earth. Flames also have a well-known capacity for growth.

Biochemical. A biochemical or molecular biological definition sees living organisms as systems that contain reproducible hereditary information coded in nucleic acid molecules and that metabolize by controlling the rate of chemical reactions using proteinaceous catalysts known as enzymes (*q.v.*). In many respects, this is more satisfying than the physiological or metabolic definitions of life. There are, however, even here, the hints of counterexamples. There seems to be some evidence that a virus-like agent called scrapie contains no nucleic acids at all, although it has been hypothesized that the nucleic acids of the host animal may nevertheless be involved in the reproduction of scrapie. Furthermore, a definition strictly in chemical terms seems peculiarly vulnerable. It implies that were man able to construct a system that had all the functional properties of life, it would still not be alive if it lacked the molecules that earthly biologists are fond of — and made of.

Instructions for living systems

Genetic. All organisms on earth, from the simplest cell to man himself, are machines of extraordinary powers, effortlessly performing complex transformations of organic molecules, exhibiting elaborate behaviour patterns, and indefinitely constructing from raw materials in the environment more or less identical copies of themselves. How could machines of such staggering complexity and such stunning beauty ever arise? The answer, for which today there is excellent scientific evidenne, was first discerned by the evolutionist Charles Darwin in the years before the publication in 1859 of his epoch-making work, the *Origin* of Species. A modem rephrasing of his theory of natural selection goes something like this: Hereditary information is carried by large molecules known as genes, comprised of nucleic acids. Different genes are responsible for the expression of different characteristics of the organism. During the reproduction of the organism the genes also reproduce, or replicate, passing the instructions for various characteristics on to the next generation. Occasionally, there are imperfections, called mutations, in gene replication. A mutation alters the instructions for a particular characteristic or characteristics. It also breeds true, in the sense that its capability for determining a given characteristic of the organism remains unimpaired for generations until the mutated gene is itself mutated. Some mutations, when expressed, will produce characteristics favourable for the organism; organisms with such favourable genes will reproduce preferentially over those without such genes. Most mutations, however, turn out to be deleterious and often lead to some impairment or to death of the organism. To illustrate, it is unlikely that one can improve the functioning of a finely crafted watch by dropping it from a tall building. The watch may run better, but this is highly improbable. Organisms are so much more finely crafted than the finest watch that any random change is even more likely to be deleterious. The accidental beneficial and inheritable change, however, does on occasion occur; it results in an organism better adapted to its environment. In this way organisms slowly evolve toward better adaptation, and, in most cases, toward greater complexity. This evolution occurs, however, only at enormous cost: man exists today, complex and reasonably well adapted, only because of billions of deaths of organisms slightly less adapted and somewhat less complex. In short, Darwin's theory of natural selection states that complex organisms developed, or evolved, through time because of replication, mutation, and replication of mutations. A genetic definition of life therefore would be: a system capable of evolution by natural selection.

Genetic definition of life

This definition places great emphasis on the importance of replication. Indeed, in any organism enormous biological effort is directed toward replication, although it confers no obvious benefit on the replicating organism. Some organisms, many hybrids for example, do not replicate at all. But their individual cells do. It is also true that life defined in this way does not rule out synthetic duplication. It should be possible to construct a machine that is capable of producing identical copies of itself from preformed building blocks littering the landscape but that arranges its descendants in a slightly different manner if there is a random change in its instructions. Such a machine would, of course, replicate its instructions as well. But the fact that such a machine would satisfy the genetic definition of life is not an argument against such a definition; in fact, if the building blocks were simple enough, such a machine would have the capability of evolving into very complex systems that would probably have all the other properties attributed to living systems. The genetic definition has the additional advantage of being expressed purely in functional terms: it does not depend on any particular choice of constituent molecules. The improbability of contemporary organisms—dealt with more fully below—is so great that these organisms could not possibly have arisen by purely random processes and without historical continuity. Fundamental to the genetic definition of life then is the belief that a certain level of complexity cannot be achieved without natural selection.

Life as an ordered system

Thermodynamic. Thermodynamics distinguishes between open and closed systems. A closed system is isolated from the rest of the environment and exchanges neither light, heat, nor matter with its surroundings. An open system is one in which such exchanges do occur. The second law of thermodynamics states that, in a closed system, no processes can occur that increase the net order (or decrease the net entropy) of the system (see THERMODYNAMICS). Thus the universe taken as a whole is steadily moving toward a state of complete randomness, lacking any order, pattern, or beauty. This fate has been known since the 19th century as the heat death of the universe. Yet living organisms are manifestly ordered and at first sight seem to represent a contradiction to the second law of thermodynamics. Living systems might then be defined as localized regions where there is a continuous increase in order. Living systems, however, are not really in contradiction to the second law. They increase their order at the expense of a larger decrease in order of the universe outside. Living systems are not closed but rather open. Most life on earth, for example, is dependent on the flow of sunlight, which is utilized by plants to construct complex molecules from simpler ones. But the order that results here on earth is more than compensated by the decrease in order on the sun, through the thermonuclear processes responsible for the sun's radiation.

Some scientists argue on grounds of quite general open-system thermodynamics that the order of a system increases as energy flows through it, and moreover that this occurs through the development of cycles. A simple biological cycle on the earth is the carbon cycle. Carbon from atmospheric carbon dioxide is incorporated by plants and converted into carbohydrates through the process of photosynthesis. These carbohydrates are ultimately oxidized by both plants and animals to extract useful energy locked in their chemical bonds. In the oxidation of carbohydrates, carbon dioxide is returned to the atmosphere, completing the cycle. It has been shown that similar cycles develop spontaneously and in the absence of life by the flow of energy through a chemical system. In this view, biological cycles are merely an exploitation by living systems of those thermodynamic cycles that pre-exist in the absence of life. It is not known whether open-system thermodynamic processes in the absence of replication are capable of leading to the sorts of complexity that characterize biological systems. It is clear, however, that the complexity of life on earth has arisen through replication, although thermodynamically favoured pathways have certainly been used.

The existence of diverse definitions of life surely means that life is something complicated. A fundamental understanding of biological systems has existed since the second half of the 19th century. But the number and diversity of definitions suggest something else as well. As detailed below, all the organisms on the earth are extremely closely related, despite superficial differences. The fundamental ground pattern, both in form and in matter, of all life on earth is essentially identical. As will emerge below, this identity probably implies that all organisms on earth are evolved from a single instance of the origin of life. It is difficult to generalize from a single example, and in this respect the biologist is fundamentally handicapped as compared, say, to the chemist or physicist or geologist or meteorologist, who now can study aspects of his discipline beyond the earth. If there is truly only one sort of life on earth, then perspective is lacking in the most fundamental way.

LIFE ON EARTH

Mechanism and vitalism. Human beings are ambulatory collections of some 10^{14} cells. Human cells are in many fundamental respects similar to those that make up all the other animals and plants on the earth. Each cell typically consists of a central, usually spherical, nucleus and an outer more heterogeneous region, termed the cytoplasm. The substance of nucleus and cytoplasm together has for many decades been called protoplasm. Use of this term implied that there was some special substance underlying living organisms. In the use of the word protoplasm there is occasionally an implication that life cannot be explained solely by physics and chemistry, that some mysterious "vital force" must be invoked. A living cell is a marvel of detailed and complex architecture. Seen through a microscope there is an appearance of almost frenetic activity. On a deeper level it is known that molecules are being synthesized at an enormous rate. Almost any enzyme catalyzes the synthesis of more than 100 other molecules per second. In ten minutes, a sizable fraction of the total mass of a metabolizing bacterial cell has been synthesized. The information content of a simple cell has been estimated as around 10'' bits, comparable to about a hundred million pages of the *Encyclopædia Britannica.* Faced with all this or its equivalent, it is not surprising that early biologists felt despair at ever being able to understand the detailed workings of life.

A Stone Age man, confronted for the first time with a watch, might also deduce that there was some special watch substance in nature, or perhaps even a god of the watch. In ancient times, the most common of biological activities, such as the hatching of an egg or the blooming of a flower, were attributed to the intercession of a deity. After the epochal work of Sir Isaac Newton, when the motion of the planets and comets of the solar system was predictable to some very great precision and understood on the basis of an underlying principle, the idea developed that organisms were also nothing more than a particularly intricate kind of clockwork. But when early investigations failed to unveil the clockwork, a kind of ghostly mainspring was invented—the "vital force." This force was a

"Vital force"

rebellion from mechanistic biology, an explanation of all that mechanism could not explain or for which mechanism could not be found. It also appealed to those who felt debased by the implication that they were "nothing more" than a collection of atoms, that their urges and apparent free wills arose merely from the interaction of an enormously large number of molecules in a way that, although too complex to use predictably, was in principle determined.

Not only is there no evidence for a vital force but the idea itself is hardly thought out; it is a sort of catchall concept, covering anything otherwise inexplicable. The alternative approach, that all organisms are made of atoms and nothing else, has proven especially useful and has led to a fundamental new understanding of biological systems. This situation does not imply, of course, that atoms cannot be put together in so complex a way that their collective behaviour is too difficult to understand in terms of the individual atoms; in this sense there may be particular laws of biology not readily derivable from the elementary interaction of atoms. But this is a very different thing from a vital force. Indeed, there is nothing debasing in the thought that man is made of atoms alone; it means he is intimately connected with the matter that comprises the inanimate universe. What a wonder that atoms can be put together in so complex a pattern as to produce man. Man is a tribute to the subtlety of matter. As the American anthropologist Loren Eiseley has written, ". . . if 'dead' matter has reared up this curious landscape of fiddling crickets, song sparrows, and wondering men, it must be plain even to the most devoted materialist that the matter of which he speaks contains amazing, if not dreadful powers. . . ." *(The Immense* Journey, Random House, New York, 1957.)

Nucleic acids. It is now known that many if not all of the fundamental properties of cells are a function of their nucleic acids, their proteins, and the interactions among these molecules. Within the nuclear regions of cells is a mélange of twisted and interwoven fine threads, the chromosomes. During cell division, in all but the simplest organisms, the chromosomes display an elegantly choreographed movement, separating so that each daughter cell of the original cell receives an equal complement of chromosomal material. This pattern of segregation corresponds in all details to the theoretically predicted pattern of segregation of the genetic material implied by the fundamental genetic laws (see HEREDITY). The chromosomes are composed of nucleic acids and proteins in a combination called nucleoprotein. The nucleic acid stripped of its protein is known to carry genetic information and to regulate cellular metabolism; the protein in nucleoprotein undoubtedly plays some secondary, probably regulatory, role.

The role of nucleic acids

The specific carrier of the genetic information in higher organisms is a nucleic acid known as DNA, short for deoxyribonucleic acid. DNA is a double helix, two molecular coils wrapped around each other and chemically bound one to another by bonds connecting adjacent bases. Each helix has a backbone that consists of a long sequence of alternating sugars and phosphates. Attached to each sugar is a base. Each sugar–phosphate–base combination is called a nucleotide; a nucleic acid strand can be thought of as a sequence of nucleotides. There is a very significant one-to-one base pairing in the connection of adjacent helices, in the sense that once the sequence of bases along one helix is specified, the sequence along the other is also specified. The specificity of base pairing plays a key role in the replication of the DNA molecule, where each helix makes an identical copy of the other from molecular building blocks in the cell. These nucleic acid replication events are mediated by enzymes, and with the aid of enzymes have been produced in the laboratory.

Ribonucleic acid (RNA) differs from DNA in having a slightly different five-carbon sugar, and in replacing one of the four bases that make up DNA by a slightly different base. RNA does not appear to exist in a double-stranded form. Now DNA, RNA, and the enzymes have a curiously interconnected relation, which appears ubiquitous in all organisms on earth today.

Commonalities among organisms on earth. The genetic code was broken in the 1960s. It was found that three consecutive nucleotides code for one amino acid of a protein molecule; *e.g.,* an enzyme. By controlling the synthesis of enzymes, the nucleic acids control the functioning of the cell. Of the four different bases taken three at a time, there are 43 = 64 possible combinations. The meaning of each of these combinations, or codons, is known. Most of them represent a particular amino acid. A few of them represent punctuation marks; for example, instructions to start or stop a synthesis. Some of the code is degenerate in the sense that more than one nucleotide triplet may specify a given amino acid. These interactions among nucleic acids and proteins seem absolutely central to living processes on earth today. Not only are these processes apparently the same in all organisms on earth but even the particular dictionary that is used for the transcription of nucleic acid information into protein information seems to be essentially the same in all organisms. Moreover, this code has various chemical advantages over other conceivable codes. The complexity, ubiquity, and advantages of these processes clearly argue that the present interactions among proteins and nucleic acids are themselves the product of a long evolutionary history. At the time of the origin of life this very complex replication and transcription apparatus could of course not have been in operation. A fundamental problem in the origin of life is the question of the origin and early evolution of the genetic code.

Energy-storing molecules

There are many other commonalities among organisms on earth. For example, there is only one class of molecules that store energy for biological processes until the cell has use for it, and these molecules are all nucleotide phosphates. The most common example is ATP (adenosine triphosphate). For this very different function, a molecule identical to the building blocks of the nucleic acids is employed. There are metabolically important molecules —*e.g.*, molecules known as FAD (flavin adenine dinucleotide) and coenzyme A—which include subunits similar to the nucleotide phosphates. Porphyrins represent another category of ubiquitous molecules. Porphyrins are the chemical basis of hemoglobin, which carries oxygen molecules through the bloodstreams of animals; of chlorophyll, which is the fundamental molecule mediating photosynthesis in plants; and of the colours that many animals display. The left- or right-handedness of many biological molecules--discussed more fully below—runs identically through all organisms on earth. In fact, of the billions of possible organic compounds, less than 1,500 are employed by contemporary life on earth, and these 1,500 are constructed from less than 50 simple molecular building blocks. Similarly, organisms as diverse as paramecia and human sperm cells have little whiplike appendages called cilia or flagella used to propel themselves through their liquid environments. The cross-sectional structure of the cilia and flagella is almost always nine pairs of peripheral and one pair of internal fibres. There is no immediately obvious selective advantage of the 9:1 ratio. These commonalities indicate that a few basic chemical and functional patterns are being used over and over again, reflecting the extremely close relations all organisms on earth have to one another. Many biologists believe that these commonalities—particularly where no obvious selective advantage exists—imply that all organisms on the earth are descendants of a single common ancestor. But it is possible that there are more subtle selective advantages. The issue may have to await the first detailed study of an extraterrestrial organism.

The number of possible ways of putting nucleotides together in a chromosome is enormous. The renowned geneticist H. J. Muller estimated that in a human chromosome there are about 4 x 10^9 base pairs. Each base pair position could be filled by any one of four possible bases; accordingly, the number of possible varieties of human chromosomes is $44^{\times 10^9}$ ($102.4^{\times 10^9}$), an inconceivably large number. By contrast, the number of elementary particles (electrons and protons) in the entire physical universe is only about 10^{80}. Thus a human being is an extraordinarily improbable object. Most of the $10^{2.4 \times 10^9}$

possible sequences of nucleotides would lead to complete biological malfunction. Our nucleotides work because natural selection, over a 4,000,000,000-year history of life, has destroyed enormous numbers of combinations that did not work. But there still may be combinations that work far better than any now present, and the future holds the promise that man will be able to assemble nucleotides in any desired sequence to produce whatever characteristics of human beings are thought desirable, an awesome and disquieting prospect.

Metabolism. The chemical bonds that make up living organisms have a certain probability of spontaneous breakage. Accordingly, mechanisms must exist to repair this damage, or to replace the broken molecules. In addition, the meticulous control that cells exercise over their internal activities requires the continued synthesis of new molecules. These processes of synthesis and breakdown of the organic molecules of the cell are collectively termed metabolism, and for synthesis to keep ahead of the thermodynamic tendencies toward breakdown, energy must be supplied to the living system. Organisms acquire this energy by two general methods. Some organisms are heterotrophs, acquiring their energy by the controlled breakdown of pre-existing organic molecules (food)—generally those supplied by other organisms. Human beings and most other animals are heterotrophs. Alternatively, organisms may be autotrophs, acquiring their useful free energy from some other source, either from the energy of sunlight, in which case the organism is called a photoautotroph, or from the controlled chemical reaction of inorganic materials, in which case the organism is known as a chemoautotroph. Organisms that use both modes are called photochemoautotrophs.

Methods of acquiring energy

A green plant is a typical example of a photoautotroph. It uses sunlight to break water into oxygen and hydrogen. Hydrogen is then combined with carbon dioxide to produce such energy-rich organic molecules as ATP and carbohydrates, and the oxygen is released back into the atmosphere. Many animals, on the other hand, utilize the atmospheric oxygen to combine chemically with organic materials they have eaten and release carbon dioxide and water as waste products in extracting energy from the organic materials. This is an example of an ecological cycle in which a material (here carbon) is pumped through two different organisms.

More generally, such metabolic cycles—used by the organism to extract useful energy from the environment—can be described in terms of oxidation-reduction reactions. In the case of respiration, molecular oxygen accepts electrons from glucose or other sugars. The oxygen is said to be an electron acceptor (it has a great affinity for electrons), the glucose an electron donor. This is the prototype of oxidation-reduction reactions, but not all such reactions necessarily involve oxygen. Biological electron acceptors other than oxygen include nitrates, sulfates, carbonates, nitrogen, and methanol. Biological electron donors other than sugars include nitrogen, sulfides, methane, ammonia, and methanol. For acceptor-donor transformations to occur over any period of time, biological cycles are necessary. It is possible that, for geologically short periods of time, organisms have lived off a finite supply of material, but for any long-term continuance of life, a dynamic cycling of matter, involving at least two different varieties of organisms, is necessary. If there is life on other planets, a similar cycling must exist. A search for such molecular transformations is one method of detecting extraterrestrial life.

On the earth, all such useful biological electron transfer reactions lead to the net production of one or more molecules of ATP. Two of the three phosphates of this molecule are held by "energy-rich" bonds sufficiently stable to survive for long periods of time in the cell, but not so strong that the cell cannot tap these bonds for energy when needed. ATP and very similar molecules, all of them having a base, a five-carbon sugar, and three phosphates, are, so far as is known, the general and unique energy currency of living systems on earth.

Metabolic processes do not occur in one step. The ordinary sugar, glucose, is not oxidized to carbon dioxide and water by living cells in the same way that occurs if a flame is applied to glucose in air. The resulting release of energy would be much too sudden, and concentrated in too small a volume, for such a process to be utilized safely by the cell. Instead, the glucose is broken down by a series of successive and coordinated steps, each mediated by a particular and specific enzyme. In almost all organisms that metabolize glucose, the sugar is first broken down in a set of anaerobic steps (that is, in the absence of oxygen). The total number of such steps is about 11. Some organisms are anaerobes; that is, they do not utilize molecular oxygen. In them the anaerobic steps are as far as the glucose metabolism is carried. Other organisms, including man, carry the oxidation of glucose further, gingerly combining glucose breakdown products with molecular oxygen. Such aerobic oxidation of glucose requires about 60 more enzymatically catalyzed steps. Another indication of the relative simplicity of the anaerobic breakdown of sugar is that all the enzymes used are free in solution in the cell; the aerobic steps use enzymes that are localized in specific regions of the cell. The complete aerobic breakdown of sugar to carbon dioxide and water is about ten times more efficient than the breakdown accomplished by anaerobes; ten times as many ATP molecules are produced. Similar themes and variations exist for the metabolism of other molecules (see METABOLISM).

Efficiency of aerobic oxidation

The energy made available in this way to ATP is used in a variety of ways by the cell; for example, for motility. When an amoeba extends pseudopods, or a man walks, ATP molecules are being tapped for their energy-rich phosphate bonds. In addition, ATP molecules are used for the synthesis of molecules that the organism needs and does not have available. Among such molecules may be amino acids, the particular five-carbon sugars involved in nucleic acids, the nucleic acid bases, and so on. Each of these synthetic processes is again controlled and enzymatically mediated and may start from a variety of building blocks available to the organism, some simple, some more complex. For example, the amino acid L-leucine is produced from pyruvic acid, itself the product of the anaerobic breakdown of glucose. Synthesis of L-leucine from pyruvic acid involves eight enzyme-mediated steps and the addition of acetic acid and water.

These exquisitely interlocked and controlled metabolic steps are not usually performed in a diffuse manner all over the cell. Instead there is, at least in all higher organisms, a marvellously architectured cellular interior with particular specialized regions where particular chemical reactions are performed. Those oxidation-reduction reactions that involve molecular oxygen occur in an inclusion within the cytoplasm called the mitochondrion. The mitochondrion itself has an intricate substructure, and particular enzymes are thought to reside in particular sites within it; the molecule being metabolized may be passed on from one enzyme to another as through a conveyor belt in a factory. Similarly, photosynthesis occurs in a cytoplasmic inclusion called a chloroplast, which contains the chlorophyll and other pigments that absorb visible light, as well as the detailed enzymatic apparatus for the photosynthetic process. Chloroplasts and mitochondria, as well as other cytoplasmic inclusions at the base of flagella and cilia, all contain DNA. Moreover, this DNA has a somewhat different distribution of bases from that of the nucleus. It has been suggested that the cytoplasmic inclusions are the remnants of once free-living forms that, because of the favourable conditions found there, have taken up residence in the insides of other organisms.

The work of the mitochondrion

Nucleic acids are known to pass from cell to cell and to perform their replication and coding functions efficiently in the new cell. In fact, viruses are essentially strands of nucleic acid, with a protein coat, that operate in just this way. It is also known that pieces of the genetic material from one cell may migrate into another cell of the same species and produce genetic and permanently heritable changes there. Alternatively, part of the virus nucleic acid may be permanently bound to the nuclear DNA of a host cell. It is likely that a virus is a degenerate form, now highly specialized to live off a specific host, of an organism once free-living and much more generally capable of performing a wide range of metabolic tasks. A virus must use the genetic transcription apparatus of its host cell. Many viruses do this extremely efficiently, turning a bacterium from a factory for making other bacteria into a factory for making viruses. In some cases it takes no more than ten minutes for a bacterium infected by a single virus to produce a hundred new virus particles, which then burst forth from the host bacterium, destroying it. The line between benign or useful cytoplasmic inclusions and infective agents is not a very sharp one (see VIRUS).

Differences in nuclear structure

Eucaryotes and procaryotes. In the very simplest one-celled organisms one may distinguish between eucaryotic and procaryotic cells. Many familiar one-celled organisms, such as paramecia and amoebas, as well as the cells of all higher organisms including man, are eucaryotic. Such cells undergo mitosis, a fundamental sequence of events that occurs after DNA replication and that ensures that the DNA is precisely and equally distributed to the daughter cells. Eucaryotic cells have nucleoprotein in their nuclei, There is a membrane that separates the nucleus from the cytoplasm; Mitochondria are generally present in the cytoplasm, as is a very intricately convoluted structure, called the endoplasmic reticulum, that probably serves as the anchoring point for many cytoplasmic enzymes not contained in such inclusions as mitochondria or chloroplasts.

On the other hand there are procaryotic cells, which are most generally typified by the bacteria and the blue-green algae. In these cells nuclear division is nonmitotic, there is no nucleoprotein, and a nuclear membrane is absent. While eucaryotic cells may have more than one chromosome, procaryotic cells have one chromosome only, and that one is dispersed in the cytoplasm. Mitochondria, chloroplasts, and the endoplasmic reticulum are always absent. It is clear from this description that the procaryotes are in many respects more primitive than the eucaryotes. A basic unsolved evolutionary question concerns the evolution of procaryotes into eucaryotes.

An interesting subject of biological speculation concerns what the smallest and simplest contemporary free-living organism might be. The smallest free-living cells now known are the pleuropneumonia-like organisms (PPLO). While an amoeba has a mass of 5×10^{-7} grams, a PPLO weighs 5×10^{-16} grams and is only about $^1/_{10}$ of a micrometre across. It can be seen only in the electron microscope. Such organisms grow very slowly. There may be smaller organisms that grow even more slowly, but they would be extremely difficult to detect. Even an organism of the size of PPLO has room for only about a hundred enzymes. A much smaller organism would have room for many fewer enzymes, and its ability to accomplish the functions that contemporary living systems must accomplish would be severely compromised. Were there, however, an environment in which all the necessary organic building blocks and such energy sources as ATP were provided "free," a functioning organism could be substantially smaller than PPLO. In fact the inside of a cell provides just such an environment; this is why infectious agents, such as viruses, can be substantially smaller than PPLO. But it must be emphasized that such agents are not free-living organisms.

Metazoa, embryology, and sex. The distinction between single-celled and many-celled organisms (in animals, between protozoa and metazoa) is far from a sharp one. An interesting illustration is the slime molds, which undergo an extraordinary sequence of events during their life cycle. The cycle begins with single cells, somewhat like amoebas, which swarm, or combine, into a slimy mass with many nuclei called a plasmodium. The plasmodium in turn forms a sluglike mass that is certainly a multicelled organism. The slug develops into a stalked, fruitlike sporangium, still multicellular. The sporangium produces spores with cellulose cell walls similar to those of plants. The spores in turn germinate into small cells bearing flagella. The flagella are lost and the life cycle is completed with the production of an amoeboid form (for details, see SLIME MOLD).

Biology is replete with life cycles of comparable complexity. The swarming of individual cells to form a plasmodium may in fact be an example of the events that led to the production of metazoa in the early history of the earth. Such life cycles, while apparently very exotic, are shared by many organisms, including man, where a one-celled, free-swimming sperm stage is part of the life cycle.

The problem of development

The life cycle of slime molds, or men, or any other multicellular organism brings up a fundamental and still largely unsolved problem. These organisms develop from a single cell that has a single complement of the genetic material. These cells then divide, forming many identical cells. The very early embryology of man goes through stages with 2, 4, 8, 16, etc., cells. Since the genetic information is identical in each cell, how does it ever happen that cells become specialized, forming hair cells, teeth cells, liver cells, blood cells, or bone cells? How can any given cell "know" what sort of specialized cell it must become, since all cells contain identical nucleic acids? Possibly the answer to this question has to do with geometry. After the 16- or 32-cell stage, there is a distinct difference between a cell on the inside of the embryo, which is entirely surrounded by cells, and a cell on the outside of the embryo, which is not entirely surrounded by other cells. One of the earliest major steps in embryonic development is a distinction in function between interior cells (the endoderm) and exterior cells (the ectoderm). There are physical and chemical interactions among adjacent cells. Perhaps any cell then has the capability of becoming any specialized cell, but cells are, as a result of their external cellular environment, called upon to develop in different ways. Occasional embryonic anomalies or cysts occur in which, for example, hair or teeth develop in totally inappropriate portions of the body. Similarly, eyes have been caused to develop on the limbs of frogs. Such incidents demonstrate the capability of the "wrong" cells to produce particular cellular specializations (see GROWTH).

Much of the beauty and diversity of contemporary life on earth is due to sex. A totally asexual organism will be genetically identical to its (single) parent except for occasional mutations. The development of any major new adaptation would then require the acquisition of large numbers of appropriate mutations. Consider, for example, how the ability of an organism to metabolize a given molecule depends on the interaction of many enzymes, each produced by the transcription of the genetic information in hundreds of nucleotides, each nucleotide being the product of a single mutation. Thus, the chance development of any advantageous adaptation in an asexual organism requires the mutations to wait in line for a fortuitous juxtaposition.

Sex: an added dimension

Sex solves this problem in an elegant way. The genetic material of the parents is reassorted so that totally new combinations of genes are produced. In this way mutations acquired by any member of the population are rather quickly distributed to other members, and mutations arising in separate organisms can be combined. The likelihood of producing a useful sequence of mutations is thereby greatly enhanced. The advantages of sexual reproduction are so great that even many simple forms, such as bacteria or protozoa, which largely reproduce asexually, have occasional sexual encounters. While two sexes are clearly adequate for such a random assortment of genetic material, some organisms have developed more sexes: paramecia, for example, have somewhere between five and ten sexes, defined in terms of the elaborate taboos about which organisms can combine their genetic material. In the process of genetic reassortment, some organisms make a very large number of attempts; for example, frogs lay millions of eggs at a time, and the number of sperm cells in a single human ejaculation is about 3×10^8 (see SEX AND SEXUALITY).

The varieties of organisms and environments. The environment of the earth is heterogeneous. There are mountains, oceans, and deserts, extremes of temperature and humidity. In addition, there are diverse microenvironments: oxygen-depleted oceanic oozes, ammonia-rich soils, mineral deposits with a high radioactivity content, and so on. The environment of an organism also includes the other organisms in its surroundings. For each of these environmental situations there are corresponding ecological niches, and the variety of ecological niches populated on the earth is quite remarkable. Furthermore, ecological niches can be filled independently several times. For example, quite analogous to the ordinary mammalian wolf is the marsupial wolf that lives in Australia; the two have striking similarities in physical appearance and in predation behaviour. As another example, the same streamlined shape for high-speed marine motion has evolved independently at least three times: in *Stenopterygius* and other Mesozoic reptiles; in the tuna, which are fish; and in the dolphins, which are mammals. This case of convergent evolution must arise from the fact that hydrodynamics admits a narrow range of solutions to the problem of high-speed marine motion by large animals. Similarly, the eye has independently evolved several times among animals on the earth; apparently such a structure is the best solution to the problem of visual recording. In those cases where physics or chemistry establishes one most efficient solution to a given ecological problem, natural selection will often tend to reach the solution, but not always. Some adaptations of undoubted utility, such as tractor treads in swampy environments, have never been evolved by natural selection on the earth.

Life in extreme environments

There is an extraordinarily wide range of ecological niches to which organisms have adapted through the operation of natural selection. The same basic fabric of life has been used to produce very diverse organisms. The alga *Cyanidium caldarium* can grow in concentrated solutions of hot sulfuric acid. Other bacteria, algae, and fungi can live in extremely acidic (pH of 0) or extremely alkaline (pH near 13) environments. Procaryotic bacteria live in pools at Yellowstone National Park at temperatures above 90° C (194" F), almost at the boiling point of water. Sulfate-reducing bacteria are reported to grow and reproduce at 104" C (219" F) under very high pressures. Many organisms employ organic or inorganic antifreezes to lower the freezing point of their internal liquids, so that they can live at several tens of degrees below 0° C (32" F). Some insects use dimethyl sulfoxide as an antifreeze. Other organisms live in briny pools in which dissolved salts lower the freezing point. For example, Don Juan Pond in Antarctica has about one molecule of calcium chloride for every two water molecules and does not freeze until −45° C (−49° F). It contains a possibly unique microflora that continues to metabolize at least down to −23" C (−9" F). Biological activity does not cease at the freezing point of water; in fact some enzymes are actually more active in ice than in water. Many single-celled organisms can be frozen indefinitely to extremely low temperatures—the temperature of liquid air for example—and then be thawed with no decrease in activity. The primary damage that freezing causes is apparently due to the unavailability of liquid water and to the expansion and contraction attendant to freezing and thawing. Some arthropods can be severely dehydrated and then revived simply by adding water. In the dehydrated state they can be brought to any temperature from close to absolute zero to above the boiling point of water without apparent damage. When encysted in response to dehydration, some such organisms seem indistinguishable from a weathered grain of sand.

The great majority of familiar organisms on the earth, however, are much more sensitive to the temperature of their surroundings. Warm-blooded animals internally regulate their temperatures for this reason. A human being whose body temperature drops below 30" C (86° F) or rises above 40° C (104" F) soon dies. Organisms that inhabit cold climates have special insulating layers of fat and fur. Other organisms adapt to seasonal temperature changes by producing dormant forms, such as spores or eggs, to survive the low temperatures. In all cases dormancy appears to be accompanied by dehydration.

Importance of water

Since organisms are composed largely of water, the availability of water is clearly a limiting factor. Here also, however, remarkable adaptations exist. Certain micro-organisms can live on the water adsorbed on a single crystal of salt. Other organisms, such as the kangaroo rat and the flour beetle, obtain no water at all in the liquid state, relying entirely on metabolic water; that is, on water released from chemical bonds through the metabolism of food. A variety of plants, including Spanish moss, live in environments where they have no contact with groundwater—for example, on telephone wires—apparently extracting water directly from the air, although such plants require a relatively high humidity. Plants that live in deserts and other very dry environments have evolved wide-spreading root systems that adsorb subsurface water from a great volume of adjacent soil.

Organisms have been found from the stratosphere to the ocean depths. Bacteria and fungal spores have been discovered near the base of the stratosphere by balloons, and searches for organisms at much greater altitudes (up to 100,000 feet) have been attempted with ambiguous results. Birds have been observed flying at altitudes as great as 27,000 feet, and jumping spiders have been found at 22,000 feet on Mt. Everest. At the opposite extreme, micro-organisms, fish, and a variety of other metazoa have been recovered from the ocean depths down to thousands of feet, where the corresponding pressures are hundreds of times that at sea level. At these depths no light can penetrate and the organisms, some of which are quite large and include unique phosphorescent adaptations to the dark, ultimately live off particles of organic matter raining down from the upper reaches of the oceans.

There is a range of adaptations to the radiation environment of the earth. Some micro-organisms are readily killed by the small amount of solar ultraviolet light that filters through the earth's atmosphere at wavelengths near 3000 angstrom units (A; 1Å = one ten billionth of a metre). On the other hand, the bacterium *Pseudomonas radiodurans* thrives in the large neutron flux at the cores of swimming-pool reactors, to the continuing annoyance of nuclear physicists. Organisms can avoid radiation by shielding. For example, some algae and some desert plants live under a superficial coating of soil or rocks that are more transparent to visible light than to ultraviolet light. In addition, organisms have active methods of undoing the damage produced by radiation. Some of these repair mechanisms work in the dark; others require visible light. The usual reason for the ultraviolet sensitivity of organisms is that their nucleic acids absorb ultraviolet light very effectively at a wavelength near 2600 A. Generally speaking, there is an upper limit to the amount of ionizing radiation (such as gamma rays, X-rays, electrons or protons) that an organism can receive without being killed: in the vicinity of 1,000,000 roentgens. Such a lethal dose applies only to extremely radiation-resistant micro-organisms; mammals, for example, are killed by much lower doses because there is more that can go wrong with such complex organisms. A lethal dose of ionizing radiation for human beings is a few hundred roentgens applied to the whole body. A thermonuclear weapon dropped on a populated area may deliver, through direct radiation and fallout, doses of a few hundred roentgens or more to people within a radius of some tens of miles of the target. Much smaller doses can produce a variety of diseases and predominantly deleterious mutations in the hereditary material. Moreover, the effect of small doses is cumulative. But until very recently human beings have not lived in environments characterized by large doses of ionizing radiation (see RADIATION, BIOLOGICAL EFFECTS OF).

Size range of living things

The sizes of organisms on the earth vary greatly. As discussed above, the smallest free-living organisms on the earth, PPLO, are about 1000 A in diameter; a limitation on the size of the smallest free-living organism is its volume: it must contain all the molecules necessary for metabolism. A variety of influences place an upper limit to the size of organisms. One is the strength of biological materials. Galileo calculated in 1638 that a tree taller than roughly 300 feet would, when displaced slightly from the vertical (for example, by a breeze), buckle under its own weight. (Sequoias, some of which exceed 300 feet, are apparently near the upper limit of height for an organism.) Because of the buoyancy of water, large whales are not presented with such stability problems, but other difficulties arise. For a fixed shape, the volume of tissues to be nourished increases as the cube of the characteristic length of the organism, but the surface of the gut, which adsorbs the ingested food, increases only as the square of the length. As the length is increased, a point of diminishing returns is ultimately reached.

The range of organic molecules that organisms on earth can metabolize is very wide and occasionally includes such foods as formaldehyde or petroleum, which seem unlikely from a human point of view. *Pseudomonas* bacteria are capable of using almost any organic molecule as a source of carbon and of energy, provided only that the molecule is at least slightly soluble in water. Micro-organisms cannot metabolize plastics, not because of any fundamental chemical prohibitions but probably because plastics have not been part of the environment of micro-organisms for very long. Man tends to think of oxygen as extremely important for life, but there are facultative anaerobes that can take their oxygen or leave it, and obligate anaerobes that are actually poisoned by oxygen. Such organisms use a variety of alternative electron acceptors, as previously discussed.

Chemical constituents

The water content of organisms usually represents between 50 and 90 percent of the live weight. Unless there is a massive mineral skeleton, the dry matter of organisms constitutes about one-half carbon by weight, reflecting the fact that organic molecules are based upon carbon. A wide variety of other chemical elements are used for diverse functions. Amino acids are made of nitrogen and sulfur in addition to carbon, hydrogen, and oxygen. Nucleic acids, as has been seen, employ phosphorus in addition to hydrogen, nitrogen, oxygen, and carbon. Sodium and potassium are used in maintaining the electrolyte balance, and calcium and silicon as structural materials. Iron plays a fundamental role in the transport of molecular oxygen as part of the hemoglobin molecule. In some ascidians (sea squirts), however, vanadium replaces iron. Ascidian blood also contains unusually large amounts of niobium, tantalum, titanium, chromium, manganese, molybdenum, and tungsten. The vanadium and niobium compounds in ascidian blood may be adaptations to low oxygen levels. Occasional organisms use selenium or tellurium as electron acceptors; others may produce the fully saturated gas hydrides of arsenic, phosphorus, or silicon, as metabolic wastes. Still others form compounds of carbon with such halogens as chlorine or iodine. Many of the foregoing elements, plus copper, zinc, cobalt, and possibly gallium, boron, and scandium, perform particular functions in the enzymatic apparatus of cells. Many of these elements, both the uncommon ones and those as common as phosphorus, are very highly concentrated in organisms over their general availability in the environment. This concentration must indicate that such chemicals play unique functional roles where other more abundant elements will not serve.

Behaviour and sensory capabilities. Analogous to the wide range of physiological adaptations and the great variety of elements used by organisms on earth, there is an enormous range of behaviour patterns and sensory capabilities. Coded into its nucleic acids is the information that allows a bird raised from the egg in the absence of other birds to migrate when migration time arrives, to build a nest characteristic of its species, or to engage in elaborate courtship rituals. Those birds that do not perform acceptably do not leave descendants. Such behavioral information must itself have evolved. Rats that pass through mazes easily can be interbred, as can rats that pass through with difficulty; eventually two populations with inherited characteristics called "maze-smart" and "maze-dumb" will be produced. Fruit fly populations attracted to the light can be separated from those that avoid light. Classical genetic crossing experiments reveal that the two populations differ largely in a small number of genes for phototropism. Similar genetic determinants of behaviour exist in man. Possession of a supernumerary Y-chromosome in males is strikingly correlated with aggressive tendencies—which may, however, have been a selective advantage in more primitive societies. Myopia may have had strong survival value in earlier times: near-sighted males, useless in the hunt, stayed home and painted the walls of the cave. As technology develops, natural selection enters new behavioral arenas; for example, in an age of artificial contraception, the clumsy and forgetful preferentially reproduce.

Response to the electromagnetic spectrum

Human beings use only a small part of the total electromagnetic spectrum, the part called visible light, which extends from about 4000 to about 7000 A in wavelength. While many plants and animals are sensitive to this same range of wavelengths, many of them are sensitive to other wavelengths as well. Most insects are sensitive to ultraviolet light at wavelengths below 4000 A, and many flowering plants take advantage of this fact and present patterns visible only in the ultraviolet range. Honeybees use polarized light, which the unaided human eye is quite unable to detect, for direction finding on partly cloudy days. The "pit" of such pit vipers as the rattlesnake is an infrared receptor and direction finder. These reptiles can sense the thermal radiation emitted by warm-blooded prey, radiation to which human beings are completely insensitive.

It is common knowledge that some animals (for example, dogs) are sensitive to sounds that the human ear cannot detect. Bats emit and detect sound waves at ultrahigh frequencies, in the vicinity of 100,000 cycles per second, about five times the highest frequency to which the human ear is sensitive. Bats use these sounds not so much to communicate, however, as to echolocate their prey and were doing this for millions of years before radar and sonar were invented. The audio receptors of many moths that are prey to bats are responsive only to the frequencies emitted by the bats. When the bat sounds are heard, the moths take evasive action. Dolphins have a very wide frequency range and several communication channels, as well as a "click" echolocator. Dolphins and whales use their blowholes rather than their mouths to utter these sounds. Sharks and other marine predators are said to locate their prey by the low-frequency sounds the prey makes when in distress. Some animals develop highly specialized and exotic organs for the detection or transmission of sound—for example, a European grasshopper has a relatively large parabolic antenna on its back that looks very much like a small radio telescope. This antenna is used for producing noises evidently thought attractive by the female of the species.

Many organisms are capable of smell and taste; that is, the detection of specific chemical molecules. According to one theory of smell, there are particular olfactory sensors, each receptive only to a specific chemical group on airborne molecules. The ultimate in olfactory specialization is probably the male silkworm moth: with its feathery antennae it is able to smell essentially nothing except the chemical sex attractant discharged by the female of the species. But it can detect this molecule very well, needing an impact of only 40 molecules per second on its antennae to produce a marked response. One female silkworm moth need release only 10^{-8} grams of sex attractant per second in order to attract every male silkworm moth in a volume hundreds of metres to kilometres on a side.

Extraordinary senses

Besides the senses of sight, hearing, smell, taste, and touch, various animals have a wide variety of other senses (see SENSORY RECEPTION). Man has an inertial orientation system and accelerometer in the cochlear canal of the ear. The water scorpion (*Nepa*) has a fathometer sensitive to hydrostatic pressure gradients. Most higher plants have chemically amplified gravity sensors. Fireflies and squids communicate with their own kind by producing time sequences or patterns of light on their bodies. The African freshwater fish *Gymnarchus niloticus* operates a dipole electrostatic field generator and a sensor to detect the amplitude and frequency of disturbances in the impressed field, an adaptation well suited for its nocturnal activities in turbulent waters. Other organisms have salinity sensors, or humidity sensors. There may be sensors involved in homing instincts of animals that have not yet been discovered. All of these senses confer upon their possessors an awareness of the environment that may be very different from that of such other organisms as man. Man, however, has the remarkable ability to extend his sensory and intellectual capabilities artificially, through the use of instrumentation.

THE ORIGIN OF LIFE

Hypotheses of origins. Perhaps the most fundamental and at the same time the least understood biological problem is the origin of life. It is central to many scientific and philosophical problems and to any consideration of extraterrestrial life. Most of the hypotheses of the origin of life will fall into one of four categories:

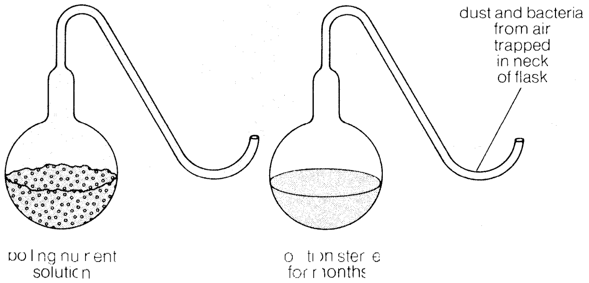
1. The origin of life is a result of a supernatural event; that is, one permanently beyond the descriptive powers of physics and chemistry.
2. Life—particularly simple forms—spontaneously and readily arises from nonliving matter in short periods of time, today as in the past.
3. Life is coeternal with matter and has no beginning; life arrived on the earth at the time of the origin of the earth or shortly thereafter.
4. Life arose on the early earth by a series of progressive chemical reactions. Such reactions may have been likely or may have required one or more highly improbable chemical events.

The early theological view

Hypothesis 1, the traditional contention of theology and some philosophy, is in its most general form not inconsistent with contemporary scientific knowledge, although this knowledge is inconsistent with a literal interpretation of the biblical accounts given in chapters 1 and 2 of Genesis and in other religious writings. Hypothesis 2 (not of course inconsistent with 1) was the prevailing opinion for centuries. A typical 17th-century view follows:

> [May one] doubt whether, in cheese and timber, worms are generated, or, if beetles and wasps, in cowdung, or if butterflies, locusts, shellfish, snails, eels, and such life be procreated of putrefied matter, which is to receive the form of that creature to which it is by formative power disposed[?] To question this is to question reason, sense, and experience. If he doubts this, let him go to Egypt, and there he will find the fields swarming with mice begot of the mud of the Nylus [Nile], to the great calamity of the inhabitants.

It was only in the Renaissance, with its burgeoning interest in anatomy, that such transformations were realized to be impossible. A British physiologist, William Harvey, during the mid-17th century, in the course of his studies on the reproduction and development of the king's deer, made the basic discovery that every animal comes from an egg. An Italian biologist, Francesco Redi, in the latter part of the 17th century, established that the maggots in meat came from flies' eggs, deposited on the meat. And an Italian priest, Lazzaro Spallanzani, in the 18th century, showed that spermatozoa were necessary for the reproduction of mammals. But the idea of spontaneous generation died hard. Even though it was proved that the larger animals always came from eggs, there was still hope for the smaller ones, the micro-organisms. It seemed obvious that, because of their ubiquity, these microscopic creatures must be generated continually from inorganic matter.



dust and bacteria from air trapped in neck of flask
boiling nutrient solution
solution sterile for months

Pasteur's swan-necked flask experiment (see text).

Meat could be kept from going maggoty by covering it with a flyproof net, but grape juice could not be kept from fermenting by putting over it any netting whatever. This was the subject of a great controversy between the famous French bacteriologists Louis Pasteur and F.A. Pouchet in the 1850s, in which Pasteur triumphantly showed that even the minutest creatures came from germs floating in the air, but that they could be guarded against by suitable filtration. Actually, Pouchet was arguing that life must somehow arise from nonliving matter; if not, how had life come about in the first place?

Life from outer space

Toward the end of the 19th century Hypothesis 3 gained currency, particularly with the suggestion by a Swedish chemist, S.A. Arrhenius, that life on earth arose from panspermia, micro-organisms or spores wafted through space by radiation pressure from planet to planet or solar system to solar system. Such an idea of course avoids rather than solves the problem of the origin of life. In addition, it is extremely unlikely that any micro-organism could be transported by radiation pressure to the earth over interstellar distances without being killed by the combined effects of cold, vacuum, and radiation.

Pasteur's work discouraged many scientists from discussing the origin of life at all. Moreover they were anxious not to offend religious feeling by probing too deeply into the subject. Although Darwin would not commit himself on the origin of life, others subscribed to Hypothesis 4 more resolutely, notably the famous British biologist T.H. Huxley in his *Protoplasm, the Physical Basis of Life* (1869), and the British physicist John Tyndall in his "Belfast Address" of 1874. Although Huxley and Tyndall asserted that life could be generated from inorganic chemicals, they had extremely vague ideas about how this might be accomplished. The very phrase "organic molecule" implies that there exists a special class of chemicals uniquely of biological origin, despite the fact that organic molecules have been routinely produced from inorganic chemicals since 1828. In the following discussion the word organic carries no imputation of biological origin. In fact the problem largely reduces to finding an abiological source of appropriate organic molecules.

The primitive atmosphere. Darwin's attitude was: "It is mere rubbish thinking at present of the origin of life; one might as well think of the origin of matter." The two problems are, in fact, curiously connected, and modern scientists are thinking about the origin of matter. There is convincing evidence that thermonuclear reactions and subsequent explosions in the interiors of stars generate all the chemical elements more massive than hydrogen and helium and then distribute them into the interstellar medium from which subsequent generations of stars and planets form. Because of the commonality of these thermonuclear processes, and because some thermonuclear reactions are more probable than others, there exists a cosmic distribution of the major elements, so far as is known, throughout the universe. Table 1 compares, for some atoms of interest, the relative numerical abundances in the universe as a whole, on the earth, and in living organisms.

Table 1: Relative Abundances of the Elements (percent)

atom	universe	life (terrestrial vegetation)	earth (crust)
Hydrogen	87	16	3
Helium	12	0*	0
Carbon	0.03	21	0.1
Nitrogen	0.008	3	0.0001
Oxygen	0.06	59	49
Neon	0.02	0	0
Sodium	0.0001	0.01	0.7
Magnesium	0.0003	0.04	8
Aluminum	0.0002	0.001	2
Silicon	0.003	0.1	14
Sulfur	0.002	0.02	0.7
Phosphorus	0.00003	0.03	0.07
Potassium	0.000007	0.1	0.1
Argon	0.0004	0	0
Calcium	0.0001	0.1	2
Iron	0.002	0.005	18

*0% here stands for any quantity less than 10^{-6}%.

Composition of life

There is of course some variation in composition from star to star, from place to place on the earth, and from organism to organism, but such comparisons are nevertheless very instructive. The composition of life is intermediate between the average composition of the universe and the average composition of the earth. Ninety-nine percent both of the universe and of life is made of the six atoms, hydrogen (H), helium (He), carbon (C), nitrogen (N), oxygen (O), and neon (Ne). Can it be that life on earth arose when the chemical composition of the earth was much closer to the average cosmic composition, and that some subsequent events have changed the gross chemical composition of the earth?

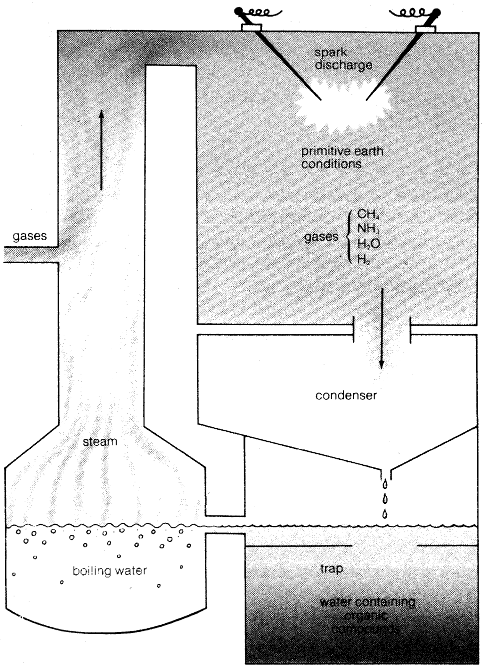
The Jovian planets (Jupiter, Saturn, Uranus, and Neptune) are much closer to cosmic composition than is the earth. They are largely gaseous, with atmospheres composed principally of hydrogen and helium. Methane (CH,) and ammonia (NH_3) have been detected in smaller quantities, and neon and water are suspected. This circumstance very strongly suggests that the Jovian planets were formed out of material of typical cosmic composition. They have very large masses, and because they are so far from the sun their upper atmospheres are very cold. Therefore it is impossible for atoms in the upper atmospheres of the Jovian planets to escape from their gravitational fields; escape was probably very difficult even during planetary formation. The earth and the other planets of the inner solar system, however, are much less massive and most have hotter upper atmospheres. It is possible for hydrogen and helium to escape from the earth today, and it may well have been possible for much heavier gases to have escaped during the formation of the earth. It is reasonable to expect that in the very early history of the earth a much larger abundance of hydrogen prevailed, which has subsequently been lost to space. Thus the atoms carbon, nitrogen, and oxygen were present on the primitive earth, not as CO_2 (carbon dixoide), N_2, and O_2 as they are today but rather in the form of their fully saturated hydrides, CH_4 (methane), NH_3 (ammonia), and H_2O. In the geological record, the presence of such reduced minerals as uraninite (UO_2) and pyrite (FeS_2) in sediments formed several billions of years ago implies that conditions then were considerably less oxidizing than they are today.

In the 1920s J.B.S. Haldane in Britain and A.I. Oparin in the Soviet Union recognized that the abiological production of organic molecules in the present oxidizing atmosphere of the earth is highly unlikely; but that, if the earth once had more reducing (in this context, hydrogen-rich) conditions, the possible abiogenic production of organic molecules would have been much more likely. If large numbers of organic molecules were somehow synthesized on the primitive earth, there would not necessarily be much trace of them today. In the present oxygen atmosphere, largely produced by green-plant photosynthesis, such molecules would tend, over geological time, to be oxidized to carbon dioxide, nitrogen, and water. In addition, as Darwin recognized, the first micro-organisms would consume prebiological organic matter produced prior to the origin of life.

Synthesis of amino acids

Production of simple organic molecules. The first deliberate experimental simulation of these primitive conditions was carried out in 1953 by a U.S. graduate student, S.L. Miller, under the guidance of the eminent chemist H.C. Urey. A mixture of methane, ammonia, water vapour, and hydrogen was circulated through a liquid water solution and continuously sparked by a corona discharge elsewhere in the apparatus. The discharge may be thought to represent lightning flashes on the early earth. After several days of exposure to sparking, the solution changed colour. Subsequent analysis indicated that several amino and hydroxy acids, intimately involved in contemporary life, had been produced by this simple procedure. The experiment is in fact so elementary, and the amino acids can so readily be detected by paper chromatography, that the experiment has been repeated many times by high school students. Subsequent experiments have substituted ultraviolet light or heat as the energy source or have altered the initial abundances of gases. In all such experiments amino acids have been formed in large yield. On the early earth there was much more energy available in ultraviolet light than in lightning discharges. At long ultraviolet wavelengths, in which methane, ammonia, water, and hydrogen are all transparent, but in which the bulk of the solar ultraviolet energy lies, the gas hydrogen sulfide (H_2S) is a likely ultraviolet absorber.

Following such reasoning, a U.S. astrophysicist, Carl Sagan, and his colleagues made amino acids by long wavelength ultraviolet irradiation of a mixture of methane, ammonia, water, and HS. The amino acid syntheses, at least in many cases, involve hydrogen cyanide and aldehydes (*e.g.*, formaldehyde) as gaseous intermediaries formed from the initial gases. It is quite remarkable that amino acids, particularly biologically abundant amino acids, can be made so readily under simulated primitive conditions. When laboratory conditions become oxidizing, however, no amino acids are formed, suggesting that reducing conditions were necessary for prebiological organic synthesis.



Miller–Urey spark-discharge apparatus.

Under alkaline conditions, and in the presence of inorganic catalysts, formaldehyde spontaneously reacts to form a variety of sugars, including the five-carbon sugars fundamental to the formation of nucleic acids and such six-carbon sugars as glucose and fructose, which are extremely common metabolites and structural building blocks in contemporary organisms. Furthermore, the nucleotide bases as well as porphyrins have been produced in the laboratory under simulated primitive earth conditions by several investigators. While there is still debate on the generality of the experimental synthetic pathways and on the stability of the molecules produced, most if not all of the essential building blocks of proteins, carbohydrates, and nucleic acids can be readily produced under quite general primitive reducing conditions, plus probably, ATP as well.

Polymerization as dehydration reactions

Production of polymers. The construction of polymers, long-chain molecules made of repeating units of these essential building blocks,·however, is a much more difficult experimental problem. Polymerization reactions are generally dehydrations, in which a molecule of water is lost in the formation of a two-unit polymer. Dehydrating agents must be used to initiate polymerization. The polymerization of amino acids to form long protein-like molecules has been accomplished through dry heating by a U.S. investigator, S.W. Fox. The polyamino acids that are formed are not random polymers and have some distinct catalytic activities. The geophysical generality of dry heating and return to solution, however, has been questioned. Long polymers of amino acids can also be produced from hydrogen cyanide and anhydrous liquid ammonia. Some evidence exists that nucleotide bases and sugars can be combined in the presence of phosphates or cyanides under ultraviolet irradiation. Some condensing agents such as cyanamide are efficiently made under simulated primitive conditions. Despite the breakdown by water of molecular intermediates, condensing agents are often quite effective in inducing polymerization, and polymers of amino acids, sugars, and nucleotides have all been made this way.

A famous British scientist, J.D. Bernal, has suggested that adsorption of molecular intermediates on clays or other minerals may have concentrated these intermediates. Such concentration could offset the tendency for water to break down polymers of biological significance. Of special interest is the possibility that such concentration matrices included phosphates, for this would help explain how phosphorus could have been incorporated preferentially into prebiological organic molecules at a time when biological concentration mechanisms did not yet exist. Mineral catalysis implies that organic synthesis could also occur in deep water where ultraviolet light had been filtered out.

Quite apart from concentration mechanisms, the primitive waters themselves may have been a not very dilute solution of organic molecules. If all the surface carbon on the earth were present as organic molecules in the contemporary oceans, or if many known ultraviolet synthetic reactions producing organic molecules were permitted to continue for a billion years with products dissolved in the oceans, a 1 percent solution of organic molecules would result. For similar reasons, Haldane suggested that the origin of life occurred in a "hot dilute soup." In addition, concentration mechanisms do exist, such as evaporation or freezing of pools or adsorption on interfaces or the generation of colloidal enclosures called coacervates.

The origin of the code. It has been shown that all the essential building blocks for life and their polymers may have been produced in some fair concentration on the primitive earth. This possibility is certainly relevant to the origin of life, but it is not the same thing as the origin of life. By the genetic definition of life discussed in *Definitions of life,* above, a self-replicating, mutable molecular system, capable of interacting with the environment, is required. In contemporary cells the nucleic acids are the sites of self-replication and mutation. Laboratory experiments have already shown that polynucleotides can be produced from nucleotide phosphates in the presence of a specific enzyme of biological origin and a pre-existing "primer" nucleic acid molecule. If the primer molecule is absent, polynucleotides are still formed, but they of course contain no genetic information. Once such a polynucleotide spontaneously forms it then acts as primer for subsequent syntheses.

Production of polynucleotides

Imagine a primitive ocean filled with nucleotides and their phosphates and appropriate mineral surfaces serving as catalysts. Even in the absence of the appropriate enzyme it seems likely, although not yet proved, that spontaneous assembly of nucleotide phosphates into polynucleotides occurred. Once the first such polynucleotide was produced it may have served as a template for its own reproduction, still of course in the absence of enzymes. As time went on there were bound to be errors in replication. These would be inherited. A self-replicating and mutable molecular system of polynucleotides, eventually leading to a diverse population of such molecules, may have arisen in this way. Alternatively, the primitive hereditary material may have involved some other molecule altogether, but no concrete suggestion for such a molecule has ever been proposed.

In any case, a population of replicating polynucleotides cannot quite be considered alive because it does not significantly influence its environment. Eventually, all the nucleotides in the ocean would have been tied in polynucleotides and the entire synthetic process would then have ground to a halt. So far as is known, polynucleotides have no catalytic properties, and proteins have no reproductive properties. It is only the partnership of the two molecules that makes contemporary life on earth possible. Accordingly, a critical and unsolved problem in the origin of life is the first functional relation between these two molecules, or, equivalently, the origin of the genetic code. The molecular apparatus ancillary to the operation of the code —the activating enzymes, adapter RNAs, messenger RNAS, ribosomes, and so on—are themselves each the product of a long evolutionary history and are produced according to instructions contained within the code. At the time of the origin of the code such an elaborate molecular apparatus was of course absent.

It has been proposed that a weak but selective chemical bonding does exist, even in the absence of any of this apparatus, between amino acids and nucleotides. There need not be a very great selectivity; a given nucleotide sequence might in primitive times have coded for many different amino acids or, conversely, the same amino acid may have been coded for by several different nucleotide sequences. All that is required is that a particular linear sequence of nucleotides must code for some nonrandom sequence of amino acids. The active sites largely responsible for the catalytic activity of contemporary enzymes are generally only five or six amino acids long; the remainder of the enzyme is devoted to more sophisticated functions, such as arranging for the enzyme to be turned on and off by the machinery of the cell. With, say, 20 different varieties of amino acids available in the primitive environment, the chance of any given active site being produced by a random sequence of nucleotides is one in 20^5, or one in about 3,000,000. But 3,000,000 combinations to form units five amino acids long is not a very large number for the chemistry and time periods in question. To conclude this speculation, then, if polynucleotides were initially capable of crude, nonenzymatic replication, and if a crude primitive genetic code existed, then any one of a very large number of catalytic properties was available to some self-replicating polynucleotides on the primitive earth. This situation is all that would be necessary for the origin of life; those polynucleotides that could code for a primitive protein having catalytic properties furthering the replication of the polynucleotide would preferentially replicate. Other polynucleotides coding for less effective proteins would have replicated more slowly. The foregoing is one of several possibilities for the origin of the first living systems. Many separate and rather diverse instances of the origin of life may have occurred on the primitive earth, but competition eventually eliminated all but one line. Every organism on earth today would be a descendant of that line.

The earliest living systems. One curious feature of biological organic molecules is their optical activity: they rotate the plane of a beam of plane-polarized light. Organic molecules produced abiologically do not show optical activity. Molecules made of the same units can be put together in complementary ways like a left- and right-handed glove. The same building blocks can be used to produce molecules that are three-dimensional mirror images of each other. This asymmetry is responsible for optical activity. At the time of the origin of life, organic molecules, corresponding both to left- and right-handed forms, were produced. The laboratory simulation experiments always produce both types. But the first living systems could have been made only of one type, for the same reason that carpenters do not use random mixtures of screws with left- and right-handed threads. Whether left- or right-handed activity was adopted was probably purely a matter of chance, but once a particular asymmetry was established in the first living systems, it maintained itself. This belief implies that optical activity should be a feature of life on any planet, and also that the chances should be equal of finding a given terrestrial organic molecule or its mirror image molecule in extraterrestrial life forms.

Optical activity of biological molecule

The first living systems probably resided in a molecular garden of Eden, where all the building blocks that contemporary organisms must work hard at synthesizing were available free. Under such conditions the numbers of organisms must have increased very rapidly. But such increases cannot go on indefinitely. In time the supply of some molecular building block must have become short. Those primitive organisms that had the ability to synthesize the scarce building block, say A, from a more abundant one, say B, clearly had a competitive advantage over those organisms that could not perform such a synthesis. In time, however, the secondary source of supply, B, would have also become depleted and those organisms that could produce it from a third building block, *C,* would have preferentially replicated. A U.S. biochemist, N.H. Horowitz, has proposed that in this way the enzymatic reaction chains of contemporary organisms—each step catalyzed by a particular enzyme—originally evolved.

Even the evolution of enzymatic reaction chains may have occurred in free nucleic acids before the origin of the cell. The cell may have arisen in response to the need for maintaining a high concentration of scarce building blocks or enzymes, or as protection against the gradually increasing abundance of oxygen on the primitive earth. Oxygen is a well-known poison to many biological processes, and in contemporary higher organisms the mitochondria that handle molecular oxygen are kept in the cytoplasm, far from contact with the nuclear material. Even today processes are known whereby polyamino acids form small spherical objects, microns to tens of microns across, with some of the properties of cells. These objects, called proteinoid microspheres by Fox, are certainly not cells, but they may indicate processes by which the ancestors of cells arose. Procaryotic cells almost certainly preceded eucaryotic cells and the evolution of so extremely complex an apparatus as the mitotic spindle (which ensures equal segregation of replicated chromosomes) must have taken very long periods of time to evolve.

Proteinoid micro-spheres

The development of mitochondria and chloroplasts (each of which contains its own DNA) in the eucaryotic cell may have been the result of a symbiosis, a cooperative arrangement entered into at first tentatively by originally free-living cells.

As the competition for building blocks increased among early life forms, and also perhaps as the abiological production of organic molecules dwindled because of the increasing oxygen abundance, the strictly heterotrophic way of life became more and more costly. The utilization of porphyrins, which are also made abiologically, by primitive photoautotrophs would have had great selective advantage. Many of the intermediates and enzymes in photosynthesis and in the anaerobic breakdown of carbon compounds are similar, but there is no generally accepted view of the origin of the photosynthetic process. Photosynthesis in procaryotes is more primitive than in such eucaryotes as green plants. In bacteria, water is not the ultimate source of hydrogen atoms for reducing carbon dioxide, and therefore oxygen is not produced. In addition, when a chlorophyll-containing cell is exposed both to light and to oxygen, it is killed unless it also contains an accessory carotenoid pigment. Thus green-plant photosynthesis had to wait until the appearance of carotenoids while bacterial photosynthesis, which does not produce oxygen, could function without carotenoids.

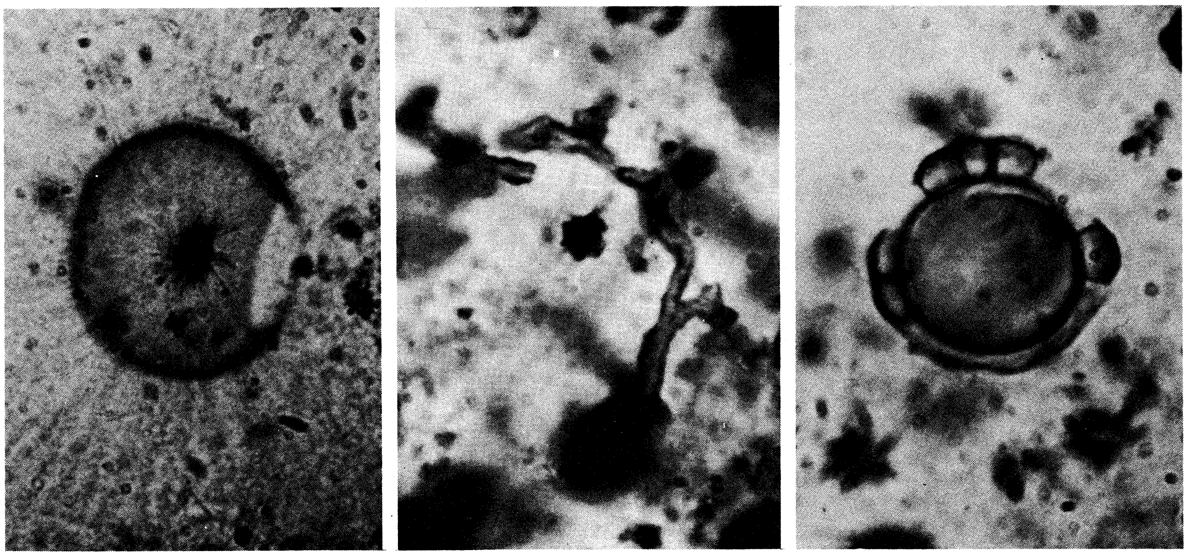
The antiquity of life. Among the oldest known fossils are those found in the Fig Tree chert from the Transvaal, dated at 3,100,000,000 years old. These organisms have been identified as bacteria and blue-green algae. It is very reasonable that the oldest fossils should be procaryotes rather than eucaryotes. Even procaryotes, however, are exceedingly complicated organisms and very highly evolved. Since the earth is reliably known to be itself only about 4,500,000,000 years old, this suggests that the origin of life must have occurred within a few hundred million years after the origin of the earth.

By performing chemical analyses on the oldest sediments, it is possible to say something about the sorts of organic molecules produced, either biologically or abiologically, in primitive times. Thus, amino acids and porphyrins have been identified in the oldest sediments, as have pristane and phytane, typical breakdown products of chlorophyll. There are several indications that these organic molecules, dating from 2,000,000,000 to more than 3,000,000,000 years ago, are of biological origin. For one thing their long-chain hydrocarbons show a preference for a straight chain geometry, whereas known abiological processes tend to produce a much larger proportion of branched chain and cyclic hydrocarbon molecular geometries than have been found in these sediments. Abiological processes tend to produce equal amounts of long-chain carbon compounds with odd and with even numbers of carbon atoms. But the oldest sediments show a distinct preference for odd numbers of carbon atoms per molecule, as do products of undoubted biological origin. Finally, a C^{12} enrichment, for which no abiological process seems able to account, has been discovered in the oldest sediments, evidence that suggests that plantlike life, which concentrates the carbon isotope C^{12} preferentially to C^{13}, was present very early. These departures from thermodynamic equilibrium are often considered to be compelling signs of biological activity. Such evidence again points to the great antiquity of life on earth.

Oceanic origin of life

The fossil record, in any complete sense, goes back only about 600,000,000 years. In the layers of sedimentary rock known by geological methods and by radioactive dating to be that old, most of the major groups of invertebrates appear for the first time. All these organisms appear adapted to life in the water, and there is no sign yet of organisms adapted to the land. For this reason, and because of a rough similarity between the salt contents of blood and of seawater, it is believed that early forms of life developed in oceans or pools. With no evidence for widespread oxygen-producing photosynthesis before this time, and for cosmic abundance reasons described above, the oxygen content of the earth's atmosphere in Precambrian times was very likely less than today. Accordingly, in Precambrian times, solar ultraviolet radiation, especially near the wavelength of 2600 A, which is particularly

By courtesy of Elso S. Barghoorn



Photomicrographs of 2,000,000,000-year-old organisms from the geological stratum called the Gunflint Chert. These organisms are about ten microns across. Organisms more than 1,000,000,000 years older are known.

destructive to nucleic acids, may have penetrated to the surface of the earth, rather than being totally absorbed in the upper atmosphere by ozone as it is today. In the absence of ozone, the ultraviolet solar flux is so high that a lethal dose for most organisms would be delivered in less than an hour. Unless extraordinary defense mechanisms existed in Precambrian times, life near the earth's surface would have been impossible. Sagan has suggested that life at this time was generally restricted to some tens of metres and deeper in the oceans, at which depths all the ultraviolet light would have been absorbed, although visible light would still filter through. As the amount of atmospheric oxygen and ozone increased, due both to plant photosynthesis and to the photodissociation of water vapour and the escape to space of hydrogen from the upper atmosphere, life increasingly close to the earth's surface would have been possible. It has been suggested that the colonization of the land, about 425,000,000 years ago, was possible only because enough ozone was then produced to shield the surface from ultraviolet light for the first time.

Life then had insinuated itself between the sun and the earth. It diverted solar energy to its own uses and contrived more and more ways of exploiting more and more environments. Some experiments were faulty and the lines became extinct; others were more successful and the lines filled the earth. Evolution through natural selection directed the proliferation of a growing array of life forms throughout the biosphere (see EVOLUTION; PHYLOGENY).

EXTRATERRESTRIAL LIFE

It is not known what aspects of living systems are necessary in the sense that living systems everywhere must have them; it is not known what aspects of living systems are contingent in the sense that they are the result of evolutionary accident, so that somewhere else a different sequence of events might have led to different characteristics. In this respect the possession of even a single example of extraterrestrial life, no matter how seemingly elementary in form or substance, would represent a fundamental revolution in biology. It is not known whether there is a vast array of biological themes and counterpoints in the universe, whether there are places that have fugues, compared with which our one tune is a bit thin and reedy. Or it may be that our tune is the only tune around. Accordingly the prospects for life on other planets must be considered in any general discussion of life.

The chemistry of extraterrestrial life. The significance of the search for life beyond the earth has already been discussed. What are the methods and prospects for such a search? Each of the definitions of life described in *Definitions* of *life,* above, implies a method of searching for life. Particular physiological functions, particular metabolic activities, such specific molecules as proteins and nucleic acids, self-replication and mutation, processes not in closed-system thermodynamic equilibrium—all these might be sought. All the search methods significantly depend upon chemistry.

Life on earth is structurally based on carbon and utilizes water as an interaction medium. Hydrogen and nitrogen have significant accessory structural roles; phosphorus is important for energy storage and transport, sulfur for three-dimensional configuration of protein molecules, and so on. But must these particular atoms be the atoms of life everywhere, or might there be a wide range of atomic possibilities in extraterrestrial organisms? What are the general physical constraints on extraterrestrial life?

Prerequisites for life

In approaching these questions several criteria can be used. The major atoms should tend to have a high cosmic abundance. A structural molecule for making an organism at the temperature of the planet in question should not be extremely stable, because then no chemical reactions would be possible; but it should not be extremely unstable, because then the organism would fall to pieces. There should be some medium for molecular interaction. Solids are not appropriate because the diffusion times are very long. Such a medium is most likely a liquid (but could possibly be a very dense gas) that is stable in a number of respects. It should have a large temperature range (for a liquid, the temperature difference between freezing point and boiling point should be large). The liquid should be difficult to vaporize and to freeze; in fact, it should be very difficult to change its temperature at all. In addition it should be an excellent solvent. There should also be some gas on the planet in question that could be used in various biologically mediated cycles, as CO_2 is in the carbon cycle on earth.

The planet, therefore, should have an atmosphere and some near-surface liquid, although not necessarily an ocean. If the intensity of ultraviolet light or charged particles from the sun is intense at the planetary surface, there must be some place, perhaps below the surface, that is shielded from this radiation but that nevertheless permits useful chemical reactions to occur. Since after a certain period of evolution, lives of unabashed heterotrophy lead to malnutrition and death, autotrophs must exist. Chemoautotrophs are, of course, a possibility but the inorganic reactions that they drive usually require a great deal of energy; at some stage in the cycle, this energy must probably be provided by sunlight. Photoautotrophs, therefore, seem required. Organisms that live very far subsurface will be in the dark, making photoautotrophy impossible. Organisms that live slightly subsurface, however, may avoid ultraviolet and charged particle radiation and at the same time acquire sufficient amounts of visible light for photosynthesis.

Thermodynamically, photosynthesis is possible because the plant and the radiation it receives are not in thermodynamic equilibrium; for example, on the earth a green plant may have a temperature of about 300" K while the sun has a temperature of about 6,000" K. (K = Kelvin temperature scale, in which 0° K is absolute zero; 273" K, the freezing point of water; and 373" K, the boiling point of water at one atmosphere pressure.) Photosynthetic processes are possible in this case because energy is transported from a hotter to a cooler object. Were the source of radiation at the same (or at a colder) temperature as the plant, however, photosynthesis would be impossible. For this reason the idea of a subterranean plant photosynthesizing with the thermal infrared radiation emitted by its surroundings is untenable, as is the idea that a cold star, with a surface temperature similar to that of the earth, would harbour photosynthetic organisms.

Chemical requirements

It is possible to approach some of the foregoing chemical requirements and see just which atoms are implied. When atoms enter into chemical combination, the energy necessary to separate them is called the bond energy, a measure of how tightly the two atoms are bound to each other. Table 2 gives the bond energies of a number of chemical bonds, mostly involving abundant atoms. The energies are in electron volts (eV; 1 eV = 1.6×10^{-12} ergs). The symbols are as follows: H, hydrogen; C, carbon; N, nitrogen; 0, oxygen; S, sulfur; F, fluorine; Si, silicon; Bi, bismuth (very underabundant, biologically uninteresting, and present only as an illustration of the relatively weak chemical bonds in some metals). Bond energies generally vary between 10 eV and about 0.03 eV; double and triple bonds where two or three electrons are shared between two atoms tend to be more energetic than single bonds, single

Table 2: Energies of Representative Chemical Bonds

(Hydrogen bonds 0.08–0.45 eV; van der Waals bonds 0.04 eV)

bond	energy (eV)	bond	energy (eV)
N≡N	9.8	Si—0	3.8
C≡N	9.4	C—0	3.7
CEC	8.4	C—C	3.6
C—0	7.4	S—H	3.5
C=C	6.4	Si—H	3.1
H—F	5.4	C—N	3.0
O—H	4.8	Si—Si	1.8
N=N	4.4	N—N	1.7
C—H	4.3	Bi—Bi	1.1
N—H	4.1	O_2N—NO_2	0.57

bonds more energetic than hydrogen bonds where a hydrogen atom is shared between two other atoms, and hydrogen bonds more energetic than the very weak (van der Waals) forces that arise from the attraction of the electrons of one atom for the nucleus of another. At room temperature, atoms, free or bound, move with an average kinetic energy corresponding to about 0.02 eV. Some of the atoms have greater energies, some lesser. At any temperature a few will have energies greater than any given bond energy; hence bonds occasionally will break. The higher the temperature, the more atoms there are moving with sufficient energy to spontaneously break a given bond.

Suppose it is decided arbitrarily (although the decision will not critically affect the conclusions) that for life to exist at any time the fraction of bonds broken by random thermal motions must be no larger than 0.0001 percent. It then turns out that any hypothetical life where the structural bonds are based upon van der Waals forces can only exist where the temperature is below 40" K, for hydrogen bonds below about 400° K, for bonds of 2 eV below 2,000" K, and for bonds of 5 eV below 5,000" K. Now, 2,000" to 5,000" K are typical surface temperatures of stars; 400" K is somewhat above the highest surface temperature found on earth; and 40" K is about the cloud-top temperature of distant Neptune. Thus, over the entire range of temperatures, from cold stars to cold planets, there seem to exist chemical bonds of appropriate structural stability for life, and it would appear premature to exclude the possibility of life on any planet on grounds of temperature.

Life on earth lies within a rather narrow range of temperature. Above the normal boiling point of water, much loss of configurational structure or three-dimensional geometry occurs. At these temperatures proteins become denatured, in part because above the boiling point of water the hydrogen bonding and van der Waals forces between water and the protein disappear. Also, similar bonds within the protein molecule tend to break down. Proteins then change their shapes, their ability to participate in lock-and-key enzymatic reactions is gravely compromised, and the organism dies. Similar structural changes, some of them connected with the stacking forces between adjacent nucleotide bases, occur in the heating of nucleic acids. But it is significant that these changes are not fragmentations of the relevant molecules but rather changes in the ways they fold. There appears to be no reason that configurational bonds should not have been evolved that are stable at higher temperatures than terrestrial organisms experience. On planets hotter than the earth there seems to be no reason that slightly more stable configurational forces should not be operative in the local biochemistry.

Molecular factors

While the bonds that characterize life on earth are too weak at high temperatures, they are too strong at low temperatures, tending to slow down the rates of chemical reactions generally. There are less stable bonds (*e.g.*, hydrogen bonds, silicon–silicon bonds, and nitrogen-nitrogen bonds), however, that might play structural roles at significantly lower temperatures. At higher temperatures, multiple bonds (*e.g.*, in aromatic, or ring-shaped, hydrocarbons) might be utilized for life. There clearly is a rich variety of little-studied chemical reactions that proceed at reasonable rates either at much lower or at much higher temperatures than those on earth.

Except for bismuth and fluorine, all the atoms in Table 2 have relatively high cosmic abundances. At terrestrial temperatures, carbon is the unique atom for biological structure. Not only does it have high abundance but it forms a staggering variety of compounds of great stability, it lends itself to compounds that are configured by weaker bonds, and it enters into multiple bonds. These double- and triple-bonded molecules, among other useful properties, absorb long wavelength ultraviolet light, a process leading to the synthesis of a variety of more complex molecules. A photon of ultraviolet light at a wavelength of 2000 A has an energy of 6.2 eV, capable of breaking many bonds, and permitting more complex reactions among the resulting molecular fragments. Photons of blue light have energies of about 3 eV, and of red light about 2 eV.

Silicon compounds do not form double bonds. Silicon–oxygen bonds are slightly more stable than carbon-carbon bonds, but they tend to produce molecules like the silicates, which are crystals of the same unit repeated over and over again, rather than molecules with aperiodic side chains with potential information content. On low-temperature planets, silicon–silicon bonds are more promising than carbon bonds in terms of reaction times, but they do not form double bonds and the carbon abundance is likely to be greater. Nevertheless, silicon compounds may be of limited biological importance both on high-temperature and low-temperature worlds.

Hydrogen bonding confers on liquids the stability properties necessary for life. There seem to be very few reasonable candidates for liquid interaction media. By all odds water is the most suitable. The other candidates, all to some extent hydrogen bonded, are ammonia, hydrogen fluoride, hydrogen cyanide, and mixtures of liquid hydrocarbons. Hydrogen fluoride can be excluded because it is too scarce cosmically. The hydrocarbons are not good solvents of salts, but life elsewhere may not be based on the same acid–base chemistry as life on earth. The liquid range of water is larger than commonly thought, ranging from about 210" K in saturated salt solutions to 647" K at enormous atmospheric pressures. Water is the biological liquid medium of choice above 200" K, particularly in view of its extremely high cosmic abundance. At lower temperatures ammonia or hydrogen cyanide could serve as a liquid medium.

There are functional roles for specific atoms in biology, but except for considerations of structure and a liquid interaction medium they do not seem fundamental. For example, the energy-rich phosphate bonds in ATP are in fact of relatively low energy; they are about as energetic as the hydrogen bonds (see Table 2). The cell must store up large numbers of these bonds to drive a molecular degradation or synthesis. On high-temperature worlds the energy currency may be much more energetic per bond, and on low-temperature worlds much less energetic per bond.

It may be concluded that, in our present state of ignorance, it is premature to exclude life on grounds of temperature on any other planet, particularly when account is taken of the temperature heterogeneity of the other planets. But life does require an interaction medium, an atmosphere, and some protection from ultraviolet light and from charged particles of solar origin.

The conclusion that for the earth, carbon-based aqueous life is the most appropriate may be slightly suspect, since terrestrial life is manifestly carbon based and aqueous. In 1913 a U.S. biochemist, L.J. Henderson, published The Fitness of the Environment in which the biological advantages of carbon and water were stressed for the first time in terms of comparative chemistry. He was struck by the fact that those very atoms that are needed are just those atoms that are around; it remains a remarkable fact that atoms most useful for life do have very high cosmic abundances.

Exobiology

The search for extraterrestrial life. Exobiology, a term coined by a U.S. biologist, J. Lederberg, for the study of extraterrestrial life, has been called a science without a subject matter. It is certainly true that, as of the early 1970s, no strong evidence for life beyond the earth has been adduced. Exobiology, however, has deep significance even if extraterrestrial life is never found. The mere design of exobiological experiments forces man to examine critically the generality of his assumptions about life on earth. In addition, a lifeless neighbouring planet presents a very interesting quandary: How is it that life has originated and evolved on earth, but not on the planet in question? There is an entire spectrum of possibilities. A given planet may be lifeless and have no vestiges of primitive organic matter and no fossils of extinct life. It may be lifeless but may have either organic chemical or fossil relics. It may possess life of a simple sort or life of a quite complex biochemistry, physiology, and behaviour. It may possess intelligent life and a technical civilization. Establishment of any one of these five possibilities would be of fundamental biological importance.

The difficulties and opportunities inherent in exobiological exploration, in determining which of these five possibilities applies to a given planet, is most clearly grasped by imagining the situation reversed, with man on some neighbouring planet, say Mars, examining the earth for life with the full armoury of contemporary scientific instrumentation and knowledge. First a distinction must be made between remote and *in situ* testing. In remote testing light of any wavelength reflected from or emitted by the target planet can be examined, but with *in situ* studies samples of the planet must be acquired by visiting them or by sending instruments that land on the planet, perform experiments, and radio back their findings. Since biological exploration involves the detailed characterization of any life found, rather than its mere detection, *in situ* experiments are necessary even if remote experiments are successful.

Sensing methods

The bulk of the remote sensing methods are directed toward finding some thermodynamic disequilibrium on the planet. This may be a chemical disequilibrium, a mechanical disequilibrium, or *a* spectral disequilibrium. For example, it would be quite easy to determine spectroscopically from Mars that the earth's atmosphere contains large amounts of molecular oxygen and about one part per million (10^6) of methane. It would also be possible to calculate that, at thermodynamic equilibrium, the abundance of methane should be less than one part in 10^{35}. This huge discrepancy implies the existence of some process continuously generating methane on the earth so rapidly that methane increases to a very large steady-state abundance before it can be oxidized by oxygen. Now such a methane-production mechanism need not be biological. It is conceivable that relatively stable aromatic hydrocarbons were produced abiologically in the early history of the earth and that their slow thermal degradation leads to *a* continuous loss of methane from the planetary subsurface. But this and similar nonbiological explanations of the observed disequilibrium are unlikely. From Mars this thermodynamic discrepancy would be considered not as proof of life on earth but as *a* significant hint of life on earth. In fact the methane abundance on the earth is produced by bacteria that, in the course of the reduction of a more oxidized form of carbon, release methane. Some methane bacteria live in swamps (hence, the term marsh gas for methane), and others — a significant fraction — live in the intestinal tracts of cows and other ruminants. The methane abundance over India is probably larger than over most other areas of the world, and if an extraterrestrial observer knew how to interpret the methane disequilibrium accurately (which is unlikely) it would be possible for him to deduce cows on earth by spectrochemical analysis. The existence of relatively large quantities of methane in the presence of an excess of oxygen would remain a tantalizing but enigmatic hint of life on earth. Similarly, the large amount of oxygen might itself be a sign of life if one could reliably exclude the possibility that the photodissociation of water and the escape to space of hydrogen were the source of oxygen. Also such relatively complex reduced organic molecules as terpenes, a hydrocarbon given off by plants, might conceivably be detected spectroscopically, perhaps by a spectrometer in orbit about the earth. Not only would the chemical disequilibrium of terpenes in an excess of oxygen be suggestive of life, but equally suggestive would be the fact that terpenes are much more abundant over forested areas than over deserts.

Photographic observation

Photographic observations of the daytime earth from Mars would give equivocal results. Even with a resolution of 100 metres (that is, an ability to discriminate fine detail at high contrast only if its components are more than 100 metres apart) — better than the best Mariner photos of Mars at the end of the 1960s, and about a thousand times better than the best ground-based photographs of Mars — it would be extremely difficult to discern cities, canals, bridges, the Great Wall of China, highways, and other large-scale accoutrements of the earth's technical civilization. In satellite photographs with 100-metres resolution only about one in a thousand random photographs of the earth yields features even suggestive of life. As the ground resolution is progressively improved, it becomes increasingly easy to make out the regular geometrical patterns of cultivated fields, highways, airports, and so on. But these are only the products of a civilization recently developed on earth, and even photographs of the earth with a ground resolution of 10 metres, but taken 100,000 years ago, would still have shown no clear sign of life. The lights of the largest cities might be just marginally detectable from Mars at night. Seasonal changes in the colour or darkness of plants would be detectable from Mars, but such cycles might easily have nonbiological explanations, and their accurate interpretation would be difficult.

To detect individual animals a ground resolution of a few metres is required, and even here a low sun and long shadows are generally necessary. This detection could be accomplished with a large telescope in earth orbit. It would then be possible to determine, for example, that objects with the general shape of cows are frequent on the earth. But suppose that members of the civilization examining the earth thus remotely are not even approximately quadrupedal and do not immediately associate the shape of cows with life. They would nevertheless be able to

(Left) Eastern seaboard of the United States photographed by a TIROS weather satellite; Cape Cod (right), Long Island (centre), and Delaware Bay (centre left) can be seen. (Right) Surface of Mars photographed by Mariner 4 spacecraft. Both photographs at one-kilometre resolution. No sign of life, intelligent or otherwise, can be discerned on either planet.

deduce life. They would observe that certain locales on earth have a quantity of raised lumps connected to the ground by four stilts. It would be possible to calculate that wind and water erosion would cause the lumps to topple to the ground in geologically short periods of time. Such stilted lumps are mechanically unstable; they are not in equilibrium; if pushed hard, they fall. Accordingly, there must be a process for generating stilted lumps on the earth, and in short periods of time. It would be very difficult to avoid the implication that this generation process is biological.

Radio emission

A third detection technique arises upon scanning the radio spectrum of the earth. Because of domestic television transmission, the high-frequency end of the AM broadcast band, and the radar defense networks of the United States and of the Soviet Union, the amount of energy put out by the earth to space at certain radio frequencies is enormous. At some frequencies, if this radiation were interpreted as ordinary thermal emission, the temperature of the earth would have to be hundreds of millions of degrees, according to an estimate made by a Soviet astrophysicist, I.S. Shklovskii. Moreover, it would be possible to determine that this radio "brightness temperature" of the earth had been steadily increasing with time over the last several decades. Finally, it would be possible to analyze the frequency and time variation of these signals and deduce that they were not purely random noise.

Now imagine *in situ* studies by vehicles that enter the earth's atmosphere and land at some predetermined locale. There are many places on the earth (the ocean surface, the Gobi Desert, Antarctica) where large organisms are infrequent and a life-detection attempt based solely on television searches for large life forms would be a risky investment. On the other hand, if such an experiment were successful (the camera records a dolphin cavorting, a camel chewing its cud, a penguin waddling) it would provide quite convincing evidence of life.

Although the oceans, the Gobi Desert, and Antarctica are relatively devoid of large life forms, they are in many places replete with minute life forms. Therefore, micro-organism detectors would be a good investment. A television camera coupled to a microscope (optical or electron) would be a promising life detector if the sample acquisition problem could be solved: the early Dutch microscopist Anton van Leeuwenhoek had no difficulty at all in identifying as alive the little "animalcules" that he found in a drop of water, although nothing similar had previously been seen in the history of man.

In addition to morphological criteria for the detection of micro-organisms, there are metabolic and chemical criteria. For example, a sample of terrestrial soil, or seawater, say, might be acquired and introduced into a chamber containing food the investigators guess the earthlings might find tasty. Such food might be an abundant product of prebiological organic synthetic experiments. It could then be determined whether any characteristic molecules, such as carbon dioxide or ethanol, are produced metabolically, or whether the medium containing food and terrestrial sample changes its acidity or becomes cloudy because of the growth of micro-organisms, or it might be investigated whether there is heat given off in the chamber containing sample and food. Alternatively, photosynthesis could be tested by measuring the fixation of some gas, say carbon dioxide, as a function of illumination provided artificially to the sample by the instrument. Along chemical lines a direct test of terrestrial soil or seawater for optical activity might be made. Organic molecules could certainly be searched for with a combined gas chromatograph and mass spectrometer, or by a remote analytic chemistry laboratory. The detection of any organic matter would of course be interesting and relevant, whether or not it was biological in origin. Such criteria as have been used in the analysis of Precambrian sediments (described in *The antiquity of life,* above) might be used to test for biological origin.

Ambiguities of tests for life

It is remarkable, however, that many of these tests are ambiguous. It would be possible, for example, for the Martian investigator to guess wrong about what terrestrial organisms eat and to make incorrect assumptions about their structural chemistry or their interaction medium. If forms of regular geometry that do not move were detected microscopically, there might be serious questions of biological versus mineralogical origin. Chemical criteria (such as the expectation that if odd-numbered carbon chains are more prominent than even-numbered carbon chains, then life is detected) might not be valid unless it was certain which processes actually occurred in the prebiological organic chemistry of the planet in question. In addition, there might be the galling problem of contamination. The Martians' spacecraft might carry living organisms from their own planet and report them as detected on the planet earth. For this reason great care would have to be taken that spacecraft were rigorously sterilized.

In fact, many of these problems have already arisen in an analysis of a variety of meteorite called carbonaceous chondrites. These meteorites, which fall on earth probably from the asteroid belt contain about 1 percent organic matter by mass, far too much to be largely the result of terrestrial contamination. The most abundant organic molecules, however, are not clearly of biological origin, and some of the biologically more interesting molecules may be contaminants. Reports of optical activity have been contested and might alternatively be due to contamination. Geometrically interesting microscopic inclusions have been detected in these bodies. The most abundant inclusions, however, are probably mineralogical in origin, while the most highly structured and lifelike are very rare and, at least in some cases, are obviously due to contamination (in one case by ragweed pollen). Finally, claims have been made of the extraction of viable micro-organisms from the interiors of carbonaceous chondrites. These meteorites are porous, however, and "breathe" air in and out during their entry into the atmosphere. There also have been significant opportunities for their contamination after arrival on the earth. Moreover, one of the organisms extracted was a facultative aerobe. Since, as of the early 1970s, no planet in the solar system besides the earth was known to contain significant quantities of molecular oxygen, it seems quite curious that the complex electron transfer apparatus required for oxygen metabolism would be evolved out on the asteroid belt in expectation of ultimate arrival on the earth. Here, again, contamination has proved a serious hazard. The large amounts of organic matter found in carbonaceous chondrites, however, suggest that the production of organic molecules occurred with very great efficiency in the early history of the solar system.

From such a hypothetical exercise as the instrumental detection of life on earth by an extraterrestrial observer, and from the actual experience acquired in the analysis of carbonaceous chondrites, the following conclusions can be drawn: There is no single and unambiguous "life detector." There are instruments of great generality that make few ambiguous assumptions about the nature of extraterrestrial organisms, particularly their chemistry. These systems, however, require a fair degree of luck (an animal must walk by during the operating lifetime of the instrument), or they require the solution of difficult instrumental problems (such as the acquisition and preparation of samples for remote microscopic examination). Other instruments, such as metabolism detectors, have great sensitivity and are directed at the more abundant micro-organisms. They are quite specific, however, and are critically dependent upon certain assumptions (for example, that extraterrestrial organisms eat sugars) that are in the early 1970s no better than informed guesses. Therefore, an array of instruments, both very general and very specific, seems required. Stringent sterilization of such spacecraft appears necessary, both to avoid confusion of the life-detection experiments, and to prevent interaction of contaminants with the indigenous ecology. Many of the instruments and strategies discussed in the preceding paragraphs continua to be adapted by the United States and the Soviet Union in attempts to search for life on the moon and the nearby planets (see SPACE EXPLORATION).

An exobiological survey of the solar system. A brief survey of the physical environments and biological pros-

Biological prospects of the moon

pects of the moons and planets of the solar system, so far as is known by the early 1970s, follows. The moon's surface seems inhospitable to life of any sort. The diurnal temperatures range from about 100" to about 400" K. In the absence of any significant atmosphere or magnetic field, ultraviolet light and charged particles from the sun penetrate unimpeded to the lunar surface, delivering in less than an hour a dose lethal to the most radiation-resistant micro-organism known. For other reasons already mentioned, the absence of an atmosphere and of any liquid medium on the surface also argues against life. The subsurface environment of the moon is not nearly so inclement. About a metre or so subsurface there is no penetration of ultraviolet light or solar protons, and the temperature is maintained at a relatively constant value about 230" K. Even there, however, the absence of an atmosphere and the probable absence of abundant liquids make the biological prospects rather dim.

It is not out of the question, however, that prebiological organic matter, produced in the early history of the moon, might be found sequestered beneath the lunar surface. Such organic matter may have been produced either in an original lunar atmosphere that has subsequently been lost to space, or in a secondary lunar atmosphere produced by release of gases after the formation of the moon, and also subsequently lost to space. The depth at which such organic matter may be found depends upon the unknown history of the early lunar atmosphere, if any, and upon whether the moon has, on the whole, gained or lost matter due to meteoritic impact. An apparent gaseous emission near the lunar crater Alphonsus was recorded in 1958 and a spectral identification was made of the molecule C_2, a likely organic fragment, but this identification subsequently has been disputed.

Because of contamination by unmanned spacecraft, the lunar surface had accumulated a microbial load estimated by the late 1960s at some 100,000,000 micro-organisms. Since such organisms will be immediately killed unless shielded from radiation, and since the likelihood of their growth seems remote, such contamination may not be a serious problem in subsequent microbial analysis of returned lunar samples. A much more serious contamination problem occurs during the acquisition of such samples by astronauts. Samples obtained during the historic Apollo 11 moon landing in July 1969 were tested for possible organic molecules, but results were inconclusive. Such a finding might shed significant light on the early history of organic molecules in the solar system.

The environment of Mercury is rather like that of the moon. Its surface temperatures range from about 100" to about 620" K, but about a metre subsurface the temperature is constant, very roughly at comfortable room temperature on earth. But the absence of any significant atmosphere, the unlikelihood of bodies of liquid, and the intense solar radiation make life unlikely.

The possibility of life on Mars

Mars has long been considered a likely abode for life. It has a thin atmosphere comprised largely of carbon dioxide. The surface pressure is equivalent to the pressure at an altitude about 100,000 feet above the earth's surface. Small amounts of carbon monoxide and water also have been detected, and molecular nitrogen may be present. Ultraviolet spectroscopy of Mars from rockets and from the space probes Mariners 6 and 7 indicates that ultraviolet light at wavelengths longer than 2000 A is falling unimpeded upon the Martian surface. The temperature at an equatorial noontime locale on Mars is about 300" K (about 85° F), comfortable by terrestrial standards. The variation from day to night at the equator, however, or from equator to pole at noontime are both over 100" K. The nighttime and polar temperatures on Mars are very cold—so cold that atmospheric water vapour probably condenses out each night on Mars, and atmospheric water vapour and carbon dioxide probably condense out at the winter pole, accounting for the polar caps. While large open pools of pure liquid water are not expected on Mars because of the low atmospheric pressures, briny pools in salt deposits are possible, and there is some reason to believe that liquid water may form temporarily each morning on Mars in soil interstices where the vaporization of water is limited by diffusion.

Experiments have been performed in which terrestrial micro-organisms are introduced into simulated Martian environments. In one set of experiments every sample of terrestrial soil from a wide variety of locales contained some micro-organisms that survived Martian conditions indefinitely. These were micro-organisms capable of living in the absence of oxygen; they were shielded from ultraviolet light by small grains of surface material and had some degree of tolerance to cold. The Martian surface contains a reddish material (probably ferric oxide) that strongly absorbs ultraviolet light. When small quantities of water were introduced into simulated Martian environments in experiments, growth of terrestrial micro-organisms occurred. Even when liquid water was available for only about 15 minutes a day, significant growth occurred. These experiments suggest that there are no insuperable physical or chemical problems even for terrestrial life on Mars and emphasize the necessity for sterilization of Mars-bound space vehicles. Since Martian organisms, if any, should be even better adapted to the Martian environment than terrestrial organisms, such experiments indicate, although they certainly do not prove, that Mars may be an abode of life. Hypothetical and speculative ecological schemes have been designed in which, for example, photosynthetic organisms live slightly subsurface where ultraviolet light does not penetrate but where visible light does, or in which organisms have evolved shields opaque to ultraviolet light but transparent to visible light.

Direct evidence for life on Mars has been claimed for many decades. The prevailing opinion in the early 1970s, however, was that such remote clues to life on Mars must be interpreted with great caution. The corresponding difficulty in detecting life on earth from a vantage point on Mars has already been mentioned. The first such argument was posed by a French astronomer, E.L. Trouvelot in 1884: "Judging from the changes that I have seen to occur from year to year in these spots, one could believe that these changing grayish areas are due to Martian vegetation undergoing seasonal changes." The seasonal changes on Mars have been reliably observed, not only visually but also photometrically. There is a conspicuous springtime increase in the contrast between the bright and dark areas of Mars. Accompanying colour changes have been reported, but their reality has been disputed. While such changes have been attributed to the growth of vegetation, seasonally variable dust storms are an equally convincing possibility.

The most famous case, historically, for life on Mars is the discovery of the "canals," a set of apparent thin straight lines that cross the Martian bright areas and extend for hundreds and sometimes thousands of kilometres. They change seasonally as do the Martian dark areas. These lines, first systematically observed by an Italian astronomer, G.V. Schiaparelli, in 1877, were further cataloged and popularized by a U.S. astronomer, Percival Lowell, around the turn of the century. Lowell argued from the unerring straightness of the lines that they could not be of geological origin but must instead be the artificial constructs of a race of intelligent Martians. He suggested that they might be channels carrying water from the melting polar caps to the parched equatorial cities of Mars. While considerable skepticism has been expressed about these straight lines, there is no doubt that approximately rectilinear features do exist on the Martian surface. Less exciting explanations, however, are more probable, including crater chains, terrain contour boundaries, faults, mountain chains, and ridges analogous to the suboceanic ridge systems that are features of the earth.

Several spectroscopic claims have been advanced for the existence of organic molecules on Mars in quantities representing a marked thermodynamic disequilibrium. The difficulties in unambiguous detection of such molecules from the earth have proved to be very great, however, and no such claims have stood the test of time. Thus, while life on Mars seems possible, there is no direct evidence for its

Photograph, from a TIROS weather satellite, of a region near Cochrane, Ontario. The crisscross pattern in white (top left) shows logging swaths, a sign of intelligent life on earth.

presence. Mars stands lonely and enigmatic in the night sky, awaiting more direct explorations.

Features of Venus

According to both ground-based and spaceborne observations, the average surface temperatures of Venus are around 750° K. It does not seem likely, either at the poles or on the tops of the highest Venus mountains, that the surface temperature will be below 400" K, and noontime temperatures are probably significantly hotter than 700" K. Thus, quite apart from the other surface conditions, the temperatures on Venus seem too hot for terrestrial life. It is still not possible to exclude a Venus surface life with a rather different chemistry, although hydrogen bonding would be much less suitable for the geometrical configuration of polymers on Venus than it is on earth. The clouds of Venus, however, are another matter. There, carbon dioxide, sunlight, and (according to the results of the Venera space vehicles) water are to be found. These are the prerequisites for photosynthesis. Some molecular nitrogen also is expected at the cloud level, and some supply of minerals can be expected from dust convectively raised from the surface. The cloud pressures are about the same as on the surface of the earth, and the temperatures in the lower clouds also are quite earthlike. Despite the fact that there is little oxygen, the lower clouds of Venus are the most earthlike extraterrestrial environment known. While there are no recorded cases of organisms on earth that lead a completely airborne existence throughout their life cycle, it is not impossible that such organisms could exist in the vicinity of the Venus clouds, perhaps buoyed, as is a fish by its swim bladder, to avoid downdrafts carrying them to the hotter lower atmosphere.

A similar speculation can be entertained with regard to the lower clouds of Jupiter. On Jupiter the atmosphere is composed of hydrogen, helium, methane, ammonia, and probably neon and water vapour. But these are exactly those gases used in primitive earth-simulation experiments directed toward the origin of life. Laboratory and computer experiments have been performed on the application of energy to simulated Jovian atmospheres. In addition to the immediate gas-phase products, such as hydrogen cyanide and acetylene, more complex organic molecules, including aromatic hydrocarbons, are formed in lower yield. The visible clouds of Jupiter are vividly coloured, and it is possible that their hue is due to such coloured organic compounds. There is also an apparent absorption feature near 2600 A, in the ultraviolet spectrum of Jupiter, which has been attributed both to aromatic hydrocarbons and to nucleotide bases. In any event it is likely that organic molecules are being produced in significant yield on Jupiter; it is possible that Jupiter is a vast planetary laboratory that has been operating for 5,000,000,000 years on prebiological organic chemistry.

Satellites and comets of the solar system

The other Jovian planets, Saturn, Uranus, and Neptune, are similar in many respects to Jupiter, although much less is known about them. Their cloud-top temperatures progressively decrease with distance from the sun. In the case of Saturn, microwave studies have indicated that the atmospheric temperature increases with depth below the clouds; similar situations are expected on Jupiter, Uranus, and Neptune. Thus, it is by no means clear that the low temperatures of the upper clouds of the Jovian planets apply to the lower clouds, or to the underlying atmosphere. The environment of Pluto is almost completely unknown. In addition to these planets, the solar system contains 32 natural satellites, some of which, such as Titan, a satellite of Saturn, and Io, a satellite of Jupiter, appear to have atmospheres. There are also tens of thousands of comets, which, judging from their spectra, contain organic molecules, as well as some thousands of asteroids and asteroidal fragments revolving about the sun between the orbits of Mars and Jupiter. These are the presumed sources of the carbonaceous chondrites, which contain organic matter.

In short, there is a wide range of environments of biological interest within the solar system. There is no direct evidence for extraterrestrial life on these planets, but, on the other hand, there is no strong evidence against life on many of these worlds. Beyond this is the near certainty that biologically interesting organic molecules will be found throughout the solar system.

Intelligent life beyond the solar system. For thousands of years man has wondered whether he is alone in the universe or whether there might be other worlds populated by creatures more or less like himself. The common view, both in early times and through the Middle Ages, was that the earth was the only "world" in the universe. Nevertheless, many mythologies populated the sky with divine beings, certainly a kind of extraterrestrial life. Many early philosophers held that life was not unique to the earth. Metrodorus, an Epicurean philosopher in the 3rd and 4th centuries BC, argued that "to consider the earth the only populated world in infinite space is as absurd as to assert that in an entire field sown with millet, only one grain will grow." Since the Renaissance there have been several fluctuations in the fashion of belief. In the late 18th century, for example, practically all informed opinion held that each of the planets was populated by more or less intelligent beings; in the early 20th century, by contrast, the prevailing informed opinion (except for the Lowellians) held that the chances for extraterrestrial intelligent life were insignificant. In fact the subject of intelligent extraterrestrial life is for many people a touchstone of their beliefs and desires, some individuals very urgently wanting there to be extraterrestrial intelligence, and others wanting equally fervently for there to be no such life. For this reason it is important to approach the subject in as unbiased a frame of mind as possible. A respectable modern scientific examination of extraterrestrial intelligence is no older than the 1950s. The probability of advanced technical civilizations in our galaxy depends on many controversial issues.

The Green Bank formula

A simple way of approaching the problem, which illuminates the parameters and uncertainties involved, has been devised by a U.S. astrophysicist, F.D. Drake. The number N of extant technical civilizations in the galaxy can be expressed by the following equation (the so-called Green Bank formula):

$$N = R_* f_p n_e f_l f_i f_c L$$

where R_* is the average rate of star formation over the lifetime of the galaxy; f_p is the fraction of stars with planetary systems; n_e is the mean number of planets per star that are ecologically suitable for the origin and evolution of life; f_l is the fraction of such planets on which life in fact arises; f_i is the fraction of such planets on which intelligent life evolves; f_c is the fraction of such planets on which a technical civilization develops; and L is the mean lifetime of a technical civilization. What follows is a brief consideration of the factors involved in choosing numerical values for each of these parameters, and an indication of some currently popular choices. In several cases these estimates are no better than informed guesses and no very great reliability should be pretended for them.

There are about 2×10^{11} stars in the galaxy. The age of the galaxy is about 10^{10} years. A value of $R_* = 10$ stars per year is probably fairly reliable. While most contemporary theories of star formation imply that the origin of planets is a usual accompaniment of the origin of stars, such theories are not well enough developed to merit much confidence. Through the painstaking measurement of slight gravitational perturbations in the proper motions of stars, it has been found that about half of the very nearest stars have dark companions with masses ranging from about the mass of Jupiter to about 30 times the mass of Jupiter. The nearest of these dark companions orbit Barnard's star, which is only six light years from the sun and is the second nearest star system. The most direct indication that planetary formation is a general process throughout the universe is the existence of satellite systems of the major planets of our own solar system. Jupiter, with 12 satellites, Saturn with 10, and Uranus with 5, each closely resemble miniature solar systems. It is not known what the distribution of distances of planets from their central star are in other solar systems and whether they tend to vary systematically with the luminosity of the parent star. But considering the wide range of temperatures that seem to be compatible with life, it can be tentatively concluded that $f_p n_e$ is about one.

Because of the apparent rapidity of the origin of life on earth, as implied by the fossil record, and because of the ease with which relevant organic molecules are produced in primitive earth simulation experiments, the likelihood of the origin of life over a period of billions of years seems high, and some scientists believe that the appropriate value of f_l is also about one. For the quantities of f_i and f_c the parameters are even more uncertain. The vagaries of the evolutionary path leading to the mammals, and the unlikelihood of such a path ever being repeated has already been mentioned. On the other hand, intelligence need not necessarily be restricted to the same evolutionary path that occurred on the earth; intelligence clearly has great selective advantage, both for predators and for prey.

Similar arguments can be made for the adaptive value of technical civilizations. Intelligence and technical civilization, however, are clearly not the same thing. For example, dolphins appear to be very intelligent, but the lack of manipulative organs on their bodies has apparently limited their technological advance. Both intelligence and technical civilization hove evolved about halfway through the relevant lifetime of the earth and sun. Some, but by no means all, evolutionary biologists would conclude that the product $f_i f_c$ taken as 10^{-2} is a fairly conservative estimate.

Still more uncertain is the value of the final parameter, L, the lifetime of a technical civilization. Here, fortunately for man, but unfortunate for the discussion, there is not even one example. Contemporary world events do not provide a very convincing counterargument to the contention that technical civilizations tend, through the use of weapons of mass destruction, to destroy themselves shortly after they come into being. If we define a technical civilization as one capable of interstellar radio communication, our technical civilization is only a few decades old. If then L is about ten years, multiplication of all of the factors assumed above leads to the conclusion that there is in the second half of the 20th century only about one technical civilization in the galaxy—our own. But if technical civilizations tend to control the use of such weapons and avoid self-annihilation, then the lifetimes of technical civilizations may be very long, comparable to geological or stellar evolutionary time scales; the number of technical civilizations in the galaxy would then be immense. If it is believed that about 1 percent of developing civilizations make peace with themselves in this way, then there are about 1,000,000 technical civilizations extant in the galaxy. If they are randomly distributed in space, the distance from the earth to the nearest such civilization will be several hundred light-years. These conclusions are, of course, very uncertain.

Communications with extraterrestrial civilizations

How is it possible to enter into communication with another technical civilization? Independent of the value of L, the above formulation implies that there is about one technical civilization arising every decade in the galaxy. Accordingly, it will be extraordinarily unlikely for man soon to find a technical civilization as backward as his. From the rate of technical advance that has occurred on the earth in the last few hundred years, it seems clear that man is in no position to project what future scientific and technical advances will be made even on earth in the next few hundred years. Very advanced civilizations will have techniques and sciences totally unknown to 20th-century man. Nevertheless man already has a technique capable of communication over large interstellar distances. This technique, already encountered in the discussion of life on earth, is radio transmission. Imagine that we employ the largest radio telescope available on earth, the 1,000-foot-diameter dish of Cornell University, the Arecibo Observatory in Puerto Rico, and existing receivers. and that the identical equipment is employed on some transmitting planet. How distant could the transmitting and receiving planets be for intelligible signals to be transmitted and received? The answer is a rather astonishing 1,000 light-years. Within a volume centred on the earth, with a radius of 1,000 light-years, there are over 10,000,000 stars.

There would of course be problems in establishing such radio communication. The choices of frequency, of target star, of time constant, and of the character of the message would all have to be selected by the transmitting planet so that the receiving planet would, without too much effort, be able to deduce the choices. But none of these problems seem insuperable. It has been suggested that there are certain natural radio frequencies (such as the 1420-megacycle line of neutral hydrogen) that might be tuned to; the first choice might be to listen to stars of approximately solar spectral type: in the absence of a common language there nevertheless are messages whose intelligent origin and intellectual content could be made very clear without making many anthropocentric assumptions.

Because of the expectation that the earth is relatively very backward, it does not make very much sense to transmit messages to hypothetical planets of other stars. But it may very well make sense to listen for radio transmissions from planets of other stars. Project Ozma, a very brief program of this sort, oriented to two nearby stars, Epsilon Eridani and Tau Ceti, was organized in 1960 by Drake. On the basis of the Green Bank formula, it would be very unlikely that success would greet an effort aimed at two stars only 12 light-years away, and Project Ozma was unsuccessful. It remains, however, the first pioneering attempt at interstellar communication. Related programs were organized on a larger scale and with great enthusiasm in the 1960s in the U.S.S.R., where a state scientific commission devoted to such an effort was organized. Other communication techniques including laser transmission and interstellar spaceflight have been discussed seriously and may not be infeasible, but if the measure of effectiveness is the amount of information communicated per unit cost, then radio is the method of choice.

The search for extraterrestrial intelligence is an extraordinary pursuit, in part because of the enormous significance of possible success, but in part because of the unity it brings to a wide range of disciplines: studies of the origins of stars, planets, and life; of the evolution of intelligence and of technical civilizations; and of the political problem of avoiding man's self-annihilation. But at least one point is clear. In the words of Loren Eiseley (also from *The Immense* Journey),

> Lights come and go in the night sky. Men, troubled at last by the things they build, may toss in their sleep and dream bad dreams, or lie awake while the meteors whisper greenly overhead. But nowhere in all space or on a thousand worlds will there be men to share our loneliness. There may be wisdom; there may be power; somewhere across space great instruments, handled by strange, manipulative organs, may stare vainly at our floating cloud wrack, their owners yearning as we yearn. Nevertheless, in the nature of life and in

the principles of evolution we have had our answer. Of men [as are known on earth] elsewhere, and beyond, there will be none forever.

Life-Span

It is a commonplace that organisms die, some after only a brief existence, like that of the mayfly whose adult life burns out in a day, and others whose term seems almost endless, like that of the gnarled bristlecone pines that have lived thousands of years. The limits of the life-span of each species appear to be determined ultimately by heredity. Locked within the code of the genetic material are instructions that specify the age beyond which a species cannot live given even the most favourable conditions. But many environmental factors act to diminish that upper age limir, for conditions are never altogether favourable.

GENERAL BACKGROUND

Maximum and average life-spans

The maximum life-span is a theoretical number whose exact value cannot be determined from existing knowledge about an organism; it is often given as a rough estimate based on the longest lived organism known to date. A mole meaningful measure is the average life-span, a statistical concept derived by the analysis of mortality data for populations of each species. A related term is the expectation of life, a hypothetical number computed for humans from mortality tables drawn up by insurance companies. It represents the average number of years that a group of persons, all born at the same time, might be expected to live, and it is based on the changing death rate over many past years.

The concept of life-span implies that there is an individual whose existence has a definite beginning and end. What constitutes the individual in most cases presents no problem: among organisms that reproduce sexually the individual is a certain amount of living substance capable of maintaining itself alive and endowed with hereditary features that are in some measure unique. In some organisms, however, extensive and apparently indefinite growth takes place and reproduction may occur by division of a single parent organism, as in many protists, including bacteria, algae, and protozoans. If these divisions are incomplete, a colony results; if the parts separate, genetically identical organisms are formed. In order to consider life-span in such organisms, the individual must be defined arbitrarily since the organisms are continually dividing. In a strict sense, the life-spans in such instances are not comparable to those forms that are sexually produced.

The beginning of an organism can be defined by the formation of the fertilized egg in sexual forms; or by the physical separation of the new organism in asexual forms (many invertebrate animals and many plants). In animals generally, birth is considered to be the beginning of the life-span. The timing of birth, however, is so different in various animals that it is only a poor criterion. In many marine invertebrates the hatchling larva consists of relatively few cells, not nearly so far along toward adulthood as a newborn mammal. For even among mammals, variations are considerable. A kangaroo at birth is about an inch long and must develop further in the pouch, hardly comparable to a newborn deer, who within minutes is walking about. If life-spans of different kinds of organisms are to be compared, it is essential that these variations be accounted for. The end of an organism's existence results when irreversible changes have occurred to such an extent that the individual no longer actively retains its organization. There is thus a brief period during which it is impossible to say whether the organism is still alive, but this time is so short relative to the total length of life that it creates no great problem in determining life-span.

Potential immortality

Some organisms seem to be potentially immortal. Unless an accident puts an end to life, they appear to be fully capable of surviving indefinitely. This faculty has been attributed to certain fishes and reptiles, which appear to be capable of unlimited growth. Without examining the various causes of death in detail (see DEATH) a distinction can be made between death as a result of internal changes (*i.e.*, aging) and death as a result of some purely external factor, such as an accident. It is notable that the absence of aging processes is correlated with the absence of individuality. In other words, organisms in which the individual is difficult to define, as in colonial forms, appear not to age.

HUMAN BEINGS

The exact duration of human life is unknown, although there is presumably a maximum life-span for the human race established in the genetic material. At first thought, this statement seems irrational. Surely no human being can live 1,000 years. Even though all may agree that the likelihood of an individual living 1,000 years is infinitesimal, there is no scientific proof that this statement is or is not true. The indeterminacy of the maximum limit of human life is made more comprehensible if one chooses a number that may appear to be a more reasonable limit.

Since there is no verified instance of a person having lived 150 years, this number may, for purposes of illustration, be arbitrarily accepted as the maximum limit of the span of human life. But if the possibility is admitted that an individual may live exactly 150 years, there is no valid reason for rejecting the possibility that some other individual may live 150 years and one minute. And if 150 years and one minute is accepted, why not 150 years and two minutes, and so on? Thus, based on existing knowledge of longevity, a precise figure for the span of human life cannot be given.

Studies on longevity. Much information concerning the inheritance of longevity has come from the study of genealogical records of nobility and landed gentry.

The early genealogical studies were criticized on the grounds that the downward trend in the death rate (attributable generally to scientific advancements) introduced a spurious correlation in statistics derived from records extending over long periods of time. It was argued that in some instances records were included of persons who, at the time of the study, had not had the opportunity of living out their possible life-span. The general finding of such investigations was that the expectation of life of sons of long-lived parents (*i.e.*, those living to age 70 years or older) was greater than that of sons of shorter-lived parents (*i.e.*, those having attained less than age 50 at the time of death).

An American biostatistician attempted to avoid the defects of genealogical studies by collecting records of the family histories of 365 nonagenarians (90-year-old persons) and of a comparison group of 143 individuals of

The TIAL concept

varying ages, selected because all of their six immediate ancestors were dead. The study introduced the concept of "total immediate ancestral longevity," or TIAL—the sum of the ages at death of the two parents and the four grandparents of a given person—as a measure of longevity. This number is unlikely to be greater than 600 or less than 90. The average TIAL of the nonagenarians and centenarians definitely exceeded that of the comparison group. This held true not only for the six immediate ancestors as a group but also for each category—father, mother, paternal and maternal grandparents. In the same study, investigators also computed the expectation of life for sons of fathers as classified in three groups by age at death: (1) under age 50, (2) from age 50 to age 79, and (3) age 80 or over. The expectation of life for the three groups at birth was 47.0, 50.5, and 57.2 years, respectively. The same relative ranking continued through the lifetime of the sons, their expectation of life at age 40 being 27.3, 28.9, and 32.0 years, respectively.

While certain doubts have been raised about the validity of these as well as earlier studies, taken at their face value, these data show clearly that long-lived persons had parents and grandparents who lived longer than the parents and grandparents of shorter lived persons.

Since longevity is important in life insurance underwriting, several studies have been made of the relationship between heredity and the life-span by an analysis of life insurance records. Such analyses showed that policyholders both of whose parents were living when the policy was written live longer than those whose parents were dead when the policy was written. These results are in conformity with those obtained from genealogical records and family histories.

Each of the various types of studies of the inheritance of longevity—genealogical records, life insurance records, and family histories of the general population—has limitations that restrict the applicability of the findings. The principal studies indicate, nevertheless, that the children of long-lived parents are more likely to be long-lived than are the children of short-lived parents. Conversely, the immediate ancestors—parents and grandparents—of long-lived persons on the average are older at death than are the immediate ancestors of persons who die at a relatively young age. These studies support the conclusion, mentioned earlier, that longevity is determined in part by heredity.

Actual versus possible life-span. It should be observed that this conclusion relates to the inheritance of longevity—the observed expression of the span of life—and not to the span of life itself. The actual length of life itself is shorter than the possible life-span, since the former reflects the effect of unfavourable environmental factors. In the absence of any biological data from which the maximum limit of the span of life can be determined precisely, an estimate of the limit must be obtained from observation of the actual length of life of persons who already have died. But such observations cannot establish a fixed limit for the span of life.

The estimation of the length of the span of life from observed data is a form of sampling from a large but incomplete population. The tabulation of the ages at death of a large number of persons from a large general population of the United States will give an asymmetrical frequency distribution with two modes, or peaks, of highest frequency: the first at age less than one year and the second between ages 75 and 80 years. The frequency distribution is bounded by age zero at the lower limit but there is no boundary at the upper limit. The number of deaths of persons whose length of life is near the upper limit of this frequency distribution (*e.g.*, 100 years or more) varies from year to year. The age of the oldest person dying also varies from year to year.

The number of deaths of centenarians (100-year-old persons) depends in part upon the number of deaths counted. Ages at death are frequently unverified, so that the true numbers of centenarians almost certainly deviate from those given in official vital statistics. Moreover, only a very small proportion of the deaths that have occurred throughout the history of the human race have been registered. The potential number of future deaths greatly exceeds the number that already has occurred. Statistical theory supports the expectation that as the total number of deaths continues to increase, the death of a person whose length of life will be longer than that of any person previously known will be recorded.

Observation of the length of life of persons who have died can show that it is possible for a human being to live to the oldest age recorded as of any specified date and can provide an estimate of the relative frequency or probability of that event. But such observations do not provide a logical basis for fixing any age as the maximum possible limit of the life-span.

The continuation of the worldwide decline in the death rate will naturally result in an increase in the number of persons who live until age 100 years or more. Since the number of persons who may live to an advanced age, such as 110 or 115 years, is directly related to the number of persons who live to age 100, an increase in the latter number will increase the probability that the death of an individual attaining some greater age (*e.g.*, 115 years) will be recorded at some future date.

Famous age records

Many instances of persons alleged to have died at an age considerably greater than 100 years have been recorded. Statements concerning the age at death of biblical characters such as Methuselah can be dismissed, since scientific verification is impossible. Three of the most frequently cited cases of more recent times are: Thomas Parr, who died in November 1635 at the alleged age of 152 years; Henry Jenkins, who died in December 1670 at the alleged age of 169 years; and Catherine, countess of Desmond, who died in 1604 at the alleged age of 140 years. William Harvey, a famous English physician, performed an autopsy on Thomas Parr and the account of the autopsy was cited for many years as evidence that Harvey—in his paper—had confirmed Parr's age. Quite apart from the fact that it is impossible accurately to determine the age of a person by an autopsy, Harvey made no attempt to verify Parr's age but merely referred to the current estimates. Subsequent investigations have revealed that no proof exists of the age at death of any of these three individuals and that their reported ages were based solely upon hearsay.

An example with more definite documentation is that of Christian Jacobsen Drakenberg, stated to have been born on November 18, 1626, and to have died on October 9, 1772, aged 145 years and 325 days. Although the authenticity of his age was attested to by many persons, including two celebrated Scandinavian actuaries, later investigations cast doubt upon the record. It is difficult to accept the statements concerning Drakenberg's age at death, since this age is more than 30 years greater than the next oldest verified age at death—a difference that in itself casts doubt on its authenticity.

Of eight individuals for whom records substantiate the fact that each had lived more than 108 years, seven were females. Six of the eight were more than 110 years old at death. The oldest was Pierre Joubert, who was born July 15, 1701, and died November 16, 1814, aged 113 years and 124 days. Discounting the Drakenberg record, this is the oldest age at death that has been generally accepted as authentic.

It may be concluded that the span of human life is at least 114 years, but that this is not the maximum upper limit. This does not mean the span of life of each individual now living or to be born in the future is at least 114 years. The span of life, since it is determined by heredity, varies from one individual to another as do other genetically determined traits.

Factors influencing life-span of man

A significant proportion of human embryos and fetuses die before birth. Other infants at birth have defects that limit their span of life to a few years. Some malformations (*e.g.*, certain cardiovascular defects) are developmental rather than genetic in the strict sense of the word and can be corrected so that the length of life of such persons is extended.

In the past the length of life of most individuals has been considerably shorter than their possible span of life because of unhealthful environmental factors. As these factors are increasingly brought under control or eliminated, the actual length of life will approach more closely the span of life. At the end of the 18th century the expectation of life at birth in North America and northwestern Europe was about 35 or 40 years. By 1970 it exceeded 70 years, and at some future date the death of a person at an authenticated age of more than 114 years can be expected.

There is no evidence that the span of human life has increased since the beginning of recorded history. Neither is there any evidence that the death rate of centenarians has decreased. The expected increase in the number of centenarians results from a decrease in the death rate at ages under 100 years and not from any demonstrable increase in the maximum length of the span of life. The remarkable increase in the average length of life during the past 2,000 years—from 20–25 years to 70 years under favourable conditions—has increased the likelihood that a person may live to the maximum limit of his span of life.

SUBHUMAN ANIMALS

Much of what is known of the length of life of animals other than man derives from observations of domesticated species in laboratories and zoos. One has only to consider how few animals reveal their age to appreciate the difficulties involved in answering the apparently simple question of how long they live in nature. In many fishes, a few kinds of clams, and an occasional species of other groups, growth is seasonal, so that annual zones of growth, much like tree rings, are produced in some part of the organism. Among game species, methods of determining relative age by indicators such as the amount of tooth wear or changes in bone structure have yielded valuable information. Bird bands and other identifying marks also make age estimation possible. But one of the consequences of the fact that animals move is that very little is known about the life-span of most species as they exist in nature.

Maximum and average longevity. The extreme claims of longevity that are occasionally made for one species or another have consistently been proven false when subjected to critical scrutiny. Although the maximum life-span that has been observed for a particular species cannot be considered absolute, since a limited number of individuals at best has been studied, this datum probably provides a fair approximation of the greatest age attainable for this kind of animal under favourable conditions. Animals in captivity, which provide most of the records of extreme age, are exposed to far fewer hazards than those in the wild. In the accompanying table of maximum longevity, particular species have been so selected as to encompass the known range of longevity of other members of the taxonomic group to which they belong.

Table 1: Maximum Longevity of Animals in Captivity*

animal	life-span in years	animal	life-span in years
Mammals		Amphibians	
Bat (*Eptesicus fuscus*)	2	European black salamander (*Salamandra atra*)	
Grizzly bear (*Ursus horribilis*)	31	Spotted salamander (*Ambystoma maculatum*)	25
Cat (*Felis catus*)	21	Frog (*Rana* species)	5–15
Chimpanzee (*Pan troglodytes*)	37	Fishes	
Dog (*Canis familiaris*)	34	Eel (*Anguilla rostrata*)	6
Elephant, Indian (*Elephas maximus*)	57	Goldfish (*Carassius auratus*)	25
Goat (*Capra hircus*)	18	Sturgeon (*Acipenser transmontanus*)	50
Golden hamster (*Mesocricetus auratus*)	1.8	Insects	
Horse (*Equus caballus*)	62	Ant (*Lasius* species)	15
Lion (*Panthera leo*)	29	Buprestid beetle (*Buprestis splendens*)	30
Mouse (*Mus musculus*)	3	Fruit fly (*Drosophila melanogaster*)	0.1
Ox (*Bos taurus*)	30	**Arachnids**	
Squirrel, gray (*Sciurus carolinensis*)	15	Bird spider (*Avicularis avicularis*)	15
Wild boar (*Sus scrofa*)	27	Rocky Mountain wood tick (*Dermacentor andersoni*)	3-4
Birds		Crustaceans	
Blue jay (*Cyanocitta cristata*)	4	Crayfish (*Astacus fluviatilis*)	30
Canary (*Serinus canaria*)	24	Water flea (*Daphnia magna*)	0.2
Macaw (*Ara macao*)	64	Mollusks	
Nightingale (*Luscinia luscinia*)	3.8	Clams, various species	1–10
Pigeon (*Columba livia domestica*)	35	Snails, various species	1–30
Titmouse (*Parus major*)	9	Annelid worms	
Reptiles		Earthworm (*Lumbricus terrestris*)	10
Alligator (*Alligator mississipiensis*)	56	Medicinal leech (*Hirudo medicinalis*)	27
Garter snake (*Thamnophis sirtalis*)	6	Rotifers	
Box turtle (*Terrapene carolina*)	123	Various species	0.03–0.1
Giant tortoise (*Testudo elephantopus*)	177		
Water turtle (*Pseudemys scripta*)	7		

*Condensed and adapted from W.S. Spector (ed.), *Handbook of Biological Data*, 1956.

Environmental influences. Life-span usually is measured in units of time. Although this may seem eminently logical, certain difficulties may arise. In cold-blooded animals in general, the rate of metabolism that determines the various life processes varies with the temperatures to which they are exposed. If aging depends on the expenditure of a fixed amount of vital energy, an idea first proposed in 1908, life-span will vary tremendously depending on temperature or other external variables that influence life-span. There is considerable evidence attesting at least to the partial cogency of this argument. So long as a certain range is not exceeded, cold-blooded invertebrates do live longer at low than at high temperatures. Rats in the laboratory live longest on a somewhat restricted diet that does not permit maximum metabolic rate. Of perhaps even greater significance is the fact that many animals undergo dormant periods. Many small mammals hibernate; a number of arthropods have life cycles that include periods during which development is arrested. Under both conditions the metabolic rate becomes very low. It is questionable whether such periods should be included in computing the life-span of a particular organism. Comparisons between species, some of which have such inactive periods while others do not, are dangerous. It is possible that life-span could be measured more adequately by total metabolism; however, the data that are necessary for this purpose are almost entirely lacking.

Temperature effects

Length of life is controlled by a multitude of factors, which collectively may be termed environment, operating on a genetic system that determines how the individual will respond. It is impossible to list all the environmental factors that may lead to death. For analytical purposes it is, however, useful to make certain formal separations. Every animal is exposed to (1) a pattern of numerous events, each with a certain probability of killing the individual at any moment and, in the aggregate, causing a total probability of death or survival; (2) climatic and other changes in the habitat, modifying the frequency with which the various potentially fatal events occur; and (3) progressive systemic change, inasmuch as growth, reproduction, development, and senescence are characteristics intrinsic in the organism and capable of modifying the effects of various environmental factors.

Patterns of survival. Consider a group of similar animals of the same age. Although no two individuals can have precisely the same environment, let it be assumed that the environment of the group remains effectively constant. If the animals undergo no progressive physiological changes, the factors causing death will produce a death rate that will remain constant in time. Under these conditions, it will take the same amount of time for the population to become reduced to one-half its former number, no matter how many animals remain at the beginning of the period considered. The animals therefore survive according to the pattern of an accident curve. This is the sense in which many of the lower animals are immortal. Although they die, they do not age; how long they have already lived has no influence on their further life expectation.

Another group of animals may consist of individuals that differ markedly in their responses to the constant environment. They may be genetically different, or their previous development may have caused variations to arise. Those individuals that are most poorly suited to the new environment will die, leaving survivors that are better adapted. The same result can also be achieved in other ways. If the environment varies geographically, those individuals that happen to find areas in which existence can be maintained will survive, while the remainder will die. Or, as a result of their own properties, animals in a constant environment may acclimate in a variety of ways, thus adjusting to the existing conditions. The pattern of survival that results in each of these cases is one in which the death rate declines with time, as illustrated by the selection–acclimation curve.

In the absence of death from other causes, all members of a population may exist in their environment until the onset of senescence, which will cause a decline in the ability of individuals to survive. In a sense they can be considered to wear out as does a machine. Their survival is best described by individual differences among members of the population that determine the curvature of the survival line (wearing-out curve). The more the population varies, the less abrupt is the transition from total survival to total death.

Under the actual conditions of existence of animals the three types of survival (accident pattern, selection–acclimation pattern, wearing-out pattern) above all enter as components of the realized survival pattern. Thus in animals that are carefully maintained in the laboratory, survival is approximately that of the wearing-out pattern. Environmental accidents can be kept to a minimum under these conditions, and survival is almost complete during the major part of the life-span. In all known cases, however, the early stages of the life-span are characterized by a noticeable contribution of the selection–acclimation pattern. This must be interpreted as a result of developmental changes that accompany the early life of the individuals and of selective processes that operate on those organisms whose genetic constitutions are ill fitted for that environment.

Highest mortality in aquatic animals

In some of the larger mammals in nature, the existing evidence points to a similar survival pattern. In a variety of other animals, however, and including fishes and invertebrates, mortality in the young stages is so high that the selection–acclimation curve predominates. One estimate places the mortality of the Atlantic mackerel during its first 90 days of life as high as 99.9996 percent. Since some mackerel do live for several years, a mortality rate that decreases with age is indicated. Similar considerations probably apply to all those animals that have larval stages that serve as dispersal mechanisms.

When the postjuvenile portion of the life-span is considered by itself, a number of animals for which such information has been gathered — including primarily fishes and birds — have survivorship curves that are dominated by the accident pattern. In these species in nature, death from old age apparently is rare. Their chance of surviving to an advanced age is so small that it may be statistically negligible. In modem times, human predation is a large factor in the mortality of these species in many cases. Since deaths from fishing and hunting are largely independent of age, once an animal has reached a certain minimum size, such a factor only makes the survival curve steeper but does not change its shape. One consequence of such increased mortality is that fewer old and large individuals are noticed in a population.

More complex survival patterns, such as the hypothetical one illustrated, undoubtedly exist. They should be looked for in those species in which extensive reorganization of the animal is part of the normal life cycle. In effect, these animals change their environment radically, in some cases several times during a lifetime. The frog offers a familiar example. During its period of early development and until shortly after hatching, the animal is subject to major internal, and some external, change. As a tadpole it is adjusted to an aquatic, herbivorous life. The metamorphosis to the terrestrial, carnivorous adult form is accompanied by varied physiological stresses that must be expected to produce a temporary increase in mortality rate. In some insects the eggs, larvae, pupae, and adults are exposed lo and respond to quite different environments, and a survivorship pattern even more complex than that described by the composite curve may exist.

The same species will exhibit changed survival in different environments. In captivity an animal population may approach the wearing-out pattern; in its natural habitat survivorship may vary with age in a quite different way. Although one can assign a maximum potential life-span to an individual — while realizing that this maximum may not be attained — it is impossible to specify the survivorship pattern unless the environment is also specified. This is another way of saying that life-span is the joint property of the animal and the environment in which it lives. (P.W.F.)

PLANTS

Plants grow old as surely as do animals; however, a generally accepted definition of age in plants has not yet been realized. If the age of an individual plant is that time interval between the reproductive process that gave rise to the individual and the death of the individual, the age attained may be given readily for some kinds of plants but not for others. Table 2 lists maximum ages, both estimated and verified, for some seed plants.

Problem of defining age. An English oak that has 1,000 annual rings in the trunk is 1,000 years old. But age is less certain in the case of an arctic lupine that germinated from a seed that, containing the embryo, had been lying in a lemming's burrow in the arctic permafrost for 10,000 years.

Ageless embryonic tissue

The mushroom caps that appear overnight last for only a few days, but the network of fungus filaments in the soil (the mycelia) may be as old as 400 years. Because of important differences in structure, the life-span of higher plants cannot be compared with that of higher animals. Normally, embryonic cells (that is, cells capable of changing in form or becoming specialized) cease to exist very early in the life of an animal. In plants, however, embryonic tissue — the plant meristems — may contribute to growth and tissue formation for a much longer time, in

Table 2: Maximum Ages for Some Seed Plants

'Exaggerated estimates for this historic specimen reach 6,000 years. †Scars on root-stock counted. ‡According to Buddhist and Roman history.

some cases throughout the life of the plant. Thus the oldest known trees, bristlecone pines of California and Nevada, have one meristem (the cambium) that has been adding cells to the diameter of these trees for, in many cases, more than 4,000 years and another meristem (the apical) that has been adding cells to the length of these trees for the same period. These meristematic tissues are as old as the plant itself; they were formed in the embryo. 'The wood, bark, leaves and cones, however, live for only a few years. The wood of the trunk and roots, although dead, remains a part of the tree indefinitely, but the bark, leaves, and cones are continually in the process of dying and sloughing off.

Among the lower plants only a few mosses possess structures that enable an estimate of their age to be made. The haircap moss (*Polytrichum*) grows through its own stem tip each year, leaving a ring of scales that marks the annual growth. Three to five years' growth in this moss is common, but life-spans of ten years have been recorded. The lower portions of such a moss are dead, though intact. Peat moss (*Sphagnum*) forms extensive growths that fill acid bogs with a peaty turf consisting of the dead lower portions of mosses whose living tops continue growing. Mosses that become encrusted with lime (calcium carbonate) and form "tufa" beds several metres thick also have living tips and dead lower portions. On the basis of their observed annual growth, some tufa mosses are estimated to have been growing for as long as 2,800 years.

No reliable method for determining the age of ferns exists, but on the basis of size attained and growth rate, some tree ferns are thought to be several decades old. Some club mosses, or lycopsids, have a "storied" growth pattern similar to that of the haircap moss. Under favourable conditions some specimens live five to seven years.

The woody seed plants, such as conifers and broadleaf trees, are the most amenable to determination of age. In temperate regions, where each year's growth is brought to an end by cold or dryness, every growth period is limited by an annual ring—a new layer of wood added to the diameter of the tree. These rings may be counted on the cut ends of a tree that has been felled or, using a special instrument, a cylinder of wood can be cut out and the growth rings counted and studied. In the far north growth rings are so close together that they are difficult to count. In the moist tropics growth is more or less continuous, so that clearly defined rings are difficult to find.

Errors in estimating **age**

Often the age of a tree is estimated on the basis of its diameter, especially when the average annual increase in diameter is known. The source of greatest error in this method is the not infrequent fusing of the trunks of more than one tree, as, for example, occurred in a Montezuma cypress in Santa Maria del Tule, a little Mexican village near Oaxaca. This tree, described by the Spanish explorer Hernan Cortés in the early 1500s, was earlier estimated on the basis of its great thickness to be 6,000 years old; later studies, however, proved it to be actually three trees grown together. Estimates of the age of some English yews have been as high as 3,000 years, but these figures, too, have turned out to be based on the fusion of close-growing trunks, none of which is more than 250 years old. Increment borings of single bristlecone pines have shown several specimens in Inyo National Forest, California, to be 4,600 years old; one, about 4,900 years old, was felled in the summer of 1964 in Nevada's Humboldt National Forest.

Growing season of seed plants. *Annuals.* Plants, usually herbaceous, that live for only one growing season and produce flowers and seeds in that time are called annuals. They may be represented by such plants as corn and marigolds, which spend a period of a few weeks to a few months rapidly accumulating food materials. As a result of hormonal changes—brought about in many plants by changes in environmental factors such as day length and temperature—leaf-producing tissues change abruptly to flower-producing ones. The formation of flowers, fruits, and seeds rapidly depletes food reserves and the vegetative portion of the plant usually dies. Although the exhaustion of food reserves often accompanies death of the plant, it is not necessarily the cause of death.

Biennials. These plants, too, are usually herbaceous. They live for two growing seasons. During the first season, food is accumulated, usually in a thickened root (beets, carrots); flowering occurs in the second season. As in annuals, flowering exhausts the food reserves, and the plants die after the seeds mature.

Perennials. These plants have a life-span of several to many years. Some are herbaceous (iris, delphinium), others are shrubs or trees. The perennials differ from the above-mentioned groups in that the storage structures are either permanent or are renewed each year. Perennials require from one to many years growth before flowering. The preflowering (juvenile) period is usually shorter in trees and shrubs with shorter life-spans than in those with longer life-spans. The long-lived beech tree (*Fagus sylvatica*), for example, passes 30–40 years in the juvenile stage, during which time there is rapid growth but no flowering.

Some plants—cotton and tomatoes, for example—are perennials in their native tropical regions but are capable of blooming and producing fruits, seeds, or other useful parts in their first year. Such plants are often grown as annuals in the temperate zones.

Longevity of seeds. Although there is great variety in the longevity of seeds, the dormant embryo plant contained within the seed will lose its viability (ability to grow) if germination fails to occur within a certain time. Reports of the sprouting of wheat taken from Egyptian tombs are unfounded, but some seeds do retain their viability a long time. Indian lotus seeds (actually fruits) have the longest known retention of viability (see above). On the other hand, seeds of some willows lose their ability to germinate within a week after they have reached maturity.

The oldest living seeds

The loss of viability of seeds in storage, although hastened or retarded by environmental factors, is the result of changes that take place within the seed itself. The changes that have been investigated are: exhaustion of food supply; gradual denaturing or loss of vital structure by protoplasmic proteins; breakdown of enzymes; accumulation of toxins resulting from the metabolism of the seed. Some self-produced toxins may cause mutations that hamper seed germination. Since seeds of different species vary greatly in structure, physiology, and life history, no single set of age factors can apply to all seeds.

Life-Support Systems

A life-support system is any mechanical device that enables man to live, and usually work, in an environment in which he could not otherwise survive. A key factor in this definition, though unstated, is time. Just as a man might work underwater for a minute or two merely by holding his breath, he might possibly live in a confined space without supplementary support for quite some time. Eventually, however, he must exchange gases, nutrients, water, waste, and energy with the environment in order to survive. A life-support system provides an artificial mechanism for making these exchanges.

Life-support priorities

In a small, closed, isolated space, such as a spacecraft or submarine, the maintenance of a suitable atmosphere for breathing is generally the most immediate problem, followed by concern for water and food and a method of waste disposal. Temperature, comfort, the danger of contaminants, and psychological factors must also be considered.

Man is best adapted to an environment temperature in the vicinity of 20" C (68" F) and air pressure equivalent to that on the earth at sea level (one atmosphere); he does best breathing a gas containing about 20 percent oxygen; and he has certain nutritional requirements. Two matters of degree must be considered here: the first is time, as mentioned above, and the second is comfort. Just as it is obvious that a man can live longer without food than without breathing, it is obvious that he can survive conditions that, though not fatal, make it extremely difficult for him to do creative work. Life-support systems, therefore, aim to provide conditions of comfort, efficiency, and safety in a working environment.

This article is outlined as follows:

I. Basic principles of life support in unfavourable environments

NEEDS OF MAN

The life-support engineer is concerned with providing the best environment for man to work in and with devising ways in which he can exchange materials and energy with his surroundings.

Oxygen. Man's most vital point of contact with the environment is his lung; his most urgent needs relate to respiration. Any satisfactory life-support system must supply oxygen at pressures sufficient to provide adequate amounts in the blood. It is normally sufficient to provide a breathing mixture of 20 percent oxygen at sea-level pressure.

A normal man consumes about 250 millilitres, or about one-half pint, of oxygen per minute when resting; he consumes 400 to 500 millilitres per minute when moderately active, perhaps one litre per minute when moving around briskly, and up to three litres per minute when exercising at peak capacity. As important as the dangers of insufficient oxygen are the risks of oxygen poisoning due to high oxygen pressure. Man can tolerate oxygen at two or three times normal atmospheric pressure for short periods. For survival over many hours or days, however, oxygen pressure should be below one-third normal atmospheric pressure.

Carbon dioxide. Man is accustomed to breathing gas that is essentially free of carbon dioxide, although small amounts may be inhaled without ill effects and large amounts can be tolerated for brief periods. Normally a man breathes out carbon dioxide at an average rate about 0.82 times his oxygen consumption. This means that a resting man would produce 200 millilitres of carbon dioxide per minute and a man moving around briskly about 800 millilitres per minute.

Pressure. Although accustomed to a so-called normal atmospheric pressure, man can tolerate a wide range of pressures, the primary limiting factor being the partial pressure of oxygen; that is, the total pressure of the gas multiplied by the proportion of oxygen in the gas. In the normal atmosphere, since the air is about 20 percent oxygen, the partial pressure of oxygen is 0.2 atmosphere. The minimum pressure for normal body function is determined by that point at which a normal blood oxygen concentration can be maintained by breathing pure oxygen. Pressures should not be reduced below this level. The limit to man's tolerance of high pressures is not yet known, but men have tolerated pressures up to 53 times the normal atmospheric level, and animals have survived pressures several times this great.

Limits of tolerance to high pressure

Temperature. Most individuals know the temperatures at which they are most comfortable; this of course is a function of individual preference, dress, level of activity, etc. In the same way, relative humidity affects comfort at a particular temperature. Most people are comfortable between a range of 60° and 75° F (16°–24° C) and a relative humidity range between 35 and 70 percent.

Energy. Virtually the same number of calories of heat must be removed from the body each day as are consumed as food. On a short-term basis, heat production can be related directly to oxygen consumption at a level of 4,800 calories per litre of oxygen used. The problem is to prevent loss of heat (and to increase heat production); but in a closed space from which heat can escape only with difficulty, some means must be provided to remove this heat and to maintain a suitable temperature.

Food. A balanced diet of about 2,000 to 4,000 kilocalories per day is needed by a moderately active man. Experience in spacecraft and other confined spaces has shown that 2,000 to 2,250 kilocalories daily is usually suitable. Virtually all experiences with men confined in life-support systems have involved complaints about food. Subjective choice of food to be used is apparently highly desirable.

Water. Water balance is critical to good health and good performance. Two to three litres of water are lost each day by normal man and must be replaced. Water is needed to keep the kidneys functioning to remove waste from the body and as perspiration to help control the body temperature. Normally a man takes in about 1,500 millilitres per day as liquid water and another 600 millilitres as part of his food and converts 300 millilitres of the food eaten into metabolic water. This water is normally removed from the body in the following quantities: 1,400 millilitres as urine, 100 millilitres as fecal water, and 900 millilitres as insensible water loss—that is, water loss through the respiratory tract and the skin but not as visible perspiration. Both sides of this equation will be increased accordingly if the man is in a situation that causes him to perspire.

Waste. On a normal diet a man produces about 150 grams per day of solid waste as feces and another 1,000 millilitres of intestinal gas. These values are increased on a vegetable diet. On an all-meat diet, the solid waste can be reduced to less than one-third of the above value.

Circadian (day–night cycle) stimuli. In addition to his ordinary needs as mentioned above, man also requires periodic stimuli to help maintain his normal 24-hour physiological periodicity. A great many of the hormonal, metabolic, and biochemical functions of the body vary throughout the 24-hour solar day, and it is felt by some authorities that metabolic disorders will result without some kind of "synchronizer" in situations in which man is removed from the normal day–night cycle.

Ionization of a closed atmosphere

Ions. Although ions are difficult to measure, and the effects of ions in the atmosphere are subjective and similarly difficult to quantify, the ionization of a closed atmosphere seems to influence the well-being of those living in and breathing it. Tests have shown that positive ions are associated with asthma, head colds, headache, and fatigue and that negative ions are associated with a general feeling of well-being. Since ions are generated by radiation from many electronic devices in spaceships and submarines, a well-planned environmental control system considers their presence.

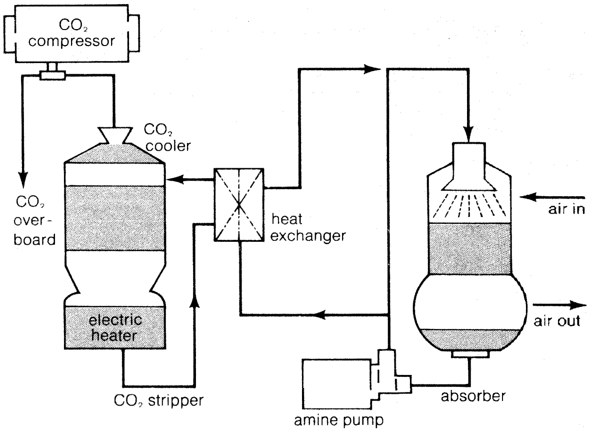
Time. Time is important in determining the characteristics of any life-support system. If only minutes are involved, provisions for oxygen supply and carbon dioxide removal may be all that will be necessary. After many minutes, other aspects of atmosphere composition, such as oxygen toxicity, gas density, temperature, and contaminants take on importance. After several hours food and water are needed, waste must be removed, and temperature and humidity need further control.

BASIC METHODS OF ATMOSPHERE CONTROL

Oxygen supply. For most uses the most expedient source of oxygen is as a compressed gas. If the rate of use is high, however, a low-temperature liquid oxygen supply may be employed, and in some systems now available oxygen can be stored for many weeks without appreciable loss. In applications in which light weight and long storage periods are criteria, a solid chemical source of oxygen may be best. There are two general types of such a source. A chlorate candle (a mixture of sodium chlorate and a small quantity of iron powder), if ignited, will burn the iron, causing decomposition of the chlorate and releasing oxygen. Second, alkaline superoxides, either sodium dioxide or potassium dioxide or both, will react with water or carbon dioxide or both to give off oxygen. There are several chemical methods by which oxygen can be removed from water or carbon dioxide; for example, by means of an electrochemical reaction. These are discussed below, under *Aviation and* space systems.

The molecular sieve

Carbon dioxide removal. The most expedient method for removing carbon dioxide from a closed atmosphere is with a so-called chemical scrubber, of which the most common are soda lime, Baralyme (a mixture of barium and calcium hydroxides), and lithium hydroxide. All three of these compounds are useful, and a choice will depend on factors such as weight, cost, and heat and water generation in the reactions. Lithium hydroxide has a disadvantage in that it produces an irritating dust. All three compounds can be used in refillable canisters through which the atmosphere is passed by means of small blowers; they cannot be regenerated and reused. One type of carbon dioxide scrubber that can be reused is a molecular sieve that absorbs carbon dioxide and from which carbon dioxide can later be removed by heating. Molecular sieves can also be used for other types of contaminant removal, including water; in fact, a limitation to their use as a scrubber is their tendency to absorb water in preference to carbon dioxide. The gas must be dried before carbon dioxide can be effectively removed by a molecular sieve. Another regenerative type of carbon dioxide removal system is an amine scrubber (such as is used on submarines; Figure 1), in which a carbon dioxide absorbing agent is heated to separate the carbon dioxide and reused in the same machine. As with oxygen, there are electrochemical methods of converting carbon dioxide to oxygen, but most of these systems require that the carbon dioxide be concentrated first.



$$2\,MEA + H_2O + CO_2 \rightleftharpoons (MEA)_2 \cdot H_2CO_3$$

Figure 1: Scrubber for removing carbon dioxide from air by absorbing the CO_2 in an amine (see text).

Contaminant removal and odour control. The most common means of removing organic molecules from a gaseous environment is to adsorb them on the surface of activated charcoal. Charcoal can also remove odours from liquids, as is necessary, for example, in recycling urine for water conservation. The effectiveness of activated charcoal depends on its immense surface area—so large that one pound of it may have as much as 9,000,000 square feet of surface. Trace organic compounds such as hydrogen, methane, and carbon monoxide can also be removed from an atmosphere with a catalytic burner in which a heated gas is passed over a catalyst such as platinum black or hopcalite.

Temperature and humidity control. Temperature and humidity are controlled in life-support systems by application of principles established in conventional engineering practice. Heat, obtained as a by-product from an engine or other source, is removed by radiation, conduction, convection, or evaporation. Humidity is usually supplied in sufficient quantity by the occupants of a system, it can be removed by chemical absorption or by condensation on cooling coils.

II. Aviation and space systems

THE ENVIRONMENT: ALTITUDE AND SPACE

The lethal altitude

If a man not acclimatized to high altitude ascends in an unpressurized airplane, he will exhibit various symptoms that indicate the effects of altitude. Evidences of lack of oxygen begin at about 10,000 feet (3,000 metres). At 18,000 feet (about 5,500 metres) the pressure is half that at sea level, and man may feel definite symptoms; he will probably lose consciousness between 25,000 and 30,000 feet (7,500–9,000 metres). If pure oxygen is breathed, a man functions normally at up to 34,000 feet (10,000 metres); here his blood has the same oxygen pressure as it would if he were breathing air at sea level. A man may continue operating to 40,000 feet (12,000 metres) without serious problems; above that altitude he cannot function well without supplementary pressure. At 52,000 feet (15,800 metres) he will have reached the point at which there is no oxygen in his lungs and will lose consciousness in about 15 seconds. At 63,000 feet (19,200 metres) the atmospheric pressure is the same as the vapour pressure of water at body temperature; thus, there is no gas other than water in a man's lungs; at this pressure the blood boils at body temperature.

Other aspects of altitude and the limits of various phenomena are shown in the table. Though other items shown have physiological significance, pressure is the most easily controlled and is thus the most important factor in life-support systems.

Mountains. Man's earliest ventures to altitudes high enough to tax his adaptation were of course made on foot, climbing mountains. La Paz, Bolivia, is nearly 12,000 feet (3,600 metres) high, and in other parts of the

Andes lifetime adaptation makes it possible for people to live at the 16,000-foot (4,800-metre) level and work at 18,000 feet (5,400 metres), without life-support equipment. In attempts to climb Himalayan peaks, courageous and well-acclimated climbers have reached altitudes as high as 28,000 feet (8,534 metres) without supplementary oxygen. In the first successful assault of the 29,028-foot (8,839-metre) Mt. Everest, however, life-support equipment was the deciding factor. In addition to boots designed especially for this mission, the successful climb of 1953 required two types of oxygen-breathing apparatus. An open-circuit type metered oxygen into the stream of air inhaled by the climber. This device could be set to deliver from one litre of pure oxygen per minute when requirements were low, as in sleeping, up to five litres per minute under difficult climbing conditions. This simple apparatus weighed only 28 pounds (12.7 kilograms). The second type, a closed-circuit apparatus, provided approximately the same duration of breathing and weighed 35 pounds (15.9 kilograms) and consisted of a breathing bag and valves arranged so that the gas exhaled by the climbers was recirculated through a soda lime canister that absorbed the carbon dioxide. The entire apparatus was filled with pure oxygen, so the user breathed oxygen undiluted by ambient air. This closed system was more likely to freeze up than the open system; it was heavier, and it generated heat. Furthermore, the user of the closed system became more dependent on the 100 percent oxygen supply; if it was lost for some reason he was likely to lose consciousness at high altitudes. Although both systems were used by members of the Everest expedition, the team that reached the top used the open-circuit type.

The Everest experience

Balloons. A 19th-century French physiologist, engineer, and physician, Paul Bert, conceptualized the basic principle of using supplementary oxygen to supply balloonists and mountain climbers who had ascended beyond the levels at which the oxygen in air is sufficient. Two of Bert's colleagues took a supply of about 150 litres of 70 percent oxygen on a balloon flight in 1875; but they failed to use it soon enough, and only one of the two survived. On this flight the oxygen was stored at ambient pressure in "goldbeater's bags" (made from cow's Intestines) and was to be inhaled by mouth tube through a humidifier containing an aromatic liquid whose purpose was both to humidify the gas and to counteract the odour of the bags. The maximum height attained by the balloon was over 28,000 feet (8,534 metres). These explorers had used oxygen on previous flights with success. Bert also designed a tank and regulator system with a capacity of 330 litres whereby mountain climbers could breathe oxygen near the peak on their ascent.

On November 11, 1935, on a mission sponsored by the National Geographic Society and the U.S. Army Air Corps, two men rode a hydrogen-filled balloon to a height of 72,395 feet (22,067 metres); this feat was particularly significant since the two had parachuted to safety 16 months earlier from a similar vehicle that had ripped apart at 60,000 feet (18,000 metres). Their magnesium alloy gondola was supplied with 45 percent oxygen and 55 percent nitrogen from a 25-litre liquefied gas container. Helium was used to drive the liquid air through the coils of an evaporator, and a battery-powered fan circulated cabin air over this coil for the removal of moisture and subsequently through a sodium hydroxide scrubber for the removal of carbon dioxide. To aid in stabilizing the interior temperature, the gondola was painted white on top and black below, to reflect and absorb heat.

Cosmic ray studies

Groups of mice and guinea pigs flown by balloon to altitudes above 100,000 feet (30,000 metres) for cosmic ray studies in the early 1950s were maintained in thin aluminum spheres with pressurized atmospheres. Oxygen was supplied from a high-pressure source. When only a few animals were involved, carbon dioxide was absorbed with soda lime in containers; with greater loads, forced air was used. Temperature was controlled by the evaporation of water into the near-vacuum at that altitude, and the cool surface of the water container condensed moisture out of the atmosphere of the capsule. Sponges were used to absorb this moisture.

A record for balloon flights was set on May 4, 1961, when a helium-filled polyethylene balloon ascended to about 113,740 feet (34,747 metres) over the Gulf of Mexico. Though the gondola was nothing more than a framework covered with venetian blinds, the balloonists were protected by special suits pressured by oxygen from a liquefied gas source and provided with electric heaters to keep the faceplates from fogging. The balloonists could reverse the blinds on their gondola from silver to black to help control temperature.

SYSTEMS USED IN HIGH-ALTITUDE AIRCRAFT

Cabin pressurization. For aircraft flying at altitudes high enough to cause illness among unprotected passengers, the most obvious and effective life-support system is a normal pressure environment, accomplished by pressurizing the occupied portions of the aircraft. The first commercial aircraft to provide cabin pressurization was the Boeing 307B, which began to carry passengers in 1940. Though some modern propeller-driven aircraft are not pressurized, pressurization is a necessity for jets that fly at high altitudes.

Aircraft cabin-pressurization systems are active systems; pressure is continuously provided to the cabin, and some is continuously leaked overboard. Because of this continuous leakage, no further provisions for carbon dioxide removal equipment are required. In reciprocating-engine aircraft, pressure is provided by an engine-driven turbine, while in jet aircraft the pressurization system is usually provided by gas drawn from the compressor section of the jet engine or from an engine-driven blower. Because of the heat of compression, the air that is drawn off the engine is very hot; even though some heat is required in the cockpit or cabin, it is generally necessary to cool the air, usually with a turbine refrigeration system, making this method of pressurization impractical at altitudes over 80,000 feet (24,000 metres).

Commercial airliners are pressurized to the equivalent of 4,000 to 8,000 feet (1,200–2,400 metres) during the climb, which may take the plane to an altitude of well over 40,000 feet (12,000 metres). All jets that operate above 20,000 feet (6,000 metres) are required to provide supplemental oxygen, through masks, in the event of cabin pressure failure. A small plastic bag attached to the mask receives piped oxygen when the passenger is not inhaling, and he inhales the next breath from this bag. Oxygen for such masks is usually supplied from pressurized cylinders, although systems now being developed hold the oxygen combined in chemical form, such as a chlorate candle. Such systems do not develop leaks, may be stored indefinitely, weigh less, and are less of a fire hazard than pressurized cylinders.

Oxygen systems. During World War I, when 20,000 feet (6,000 metres) was a significant aircraft altitude, a tube of oxygen continuously flowing and held in the lips of the pilot was generally quite adequate. By the beginning of World War II this crude system had been refined so that a continuous flow of oxygen was breathed by mask from a small balloon, which was allowed to fill between breaths. Soon this system was improved by the introduction of a demand regulator, which ensured that no gas flowed unless the pilot was inhaling. A refinement of the demand system is the pressure-demand system, which delivers oxygen to the pilot's mask at a pressure slightly higher than that of the cockpit. Increasing pressure in the mask increases pressure in the lungs and results in a higher pressure of oxygen in the blood. This system has undesirable side effects, however; the increased pressure in the mask is transmitted to the walls of the blood vessels in the chest, the diaphragm, the chest wall, and certain areas in the head and can be tolerated for only a limited time. The apparatus is, thus, generally used only in the event of cabin pressure failure.

World War II oxygen masks

The next step in the process of providing a higher oxygen pressure to the lungs of a pilot at a high altitude is a partial-pressure suit, a tightly fitting garment that covers the entire body and to which are attached bladders filled with air from the pressurization system of the aircraft. The pilot's head is enclosed in a helmet; pressurized oxygen is supplied. Because the bladders apply a counterpressure to the body, it is possible to supply a much higher pressure to the breathing gas than with the pressure-demand system alone. A pressure-demand system provides normal function at an altitude of 43,000 feet (13,000 metres); a partial-pressure suit, on the other hand, permits normal function at an altitude of 60,000 feet (18,200 metres).

The most recent step in the development of personal equipment for delivery of oxygen to a man exposed to reduced pressure is the full-pressure suit. Despite many refinements, the basic design is similar to that used by spacemen and lunar astronauts. The body and head are entirely enclosed in a sealed, pressurized envelope through which gas is supplied at the same pressure as the rest of the body. Full-pressure suits keep the body at a pressure equivalent to 33,000 feet (10,000 metres) above sea level; if supplied with pure oxygen, these suits effectively provide a normal oxygen level to the user's body. Since the full-pressure suit prevents effective heat exchange between the user's body and the environment, a cooling system of some sort must be provided. Pressure suits designed for use in aircraft generally have a perforated inner garment through which air can be circulated at an adjustable temperature and flow rate.

Systems for supplying oxygen have evolved along with breathing equipment. Originally, oxygen was supplied by low-pressure cylinders; in the early jets, pressures were increased, but later jets began to use low-temperature (cryogenic) systems supplied with liquid oxygen. This development was accelerated by the invention of in-flight refuelling, which meant that a small fighter plane might stay aloft for hours, its cruising time limited by its oxygen rather than by its fuel supply. Work is now in progress on an electrochemical method to separate oxygen from the air, trading energy for consumable components and providing an essentially unlimited supply of oxygen.

Research aircraft. Rocket-powered research aircraft have presented special problems in the design of life-support systems. With no engine and very little surrounding atmosphere from which to draw compressed air for cabin pressurization, such aircraft have used hermetically sealed cabins filled with pure nitrogen and equipped with a high-capacity refrigeration system. The pilot does not breathe this atmosphere but has his own breathing atmosphere supplied in his suit.

In the American X-I plane, the aircraft that first surpassed the speed of sound (1947), the life-support system was primitive. Pilots used World War II leather flying helmets over which they fitted the top of a football helmet for impact protection; they breathed through a standard demand-type oxygen mask. Later flights in later planes were flown in partial-pressure suits, which provided protection at altitudes above 50,000 feet (15,000 metres) in case of loss of cabin pressurization; on occasion this protection was needed and used. Because of the extreme cold outside the cockpit, the pilots placed a dehydrating canister on the expiratory outlets of their suits so that moisture from their breath would not escape into the cockpit and frost the windows.

The X-15 life-support system

The X-15, which exceeded altitudes of 60 miles (96.6 kilometres) and speeds six times that of sound, had a nitrogen environment cooled by a powerful refrigeration system. The suit worn by the pilot had an undergarment ventilated by oxygen; a pressure garment, and an external aluminized protective layer.

In view of the above, the question of how a supersonic transport can fly safely at altitudes of 60,000 to 70,000 feet (18,000–21.000 metres) must be dealt with. To begin with, cabin structure must be less subject to failure; this is accomplished in part by the use of armour plate either on the engine housings or on the fuselage in the areas where a lost engine turbine blade might penetrate. Pressure is supplied to the cabin by engine-driven compressors that can be turned up to a much higher speed in the event of cabin pressure loss. supplying air to the cabin faster than it can be lost through a broken window or hole.

SYSTEMS USED IN EARLY SPACE FLIGHTS WITH ANIMALS

During the years preceding manned space flights a number of significant flights were first made with animals aboard. The earliest of these were short rocket or balloon flights made to study weightlessness and cosmic rays; these were so short that life-support requirements were minimal, and the sealed capsule often was large enough to sustain the animals without special equipment.

Before the first manned space flights, Soviet investigators sent a number of dogs and other small animals on suborbital rocket missions from which they were usually recovered by parachute. Two basic life-support approaches were employed, one a sealed, insulated cabin and the other an unsealed type in which the animals were protected by space suits. The dogs used in Soviet space work were always extensively trained and conditioned to the noise, vibration, acceleration; and confinement of the flight, in order to reduce the number of variables that might affect biomedical measurements. The "sealed" cabin actually contained a calibrated leak, and a mixture of 40 percent oxygen and 60 percent nitrogen was allowed to bleed in. As the oxygen flowed in, it passed through a tube that circulated the cabin gas through carbon dioxide absorbers at a rate of about 120 litres per minute. Water vapour was removed by silica gel. Other dogs, which rode in unpressurized capsules, were trained and fitted with rubberized suits equipped with Plexiglas helmets. Oxygen flowed through the suit at six litres per minute, and pressure was maintained inside; no other steps were necessary to control carbon dioxide and water vapour. A Soviet dog rode in the second vehicle to be launched into earth orbit. On November 3, 1957, the 1,200-pound (540-kilogram) Sputnik 2 carried the 13.3-pound (6-kilogram) dog around the earth for nearly a week before she died from lack of oxygen. The spacecraft life-support system was essentially the same as that of the Vostok series that later carried the first men into orbit. Conditions in the capsule were maintained close to those found on earth,

The Soviet space dogs

with respect to air pressure, temperature, and oxygen and carbon dioxide content. Oxygen was supplied by release from a dry chemical, in conjunction with the absorption of carbon dioxide. The dog was fed a gelatinous suspension of ground meat and bread crumbs by means of an automatic feeder. Waste was collected in a rubber bag fitted to the pelvic region of the dog. Liquids were absorbed and deodorized by activated charcoal. Later (1960), two other dogs and 40 mice were recovered after 24 hours in orbit in Sputnik 5. They were the first living things to be recovered from orbit.

In 1959 two monkeys, a rhesus and a squirrel monkey, were launched to an altitude of 300 miles (480 kilometres) and a distance of 1,500 miles (2,400 kilometres) by a Jupiter rocket and were successfully recovered. Sealed in separate capsules, each was placed on a restraint couch and fitted with a helmet. The life-support system of one animal continuously received oxygen through a needle valve from a pressurized cylinder. Excess pressure was vented overboard. Carbon dioxide was absorbed by lithium hydroxide distributed in bags of small-pore plastic fabric, and water and ammonia were absorbed by similar bags of charcoal and a fused silica water absorber. Diapers helped control the amount of water and ammonia that reached the atmosphere. An electric heater and liquid nitrogen cooler provided temperature control. The unit of the other animal had an oxygen system that added oxygen to make up for that consumed by the animal, so as to maintain a constant cabin pressure. The atmosphere was nearly normal in pressure and gas composition.

SYSTEMS USED IN U.S. AND SOVIET MANNED SPACE FLIGHTS

Vostok. Manned space flight began on April 12, 1961, with a one-orbit flight in the Russian spacecraft Vostok 1. Pressure and oxygen concentration in the Vostok spacecraft were maintained at approximately those of sea level on earth. Carbon dioxide levels were kept at less than 0.5 percent throughout most of the flight. Temperatures varied from about 12° to 25° C (54"—77" F); relative humidities ranged comfortably between about 45 and 65 percent. As part of the experimental plan, conditions were maintained as close to normal as possible so that observed changes could be attributed to space flight and not to such things as high oxygen levels.

In the Vostok spacecraft a ventilating fan forced cabin air to a gas analyzer, a regenerator unit, and a dehumidifier. The gas analyzer provided readings of oxygen and carbon dioxide partial pressure. which along with cabin pressure, temperature, and humidity were displayed to the pilot and relayed to ground stations. When the cabin pressure dropped below the desired level, a regulator increased the flow through the regenerator, which absorbed carbon dioxide and generated oxygen by means of a chemical system probably based on alkali superoxides. Flow through the dehumidifier was controlled by a humidistat, which maintained humidity at desired levels much as a thermostat controls temperature. A separate temperature control system maintained cabin temperature by means of a regulator and pipes that conveyed excess heat to a radiator, where it was radiated into space.

Mercury. The first manned orbital flight in the United States space program, a three-orbit flight, was made on February 20, 1962, in a Mercury-Atlas 6 spacecraft. The life-support system for the Mercury spacecraft (Figure 2) was dual, with one subsystem to control the environment within the pilot's suit and another for the spacecraft cabin. A secondary but nonetheless important function of the cabin atmosphere control was to provide a suitable environment for operation of electronic and electrical apparatus. In the vacuum of space the insulating effect of the earth's air is missing, and artificial pressure is needed to prevent short-circuiting of high-voltage apparatus. Oxygen was circulated through the suit, entering near the waist, passing to the hands and feet, returning and exiting by way of the helmet. The system allowed the pilot to select a temperature between 50" and 90" F (10"–32" C) even if cabin temperature climbed as high as 180" F (82° C) during re-entry. As the oxygen left the helmet it entered a debris trap, then passed through a charcoal bed for odour removal and through a lithium hydroxide-carbon dioxide scrubber. A filter protected the pilot from lithium hydroxide dust. The gas was then cooled and dehumidified before passing back to the pilot. Heat was removed from the system by evaporating water into the vacuum of space. When necessary to compensate for leakage or consumption by the pilot, oxygen was bled into the system from a pair of high-pressure supply bottles. An additional cooling system worked on the cabin atmosphere independently of the suit. The pilot had instrument panel readouts of cabin pressure, temperature, oxygen partial pressure, and relative humidity.

Defects of the Mercury system

Although the Mercury system performed its function adequately, it left something to be desired in terms of temperature control and particularly of control of water vapour and perspiration. All the astronauts who flew in this series returned from their flights dehydrated, some markedly so.

Gemini. The life-support and environmental-control systems for the Gemini spacecraft included several improvements over the Mercury; among these was a capability to sustain a longer (14-day) mission duration, an extravehicular-activity capability, and the use of fuel cells for crew water supplies. These cells, which produce water as a by-product while generating electricity, are used as a water source on spaceships. Like Mercury, Gemini used a pure oxygen atmosphere. The main life-support system was divided between the pressurized cabin and a removable "adapter" section; the cabin subsystem could operate without the adapter, as on re-entry. There was also a separate suit subsystem, and the crew could choose between using the suit or the cabin system.

The primary oxygen supply is a low-temperature cryogenic container, much lighter in weight than pressurized bottles. Bottles, however, are used for the cabin system and as a backup. The cooling system uses a liquid coolant and radiates unwanted heat into space, cooling cabin, astronauts, fuel cells, and electronic equipment. Water is removed from the exhaled gas and returned to the water storage tank. The primary source of water, as mentioned above, is from the fuel cells, as a product of the electrochemical reaction.

The suit is connected to a subsystem that contains a chemical canister of lithium hydroxide and charcoal for purification. This circuit also provides for cooling, water removal, and pressurization. Oxygen enters the suit at the waist, is directed at the face, arms, and legs, and leaves the suit at the waist. The suit system is designed to handle a heat load of 125 kilocalories (500 British thermal units) per hour per man and to maintain the suit at 70" F (21° C). Though the suit is an integral part of the system, it need not be worn by the crew at all times; on the longer Gemini missions the suits were removed and the crew carried on in their long underwear.

Extra-vehicular life-support system

Another integral part of the Gemini system is the extravehicular life-support system used when one of the pilots performs activity outside the craft. This is a semi-open loop, bleeding enough oxygen overboard to maintain an acceptable carbon dioxide level in the pressurized space suit. This gas is supplied by an umbilical hose, which also contains electrical leads. Designed for up to 500 kilocalories per hour, the system proved inadequate on two Gemini flights, when the astronauts both worked so hard during their extravehicular activities that the system could not keep up; as a result the faceplates fogged, partially blinding the astronauts. During extravehicular activity, the extravehicular life-support system contains a supply of oxygen good for 10 to 22 minutes if the supply that is fed to the astronaut from the ship through a hose should fail. The suit itself is a significant improvement over the Mercury suit, having greater mobility, a micrometeorite protective outer layer, and multiple visors. A special port is provided for drinking with the suit under pressure.

Apollo. The atmosphere chosen for the Apollo space cabin was pure oxygen, though the spacecraft was fiiled initially with a mixture of oxygen and nitrogen. The system sealed well enough that nitrogen remained a part of the cabin atmosphere for some days after launch, unless opened for extravehicular activity. Actually three systems, the Apollo life-support system provided essentially the same environment as Gemini, employing somewhat similar technique. The command module operated normally from equipment installed in the service module but was switched to a self-contained system for re-entry. In addition, there was a separate system in the lunar excursion module. Lithium hydroxide was used to remove carbon dioxide, and odour control and water removal were provided. Heat was radiated into space from the service module. Water, provided by fuel cells, was recovered from the spacecraft atmosphere. Oxygen was carried in low-temperature canisters, in a semiliquid, semigas form.

The crew wore sealed space suits during launch and docking operations to protect themselves against the possibility of sudden pressure loss. At other times they wore the main suit with gloves and helmet removed for more comfort, and at still other times a "constant-wear garment," which amounted to little more than a set of flameproof long underwear. In the event of meteorite penetration causing loss of the cabin pressure seal, the oxygen system was set to provide a gush of oxygen into the cabin, sufficient to maintain pressure even with a large leak for the five minutes it takes to don the suits.

Apollo 13: disaster and survival

The life-support capabilities of the entire Apollo complex became a matter of great concern throughout the flight of Apollo 13, during the week of April 11–18, 1970. Three-quarters of the way to the moon, the crew felt an explosion and found that the oxygen had been lost from the service module. As a consequence, the fuel cells soon became inoperative. Although the astronauts were able to store some water and charge their batteries during the last few hours of fuel cell operation, the loss left the mission definitely short of "consumables"—water, electric power, and oxygen. The crew cut power in the command module and transferred to the lunar module for the necessary trip around the moon and back to earth. The life-support system of the lunar module was not adequate for the three crewmen, so it was necessary to rig up a hose from the blower inside it (where there were batteries) to the command module (where there were unexpired canisters of lithium hydroxide for carbon dioxide removal). The lunar module had adequate oxygen; but there was a shortage of water, since the guidance system in the lunar module had to be kept cool (by evaporation), and no water was being produced by the fuel cells. There was enough for the flight, however, and the crew reached earth safely. Since there was only a minimal usage of electrical equipment in the lunar module, the entire spaceship was cold and damp and uncomfortable for the crew.

Lunar suit. Because the demands are different, two types of pressure suits were designed for the Apollo mission, one for use in the spacecraft and the other for exploring the lunar surface. Next to his skin the moon explorer wore a liquid-cooling garment, essentially a loosely woven set of long underwear with a network of flexible tubing through which cooling water from the backpack, or portable life-support system, circulated. The intravehicular suit included a knitted constant-wear garment next to the skin. Moving outward from the skin, both suits had (1) a lining layer of high-temperature-resistant nylon; (2) a ventilating and pressurization system consisting of ducts for circulating pressurizing oxygen to all parts of the suit and helmet, bringing fresh oxygen in and returning it, with its water, carbon dioxide, and heat, to the backpack; (3) a bladder made of neoprene-impregnated nylon, which acted to prevent gas escape from the suit; (4) a layer of nylon cloth; and (5) a "torso-limb suit," which contained convoluted bellows joints and disconnect mechanisms for removal of gloves and helmet. For the intravehicular suit, finally, there was a nylon-lined outer layer of a special fireproof cloth made of fibre glass with each fibre coated with Teflon, a material that does not burn even in pure oxygen. For the extravehicular suit there was next a thermai meteoroid barrier of neoprene and nylon; insulation provided by several layers of aluminized flexible plastic; and an outer fireproof layer protected at points of wear with woven metal fabric. The lunar boots, worn over the regular boots like galoshes, were insulated in the same way and had layers of fireproof felt cushion and soles of silicon rubber.

Supporting the function of the suit was the portable life-support system, or backpack. Weighing 190 earth pounds (86.2 kilograms), but only one-sixth as much as that on the moon, this system provided cooling water, oxygen flow and recirculation through purification and dehumidification equipment, electric power, and communications. The oxygen supply in the pack lasted four hours and was backed up by a short-duration purge system in case of failure. Waste containment units were also built into the suit.

Eating in space. A great deal of anxiety preceded the first few space flights with regard to the problem of eating in weightless space. In early Soviet and American flights, the astronauts ate pureed food such as applesauce, squeezed from flexible tubes, and bite-size chunks of meat, dried fruit, etc. No problems arose in eating any of the foods tried, including even a bologna sandwich smuggled on board a Mercury flight. Crumbly foods such as cookies were found to be a minor problem, since the crumbs were difficult to recover from the cabin.

The problem of eating under conditions of weightlessness is only one consideration. Space food must also have minimal weight and volume; must be nutritionally adequate and supply appropriate energy; must be pathogen-free and stable in the space environment, which may include repeated decompressions, vibration, heat, radiation, and a pure oxygen atmosphere; and must produce low residue and gas. And a primary factor in mission effectiveness is that it have good taste and texture.

Weight is conserved and stability assured by the process of freeze-drying and reconstituting with water before eating. The use of hot water provides a way of serving a warm meal under difficult conditions. In addition to the dried foods there are compressed, energy-dense, bite-sized types that do not require rehydration. Thermal stabilization is used on natural foods for improved flavour and texture; this amounts to "canning" the food in plastic bags. The problem of crumbs has been solved by coating cookies, etc. with a thin, edible layer of methyl cellulose. Food on Gemini and early Apollo flights was served in plastic bags with a one-way rehydration valve and a reclosable mouthpiece; a gun similar to a water pistol was used for adding water. In later flights, when consistencies were suitable, a spoon was used. Menus included roast beef, turkey, sausage, gravy, fruit, cheese, pudding, and cereal with fruit juice, coffee, and tea.

For long-term orbiting laboratory flights, the astronauts will have flat trays with compartments for various foods and will be able to choose which of several canned dishes they wish, put them on a warmer tray, and have a meal with maximum convenience.

Energy consumption in space

Astronauts in space have eaten less than expected, probably because of the lower energy requirements of living under weightlessness and being confined to a small cabin. Energy consumption has been about 2,000–2,100 kilocalories per day in U.S. flights, while the Soviets report using about 2,500 kilocalories. In early U.S. flights extra calcium was added to the diet to help prevent decalcification of bones, but this has been discontinued as not worthwhile.

Waste. The problem of managing body wastes and urine is, like many other problems, dependent on mission duration. In the Mercury program no waste removal was necessary, the need being obviated by use of a low-residue diet for a few days before the mission. Urine was collected by a constant-wear device and retained in the spacecraft. For the longer Gemini flights a zippered opening in the crotch of the suit permitted defecation in a device called a "fecal mitten," consisting of a plastic bag with pressure-sensitive adhesive for attaching to the buttocks and a glove insert into the bag to permit use of toilet tissue before removal of the bag. Tissue and a disinfectant are contained in the bag, which is sealed after use. These devices were also used in the Apollo program, but more easily, since a formal lavatory facility was built into the cabin. The bags were stored after use.

Urine was collected during the Gemini program for analysis, the balance being vented overboard after a sample had been stored. It was collected by means of a metal receiver having an inflatable cuff and drawn into a reservoir by means of a bellows, from which a sample bag (75 cubic centimetres) was filled.

CLOSED LIFE-SUPPORT SYSTEMS

As the length of space missions increases, the approach to life support will necessarily change. Initial lunar-exploration missions can be accomplished with durations of a few weeks, and early orbiting stations or laboratories are planned for a few months but will have a resupply capability. The same applies to lunar stations. But travel to Mars and Venus with propulsion systems presently conceivable will take hundreds of days, weight will be at a premium, and resupply is not feasible. It is necessary, therefore, to develop a system that is closed (*i.e.*, cannot be resupplied from outside) for as many requirements as possible (Figure 3). To seek a completely closed system will perhaps never be feasible, and the usual trade-offs will continue to be made.

From *Astronautics & Aeronautics Magazine* (1970), a publication of the American Institute of Aeronautics and Astronautics

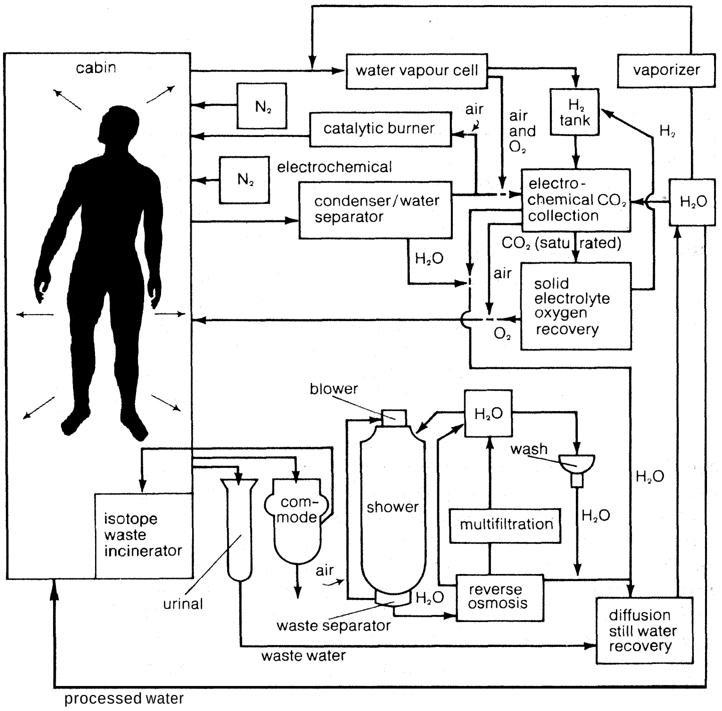

Figure 3: Advanced life-support system proposed for long U.S space flights and for U.S. space stations in the late 1970s and early 1980s.

Requirements for long--term missions

The problem reduces to one of supplying pressure, oxygen, water, food, perhaps heat, artificial gravity, protection against radiation, particles, and micro-organisms, and perhaps some psychological support such as day–night cycle stimuli; and at the same time removing carbon dioxide, gaseous toxins, humidity, solid and liquid wastes, and excess heat.

Operational spacecraft have so far involved only minor steps toward closure of any of these systems. The recirculation of an oxygen atmosphere through a chemical scrubber to remove carbon dioxide may be referred to (though incorrectly) as a "closed" system. Such a process is not really closed because it is only a means of using and reusing oxygen as a vehicle for carbon dioxide removal, and the oxygen actually consumed by the body must be replaced. Presently the only recycling that is done is the recovery and reuse of water, by condensing humidity from the atmosphere.

On long flights the savings to be gained in the use of regenerative systems are most apparent in the recovery of water, chiefly wash water but also the drinking-water–urine cycle, though it is less efficient because of the greater energy and weight required for urine reduction. Oxygen recovery will become practical in flights that exceed the efficient storage capability of low-temperature methods. Reduction of carbon dioxide to pure carbon will be practical at about the same time. Recycling metabolic products to food will effect a great saving, but this appears to be farthest in the future.

In addition to the supply of reactants and the removal of wastes there is the basic question of atmosphere composition and pressure. Oxygen tolerance limits are fairly well established, for short- and long-term exposures. The choice of total pressure and the best gas to use as the inert component are not fully determined, though it has been established that an inert diluting agent is highly desirable if not essential physiologically. Inert gas considerations include storage and handling, flow and heat transfer characteristics, fire, decompression risk, and crew comfort. Nitrogen is well understood, though helium and neon both have advantages, one of which is a reduced risk of caisson disease ("the bends") in case of decompression. This risk is increased by increased pressure, an argument for a cabin pressure of less than that on the earth at sea level. A fair compromise seems to be a pressure about one-half that on the earth at sea level, and roughly equal proportions of oxygen and inert gas.

In considering a short-term system one may select somewhat independently the control methods for each component involved. In a closed system many of these are interdependent.

Potential long-term energy

Another consideration is energy. A system that depends on consumable supplies (such as oxygen and hydrogen powering a fuel cell) to furnish its energy will have different requirements from one whose energy source is adequate and continually available. Nuclear fuels and solar cells both seem capable of fulfilling the latter requirement.

Oxygen production and carbon dioxide removal. There are a number of chemical methods of producing oxygen and removing carbon dioxide. The oxygen production methods include electrolysis of water, in which water is separated into hydrogen and oxygen by use of electric current; the Sabatier reactor, which combines carbon dioxide and hydrogen into water and methane; the Bosch reactor, which converts hydrogen and carbon dioxide into water and solid carbon; the solid electrolyte, which electrochemically separates oxygen directly from carbon dioxide; and the fused salt system, in which dehydrated air is passed through an electrolyte cell containing molten alkali carbonate, yielding oxygen and carbon. Most of the more promising methods of producing oxygen also reduce carbon dioxide, but first the carbon dioxide must be concentrated. These methods, most of which have been discussed above, include molecular sieves, solid amines, ion exchange resins, electrochemical carbonation cells, and membrane diffusion.

Waste recycling. Water may be recovered by several methods. At present urine must be treated with non-reusable chemicals before distillation. Electrochemical pretreatment that would not involve such waste is under development. Another method is vapour pyrolysis, in which urine, which is a mixture of water and various organic compounds, is placed in a distillation column along with a catalyst. The complex organic molecules in the urine are broken down by heat (pyrolized) into water and carbon dioxide; this process is assisted by the catalyst. In another recovery technique, water vapour passes through a membrane through which bacteria cannot pass, supplementing the distillation process. Wash water does not present the same problems as urine and is available in greater quantities. It is filtered through several types of filter beds, then sterilized by heat.

It does not appear likely at this time that chemical treatment methods will be found to make possible the reuse of feces. Biological methods offer some possibilities, however. One suggestion is to remove water and convert the remaining solids to fuel. In any case, feces can be stored by removing water and incinerating..

The methods described above might well be used to provide life support on year-long flights to neighbouring planets. These systems are not closed, however, and require a substantial supply of stored food while leaving solid waste and carbon. At present, it would appear that biological methods are needed to close the system. For several years space medicine investigators have been working on several possible photosynthetic systems that might eventually be expected to accomplish this closure. These include algae, of which the most often mentioned types are *Chlorella*, duckweed (Spirodela *polyrhiza*), and various higher forms such as sweet potatoes. Among biological systems, however, the most promising seems to involve *Hydrogenomonas*, a nonphotosynthetic bacterium. Cultures of these bacteria convert hydrogen, carbon dioxide, and urea from human waste to potentially useful food products.

Some authorities have suggested the possibility of raising animals on long space flights and using them to convert plant products into palatable and useful food. Any one of these small algae must be supplemented with other foods before it can form an adequate diet, for small animals and presumably for man also.

If one adds to the difficulties over and above the problems of bulk, of low-energy efficiency, and the possibility of viral or genetic disasters putting an entire system out of commission, it appears that considerable research remains to be done before a completely closed system becomes a reality. Yet the use of a biological edjunct to enrich an electrochemical routine remains inviting.

The Soviet simulator experiment

To illustrate how near to reality some of the above processes are, three Soviet scientists lived in a hermetically sealed simulator from November 1967 to November 1968. During the last part of the run the atmosphere was recycled and water was reclaimed. Carbon dioxide was concentrated, then used to make water. Special catalytic furnaces were used for atmosphere purification. Moisture was absorbed by chemical beds. Urine was reconstituted into water in several stages, including filtration and distillation. Atmospheric moisture was regenerated by filtration and ultraviolet exposure, followed by more filtration. Wash water received the same treatment plus another stage of filtration. Solid wastes were removed rather than regenerated. Food was mainly vacuum dehydrated, although a greenhouse (using a synthetic resin soil) provided cabbage, cucumbers, and watercress.

III. Underwater systems

Life-support systems that enable man to work underwater are primarily concerned with the gaseous atmosphere he must breathe. Another major problem is protection from cold water.

Undersea gaseous atmospheres can be divided into those that maintain sea-level atmospheric pressure and those that maintain ambient pressure (equivalent to that of the water outside the habitat). The sea-level atmospheric pressure category includes military submarines, research and industrial submarines, bathyscaphes, and certain underwater observation structures. In the ambient pressure category are included undersea habitats and caissons. Diving bells as currently used may be placed in either category.

SYSTEMS THAT MAINTAIN SEA-LEVEL PRESSURE

For vessels strong enough to hold out the pressure of the sea wherever they may operate, life support is intimately related to the time spent there. The problems include maintenance of a suitable atmosphere and regulation of temperature and humidity levels to within the range of comfort and good performance.

Military submarines. Life-support systems in the military submarines used before World War II require no description—they were essentially nonexistent. Every voyage was a test of endurance. There were no provisions for exhausting carbon dioxide or for adding oxygen. Ventilation was poor, humidity was always high, and the temperature was always either too hot or too cold. When the vessel was submerged for more than a few hours, oxygen could be added by bleeding air from the compressed air bank. Soda lime or lithium hydroxide granules were spread on bunks to absorb carbon dioxide, but this was not very effective.

It is generally recognized that the German submarine fleet in World War II suffered more from the inadequacies of its life-support systems than it did at the hands of the enemy. The volume of air available per man was adequate to run submerged during the hours of daylight without any problems; but when the Allies learned to detect surfaced submarines at night with radar, the duration of submergence soon exceeded the time the crew could easily endure. The problem was somewhat alleviated in the later submarines, which were equipped with snorkels that could be used to ventilate the crew quarters as well as furnish air to the diesel engines.

Postwar battery-powered submarines, with greatly improved air-conditioning systems, permitted longer periods of submergence made possible by the installation of lithium hydroxide scrubbers. These are quite simple devices, consisting of several canisters containing a bed of the absorbing agent and a fan for passing the air to be scrubbed through the bed. In addition to simplicity and modest power requirements, these scrubbers have a weight advantage over continuous systems, if they are not needed for longer than ten days. Finely divided lithium hydroxide is irritating, however, and wherever it is used it somehow manages to get into the atmosphere.

The nuclear submarines

A whole new situation presented itself when nuclear propulsion enabled the submarine to run submerged for months without surfacing. A completely controlled atmosphere had to be provided. In these crafts volume is at a premium, but weight and power requirements are not much of a problem. Chemical scrubbers, consequently, are a reasonable solution to the problem of carbon dioxide removal. In these devices, air from the crew compartment is placed in contact with a cool solution containing an organic agent, usually monoethanolamine, which readily takes up carbon dioxide, and the air is then returned to the cabin. The absorbing solution is next transferred by pump through a heat exchanger (a device that transfers heat from a warm object to a cooler object) and to a "stripper," where the carbon dioxide is driven out of solution by heat. A compressor forces the carbon dioxide overboard, and the renewed monoethanolamine is cooled by the heat exchanger and returned to the scrubber. The process is continuous or "regenerative" and requires only energy to keep it running.

In order for a closed environment to be suitable for habitation for many weeks, it is necessary to do more than remove carbon dioxide. Because crews are permitted to smoke, carbon monoxide enters the atmosphere in the submarine and is removed, along with other combustible hydrocarbons, by a catalytic burner, which operates by heating the air stream, passing it over a catalytic bed containing a mixture of copper and manganese oxides called hopcalite, cooling it again, and returning it to the cabin. Combustion products, mostly carbon dioxide and water, are handled by other components of the ship's system. Other organic contaminants, odours, etc. are removed by the carbon filter, a bed of activated charcoal through which the ship's air is circulated. Particulate matter and aerosols are removed by an electrostatic precipitator located in the galley, which is the largest source of such contamination after tobacco smoke.

Three other components complete the system. Temperature and humidity are controlled by air-conditioning equipment using conventional technology. As water is condensed on cooling coils, it takes with it soluble gaseous contaminants, mostly ammonia. Central to the entire life-support system is the atmosphere analyzer, which continuously provides readings of the levels of oxygen, carbon dioxide, hydrogen, carbon monoxide, etc. Finally, there is the matter of a source of oxygen. Some nuclear submarines are supplied by cylinders of compressed oxygen, which ultimately limits the length of time they can remain submerged. More modern vessels contain equipment for separating water into oxygen, which is used, and hydrogen, which is discharged overboard. An interesting difference between the submarine and the spacecraft is that in the submarine there is ample energy available to increase endurance by eliminating the use of a stored commodity, whereas in the spacecraft hydrogen and oxygen are used as a source of energy, via the fuel cell.

Research and working submersibles. Since about 1960 there has been an increasing interest in exploring the sea. One of the by-products of this interest has been the construction of dozens of small research submarines and industrial work boats. As a class these submersibles all have a fairly common approach to life support. Their missions are generally short enough so that little is required except carbon dioxide removal and the addition of oxygen. Almost universally they use oxygen supplied from cylinders and are equipped with Baralyme or lithium hydroxide carbon dioxide scrubbers powered by electric motors. Since virtually all of these small submersibles rely upon battery power, they are not ordinarily able to provide heating and humidity control. Pressure is kept close to that at sea level, and the normal earth atmosphere is generally maintained throughout the mission.

Bathyscaphes, which have been used to explore the deepest parts of the sea, may be compared in terms of life support to small submersibles. Dependent on battery power, they perform short missions, are not heated, and maintain pressure equal to that at sea level. A small cylinder of oxygen and a soda lime canister with a blower are all that is needed. More sophisticated systems involve automatic control and better atmosphere monitoring, but the principle is the same.

Jacques Piccard's "Ben Franklin"

One research submersible (the submarine "Ben Franklin," designed by the Swiss engineer Jacques Piccard) has a life-support system that can be considered unique. The "Ben Franklin" is designed to drift in an unpowered state, remaining submerged for several weeks at a time. The effectiveness of the system was tested on a 1,650-mile (2,640-kilometre) Gulf Stream drift mission from West Palm Beach, Florida, to the North Atlantic in 1969.

Features of the "Ben Franklin" system included: passive removal of carbon dioxide by lithium hydroxide absorption, low-temperature oxygen storage, preheated stored hot water, silica gel humidity control, and the use of the sea to absorb excess heat radiated from the vessel. The boat was designed to operate on minimal power.

The sea-level air environment in the "Ben Franklin" was maintained by using the original nitrogen in the atmosphere when the vessel was at surface and supplying oxygen from low-temperature storage. For a crew of six, oxygen consumption was 1.6 pounds (680 grams) per man per day, the equivalent of about 2,250 calories. This was consistent with the crew activities and food consumption. Carbon dioxide was removed by lithium hydroxide panels mounted in various places throughout the submarine; these depended only upon convective currents for their operation. In the 30-day mission, performance of the system was adequate, carbon dioxide levels never exceeded 1.5 percent, and absorber efficiencies were as great as 75 percent.

Temperature control was passive, in that no additional heat was supplied to the submarine other than 'that from the operation of lights and instruments and generated by the crew itself. This type of control is possible only in temperature between 55" and 75" F (13"–24" C), and operation of such a vessel in colder water will necessitate better insulation and the use of additional heat. In the Gulf Stream drift the temperature averaged 60° F (16" C), and the only thermal control exercised by the crew was change of clothing.

Although the humidity during this particular mission was never uncomfortable for the crew, humidity control is a major problem in a passive system; it was accomplished in this instance by absorption on silica gel. Some 2,400 pounds (1,089 kilograms) of silica gel were used over the 30-day period, and relative humidity was maintained between 65 and 75 percent. Condensation on the hull would accomplish water removal if the sea were 15° F (— 9"C) cooler than the cabin interior, but in the Gulf Stream this is not the case.

The mission was long enough to cause concern about trace contaminant buildup. A variety of contaminants were checked daily or weekly with gas detector tubes, small glass tubes that are filled with appropriate chemical agents through which a measured amount of gas is drawn and that change colour specifically according to the contaminants involved, with an intensity roughly proportional to the amount of contaminant present. The significant contaminants detected by this method were hydrogen, ammonia, carbon monoxide, methane, and ketones. Carbon monoxide had reached a maximum allowable level of 40 parts per million by the end of the 30-day experiment, indicating the need for a removal system on longer missions.

Since power was at a premium, the method for providing hot water was to store enough in vacuum-insulated tanks to last the entire mission. The vacuum insulation on half the water supply broke down, which created a burden in regard to the reconstitution of freeze-dried foods.

Since refrigeration was unavailable, specially packaged freeze-dried meals of about 3,000 kilocalories per day were supplied. The crew found these not entirely acceptable, primarily because the water available was not hot enough to restore the flavour properly. On future missions a greater effort will be directed toward providing palatable foods.

The waste system, like the others, was very conservative. Wash water from the sinks and showers was held in a storage tank and used for flushing the chemical toilet. Toilet waste was run through an electric grinder, mixed with a germicide, and stored. Toilet odours were forced by an electric blower through an odour-removal canister containing Purafil granules. Additional odour removal was provided by mixing activated charcoal with the lithium hydroxide used in the carbon dioxide removal panels. A battery-powered chemical adsorber and an oxidizer were provided for use when needed.

This 30-day mission indicated that the life-support system would be capable of sustaining a mission of up to 60 days with only minor modifications.

AMBIENT PRESSURE SYSTEMS

Diving. Ambient pressure life-support systems are those that involve the exposure of the users to the pressure of the surrounding water. Except for some unusual anthropomorphic pressure-resistant diving "suits," the only way an underwater worker can operate effectively in the underwater environment is to be himself at that pressure and be breathing gas supplied to him at a pressure very near to that of his lungs.

Simple diving devices

A great many reference works on the history of diving show drawings of devices whereby the diver obtains fresh air by means of a tube leading directly from his mouth to the surface. Such a system was described by Leonardo da Vinci about 1500, but neither his drawings nor his explanation of them is clear, and Leonardo may have realized that such a system would not work. The pressure differential across the chest wall, even at a depth of as little as two feet (60 centimetres) makes breathing for any length of time impossible; in addition, the circulatory system in the chest cannot tolerate this stress. This idea, however, has survived in one form in the snorkel used by skin divers. This is a simple, open tube about one foot (30 centimetres) long, curved to fit the mouth of a swimmer, and extending a few inches above the surface. This permits him to look toward the bottom without having to raise his head to breathe, and to swim easily when laden with other diving equipment.

Surface-supplied diving includes the traditional helmeted diver, trailing a stream of bubbles and peering out of a heavy brass helmet through a small round window. The life-support aspects of "hard-hat" diving are simple, though techniques for safe management of buoyancy, valves, lines, etc. are rather complicated. The hose from the surface supplies air to the helmet at a rate sufficient to flush out carbon dioxide exhaled into it by the diver, who controls this flow and by throttling the exhaust can adjust the amount of air in the suit and hence his buoyancy. The helmet and suit are fastened together as a single unit; cuffs permit the diver to use his bare hands (an important factor, since in muddy water most of the work has to be done by feel). He wears woollen underwear as insulation against the cold; if he is careful and wears a well-fitted suit, the inside remains dry.

A variation on the traditional helmet is one designed for "mixed-gas" diving, almost always with a mixture of helium and oxygen. Helium does not cause the narcosis (semiconsciousness) or "rapture of the deep" that becomes limiting when air or nitrogen–oxygen mixtures are breathed at depths beyond about 200 feet (60 metres). Gas supplied to a diver at great depths is necessarily under compression.

Other surface-supplied diving systems can be characterized as "demand" systems. The traditional helmet diver breathes from a space that is supplied with gas and either purged or scrubbed. In recent years a variety of other types of gear have been developed that have the common feature of a demand breathing regulator. This is similar to the regulators used by pilots; it supplies gas to the diver only when he inhales. The diver may wear a helmet that contains a mouthpiece or an oral–nasal mask, or he may wear a mask and a mouthpiece. For a suit he may wear a neoprene foam "wet suit," which provides about a quarter of an inch (six millimetres) of insulation but which is not sealed against water and allows a small amount of water to seep inside and be warmed to skin temperature. Alternatively he may wear a dry suit sealed to the helmet and insulated with woollen underwear, or the "constant-volume" suit, which is a dry suit with special provisions to maintain the same volume at different depths, thereby maintaining a constant buoyancy.

Scuba gear

Most of the demand-type systems are adaptable to self-contained breathing-gas-supply systems, or self-contained underwater breathing apparatus (scuba gear). These provide gas only when the suction of inhalation calls for it and can be used in any situation by merely providing a source of compressed air to the regulator.

The scuba gear used by sports divers and by some commercial divers consists of one or two tanks of compressed air, a regulator, a mouthpiece, and the necessary hoses and harness. Two basic types of scuba are available, identified as single-hose or two-hose systems. In the single-hose system the regulator is worn on the mouthpiece; this is connected to another regulator on the tank by a hose, and the exhaust gas is vented just beneath the chin of the diver. In the two-hose system the regulators (first and second stage) are mounted on the tanks on the back of the diver, who inhales and exhales through a set of two one-way valves integral with his mouthpiece. Two large corrugated hoses connect the valve system with the regulator. There are specific advantages to each of these two systems, but both are acceptable for most scuba-diving situations.

One characteristic of open-circuit scuba, the bubble trail given off by a diver, is disadvantageous in clandestine military applications; various methods have been used to solve this problem. The simplest and most expedient is a closed-circuit system containing pure oxygen and a carbon dioxide absorber. Although pure oxygen can be breathed safely only to a depth of about 25 feet (seven metres), such bubbleless systems were widely used in World War II and are still used in most of the world's navies. Pure oxygen systems are dangerous, however, and are not suitable for unqualified divers.

From another point of view the bubbles given off by a diver represent a loss of gas, limiting the duration of a dive. Attempts to extend the time a diver can work, using the amount of gas he can carry, have prompted the development of both closed and semiclosed mixed-gas systems. These maintain a breathing mixture containing an appropriate amount of oxygen and can be adjusted for use at any depth.

A semiclosed system recirculates the breathing-gas mixture through a carbon dioxide-absorbing canister and adds oxygen as needed. A mixture of inert gas and oxygen is bled at a fixed rate, sufficient to supply the oxygen requirements of the diver. A fraction of the gas expired by the diver is allowed to vent overboard. The system produces a few bubbles, but gets about ten times as much time out of a given amount of gas as would be available by open circuit alone.

The closed-circuit re-breathing apparatus

The most interesting development in scuba gear in recent years has been that of closed-circuit, mixed-gas rebreathing, which uses an electrochemical oxygen sensor to adjust the inflow of oxygen into the system. As in the other scuba, a canister of chemicals absorbs carbon dioxide. No gas at all is allowed to escape—the inert gas is reused for the entire dive time.

Still another innovation in extending the capabilities of scuba is the use of low-temperature, cryogenic gases. Although not quite as advantageous as in spacecraft, in which weight is at a premium, several hours' diving can be obtained from cryogenic open-circuit systems, and more sophisticated mixed-gas, cryogenic systems afford extremely efficient diving. These include modifications to provide carbon dioxide and humidity control by freezing these constituents out of the atmosphere breathed by the diver, and even a possible provision for a diver heat source using a catalytic magnesium burner.

Diving bells. Historically, the diving bell was used as a life-support system before the advent of adequate diving apparatus for diving to even rather shallow depths. In recent years, as the depth to which divers descend has been increased and consequently the decompression time as well, the diving bell once more has become a necessary adjunct to diving.

No longer operating like an inverted tumbler as did its ancestors, the modern diving bell, sealed at the surface, is lowered to the work site retaining surface pressure inside. The diver may take as long as he likes to inspect the job and obtain necessary tools and assistance from the surface; only when everything is ready does he compress the bell to ambient pressure. The diver then opens the hatch. exits into the water, does his job, climbs back into the bell, seals the hatch, and calls for a hoist to the surface. Gas is now vented from the bell at the controlled rate called for in the decompression tables. The bell must be stressed for both internal and external pressure, since it maintains atmospheric pressure inside initially, then holds the diver's bottom pressure or the appropriate table pressure inside during the ascent phase. The bell is lifted onto the deck of the support vessel or platform and attached to a deck decompression chamber. Pressure in the deck decompression chamber is brought up to that of the bell, the hatches between them are opened, and divers can then pass into the deck decompression chamber for a more comfortable decompression.

Submersible chambers are usually outfitted with a minimum of life-support devices, in the interest of simplicity. and to conserve weight and space. For short dives of an hour or two, no carbon dioxide scrubber is needed; usually a simple Baralyme canister with a blower is used. Oxygen for breathing is supplied directly or in mixture with an inert gas such as helium. Lights and communications are essential, and some systems are also equipped with heating and gas analysis equipment. There must of course be both pressurizing and decompression capabilities—the gas used may be attached to the bell in cylinders, or it may be supplied by hose.

Working from the bell, the diver may be supported in several ways. For short jobs, simple open-circuit scuba will work, but at continental-shelf depths these do not afford enough time. More common is the use of a lightweight open-circuit helmet supplied from the bell by hose. This method is named after the Turkish water pipe, the "hookah." Another form of hookah uses a recirculating pump to circulate gas from the bell to the diver and back, thereby permitting the bell's carbon dioxide scrubber and oxygen-makeup systems to serve the diver, and avoiding the wasteful process of open-circuit breathing.

The "hookah" system

Saturation diving. The longer a diver stays down, the longer he must decompress in order to return safely to surface pressure. For any given depth, however, there is a saturation point, at which body tissues are saturated with inert gas; after that, no matter how long a worker stays under pressure his decompression time does not increase. Reasonably safe and efficient decompression from saturation at depths up to 600 feet (180 metres) can be accomplished by a decompression at the rate of 15 minutes per foot (300 millimetres), or about 100 feet (30 metres) per day, so that no decompression tables are necessary.

In practice, saturation divers are compressed slowly to working pressure, generally in the deck chamber, and are then transferred as needed to and from the work site sealed in the diving bell. They may work several hours a day (this is usually limited by cold tolerance) and remain in the deck chamber for rest and recuperation.

Life support in the deck chamber is subject to many of the problems of closed systems, but the methods used are usually rather simple. A major constraint is fire safety; the end of every decompression will always involve an atmosphere in which flammability is greater than normal; sources of ignition and flammable materials are therefore kept to an absolute minimum. Carbon dioxide scrubbing is the major function that must be performed, along with the maintenance of a suitable oxygen level. Analysis for these two gases is an essential part of any saturation system. Humidity is controlled by condensation on cooling coils or with chemical absorbents, and temperature control is provided by conventional means, usually with a heat exchanger in the deck decompression chamber supplied with hot and cold pipes. Food and drink are passed in through a lock.

Warming the diver. Several layers of long woollen underwear under the heavy rubber suit have kept hard-hat divers warm for years. More recently, the advent of popular scuba diving has prompted the development of the wet suit, a layer of neoprene foam between the diver's skin and the water, though not sealed against water leaking inside. Insulation such as this suit affords is adequate for short, shallow dives of up to one hour in even the coldest water. But for two reasons deep helium–oxygen diving has introduced a new dimension to diver cold stress. First, at great depths the insulating value of conventional materials vanishes, since insulation utilizes dead gas space and these gas spaces are now compressed to a small fraction of their original dimensions. Second is the thermal conductivity of helium; helium removes heat several times faster than air does, both through the respiratory tract and through the skin. At 600 feet (180 metres) the heat removed by the respiratory system can be equivalent to the total metabolic heat generated by the man. So it is out of the question to try to support a deep diver by insulation alone. Some supplementary heat is essential.

Two general approaches are being pursued in the matter of insulation, a noncompressible insulation and restoring the gas space by addition of inert gas. Glass or plastic microspheres imbedded in a rubber matrix make a material with most of the insulating capability of neoprene foam but one that does not compress at depth. Such materials in 1970 were stiff, heavy, fragile, and expensive. Inert gas, such as Freon or carbon dioxide (gases that have a low thermal conductivity) can be injected between layers or in bladders of a suit to provide a dead-gas insulating layer. Though this is a feasible approach and is commercially available, it does involve added complexity and can create a buoyancy problem.

With or without adequate insulation, it is still necessary to supply heat to the diver. The most widely used method is an open-circuit hot-water system, whereby hot water is flushed through the inside of a suit and out at the extremities. Such a system requires considerable energy. The closed system has its appeal here, as in breathing. For one thing, an independent free-swimming diver cannot use the hot-water system because of the necessary hose. A closed system of tubes similar to the Apollo garment, but with warm water instead of cold, has been suggested, but the practical result is a suit made up of a series of interconected bladders rather than tubes, contained within a dry suit. One simple suit having space for about 40 pounds (18 kilograms) of warm water postpones for over an hour the cooling of the diver. Such suits require 1.2 to 2.5 kilowatts per hour to maintain a diver at 600 feet (180 metres) in water at freezing temperature. Several methods for supplying this heat are available.

Undersea habitats. There is considerable attraction in the idea of enabling underwater workers to live submerged for days or weeks at a time. Toward this end a number of undersea habitats have been designed, built, and used. The basic requirement of an undersea habitat is a ballasted container filled with a gas mixture appropriate for the depth, having an opening in the bottom for access to the sea, or a suitable system of locks. At the depths where air can be breathed it is feasible to use an open-circuit system to maintain a fresh atmosphere, merely by forcing air into the habitat and letting it bubble out. This method is not feasible where helium mixtures are used; here the minimal requirements are to provide scrubbing of carbon dioxide and maintenance of a suitable oxygen level—analysis and makeup. Temperature, humidity, and food and water are important factors in longer missions.

The first saturation dive

A new phase of man's utilization of the sea began in 1962, when a young Belgian diver remained at a depth of 200 feet (60 metres) beneath the Mediterranean Sea for 24 hours and was decompressed on deck in the same submersible chamber that took him to and from the sea floor. This experiment showed for the first time that the concept of saturation diving was valid. Though saturation diving had been in the thoughts of diving physiologists for years, the experiment demonstrated conclusively that decompression efficiency could be multiplied manyfold by extending bottom time beyond the point at which the body tissues were saturated with inert gas. Once a diver has become saturated, his decompression time is fixed at a maximum value, but he can extend his time at pressure virtually infinitely without increasing the decompression obligation.

Shortly after this experiment, Capt. Jacques-Yves Cousteau, a French biologist and co-inventor of the open-circuit demand-type scuba apparatus, operated his Conshelf I habitat about 33 feet (10 metres) below the Mediterranean Sea for seven days. In 1963 five oceanauts lived for a month in Conshelf II at a depth of about 36 feet (11 metres). A significant step occurred in 1964, when two men remained at 432 feet (132 metres) in the Caribbean for over 48 hours, in an inflated rubber "sausage," travelled to and from the bottom in the six-foot-long diving bell used earlier, and decompressed on deck in a deck decompression chamber built for the purpose. The atmosphere in their undersea house was scrubbed by an electric scrubber, odours were absorbed, and nothing was done about humidity. An electric heater was intended to provide some protection from the chilling effect of high-density helium. Gas composition was 3.6 percent oxygen, 5.6 percent nitrogen, and 90.8 percent helium. The divers were able to swim and work near their habitat by means of a "hookah" rebreather, which pumped chamber gas to a demand mask located on the diver's back and returned expired gas to the diving bell.

In the same year, the U.S. Navy started a series of experiments (Sealab I), keeping four men at 193 feet (58.8 metres) for nine days. They breathed a mixture of 79 percent helium, 17 percent nitrogen, and 4 percent oxygen. A temperature of 29" C (84" F) was found to be

The Sealab experiment

comfortable; humidity remained about 72 percent. No adverse physiological effects were noted in medical and biochemical monitoring conducted on the four divers.

Sealab II was set in 205 feet (62.5 metres) of water off the coast of California; it was a cylindrical tank 57 feet (17.4 metres) long and 12 feet (3.6 metres) in diameter. A total of 28 divers manned three 15-day tours, with one staying 30 consecutive days. The atmosphere was essentially the same as in Sealab I. The divers had free access to the sea, where temperatures were around 10° C (50" F); daily swimming in this water alone caused considerable stress. Though there were many minor changes in the blood and the biochemistry of some of the divers, none were serious or irreversible, and all could probably be associated with the general stress of the situation. For decompression, groups of divers were transferred in a sealed transfer capsule to the deck chamber. An air-conditioning and dehumidification system was equipped also with charcoal and lithium hydroxide scrubbers. Hopcalite was used in some scrubber canisters in an effort to reduce carbon monoxide concentrations that had begun to develop. Helium and oxygen were stored in compressed cylinders on board, and an umbilical cable provided access to these gases on deck of the support barge, as well as gas analysis to topside analyzers. Power and communications were also handled effectively through this cable.

Cousteau and the Conshelf III habitat

Coincidentally, at the same time the Sealab II aquanauts were in the Pacific, the Cousteau operation Conshelf III was 328 feet (100 metres) below the Mediterranean. A sphere 18 feet (5.4 metres) in diameter, the Conshelf habitat was to a large extent autonomous, though it had power and communication lines to a shore support station. Six oceanauts remained in this habitat not only for the 27 days at pressure but for a 3%-day decompression, which took place while the habitat was being towed back to its home port at Monaco. Sophisticated systems were tried in this experiment, including a liquefied gas generator designed to supply breathing oxygen and to remove humidity and carbon dioxide with the same machinery, and at the same time provide a deep freeze for food storage: helium infiltration of its insulation caused its eventual failure.

Finally, in contrast to the expense and complexity of some of the more spectacular operations, a number of simple and inexpensive shallow-water habitats have been run by students, schools, clubs, and individuals. These furnish a focal point for undersea activity and are used for study of marine biology, geology, and limnology. An example is Sublimnos, located in Lake Huron near Tobermory, Ontario, at a depth of 30 feet (9 metres). Supplied by air from a small compressor and electrical power from a generator, it is used by scientists from a number of institutions for continuous surveillance of the biology of the lake, even during the winter, when two feet of ice make routine underwater operations exceedingly difficult.

Underwater welding chambers. A recent engineering innovation has created a special set of life-support problems. Welding under dry conditions is being performed on undersea pipelines in place on the ocean floor. A chamber is placed over the pipe, the water inside is displaced with gas, and diver-welders are sent into the chamber. This situation involves at once many of the traditional problems of diving (such as decompression, inert gas narcosis, and oxygen toxicity), of welding (electric shock, eye protection, noxious fumes), of closed systems (toxic contaminants, carbon dioxide, oxygen makeup, gas logistics), of undersea habitats (humidity, helium speech, choice of gases, analysis), and of fire safety (oxygen levels, hypoxia, hydrocarbons, arcs). A major innovation helping to make safe underwater welding possible was the discovery of the "zone of no combustion." If oxygen is kept below about 6 percent, ordinary materials will not burn even if heated to their ordinary ignition temperature. At depths greater than about 60 feet (18 metres) this percentage of oxygen is enough to supply metabolic needs, and it is therefore possible to maintain an environment in which men can breathe but which will not support fire.

The "zone of no combustion"

IV. Other life-support systems

Firemen's suits. One of the most widespread of all life-support systems is the suit used by firemen. There are two principal hazards from which firemen must be protected, heat and smoke or atmospheres low in oxygen. Though heat is a very real problem, the killer in fatal fires is almost always lack of oxygen.

A suit made of closely woven asbestos alone is adequate for close approach to the periphery of a fire, and it is usually worn when entering a burning building; but by itself it does not afford protection against asphyxia, or more properly hypoxia, lack of oxygen. Neither does a conventional gas mask, since its function is only to remove (usually by means of activated charcoal) toxic agents from the air being breathed. Properly equipped firemen also wear breathing systems, by which oxygen is furnished to them in a system not easily contaminated by the noxious fumes and smoke. These may be of several types but usually are either a closed-circuit oxygen system containing a carbon dioxide absorber or an open-circuit method of breathing from a tank of compressed air. The mask usually covers the entire face because of the threat to the eyes, but it may contain a mouthpiece or mask inside the faceplate to reduce the dead space and prevent carbon dioxide buildup. The design usually includes a method of flowing the fresh gas over the faceplate to reduce fogging.

Anesthesia units. A type of closed-circuit breathing system in common use is the hospital anesthesia machine. This is a system of valves and tubes having a carbon dioxide absorber and a device for introducing a certain percentage of volatile vapour or gas, the anesthetic, into the circuit. It is usually attached to the patient by means of a tube inserted into the trachea and sealed by an inflatable cuff. The anesthetist monitors the condition of the patient, his degree of anesthesia, the amount of anesthetic, and the oxygen and carbon dioxide in the gas circuit.

Gas masks. Another system familiar to soldiers but rarely put to extensive use since World War I is the gas mask. The classical gas mask is little more than a faceplate and a set of tubes and valves that forces inspired air through a canister of activated charcoal and thereby removes aerosols and organic gases present in minute quantities. More modern versions may contain other substances specifically chosen for their ability to absorb the toxins that might be used. Such masks are of course useless in atmospheres lacking oxygen.

Light

Light, a basic aspect of the human environment, cannot be defined in terms of anything simpler or more directly appreciated by the senses than itself. Light, certainly, is responsible for the sensation of sight. Light is propagated with a speed that is high but not infinitely high. Physicists are acquainted with two methods of propagation from one place to another, as (1) particles and as (2) waves, and for a long time they have sought to define light in terms of either particles or waves. In the early 19th century a wave description was favoured, though it was difficult to understand what kind of wave could possibly be propagated across the near-vacuum of interstellar space and with the extremely high speed of 300,000 kilometres per second (186,000 miles per second). In the latter half of the 19th century a British physicist, James Clerk Maxwell, showed that certain electromagnetic effects could be propagated through a vacuum with a speed equal to the measured speed of light. Thus, in the second half of the 19th century, light was described as electromagnetic waves (see ELECTROMAGNETIC RADIATION). Such waves were visualized as analogous to those on the surface of water (transverse waves) but with an extremely short wavelength of about 500 nanometres (one nanometre is 10-metre). The analogy is valid up to a certain point but the experimental results obtained at the end of the 19th century and in the early years of the 20th century revealed properties of light that could not have been predicted from knowledge that was obtainable about other waves. These results led to the quantum theory of light, which in its primitive form asserted that, at least in regard to its emission and absorption by matter, light behaves like particles rather than waves. The results of certain important experiments on the spreading of light into shadows and other experiments (on the interaction of beams of light) that supported the wave theory found no place in a particle theory. For a time it was believed that light could not be adequately described by analogy with either waves or particles—that it could be defined only by a description of its properties. A reconciliation of wave and particle concepts did not emerge until after 1924.

Concept of light as both wave and particle reconciled

Two properties of light are, perhaps, more basic and fundamental than any others. The first of these is that light is a form of energy conveyed through empty space at high velocity (in contrast, many forms of energy, such as the chemical energy stored in coal or oil, can be transferred from one place to another only by transporting the matter in which the energy is stored). The unique property of light is, thus, that energy in the form of light is always moving, and its movement is only in an indirect way (usually to a small extent) affected by motion of the matter through which it is moving. (When light energy ceases to move, because it has been absorbed by matter, it is no longer light.)

The second fundamental property is that a beam of light can convey information from one place to another. This information concerns both the source of light and also any objects that have partly absorbed or reflected or refracted the light before it reaches the observer. More information reaches the human brain through the eyes than through any other sense organ. Even so, the visual system extracts only a minute fraction of the information that is imprinted on the light that enters the eye. Optical instruments extract much more information from the visual scene; spectroscopic instruments, for example, reveal far more about a source of light than the eye can discover by noting its colour, and telescopes and microscopes extract scientific information from the environment. Modern optical instruments produce, indeed, so much information that automatic methods of recording and analysis are needed to enable the brain to comprehend it.

From the standpoint of wave motion, blue light has a somewhat higher frequency and shorter wavelength than red. In the quantum theory, blue light consists of higher energy quanta than the red.

The subject of light is so wide and its associations are so numerous that it cannot be accommodated within one article of reasonable length. There are three main divisions of the subject of light: physical optics, physiological optics, and optical instrumentation. This article deals with physical optics; although electromagnetic theory is considered in some detail, further elucidation may be obtained in the article ELECTROMAGNETIC RADIATION. The articles entitled EYE AND VISION, HUMAN and PHOTORECEPTION include the physiological and psychological aspects of light. The article entitled OPTICS, PRINCIPLES OF is concerned with the basic theory and the technology of lenses, mirrors, and optical systems. Certain highly developed instruments constitute the subjects of specialized text articles (see TELESCOPE; MICROSCOPE; PHOTOMETRY, ASTRONOMICAL; LASER AND MASER). There is also a separate text article on SPECTROSCOPY, PRINCIPLES OF. The experimental evidence that led to the quantum theory of radiation is included in this article together with a brief statement of some of the basic ideas. The quantum theory of radiation, however, is so closely associated with the quantum theory of matter that the two must be considered together and this is done in the text article entitled MECHANICS, QUANTUM.

The following outline summarizes the contents that will be found below:

I. General considerations
    Historical survey
    Basic concepts of wave theory
    Light spectrum
    Velocity of light
II. Interference and diffraction phenomena
    Interference
    Diffraction
III. Polarization and electromagnetic theory
    Polarized light
    Electromagnetic-wave character of light
IV. The interaction of light with matter
    Reflection and refraction
    Dispersion and scattering
    Mechanical effects of light
V. Quantum theory of light
    Photons
    The wave–particle nature of light

I. General considerations

HISTORICAL SURVEY

Pythagorean hypothesis of light

From 500 BC to AD 1650. In this period, there were innumerable confusions and false starts toward an understanding of light. Sometimes an idea was stated, though not clearly, and then almost forgotten for centuries before it reappeared and was generally accepted. The uses of plane and curved mirrors and of convex and concave lenses were discovered independently in China and in Greece. References to burning mirrors go back almost to the start of history, and it is possible that Chinese and Greek knowledge were both derived from a common source in Mesopotamia, India, or Egypt. The formulation of general empirical laws and of speculation about the theory of light derives mainly from Mediterranean (Greek and Arab) sources. Pythagoras, Greek philosopher and mathematician (6th century BC), suggested that light consists of rays that, acting like feelers, travel in straight lines from the eye to the object and that the sensation of sight is obtained when these rays touch the object. In this way, the more mysterious sense of sight is explained in terms of the intuitively accepted sense of touch. It is only necessary to reverse the direction of these rays to obtain the basic scheme of modern geometrical optics. The Greek mathematician Euclid (300 BC), who accepted the Pythagorean idea, knew that the angle of reflected light rays from a mirror equals the angle of incident light rays from the object to the mirror. The idea that light is emitted by a source and reflected by an object and then enters the eye to produce the sensation of sight was known to Epicurus, another Greek philosopher of Samos (300 BC). The Pythagorean hypothesis was abandoned and the concept of rays going from the object to the eye was finally accepted about AD 1000 under the influence of an Arabian mathematician and physicist named Alhazen.

Angles of incidence and of refraction—*i.e.*, the change in direction of a light ray going from one transparent medium to another—were measured by an astronomer, Ptolemy, in the 1st century in Alexandria. He correctly deduced that the ray is bent toward the normal (*i.e.,* the direction perpendicular to a boundary plane, such as the plane separating air and water) on entering the denser medium. A Dutchman, Willebrord van Roijen Snell, discovered the so-called sine law that gives the index of refraction (a measure of the change in direction) for light in a transparent medium. The laws of reflection and refraction were brought together by a 17th-century French mathematician, Pierre de Fermat, who postulated that the rays of light take paths that require a minimum time. He assumed that the velocity of light in a more dense medium is less than that in a less dense one in the inverse ratio of the indices of refraction.

Fermat's principle

The idea of rectilinear propagation of light—that is, that it travels in a straight line—was applied to drawing and painting long ago. Euclid was familiar with the basic idea, but the main theory was developed by Leonardo da Vinci, and a complete description of shadows was given by the Danish astronomer Johannes Kepler in 1604. Kepler also was the first to apply the laws of rectilinear propagation to photometry (the measurement of light intensities).

From 1650 *to* 1895. At the beginning of this period, the result of the conflict between the corpuscular theory and the wave theory was in doubt. At the end of the period, the wave theory was generally accepted and seemed capable of explaining all known optical phenomena though, with hindsight, it can now be seen that there were some important difficulties.

Diffraction—*i.e.*, the spreading of light into shadows—was first observed in Italy in the 17th century. In England, a worker, who independently noticed diffraction, also observed the interference colours of thin films, which are commonly seen today in an oil film on a wet road surface or in the iridescent colours of a butterfly's wing. He believed that light consists of vibrations propagated at great speed. Christiaan Huygens, of Holland, greatly improved the wave theory. In England, Sir Isaac Newton did not attach much importance to the small amount of spreading of light, and he knew that strictly rectilinear propagation could not be reconciled with the wave .theory. Polarization phenomena (which can be accounted for by transverse wave motion in a single plane) discovered in the 17th century by a Danish physicist, Erasmus Bartholin, and by Huygens were not consistent with the theory of longitudinal waves (waves vibrating in the direction of propagation, like compression waves in a coiled spring), which was the only wave theory then considered. Newton therefore supported the corpuscular theory, although he did not reject the wave theory completely. He accepted a concept of a luminiferous ether, and he postulated that the particles had "fits of easy reflection" and "fits of easy transmission"; *i.e.,* he assumed that they changed regularly between (1) a state in which they were reflected at a glass surface and *(2)* a state in which they were transmitted. He thus introduced periodicity—one of the basic ideas of wave theory—in a form that anticipates the quantum mechanics. Newton, using a glass wedge, or prism, discovered that white light can be separated into light of different colours and took the first steps toward a theory of colour vision.

In the century following his death the great authority of Newton was quoted to uphold the corpuscular theory and to oppose the wave theory in a way that he probably would not have approved. It was not until the 19th century that the work of Thomas Young of England; Augustin-Jean Fresnel, François Arago, and Armand-Hippolyte-Louis Fizeau, all of France; Irish scientist Humphrey Lloyd; and German physicist Gustav Kirchhoff established the transverse-wave concept of light; *i.e.*, light is a wave vibration at right angles to the direction of travel. A universal medium pervading all space and called the ether was supposed to be some kind of elastic solid. This made it possible to accept the transmission of light through a vacuum, but there was no completely satisfactory theory of the ether or of the way in which light is modified by transparent materials like glass. The necessity for an elastic solid disappeared when Maxwell proposed an electromagnetic theory of light. He stated the laws of electromagnetism in a clear mathematical form and generalized the concept of an electric current. From his equations he predicted the existence of transverse electromagnetic waves having a constant speed c in *vacuo.* The constant c had a value of 300,000 kilometres per second and was derived from measurements on electrical circuits. It was known from the work of Ole Rømer, a Danish astronomer; Jean-Bernard-Leon Foucault of France; and others that the velocity of light was not much different from the velocity constant *c.* A.A. Michelson, a physicist in the United States, measured the velocity of light and showed that it is equal to *c* within a small margin of experimental error. This result, together with the work of a German physicist (Heinrich Rudolf Hertz) on electromagnetic waves of larger wavelength, confirmed Maxwell's predictions (see ELECTROMAGNETIC RADIATION). The existence of a connection between electromagnetism and light had, indeed, been demonstrated in England much earlier in the century by Michael Faraday, who observed the rotation of the plane of polarization of a beam of light by a magnetic field (Faraday effect).

Transverse-wave concept established

From 1900 to the present. Maxwell's theory is a theory of waves in a continuous (*i.e.*, infinitely divisible) medium. The energy of the waves is also infinitely divisible so that an indefinitely small amount can be emitted or absorbed by matter. Classical physical theories of the 19th century had predicted that in such a system the energy in equilibrium would be distributed so as to give an equal amount to each mode (frequency) of vibration. Because a continuous medium has an infinite number of modes of vibration, and the atoms (which constitute matter) have only a finite number, all the energy of the universe would be transformed into waves of high frequency. Maxwell understood this difficulty, which was later most clearly stated in the Rayleigh–Jeans law (after two English physicists, Lord Rayleigh and Sir James Hopwood Jeans) of the radiation of a blackbody (a body in which the intake and output of energy are in equilibrium). The German physicist Max Planck demonstrated that it is necessary to postulate that radiant-heat energy is emitted only in finite amounts, which are now called quanta. At first, it was hoped to retain, without modification, the theory of light as electromagnetic waves in free space and to use the quantum concept only in relation to the interaction between radiation and matter. In 1905, however, Einstein showed that, in the photoelectric effect, light behaves as if all the energy were concentrated in quanta—*i.e.*, particles of energy now called photons. In the same year, Einstein published the theory of relativity, which modified the whole of physics and gave a special role to the velocity constant *c.* Because light, in some situations, behaves like waves and, in others, like particles, it is necessary to have a theory that predicts when and to what extent each kind of behaviour is manifested. The main development of the quantum mechanics, which does precisely this, took place between 1925 and 1935.

The role of the velocity of light in relativity theory

Light from ordinary sources is emitted by atoms the phases of which are not correlated with one another, so that there is a random irregularity or incoherence between the waves emitted from different atoms. This places severe restrictions on the conditions under which the periodicity associated with wave theory can be observed. In England, Lord Rayleigh appreciated this effect and knew that, by the use of pinholes or slits and light of a narrow range of wavelength, effectively coherent light could be produced. For a long time, interest in this topic lapsed. About 1935 Frits Zernike, a Dutch physicist, and others extended the theory of coherence to include the concept of partial coherence. This appeared to be of practical importance only in a few rather special applications (*e.g.*, in the Michelson stellar interferometer; see below Interference). A theory of stimulated emission, attributable to the work of Einstein and an English physicist, Paul A.M. Dirac, postulated that under certain conditions atoms could be made to radiate in phase so that highly coherent radiation could be maintained indefinitely. The practical realization of these conditions, previously thought to be impossible, was achieved in 1960 (see article on LASER AND MASER).

Information transfer in optical systems

A second major development in the theory of light in this century is the application of so-called Fourier transform methods (a mathematical treatment of light waves) to a wide range of optical problems and, especially, to the transfer of information in optical systems (see article on OPTICS, PRINCIPLES OF).

Today, the theory of light has again reached a point at which all known terrestrial phenomena are included in one logical theory. The known unsolved problems concern the transmission of light over the vast distances of intergalactic space. Here the theory of light impinges on the science of cosmology.

BASIC CONCEPTS OF WAVE THEORY

In this section on the wave theory of light, those properties of light that are consistent with a wave theory are described using a minimum of mathematical formulation (see also WAVE MOTION). It is convenient to introduce the basic concepts of wave theory in relation to mechanical systems. Below, in the section on *Interference*, and beyond, it will be necessary to consider results obtained by more sophisticated mathematical methods, such as Fourier analysis.

General characteristics of waves. Periodicity *in* time and space. If one end of a stretched rope is vibrated, a wave will run along the rope. Figure 1 (top) represents a profile of the wave—*i.e.*, a "snapshot" of the displacement of the rope from its normal position. It gives the variation of this displacement (indicated by ξ) at different points (z) along the axis of propagation for one specific instant of time. Similarly. Figure 1 (bottom) shows the variation with time of the displacement at one arbitrary point on the axis. In Figure 1 (top) the distance between successive crests is constant and is called the wavelength (λ). Similarly, the constant time between crests in Figure 1 (bottom) is called the period (τ). The temporal frequency ($\nu_t = 1/\tau$) is the number of vibrations per unit time and the spatial frequency or wave number ($\nu_s = 1/\lambda$) is the number of waves per unit length. The wave shown in Figure 1 (top) may be represented by the cosine of an angle (ϕ) to give the displacement for a particular point on the axis at any instant of time:

$$\xi = A\cos\phi = A\cos 2\pi(\nu_t t - \nu_s z), \tag{1}$$

in which ξ is the displacement at any point z on the axis at a time *t*, A is the amplitude (the maximum displacement); the angle ϕ (phi) in this case is equal to $2\pi(\nu_t t - \nu_s z)$ and is called the phase angle, or simply, the phase.

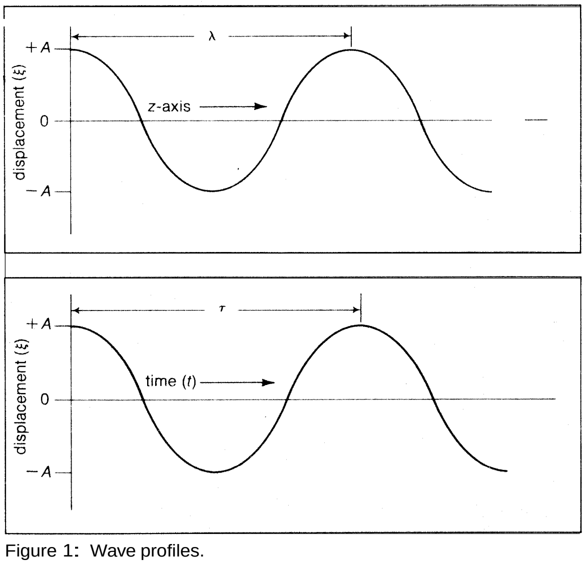

Figure 1: Wave profiles.
(Top) Variation with position at one time. (Bottom) Variation with time at one place (see text).

Energy. The energy per unit volume (W) stored in a wave motion is proportional to the square of the amplitude (A) so that, with a suitable choice of units, $W = A^2$.

Phase velocity. Any one crest moves forward a distance λ in a time τ; *i.e.*, with a velocity b of the wavelength divided by the period or the temporal frequency divided by the spatial frequency,

$$b = \frac{\lambda}{\tau} = \frac{\nu_t}{\nu_s} = \lambda\nu_t. \tag{2}$$

The velocity h is called the phase velocity because the phase angle ϕ will remain constant when the time t changes by an incremental amount t_0 and z changes by z,, $= bt_0$. (This may be seen by substituting $t = t_0$ and $z = z_0$ in the expression for this phase and using b $= \nu_t/\nu_s$.)

Relation of phase velocity to the medium

The velocity of light in vacuum (denoted by c) is the same for all frequencies; all colours travel through space with the same speed. The phase velocity (denoted by b) in a material medium, on the other hand, depends on the medium and on the temporal frequency and, hence from equation (2), on the wavelength.

Wave surfaces. Two-dimensional waves are formed by vibrating (dipping) the end of a rod up and down in the surface of a liquid. Waves spread from the point of origin (where the rod contacts the surface) and, at any moment, the phase at any point on a circle is the same; *i.e.*, if, at a given moment, the wave is at a maximum at one point on a circle then it is at a maximum everywhere on this circle, and the circle as a whole is a wave crest. Similarly, a trough is found at all points on another circle (the radius of which is $\lambda/2$ greater than that of the first circle). As the waves progress farther and farther from the origin, they become less strongly curved about the origin so that, at great distances, they are approximately plane waves.

Light waves are propagated in three dimensions and, for waves from a point source in an isotropic medium (*i.e.*, one in which the speed is the same along any radius), the phase is constant over spherical surfaces drawn about the point source as a centre. The surfaces of constant phase are called wave surfaces, and waves are called plane, spherical, ellipsoidal, and so on according to the shapes of the wave surfaces.

Reflection and refraction. The similarity between the behaviour of light waves and the surface waves of a liquid may be demonstrated with an apparatus called a ripple tank. For reflection of a train of surface waves incident on a flat object, it may be readily observed that the angle of reflection is equal to the angle of incidence. For waves that are refracted in passing from one medium of the ripple tank in which the phase velocity is b_1, to another in which the phase velocity is b_2, measurements of angles of incidence (θ_i) and refraction (θ_r) of the surface waves verify Snell's sine law of refraction for light; *i.e.*, that the ratio of the sines of the angle of incidence and refraction is a constant, or

$$\frac{\sin\theta_i}{\sin\theta_r} = \frac{b_1}{b_2} = n_{12}, \tag{3}$$

in which the constant n_{12} is called the index of refraction from medium 1 to medium 2. The index of refraction (n) from vacuum to a material medium is called the index of the medium and, for transparent mediums is always greater than unity (one). When n_{12} is less than unity, as happens when light is refracted as it passes from glass into air, the refracted ray grazes the surface if $\sin\theta_i =$

n_{12}, θ_i being the angle of incidence in the glass. At angles of incidence greater than this critical angle there is total reflection; *i.e.*, light, instead of penetrating into the air, is reflected back into the glass.

Dispersion. Newton found that, when a beam of white light is refracted by a glass prism, it is dispersed, or split, into beams of different colours. This phenomenon is now interpreted in the following way: the velocity of light in glass varies fairly rapidly with its wavelength, whereas its velocity in air varies little; rhus the index of refraction and hence the angle of refraction depend on wavelength. A beam of white light, containing as it does a wide range of wavelengths, is thus dispersed by a glass prism so that light of one wavelength emerges from it in a different direction from light of another wavelength. Because colour depends on wavelength, the emergent light forms a spectrum (see Plate). All material mediums are, to some extent, dispersive (*i.e.*, phase velocity varies with the temporal or spatial frequency).

Group velocity

Wave groups. When a stone is dropped into a quiescent pond, a few waves may be seen travelling out from the point of impact. This group of waves maintains its identity as it is propagated over a considerable distance, although it finally dies away. The velocity of tho group as a whole is called the group velocity. Careful observation shows that the group velocity is less than the phase velocity. Individual waves may be seen to appear at the back of the group, advance through it, and die out as they reach the front of the group. In a nondispersive medium the group velocity is equal to the phase velocity, while in a dispersive medium it may be greater than, less than, or equal. For light waves, the group velocity is almost always less than the phase velocity.

Interference. When two or more wave motions are present at the same place and time, the simplest assumption is that the resultant displacement (ξ_R) is the algebraic sum of the individual displacements (ξ_1, ξ_2, ξ_3, etc.), *i.e.*,

$$\xi_R = \xi_1 + \xi_2 + \xi_3 + \ldots + \xi_N. \qquad (4)$$

Nearly all observations on light are in accord with this equation, which is a statement of the principle of superposition. These phenomena constitute the subject of what is known as linear optics. The possibility that additional phenomena might be observed at high intensities of light has long been accepted, and the use of lasers in the attainment of the necessary high intensities has led to the discovery of frequency doubling and other effects that cannot be predicted from equation (4). These new observations constitute the material of nonlinear optics (see OPTICS, PRINCIPLES OF). Equation (4) is valid for all the phenomena of interference, diffraction, etc., which will be described in this article.

Two waves are said to be coherent if their phase difference remains constant during a period of observation. Figure 2 shows two equal coherent plane waves travelling across the same space, with the wave fronts inclined at a small angle α, ***AB*** representing a surface corresponding to a crest of one wave. (The surface must be assumed to be perpendicular to the page.) C_1 D_1, C, D_2, etc., represent surfaces that correspond to crests of the other wave. The intermediate dotted lines represent troughs. At points such as P_1 (and P_2, P,, . . .), a crest of one wave coincides with a crest of the other and according to the principle of superposition the displacement is twice that of either wave alone. At points Q_1, Q_2, etc., a crest of one wave meets a trough of another; so the displacements being equal and opposite, the resultant is zero. Thus, an observer looking at a plane that is perpendicular to the page and passes through A B sees a series of straight lines through P_1, P_2, P_3, etc., representing large displacement and a series of lines through &, *Q*,, Q„ etc., representing zero displacement.

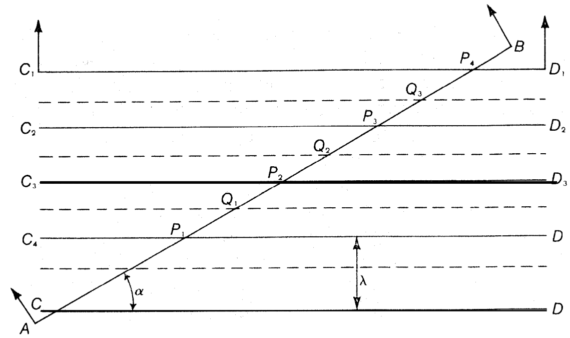

Figure 2: Interference of iwo plane waves *AB* and ***CD*** with directions inclined at an angle ***a***. The crests of ***CD*** are represented as ***C₁D₁, C₂D₂,*** etc., and the troughs are shown as broken lines (see text).

Interference fringes

There are many ways in which coherent beams of light can be made to cross at an angle of about one part in a thousand. The eye (or a low-power magnifier) can be focussed on a plane such as that through ***AB***. The resulting parallel light and dark lines are called interference fringes (Figure 3). From Figure 2 it may be seen that the separation (d) of two bright fringes is ***h/a*** or 1,000 λ if ***a*** = 0.001. When ***a*** has this value, d = 0.5 millimetre for blue-green light and this would imply that ***h*** is about 0.5 × 0.001 or 1/2,000 part of a millimetre (this is usually written 500 nanometres).

Milward T. Rodine

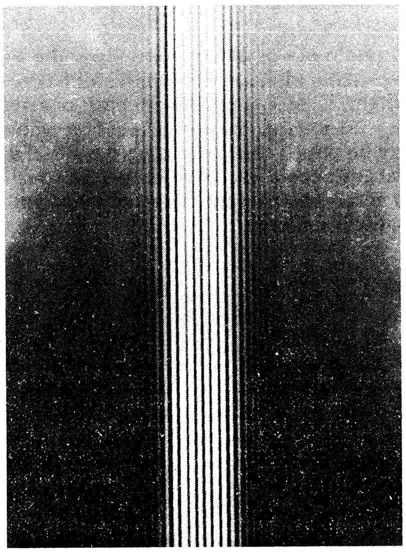

Figure 3: Two-beam interference fringes from Young's double slits or Fresnel's biprism (see text).

In this experiment the spatial periodicity of the light waves (about 2,000 waves per millimetre) has been made to produce fringes with periodicity of about two per millimetre. The spatial periodicity of a light wave is too high for the human eye, and it cannot be magnified directly. Interference methods effectively magnify it so that the resultant fringes can be seen by eye or with a convenient magnification. The following method of producing interference fringes, developed by Thomas Young, is now called Young's experiment.

In the arrangement shown in Figure 4, light of one wavelength passes through a slit S producing semicylindrical waves that are intercepted by two other slits P_1 and *P*,. The two slits P_1 and P_2 act as secondary sources of coherent, semicylindrical waves the combined effect of which is observed on the plane perpendicular to the page and designated ***AB***. In a typical case the separation (a) of P_1 and P_2 is a millimetre and the distances l_1 and l_2 are each about a metre. The slits are a centimetre or so long but are much less than a millimetre wide. They are accurately parallel to one another and, as represented in the drawing, are at right angles to the page. Because the waves from P_1 and P_2 are indirectly derived from the same small source, they are coherent. When they cross plane ***AB*** they are nearly plane because of the large radius, and they intersect at an angle ***a*** equal to 0.001. It may be shown that the intensity (I) for these fringes varies

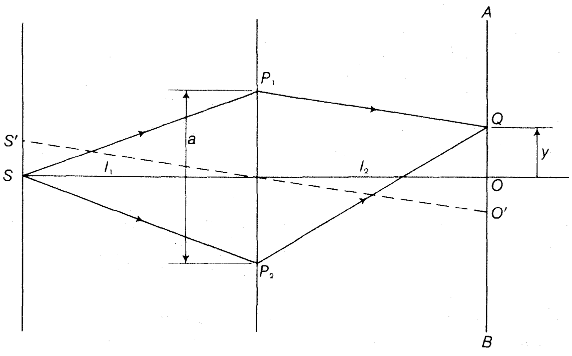

Figure 4: Young's experiment (see text).

from point to point along the line ***AB*** in the way shown in Figure 5 (curve A), which is in accord with the equation

$$I = 2A^2(1 + \cos\varepsilon) = 2I_0(1 + \cos\varepsilon), \qquad (5)$$

in which ***A*** is the amplitude of either wave, I_0 is the intensity of one wave acting alone and the phase difference $\varepsilon = 2\pi ya/\lambda l_2$. Bright fringes are seen in positions for which $\varepsilon = 2\pi p$ or $y = p\lambda/l_2a$ (in this case p is a whole number, which may be positive, zero or negative—0, ±1, ±2, ±3, etc.). Because cos ε varies from -1 to $+1$, I varies from $4I_0$ to zero. The average, in accordance with the law of conservation of energy, is 21.

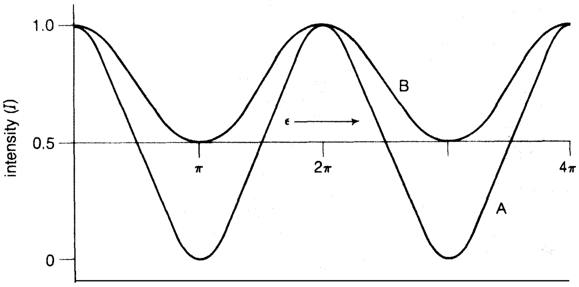

Figure 5: Interference fringes obtained in Young's experiment (see text).

Diffraction. Plane waves that pass through a restricted opening emerge as divergent waves. When the opening is less than one wavelength in diameter the emergent wave is nearly spherical. Whenever a beam of light is restricted by holes or slits or by opaque obstacles that block out part of the wave front, some spreading occurs at the edges of geometrical shadows. This effect, called diffraction, is also obtained with transparent obstacles that cause an irregularity in the wave front. Diffraction can be demonstrated by allowing a parallel beam of light to fall on a grating consisting of an array of equally spaced narrow slits. If the extent of physical separation of two adjacent slits is ***e***, then the path difference between any two adjacent rays emitted in a direction symbolized by e is $e \sin\theta$, and if this path difference is an integral number (p) of wavelengths,

$$e \sin e = p\lambda, \text{ or } \nu_s \sin\theta = pg, \qquad (6)$$

in which ν_s is the spatial frequency ($1/\lambda$) and g is the number of lines per unit width of the grating, then the waves from different slits have phases that differ by angles of $2p\pi$, and they reinforce one another. Thus, when lenses are employed with a grating, sharp lines are obtained for each wavelength at values of θ corresponding to integral values of ***p***. If white light is used, each line is drawn out into a spectrum of wavelengths because the direction of reinforcement depends on the wavelength.

Polarization. In the propagation of waves on a rope or across the surface of a liquid the displacement (as shown in Figure *1*) is in a direction perpendicular to the direction of propagation and the waves are said to be transverse. Sound waves in a gas consist of alternate dilation and compression and the displacement is in the direction of propagation. The waves are longitudinal. If a beam of longitudinal waves is propagated in a vertical direction, there is nothing to distinguish one azimuthal plane from another—everything that is true for an east–west plane is equally true for a north–south plane. With transverse waves the displacement may be in the east–west plane; in that case, there is no component in the north–south plane, and this should manifest itself in the form of a property that depends on the azimuth. Such an effect is called an azimuthal property. An ordinary beam of light from a thermal source does not exhibit any azimuthal property, but experiments show that light can have an azimuthal property and must be represented by transverse waves.

Azimuthal property

If an unsilvered glass plate has an index of refraction equal to *1.5* and the angle of incidence of a beam of light is *57°*, about *15* percent of the light will be reflected from the two glass surfaces of the plate (Figure *6*); this percentage will not be altered when the glass plate is rotated about an axis parallel to the beam of light so as to change the azimuth of the plane of reflection. If a second mirror $(G,)$, parallel to the first (G_1), is used to reflect the beam in the same plane as that of the original reflection, about 30 percent of the light incident on the second plate of glass will be reflected; but if the second plate is turned so as to reflect the light in a plane perpendicular to that of the first reflection—*i.e.*, out of the plane of the page—hardly any light will be reflected. Thus, after the first reflection, the beam of light will have acquired an azimuthal property—it will be reflected more strongly when the transverse displacement is in one azimuthal plane than when in another. Further tests will show that the transmitted light has a complementary azimuthal property; it is more strongly reflected in the perpendicular plane—though the difference is less marked

From R.W. Ditchburn, *Light* (1963); Interscience Publishing, Inc., by permission of John Wiley & Sons, Inc.

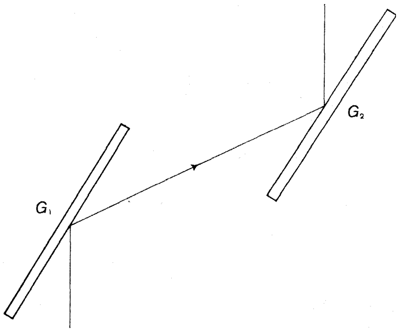

Figure 6: *Malus'* experiment.
Successive reflections at two unsilvered mirror surfaces, G_1 and G_2 (see text).

These results may be understood if ordinary light consists of a mixture of transverse waves with displacements in all azimuthal planes but only one component is reflected from a glass surface when the angle of incidence is 57°. The reflected light is said to be plane-polarized because all of the displacement of the wave is in one azimuthal plane. The transmitted light (about 85 percent of the whole) contains about *50* parts of *a* component that is polarized in a perpendicular plane and about 35 parts of light that is polarized in the same way as the reflected light. It is more strongly reflected in the plane of the page, but because it is only partially polarized, the azimuthal effect is less.

The above experiments do not show whether or not the reflected light has its displacement in the plane of reflection or perpendicular to it. It is a matter of choice whether the reflected light is said to be polarized in or perpendicular to the plane of reflection. Some controversy (and some difference of nomenclature) that formerly led to confusion was removed by the electromagnetic theory (see below). In this theory light is represented by two vectors (quantities that can be represented graphically by arrows that point in the field directions), a magnetic vector in the plane of reflection and an electric vector perpendicular to it. Confusion is avoided by specifying the plane of the electric vector instead of speaking of the plane of polarization.

The azimuthal property of reflected light at the surface of any medium—glass, plastic, a liquid—is most strongly manifested when the angle of incidence is so chosen that its tangent is equal to the index of refraction; that is, it satisfies Brewster's law (after Sir David Brewster, a British physicist), which states that, at the polarizing angle, the incident and refracted beams make an angle of 90° with one another: tan $\theta_i = n$, in which e, is the angle of incidence, called the polarizing angle, and n is the index of refraction of the medium. Nevertheless, there is some azimuthal difference after reflection at any angle except $\theta_i = 0$ or $\theta_i = 90°$. Other ways of producing polarized light are described in a later section.

Optical activity

It is found that the plane of polarization of a beam of polarized light is rotated when the beam is passed through certain mediums (especially sugar solutions). These mediums are said to be optically active. Most mediums do not normally rotate the plane of polarization, but do so when there is a magnetic field in the direction of propagation (the Faraday effect).

The wave equation. The expression for a plane wave, given in equation (1) and showing the relationship between displacement ((), the time span (t), and distance (z) along the wave, may be differentiated twice with respect to t and z; that is, to find out how the displacement changes with position and time. This operation yields the partial differential equation:

$$\frac{\partial^2\xi}{\partial z^2} = \frac{1}{b^2}\cdot\frac{\partial^2\xi}{\partial t^2}, \qquad (7a)$$

in which b is the phase velocity. For a three-dimensional wave the analogous expression is

$$\frac{\partial^2\xi}{\partial z^2} + \frac{\partial^2\xi}{\partial y^2} + \frac{\partial^2\xi}{\partial x^2} = \frac{1}{b^2}\cdot\frac{\partial^2\xi}{\partial t^2}. \qquad (7b)$$

There are many solutions of this basic equation. Some correspond to the sinusoidal plane waves, which have already been considered. Others correspond to groups of plane waves that differ slightly either in direction, or wavelength, or both. Yet another solution of the general wave equation is:

$$\xi = \frac{A}{r}\cos 2\pi(\nu_t t - \nu_s r), \qquad (8)$$

in which r is the magnitude of a radius vector drawn from the origin and A is a constant. This represents spherical waves.

Energy of a beam of light. The energy in a small volume (dV), through which plane waves are passing, is proportional to the product of the square of the amplitude (A), or its energy per unit volume (W), and the small volume; that is, $A^2dV = WdV$. The rate of transport of energy across a surface normal to the direction of propagation is proportional to the product of the energy per unit volume, the phase velocity, and a small area (dS) normal to the direction of propagation, or $WbdS$. For spherical waves, the rate of transport is inversely proportional to r^2, *i.e.*, $(A/r^2)dS$. Because the area of a sphere is $4\pi r^2$ in which r is its radius, this equation implies that the total energy crossing any sphere surrounding a point source is independent of the radius. Thus, inverse-square law for the intensity of radiation at a distance r from a point source is in accord with the law of conservation of energy—the total energy of a wave remains the same even though the wave is spread over a greater area.

Doppler–Fizeau effect. The length of a wave train emitted in one second by a stationary light source is equal to the velocity of light (c) times one second, which in itself is equal to the product of its frequency (ν_t) times its wavelength (λ)—*i.e.*, $c = \nu_t\lambda$. If the source moves away from the observer with a velocity (v) that is small compared with the velocity of light, then the length of the wave train increases so as to be numerically equal to the sum of the two velocities ($c + v$) and the number of waves remains the same. The wavelength h increases to h' by a factor $(c + v)/c$; that is h' $= (1 + v/c)\lambda$. This change was discovered by an Austrian physicist, Christian Doppler, in the 19th century in relation to sound waves and subsequently applied to light waves by Fizeau. It is called the Doppler–Fizeau effect. The Doppler–Fizeau effect is easily observed when part of the light from a gas laser is allowed to be scattered by a moving body and mixed with a little unscattered light. It is known from the study of sound waves that the beat frequency is equal to the difference between the frequencies of the two waves that are mixed. Although the frequency of light waves is extremely high (more than 10^{14} per second), the beat frequency may be a megahertz (10^6 cycles per second), which is easily detected by radio amplifiers, or even a few hundred cycles per second, which the human ear can detect. Thus, just as interference fringes provide a periodic phenomenon in which two light waves combine to produce fringes of low spatial frequency, so the Doppler–Fizeau effect produces beats the temporal frequency of which is a known, but very small, fraction of the temporal frequency of the light waves. In this way the periodicity of light in both space and time is exhibited and measured.

Beat frequency

LIGHT SPECTRUM

It was seen, in the preceding section, that white light can be dispersed into a spectrum by refraction, by diffraction, or by interference. Newton showed that if a suitably oriented slit is used to select a small region of the spectrum, the light that passes through the slit is much more homogeneous than the original white light, and he was unable to observe any further dispersion when passing this light through a second prism. Delicate methods of interferometry nevertheless show that this light is never entirely of one wavelength, however fine the slit, but covers a range (Δλ) of wavelengths. The ratio of the wavelength divided by this range, which measures the purity of the spectrum, may be a few thousand for a spectrum formed by a prism and up to a million for a spectrum formed by a large diffraction grating. It is never infinite, as it would be if Δλ were zero.

The spectrum of a hot body such as the solar photosphere is continuous (every wavelength is represented); but a German physicist, Joseph von Fraunhofer, early in the 19th century observed that the solar spectrum contains numerous dark lines appearing at certain wavelengths, which are attributed to wavelengths originally emitted by inner layers of the Sun but then absorbed by various elements (in gaseous form) in the cooler outer layers (see Plate). Emission spectra produced by electric sparks and arcs contain sharp bright lines which are characteristic of the elements in the electrodes (see SPECTROSCOPY, PRINCIPLES OF).

In monochromatic light, colour and wavelength are associated. Nevertheless, as Newton said, "the rays, to speak properly, are not coloured." Colour is a sensation in the human mind. Light of one wavelength can stimulate the visual system so that a certain colour sensation (*e.g.*, red) is produced. The way in which the visual system analyzes colour is entirely different from the way in which physical instruments form a spectrum (see EYE AND VISION, HUMAN).

There are a number of ways in which spectra are produced in nature. The rainbow is the most striking of these. The primary rainbow is formed by reflection and refraction of light in raindrops. The rays emerging from the drops are spread out, but for any given wavelength there is a minimum angle of deviation and there is a concentration of energy at this angle. For green light the minimum angle of deviation is about 138" and an observer with his back to the Sun sees the bow at an angle of 42°

Primary and secondary rainbows

to the direction of the Sun's rays. Because of the dispersion of water, the angles for different wavelengths are not exactly the same, and the red is seen on the outside and blue on the inside of the bow. A weaker rainbow is formed by rays that have been twice reflected. In this the colours are reversed. Still weaker supernumerary bows are caused by diffraction in droplets. A rainbow may be regarded as a spectrum of the Sun, but the purity is low.

VELOCITY OF LIGHT

The accepted value of the velocity of light *(c)* in vacuum is 299,792.5 ± 0.4 kilometres per second, or 186,282.4 ± 0.2 miles per second (see The Table). The velocity is the same for all wavelengths over the whole range of the electromagnetic spectrum from radio waves to gamma rays. Methods of measurement are of three types: (1) measurement of the time (T) in which a group of waves covers a known distance (*l*); (2) measurement of the frequency (ν_t) and wavelength (h) of monochromatic waves; and (3) indirect methods, such as measurement of the change of frequency or wavelength (Doppler–Fizeau effect) when a beam of light is reflected from a mirror moving with a known velocity.

The Constant c
(in kilometres per second)

	year	value
Derived from measurements of the velocity of light		
Michelson	**1927**	**299,796 ± 4**
Michelson, Pearson and Pease	**1935**	**299,774 ± 11**
Value accepted in 1941	**1941**	**299,773 ± 3**
Bergstrand	**1951**	**299,793.1 ± 0.2**
Bergstrand (mean value)	**1957**	**299,792.9 ± 0.2**
Derived from measurements on radio waves		
Essen (10' MHz)	**1950**	**299,792.5 ± 1**
Froome (2.4 and 7.5 × 10⁴ MHz)	**1951–8**	**299,792.5 ± 0.1**
Value adopted by 12th General Assembly of the Radio-Scientific Union	**1957**	**299,792.5 ± 0.4**
Derived from electrical measurements		
Rosa and Dorsey (ratio of units)	**1907**	**299,788 ± 30**
Mercier (Lecher wires)	**1923**	**299,795 ± 30**

Methods of type (3) have, so far, given an accuracy of only a few percent. Methods of type (2) cannot be used for light waves because the frequency is about 1.5 × 10^{14} hertz and is too high to be measured directly. The remainder of this section will review measurements of the velocity of light by methods of type (1) and compare the results of the best measurements with the results obtained for radio waves by methods (1) and *(2)*.

Astronomical measurements. In 1676 Rømer made careful measurements of the times at which satellites of Jupiter were eclipsed by the planet. The times observed did not agree with those calculated on the assumptions of a constant period of rotation and of instantaneous transmission of light. Starting at a time when the Earth was at its nearest to Jupiter, the apparent period increased and the eclipses became increasingly later than the calculated limes as the Earth receded from Jupiter. Similarly, the period shortened when the Earth was moving toward Jupiter. The observed times were consistent with a finite velocity of light such that the time for it to transverse the Earth's orbit is about 1,000 seconds. Taken with modern values of the size of the Earth's orbit, the derived value of the velocity is 298,000 kilometres per second. It is remarkable that this first measurement was even of the correct order; the most important conclusion was that the velocity of light is finite. An English astronomer, James Bradley (died 1762), obtained a similar value by the so-called aberration method, based on the apparent motion of stars as the Earth travels in its orbit about the Sun.

Early terrestrial experiments. In terrestrial experiments by method (1), the beam of light is periodically marked either by interrupting it at regular intervals or by modulating it (alternately increasing and decreasing its intensity). The marked beam is transmitted to a distant mirror and the return beam passes through the apparatus that interrupts or modulates the outgoing beam and then to a detector. If the time required for transmission to the distant mirror and return is ½, 3/2, 5/2, . . . , times the period of the interrupter (or modulator), then the amount that reaches the detector is small. It is usual to adjust either the path length or the period of the interrupter or modulator until the light registered by the detector is a minimum. In the earlier experiments a mechanical chopper was used as interrupter and the eye was the detector. The later experimenters used electronic modulators and photoelectric detectors.

The apparatus used by Fizeau in 1849 is shown in Figure 7, in which M_1 is a partially reflecting mirror and M_2 is a fully silvered mirror. As the speed of the wheel (which has 720 teeth) was increased from zero it was found that the light was first eclipsed by a tooth when the speed was about 12.6 revolutions per second—*i.e.*, when the time to make the round trip was 560 microseconds (0.00056 second), the length of the double path being 17.3 kilometres (about ten miles). The chief error in the measurement lay in the difficulty of determining the exact speeds at which the light received by the eye at E was at a minimum. Essentially the same method was used by others between 1874 and 1903. The accuracy gradually improved, and it was shown that the velocity is between 299,000 and 301,000 kilometres per second.

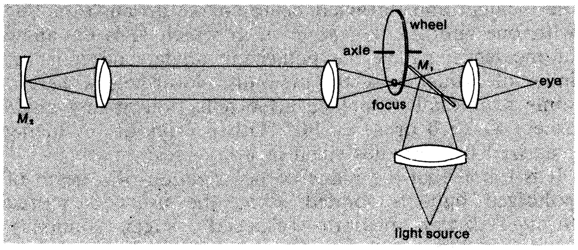

Figure 7: Fizeau's method for measuring the velocity of light.

In 1834 Sir Charles Wheatstone of England suggested a method incorporating a rotating mirror for interrupting the light that was later developed by Arago (1838) and Foucault (1850). It was considerably improved by Michelson, who made measurements over a span of over 50 years from 1879 to 1935.

Use of rotating mirror

Michelson's measurements. Figure 8 shows the arrangement used in 1927. The mirror M_3 **is** a little above the plane of the diagram, and M_3' is a little below. Light from the source *S* passes to one face of the octagonal mirror M_1 and then to M,, M,, and M,. From M_4 it goes to the mirror M_5 at a distance of about 35 kilometres (about 22 miles). It returns via M_6, M_4, M_3', and M' to the octagon. An image of *S* is seen in an eyepiece at E. The octagonal mirror rotated at 528 revolutions per second. It turned through approximately one-eighth of a revolution during the transit of the light. If the rotation were exactly one-eighth of a revolution the image would be undisplaced from the position it had when the mirrors were stationary. In some of Michelson's experiments the speed of rotation was slowly changed until this condition was obtained. In others the speed and distance were fixed, and a small displacement of the image was measured.

From R.W. Ditchburn, *Light* (1963); Interscience Publishing, Inc., by permission of John Wiley & Sons, Inc.

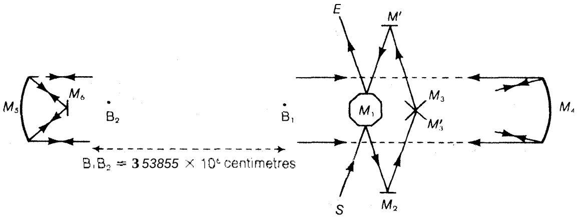

Figure 8: Michelson's Mount Wilson experiment, 1927.

It is difficult to estimate the accuracy of Michelson's

1927 and 1935 experiments, and it is no longer important to do so in view of the more accurate measurements made since 1945. His most important contribution to the measurement of the velocity was the proof that the velocity agreed with Maxwell's prediction to better than one part in a thousand. This gave confidence to those working on applications of the electromagnetic theory.

The electro-optical shutter. This device, based on the Kerr effect (see below), makes it possible to modulate a beam of light at frequencies more than 10,000 times the highest frequency of interruption used by Michelson and obtain values in reasonably good agreement with each other and with Michelson's later work. This method was greatly improved by E. Bergstrand in Sweden, who reduced the random errors by a factor of more than 30 and obtained a value for the velocity of light of 299,793.1 kilometres per second.

Radio-frequency measurements. The velocity of electromagnetic waves of radio frequency in vacuum has been measured by several methods. An English physicist, Louis Essen, measured (1950) the resonance frequency of a cavity resonator (an electromagnetic device) whose dimensions were also determined with high accuracy. Keith Davy Froome, a physicist in England, measured (1952 and 1958) the wavelength in air, corresponding to a known frequency, using a microwave interferometer. The results of these and other measurements are in agreement with those of Bergstrand to within a few parts per million. The velocity of radio waves in vacuum is thus equal, within this accuracy, to the velocity of light. The velocity of gamma rays is also the same, within the much lower accuracy of this last measurement. The Table summarizes the measurements of the velocity constant (*c*) and shows that there is now satisfactory agreement between results obtained over a wide range of conditions.

Recognition of the velocity of light as a fundamental constant

Since the publication of the special theory of relativity (1905), the constant c has been recognized as one of the fundamental constants of modern physics. For this reason, attempts will undoubtedly be made to measure it with even greater precision. The use of lasers may help, but a major improvement will require the establishment of better standards of length and time than those now available (see CONSTANTS, PHYSICAL).

Velocity in material mediums. All measurements of the velocity of light involve interruption or modulation of a beam of light so as to form groups of waves and the velocity measured is the group velocity. The difference in magnitude between the wave velocity and the group velocity of light in air is only about one part in 50,000, but in most glasses and in some liquids it is much larger. Michelson obtained 1.758 for the ratio of the velocity in air to the velocity in carbon disulfide. The inverse ratio of their indices of refraction is 1.64 and the value calculated from this for the ratio of group velocities is 1.745 for wavelength 580 nanometres, close to Michelson's observations. Bergstrand found that the ratio of the velocity in *vacuo* to the velocity in a certain glass was 1.550 ± 0.003. The refractive index of the glass was 1.519, but the ratio of c to the group velocity was 1.547. The experimental results thus agree with those calculated on the assumption that the measured velocity is the group velocity.

II. Interference and **diffraction** phenomena

INTERFERENCE

Quasi-monochromatic waves. A perfectly monochromatic wave, represented by equation (1), has constant amplitude and is not limited in space or in time. Sources of light (other than lasers) emit waves the amplitude of which varies with time. For example, a single undisturbed atom emits a damped wave (Figure 14A). Under favourable conditions the damping is so weak that 10^7 waves are emitted before the amplitude has fallen to half its initial value and the change of amplitude is not significant over a distance of several thousand wavelengths. Wave trains of this type are said to be quasi-monochromatic. Superposition of these waves gives interference when the path difference is not too large.

Photometric summation. Figure 5, curve A, shows the way in which the intensity of light varies from place to place when two monochromatic or quasi-monochromatic waves overlap. The intensity at a point in the region where the waves overlap may be expressed as the sum of two terms: (1) the sum of the intensities of each wave acting alone ($2I_0$ if each alone would give intensity I_0); (2) a term representing the interference of the waves. The second term varies from point to point along the direction of propagation between the values $-2I_0$ and $+2I_0$. Thus the total intensity varies from $4I_0$ (*i.e.*, twice the intensity sum) to zero. Now, when a large number of waves from different sources cross a certain space, the fringes caused by the interference of each pair of waves have their maxima in different places and the overall result is that, at any point, the interference terms are positive nearly as often as they are negative and their total sum is nearly zero. In this case the resultant intensity at any point caused by a number of sources is just equal to the sum of the intensities (at that point) of each source acting alone. This is the law of photometric summation and is used by illumination engineers in calculating the illumination on a surface that receives light from various sources. Interference fringes are obtained only when experimental conditions are such that the interference fringes caused by light emitted from different atoms all have their maxima in the same places (or near to the same places). The interference term then becomes a significant fraction of the summation term. This may be achieved either (1) by using two secondary sources (such as the two slits used in Young's interference experiment), which are both derived from the same primary source, or (2) by using a laser in which the source atoms are stimulated in such a way that the phase relations between them remain constant during the period of observation.

Visibility of **interference** fringes. The distribution of intensity in interference fringes, shown in Figure 5, curve A, represents an ideal that is closely approached in some experiments, but generally the distribution is such that the fluctuations that constitute the fringes are superposed upon a nearly uniform background. Michelson defined the visibility of fringes as the difference between the maximum and minimum intensity of a fringe divided by their sum, or

$$V = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}}, \tag{9}$$

in which V is the visibility, $I_{\max}$ is the maximum intensity, and $I_{\min}$ is the minimum. The fringe visibility is thus always between zero and one. When the minimum intensity is zero, the visibility equals one. Obviously, fringes for which V is less than one are obtained when waves of unequal amplitude are superposed because the weaker cannot, at any point, annul the stronger. It is also found, however, that even when the intensities are equal, the visibility is usually less than one (as shown in Figure 5, curve B). Further consideration of Young's slit experiment leads to recognition of two conditions that must be fulfilled to obtain fringes of high visibility. These relate to their geometrical condition and spectral range.

Two conditions for high visibility

Geometrical conditions. In the arrangement shown in Figure 4, the centre of the fringe system is at a position *O* on the screen, on the straight line from the source slit *S* to a position midway between P_1 and P_2 (the slits are all assumed to be extremely narrow). If slit *S* is moved to *S′* then the centre moves to *O′*. If, instead of moving the slit *S* to this new position, it is gradually widened, the intensity at any point **Q** is found by adding the intensities of waves emitted by atoms behind different parts of the slit. Because the fringes on plane *O′OQ* produced by light from different parts of slit *S* are not in register, there cannot be zero intensity at any point in the pattern. As slit *S* is widened the fringes gradually become blurred—*i.e.*, the visibility falls from unity to zero. If $I_1 = I_2$, no fringes are seen when the width of slit *S* is about equal to the distance (d_f) between successive fringes.

Spectral range. In the case in which the slit *S* is extremely narrow and the light is not all of exactly one wavelength, the path difference and the phase difference will be zero at the centre of the fringe system for all wavelengths, so that for all wavelengths there is maximum intensity at the centre O of the fringe system. Because the separation of the fringes is proportional to the wavelength, the fringes produced by light of different wavelengths gradually go out of register as the path difference is increased. With white light, one clear fringe is seen in the centre. A few coloured fringes are seen on either side because the eye makes a certain degree of separation of the colours. If a filter is used to restrict the light to a band of say 50 nanometres wide, then about ten fringes may be seen on either side, and this number is increased if the wavelength range is further restricted.

These two causes of reduced visibility differ in that the geometrical condition affects all parts of the fringe system equally and the effect of the spectral range increases as the path difference increases. In discussing these phenomena it has been assumed, in accordance with the preceding discussion, that the intensity of light from different atoms obeys the law of photometric summation. It is also assumed that the photometric law applies when different wavelengths are superposed.

Partial coherence

Coherence. When two beams of light can interact so as to produce interference fringes the visibility of which is unity, they are said to be perfectly coherent. When their interaction produces no fringes (but only photometric summation) they are said to be noncoherent or incoherent. An elaborate mathematical theory of coherence that has been developed recognizes that coherence and noncoherence are extreme cases—between them lies "partial coherence." Zernike, who contributed a great deal to the development of the subject, defined the degree of coherence γ_{12} of two sources as equal to the visibility of the fringes obtained in the most favourable circumstances using light from these sources. It has been shown that the visibility of the fringes obtained in Young's experiment depends on the width of the slit S_1, and the following mathematical relation has been derived:

$$\gamma_{12} = \frac{\sin (2\pi ad/l_1)}{2\pi ad/l_1}, \qquad (10)$$

in which d is the width of the slit S_1 (Figure 4). If d is gradually increased from zero, γ_{12} falls from one (for d equal to zero) to zero for d $= l_1 a/\lambda$, a value equal to the separation of the fringes when $l_1 = l_2$. When the width d is further increased, fringes are again seen but they are of low visibility and are reversed (*i.e.*, there is now a dark fringe in the centre).

For the case of a slit source being inaccessible for measurement, its angular width (d/l_1) can be determined by measuring the visibility of the fringes while a, the separation between P_1 and P_2, is varied. Michelson used this method to obtain the angular diameter d of a star (serving as the slit source) from measurements of the visibility of interference fringes formed in the focal plane of a telescope that receives light from two small mirrors mounted in front of the telescope's objective, separated from each other by a distance a.

The concept of coherence that has been applied to light from two pinholes may be extended to a beam of light considered as a whole. A roughly parallel beam of light is incident on a thin sheet of metal normal to the direction of propagation. Then two pinholes may be made in the sheet at A and B (Figure 9) and the visibility of the resulting fringes measured so as to obtain the mutual coherence γ_{AB}. If A and B are initially coincident and are slowly separated then γ_{AB} falls gradually from one to zero. It is possible to define a region of coherence around any point A such that if point B lies within this region the coherence is good ($\gamma_{AB} > 0.7$). Similarly, by devices such as that described in the next section it is possible to measure the mutual coherence between A and a point A' that is, as it were, downstream from A and to define a "coherence length" I, such that coherence is good when $AA' < l_c$. When, (1) the region of coherence extends across the whole beam of light, and (2) the coherence length is large, the beam is said to be highly coherent because the mutual coherence between any two points such as B and A' is high. What qualifies as a "large coherence length" depends on the type of source and the conditions of the experiment; ten centimetres is a large coherence length for the kind of source considered in the next section, but a well-stabilized gas laser may give a beam with a coherence length of many metres.

Coherence length

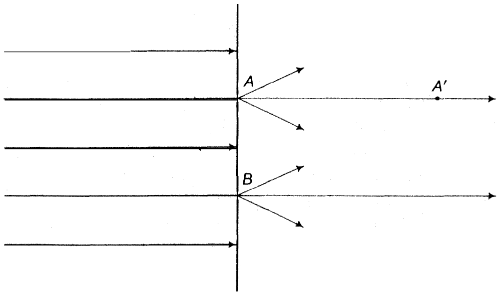

Figure 9: Two pinholes in an opaque sheet to illustrate mutual coherence between points A, A', and *B*.

In the wave equation for light already cited, the displacement and phase angle, represented by the variables ξ and ϕ, were used to specify a wave motion, but, for light, these quantities are not observable nor can they be inferred from any observations—because of the high frequency of the wave motion. The coherence γ_{12} and the phase difference, however, are observable quantities that characterize sources and beams of light. This makes them important both in theory and in practice.

Two-beam interference. In the Michelson interferometer, shown in Figure 10, the incident wave W is divided at the beam splitter BS so that part of the light is transmitted and part is reflected. After reflection at M_1 and M_2 the two parts form the wave fronts W_1 and W_2. These are copies of W, and, because corresponding points are superposed, coherence is obtained even with an extended source. The light from source S, selected by the filter at FF', is quasi-monochromatic. The plane R represents the image of M_2 that would be seen by reflection in BS. The phase differences between W_1 and W_2 are the same as if W, had been reflected from R, which is called the reference plane. M_1 may be traversed normal to itself and may also be tilted with respect to the reference plane. A compensating glass plate C having the same thickness as BS is used so that both wave fronts will pass through a total of three thicknesses of glass.

From R.W. Ditchburn, *Light* (1963); Interscience Publishing, Inc., by permission of John Wiley & Sons, Inc.

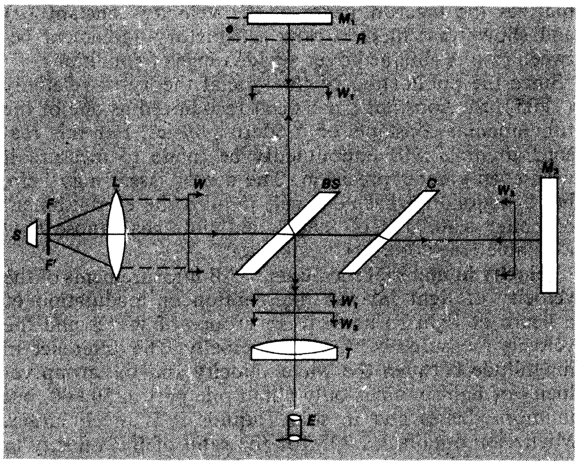

Figure 10: The Michelson interferometer.

Fringes will be formed when M_1 is adjusted to be exactly parallel to R and separated from R by a small distance e. For a hollow cone of rays, each ray will be incident on M_1 and on R at an angle 8. After passing through the instrument on their return trip, these rays will be focussed into a circular ring in focal plane FF' of the lens L. At each point on this ring two waves will be superposed and their path difference will be $2e \cos 8$. Bright rings are obtained for values of θ such that 2e $\cos \theta = p\lambda$, in which p is an integer. The appearance of these fringes is similar to that of Newton's rings (see Plate). These fringes are known as fringes of equal inclination because any one ring corresponds to a set of rays that all have the same inclination, θ, to the mirror M_1. They are conveniently observed by focussing an eyepiece E on the plane F. Because the lens T and the eyepiece E constitute a telescope focussed for an infinite distance, the fringes are said to be localized at infinity.

The apparatus may also be adjusted so that the mirror M_1 is inclined to R, the image plane of mirror M,, and nearly in coincidence with it. The incident light is rendered nearly parallel and normal to plane R. If the telescope is removed, straight line fringes can be seen by an observer who focusses his eye on the region between M_1 and R. A bright fringe is the locus of points for which $2l_p =$ ph. These fringes are called fringes of equal thickness.

Fringes of equal thickness may be formed by reflection at the two glass surfaces bounding an air film between two glass plates (Figure 11). Strictly speaking, this arrangement does not give two-beam interference because multiple reflections occur, as shown in the figure. Only the two beams A and B, however, need be considered for present purposes. Beams like B' and C', caused by multiple reflections, are weak, and unless the glass plates are fairly thin and of high optical quality, fringes formed by beams reflected from the outer surfaces of the glass plates are close together and are of poor visibility. If the arrangement is such that one of the plates is truly planar and that the other is spherical, as is the case for a convex lens lying on a glass plate, the resulting fringes of equal thickness are circles centred at the point of contact. They are known as Newton's rings (see Plate). In this situation, in which one surface is plane and the other is not, the fringes form a contour map of the nonplanar surface. They are then called contour fringes. This is a useful method for testing the flatness of a surface and determining the location of irregularities.

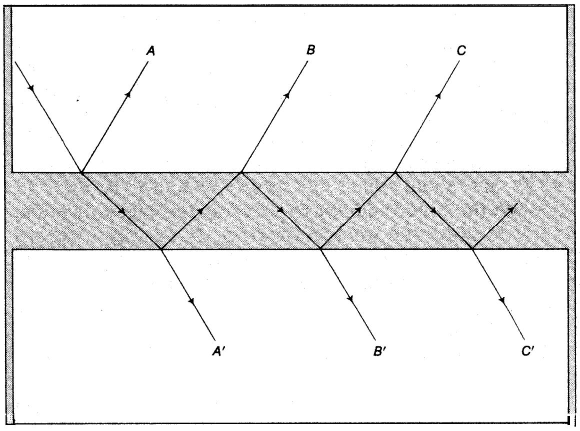

Figure 11: Interference in a thin film of air between two pieces of glass. The rays A, B, C, etc. interfere with each other, as do rays A', B', C', etc.

Newton's rings

Multiple-beam interference. If the two inner surfaces of the plates shown in Figure 11 are coated so as to make them reflect 80 percent or more of the incident light, then the resulting interference pattern will be caused by the superposition of many beams. Figure 12 shows an arrangement for producing the fringes of constant inclination by multiple beam interference. The amplitudes of successive beams are proportional to r, r^2, r^3, etc. (r is the ratio of the intensity of the reflected light to that of the incident light for one reflection). The phase differences are ϵ, 2ϵ, 3ϵ, etc., in which $\epsilon = (4\pi e \cos\theta)/\lambda$. These fringes are much sharper than those obtained with two-beam interference (see Plate).

With a large number of beams the intensity is extremely high when they are all in phase ($\epsilon = 0$), but, even when the phase difference between any two successive beams (*e.g.*, the first and the second) is quite small, the phase difference between the first and say the thirtieth beam is so large that the later beams in the series are in opposition to the earlier beams. Thus the intensity is relatively small except when the value of ϵ is close to one of the values $2p\pi$ (in which p is an integer). Multiple-beam fringes of constant inclination were used by Charles Fabry and Aifred Perot in France for resolution of spectral lines having only small differences of wavelength. Multiple-beam fringes of constant thickness have been used by an English physicist, Samuel Tolansky, to detect surface irregularities down to less than a nanometre.

Wave groups. If two pendulums that have frequencies ν_t per minute and $(\nu_t + 1)$ per minute are started together, they will gradually go out of step; after half a minute they will be moving in opposite directions and after a minute they will be together again. Over a long time they will move together once every minute. In a similar way, when two waves of slightly different frequency are moving in the same direction, they are sometimes in phase and sometimes out of phase so that the resultant is sometimes large and sometimes small, as shown in Figure 13. Two waves may be considered for which the spatial frequencies are ν_s and (v, + $\Delta\nu_s$) and temporal frequencies ν_t and $(\nu_t + \Delta\nu_t)$. The fluctuation represented by the envelope (dotted line in Figure 13) is called the beat wave. It has a temporal frequency equal to the difference $(\Delta\nu_t)$ of the temporal frequencies of the constituent waves and a spatial frequency $(\Delta\nu_s)$ equal to the difference of the spatial frequencies. It is therefore propagated with a velocity $U = \Delta\nu_t/\Delta\nu_s$. Many physical problems involve groups of waves that include a range of frequencies. It is found that, even in a dispersive medium, a group is propagated over a considerable distance as a recognizable unit. The velocity of this recognizable group is $U = d\nu_t/d\nu_s$.

From R.W. Ditchburn, *Light* (1963); Interscience Publishing, Inc., by permission of John Wiley & Sons, Inc.

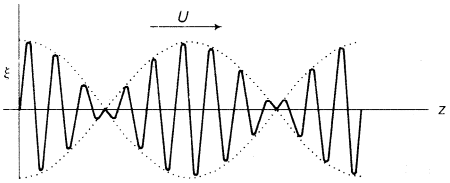

Figure 13: A simple beat wave of amplitude ξ moving with velocity U (see text).

Velocity of groups of waves

There is a certain kind of wave group for which the variation of the displacement with distance (z) along the path of propagation may be represented by the expression $h(z) \cos \nu_0 z$, in which $h(z)$ is a function that varies with z much more slowly than $\cos \nu_0 z$—*e.g.*, in Figure 13, $h(z)$ would be the function represented by the dotted line, and v, is the spatial frequency of the individual waves represented by the full line. These waves are called modulated waves. If $h(z)$ varies extremely slowly with z, the modulated wave is quasi-monochromatic in the sense described above; *i.e.*, it departs little (over distances long enough to contain many wavelengths) from a monochromatic wave. A modulated wave is completely described when $h(z)$ and ν_0 are known. It is also completely described when the amplitudes and phases of the various waves that make up the group are known. These are given by a function α dependent on the frequency ν_s, $\alpha(\nu_s)$. Because $h(z)$ and $\alpha(\nu)$ both describe the same wave group, there must be a relation between them. A mathematical theorem of a French mathematician, Jean-Baptiste-Joseph Fourier, gives this relation, making it possible to calculate either $h(z)$ or $\alpha(\nu)$ when the other is known. The average density at z is equal to $W(z)$, which is proportional to $(h[z])^2$. The energy per unit frequency range near ν_s is $G(\nu_s)$, which is proportional to $(\alpha[\nu_s])^2$.

When $h(z)$ varies very slowly with z, $\alpha(\nu)$ is large for a range of ν close to ν_0 and falls rapidly to near zero outside this range, as shown in Figure 14B. If this range in which $G(\nu_s)$ is large is ν_R, and if l_R represents a range of z over which $h(z)$ varies very little (as shown in the Figure), then it is found that ν_R and l_R are inversely proportional to one another and that their product is of the order of magnitude of unity. This represents the fact that the longer the wave train the more closely its properties agree with those of the ideal monochromatic wave, which is infinitely long and has a precisely defined frequency.

From (A) R.W. Ditchburn, *Light* (1963); Interscience Publishing, Inc., by permission of John Wiley & Sons, Inc.

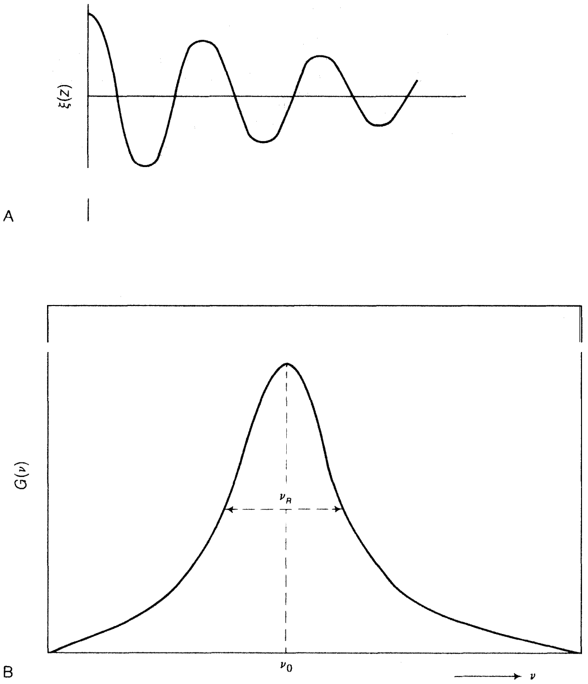

Figure 14: Damped waves.
(A) Amplitude, $\xi(z)$, as a function of distance, z. (B) Energy, $G(\nu)$, as a function of frequency, ν. The figure shows strong damping. For light emitted by free atoms, l_R would encompass 10' waves or more and ν_R would be correspondingly smaller (see text).

Undisturbed atoms emit exponentially damped waves the length of which is usually 10^7 waves or more so that ν_R is a small fraction of ν_0. Collisions increase the damping by a factor that is proportional to the pressure. The observed radiation is also modified by the Doppler–Fizeau effect, because the atoms that emit the light do not all have the same velocity. This increases the range $\Delta\nu_R$. Even when the effects of collision damping and Doppler–Fizeau effect are combined, the value of l_R for the wave trains emitted in low pressure electrical discharges is still about 10^5 wavelengths, and most of the energy is confined within a frequency range of order 10^{-5} ν_0 (corresponding to a wavelength range of less than 0.01 nanometre). These quasi-monochromatic waves are called wave groups. The light emitted by high-pressure lamps or by luminescent solids extends over a much wider range of frequency, and wave-group theory has little useful application to problems concerning non-monochromatic light from these sources.

Propagation of wave groups from stars

Wave groups in a dispersive medium. In vacuum, all components of the group have the same phase velocity, and therefore the phase relations between different members of the group are constant. A group advances as a unit without any change of the modulation function $h(z)$. In a dispersive medium, the phase relations change and $h(z)$ changes as the wave train advances, but this change is slower than might be expected. Over considerable distances the group is propagated as a recognizable whole with the group velocity U. The change of of $h(z)$ is small for passage through a gas and also for groups (for which ν_R is small) that represent sharp spectral lines. Thus these wave groups are propagated virtually unchanged through an optical instrument or, if they arrive from the Sun or stars, through the Earth's atmosphere.

In Young's experiment, Figure 4, the fringes have maximum visibility at the position O, corresponding to zero path difference and zero phase difference for all wavelengths. If a thin sheet of mica is inserted in front of slit P_1, the centre (or position of maximum visibility) is displaced upward. It was at one time thought that the new centre would be found at the point corresponding to zero phase difference for the mean wavelength in the wave group—*i.e.,* the point calculated for equal times from slits P_1 and P_2 allowing for the fact that the phase velocity in mica is less than that in air. This did not agree with experimental observation. It was found that the new centre is situated at the position where the times from P_1 and P_2 are equal when the group velocity is used to calculate the time required to traverse the piece of mica. At this position the wave train from P_1 exactly overlaps the wave train from P_2. At any other position, part of each wave train cannot take part in the interference because it does not coincide with any part of the other wave train. This light that cannot interfere forms a uniform background and so reduces the visibility of the interference fringes.

If white light is used and a fairly thick piece of mica is inserted, no fringes are obtained. This is because the wave train has changed shape so much in passing through the mica that it can no longer match the wave train that has travelled through air.

Michelson, using the apparatus shown in Figure 10, studied the decrease in visibility of interference fringes as the path difference between the two wave trains is increased. The reduction in visibility as the path difference Increases may be assigned either (1) to the fact that the parts of the wave trains that overlap are decreasing or (2) to the increasing difference between the positions of the bright fringes for different wavelengths in the group. As was seen above, the length of the wave trains and the range of the wavelength are inevitably linked, and so these alternatives (1) and (2) do not constitute two different theories. They are just two different ways of visualizing how wave trains (or wave groups) interfere.

DIFFRACTION

Theory of diffraction. Huygens assumed that every point on a wave front may be regarded as a source of spherical wavelets the envelope of which is the position of the wave front at a later time. Huygens was thus able to account for rectilinear propagation and for the laws of reflection and refraction. Fresnel added the hypothesis that the wavelets can interfere and this led to a theory of diffraction. Figure 15 shows how a coherent, monochro-

matic wave from a point source P falls on the screen S, which is opaque except for an aperture dS. Fresnel assumed that the amplitude ($d\xi_Q$) of the wavelet at Q, originating from a small area dS, is:

$$d\xi_Q = \alpha \frac{A}{r} f(\chi) dS, \tag{11}$$

in which A is the amplitude of the incident wave, α is a constant, r is the distance from dS to Q, and $f(\chi)$ is a function of χ, the inclination factor; this factor was introduced by Fresnel because he believed that the effect of the element dS would be greater in the forward direction ($\chi = 0$) than in an inclined direction. The total effect at Q was obtained by superposing the wavelets from all parts of the aperture, allowing for phase differences caused by a variation of r and also for variation of the inclination factor, $f(\chi)$. Fresnel developed an ingenious method of dividing S into a series of zones of equal area and calculating the total effect as the sum of a simple series. This method applies only to circular apertures and obstacles and then only to points on the axis of symmetry, but Fresnel also developed integrals that are more generally applicable.

Fresnel zones

Fresnel predicted that there should be a bright spot at the centre of the shadow of a circular obstacle. The experimental verification of this unexpected result gave confidence in Fresnel's wave theory of diffraction.

Fraunhofer diffraction. When the source and pattern screen are sufficiently far from the slit, the phase differences corresponding to different parts dS of the slit opening vary linearly with x and y coordinates in the plane of the aperture (Figure 16). This situation is obtained when two spherical lenses L_1 and L_2 are introduced with source P at the focus of L_1 and Q in the focal plane of L_2. Spherical waves emanating at the focus of a lens are rendered plane wherever they encounter the lens. Plane waves are made spherical by a lens. They have the same radius of curvature as the focal length of the lens. The wave falling on S is a plane wave, and the total effect at Q may be regarded as caused by a plane wave leaving S. The same result is obtained if L_1 and L_2 are replaced by a single lens (situated near S) that forms an image of P at Q_0. This is known as far-field diffraction, or Fraunhofer diffraction, and is thus distinguished from near-field, or Fresnel, diffraction. It should be understood, however, that there is only one physical theory of diffraction that is derived from the ideas of Huygens and Fresnel. Fraunhofer diffraction is of great practical importance especially in regard to the performance of optical instruments.

Groups of waves with different directions. When a plane wave is incident upon a slit as shown in Figure 16 (so that its width is limited), the emergent light may be represented by a group of plane waves. All the waves of this group have the same spatial frequency but differ in regard to direction of propagation. It is possible to define a range of angles (in the plane of the page) within which most of the light is found. If this range is θ_R and the width of the slit is w, then it is found that sin θ_R is inversely proportional to w; *i.e.*, the narrower the slit, the greater is the angular spread—sin θ_R is roughly equal to λ/d. Using Fourier's theorem it is possible to derive an equation that gives the amplitude and phase of the light diffracted in any direction as a function of the width of the slit. Extension of the calculation to diffraction by apertures or obstacles of any shape involves more lengthy mathematics but no new physical principle.

Angular power spectrum. The energy diffracted in any direction is proportional to the square of the corresponding amplitude. This energy expressed as a function of the angles that define the direction is called the angular power spectrum. It may be measured and is found to agree with that calculated when the width of the slit (or, more generally, the shape and size of the apertures) is known. There are many problems in which it is desired to carry out an inverse calculation—*i.e.*, to calculate the shape and size of the apertures from measurements of the angular power spectrum. Unfortunately, this is not, in general, possible because measurement of the angular power spectrum does not give the phase of the diffracted light. It is found, however, that measurement of the angular power spectrum yields a function (known as the auto-correlation function) of the size and shape of the obstacles or apertures responsible for the diffraction. In X-ray analysis, this function gives important information about symmetry. A complete picture of the crystal may often be obtained by combining calculations from the angular power spectrum with information derived from other sources.

It is found that when diffraction is due to a number of apertures (or obstacles) that are similar in size, shape, and orientation, the angular power spectrum (G) is the product of two factors, F and f, in which F (called the form factor) depends only on the properties of the individual aperture and f (called the structure factor) depends only on the arrangement or spacing of the elements. When the apertures are irregularly arranged, f is just equal to N (the number of apertures). Thus the diffraction halos produced by an irregular distribution of small similar objects have the same intensity distribution as the pattern for a single particle. This principle is used in a device called an eriometer to determine the size of blood corpuscles and may also be used to calculate the average size of the small particles that cause a halo around the Moon.

Diffraction by similar apertures

When N similar elements are arranged in a regular pattern, the structure factor may vary from zero to N^2. A diffraction grating (a plate having parallel lines engraved across its surface) with N lines is such a pattern, and, for any of the directions θ_p defined by equation (6), the light from all elements (lines) is in phase; the amplitude is N times that given by a single element, and thus the energy and the structure factors are proportional to the total number of lines squared—*i.e.*, $f = N^2$.

Limits of resolution. Diffraction spreads the light in optical images; so that if two objects are too close to each other, the gap between them cannot be distinguished. The distribution of intensity with radius in the image of a point source is shown in Figure 17. Rayleigh showed, theoretically and experimentally, that the images of two point sources are just resolved when their separation is such that the centre of the pattern due to one image falls on the first minimum of the pattern due to the other (Figure 18). This implies that a telescope with a perfect objective of diameter D can just resolve two stars whose

angular separation is 1.2 λ/D. Qualitatively, this agrees with a calculation that shows that most of the energy in the diffraction pattern of an aperture of width d lies within an angular range $\pm\lambda/d$.

The angular separation of the maxima resulting from light of two wavelengths λ and λ + AX in a spectrum formed by a diffraction grating is obtained by differentiating equation (6), resulting in $\Delta\theta = p\Delta\lambda/e$ cos θ. These maxima are just resolved if Ae = λ/M, in which M is the width of the beam diffracted by the grating. For a grating of N lines, this width is Ne cos θ, and the resolving power R = $\lambda/\Delta\lambda = pN$. A grating ten inches wide, for example, with 10^4 lines per inch and p = 10, has a resolving power R = 10^6.

The limit of resolution for a microscope depends on conditions of illumination and is at best about half a wavelength ($\lambda/2$), or about 250 nanometres for visible light.

III. Polarization and electromagnetic theory

POLARIZED LIGHT

Inter-
ference of
polarized
light

Interaction of plane-polarized beams. Fresnel and Arago, using an apparatus based on Young's experiment (Figure 4), investigated the conditions under which two beams of plane polarized light may produce interference fringes. They found that: (1) two beams polarized in mutually perpendicular planes never yield fringes; (2) two beams polarized in the same plane interfere and produce fringes, under the same conditions as two similar beams of unpolarized light, provided that they are derived from the same beam of polarized light or from the same component of a beam of unpolarized light; (3) two beams of polarized light, derived from perpendicular components of the same beam of unpolarized light and afterwards rotated into the same plane (*e.g.*, by using some device such as an optically active plate) do not interfere under any conditions.

Result (1) is to be expected because two displacements in perpendicular planes cannot annul one another, and result (2) is also easily understood. Result (3) shows that mutually perpendicular components of unpolarized light in a beam are non-coherent. Their phase difference varies in time in an irregular way. Unpolarized light has a randomness, or lack of order, as compared with polarized light (implying an entropy difference). This order (or lack of order), rather than the azimuthal property, is the most fundamental difference between polarized and unpolarized light. Perfectly monochromatic light is perfectly coherent and completely polarized.

Superposition of polarized beams. Two coherent beams of plane polarized light may be thought of as propagated in the *Oz* direction, one with its vector along Ox and the other with the electric vector along *Oy*; *i.e.*, the two vibrations are at right angles to each other as well as to the direction of propagation (Figure 19). If the beams have amplitudes *a*, and a_y and phases ε_x and ε_y, then, in general, the resultant vibration (R_1, R_2, and R,) may be represented in magnitude and polarization by a vector, or arrow, the tail of which touches the axis of propagation *Oz* while the point moves round the ellipse (Figure 19). It goes round once when the phase angle ϕ (see equation [1]) changes by 2π—*i.e.*, at any given place when *t* changes by y or for any one time when *z* changes by λ. The beam is said to be elliptically polarized. If the phase difference is $\pi/2$, then the axes of the ellipse are equal to *a*, and a, and are along O_x and O,.

Elliptically polarized light may be regarded as the most general type of polarized light. If the amplitudes of the two waves are equal, *a*, = *a*,, and the phase difference is still $\pi/2$, the ellipse becomes a circle and the light is said to be circularly polarized. If the phase difference ε_{xy} is not equal to $\pi/2$, the resultant is still elliptically polarized light, but the axes of the ellipse no longer coincide with the axes of coordinates. If the phase difference $\varepsilon_{xy} = 0$ or π, the ellipse shrinks to a straight line and the light is plane-polarized. If the representative vector, when viewed by an observer who receives the light, rotates in a clockwise direction, the light is said to be right-handed (or positive) elliptically polarized light. The opposite sense of rotation corresponds to left-handed (or negative) elliptically polarized light.

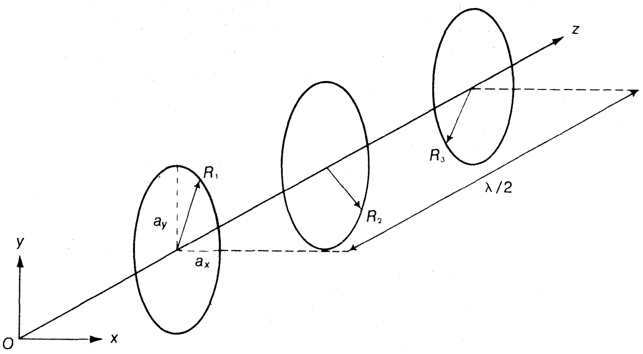

Figure 19: Progression of elliptically polarized wave (see text).

In the above analysis, elliptically polarized light is regarded as the resultant of two beams plane-polarized in perpendicular planes. Conversely, it is possible to regard plane-polarized light as the resultant of two beams of elliptically (or circularly) polarized light of the same wavelength, provided that the ellipses are similar in orientation and eccentricity, but one beam is right-handed and the other left-handed.

Double refraction. In the 17th century Bartholin showed that a ray of unpolarized light incident on a plate of calcite, unlike glass or water, is split into two rays, as shown in Figure 20. One ray, called the ordinary ray, is in the plane containing the incident ray and the normal to the surface. If the angle of incidence is varied, this ray is found to obey Snell's law of sines, equation (3). The other ray, called the extraordinary ray, is not in general coplanar with the incident ray and the normal; also, for it, the ratio of sines is not constant. The fact that Snell's law is not obeyed in certain directions implies that the velocity of light in such a medium, called anisotropic, depends on the direction of travel in it. The two rays are polarized in mutually perpendicular planes. This is known as double refraction, or birefringence.

Bire-
fringence

In order to apply Huygens' method of constructing wave fronts (see above Theory of diffraction), it is necessary to assume that, in an anisotropic medium, the wave surface from a point source consists of two sheets, or surfaces (Figure 21). The observation that one ray obeys both laws of refraction implies that one sheet must be a sphere—like the wave surface in an isotropic medium. Huygens assumed that the other sheet is an ellipsoid of revolution that touches the sphere either internally (Figure 21A) or externally (Figure 21B). There is one velocity of propagation for the direction defined by the line through the two points of contact (called the optic axis) and two velocities for any other direction corresponding to light polarized in two mutually perpendicular planes.

Crystals for which the wave surface has the form shown

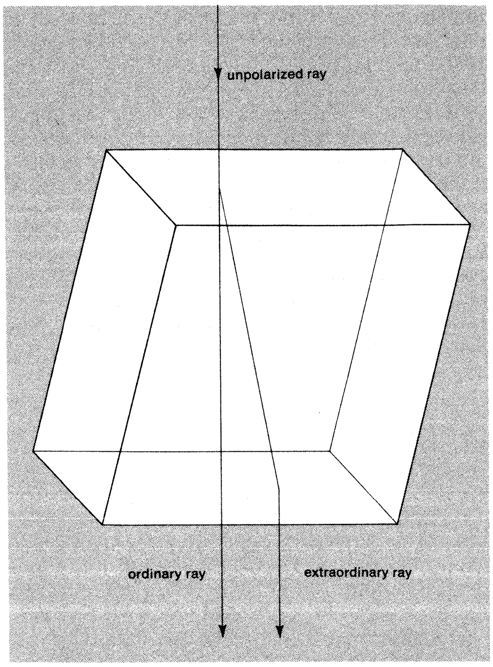

Figure 20: Double refraction showing two rays emerging when a single light ray strikes a calcite crystal at right angles to one face (see text).

in Figure 21A are said to be positive uniaxial crystals, and Figure 21B refers in a similar way to negative uniaxial crystals. Huygens thought all crystals were uniaxial, but later observations showed that the general form of the wave surface is more elaborate and is biaxial.

From R.W. Ditchburn, *Light* (1963); Interscience Publishing, Inc , by permission of John Wiley & Sons, Inc.

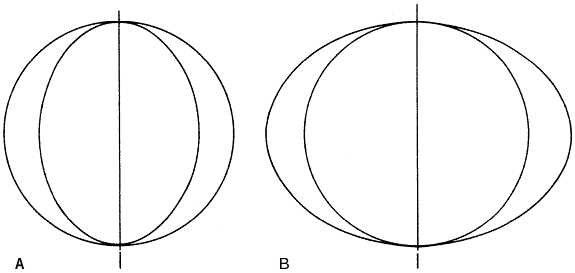

Figure 21: Wave surface for (A) positive and (B) negative uniaxial crystals.

When a parallel beam of plane-polarized light is incident normally upon a thin crystal plate and the crystal is rotated about an axis normal to the plate, two orientations will be found in which a single beam of plane-polarized light emerges; for one orientation, the light is called the ordinary ray, and for the other orientation, the extraordinary ray. Two lines may be drawn on the plate (or on its mount) to indicate the direction of the electric vector of the incident beam when the orientation is such that plane-polarized light emerges. The directions of these lines are called privileged directions for the given anisotropic plate; they are perpendicular to one another.

When light waves pass through an isotropic plate of thickness d, the phase change is $2\pi nd/\lambda$ (n is the index of refraction). For an anisotropic plate there are two indices, n_o and n_e, corresponding to the two privileged orientations, and there are corresponding phase changes, $2\pi n_o d/\lambda$ and $2\pi n_e d/\lambda$. If a beam of light, polarized in some plane other than one of the two privileged orientations, is incident on the plate, it may be resolved into two wave components (lying in two mutually perpendicular planes) that emerge with a phase difference ε_{oe} equal to $2\pi(n_e - n_o)d/\lambda$. The phase difference ε_{oe} is called the retardation of the plate. When the retardation ε_{oe} is equal to $\pm\,\pi/2$, the plate is called a quarter-wave plate, and when ε_{oe} is equal to $\pm\,\pi$, it is called a half-wave plate.

The maximum difference of $(n_e - n_o)$ for calcite, a crystal that is strongly birefringent, is about 0.17. Quarter-wave plates are often made by splitting sheets of mica. Inasmuch as the relevant difference of indices is about 0.004, a mica quarter-wave plate is about 60 wavelengths, or 0.03 millimetre thick.

When a parallel beam of plane-polarized light is incident normally on a quarter-wave plate, the emergent light is circularly polarized if the plane of the electric vector bisects the angle between the privileged directions. Otherwise the emergent light is elliptically polarized, the axes of the ellipse being parallel to the privileged directions of the quarter-wave plate. In a similar way, a suitably oriented quarter-wave plate may be used to convert elliptically polarized light to plane-polarized light.

Induced birefringence effects

Many substances that are normally isotropic become weakly birefringent when subjected to shear stress (photoelastic effect; see Plate). Birefringence is also induced by an applied electric field (Kerr effect). A restricted class of crystals that are normally birefringent shows a large change in birefringence when an electric field is applied. Weak birefringence is produced by an applied magnetic field.

Production of polarized light. Unpolarized light may be separated into two components, polarized in perpendicular planes, either (1) by reflection or (2) by refraction. A single reflection at the polarizing angle produces a well-polarized reflected beam of low intensity (*i.e.*, most of the waves are polarized in one plane) and a strong transmitted beam that is only partially polarized. A pile of glass plates provides many surfaces for reflection and thus gives a much stronger reflected beam that is still well polarized; it also considerably improves the degree of polarization of a transmitted beam.

A Nicol prism (Figure 22) is made by cutting a calcite crystal in a suitable plane relative to the crystal axes and cementing the two parts together with Canada balsam. The critical angle for total reflection is less for the ordinary ray than for the extraordinary ray. The crystal is cut at an angle (relative to the crystal axes) such that, for a cone of incident rays of divergence about 24°, the ordinary ray is totally reflected, whereas the extraordinary ray is transmitted. Both rays are almost completely polarized. A prism of this type with air instead of Canada balsam as the separation film was devised by Foucault for polarization of ultraviolet radiation.

From R.W. Ditchburn, *Light* (1963); Interscience Publishing, Inc., by permission of John Wiley & Sons, Inc.

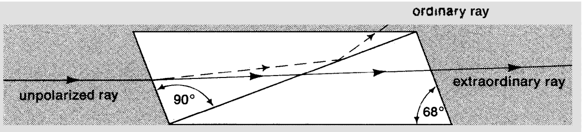

Figure 22: Nicol prism (see text).

Many crystalline substances have different absorption coefficients for the ordinary and extraordinary rays, but the difference is not large enough to provide a useful method of polarization. A series of artificial materials that polarize by absorption has been developed. Complex crystals are produced in a plastic matrix and oriented by stretching. One material of this type, called Polaroid H, transmits about 80 percent of plane-polarized light with the electric vector in one plane and less than 1 percent if the vector is in a perpendicular plane. This type of film offers the most convenient and inexpensive method of obtaining an intense beam of light that is nearly 99 percent plane-polarized.

Analysis of polarized light. Any polarizer has a preferred plane such that if an incident plane-polarized beam has the electric vector in this plane, a high intensity is passed, whereas the device rejects light polarized with the electric vector in a plane perpendicular to the preferred plane. This property implies that any polarizer may be used as an analyzer to test whether or not a given beam of light is plane-polarized. The analyzer is rotated in the beam and if the intensity I of the transmitted light is zero for some orientation, the beam is plane-polarized with the electric vector in a plane perpendicular to that for which the intensity is zero. If there is a position for which the analyzer gives a non-zero minimum, then either (1) the light is elliptically polarized or (2) it is partially polarized. Also if the intensity is not affected by rotating the analyzer, then the light is either (3) unpolarized or (4) circularly polarized. These ambiguities between (1) or (2), and (3) or (4), may be removed and the analysis of a mixture may be completed by using an analyzer and a quarter-wave plate together.

Stokes parameters and Poincairé sphere. Any mixture of different kinds of polarized light may be reduced to an equivalent amount of one kind of polarized light characterized by the orientation and length of axes of an ellipse. It may, of course, happen that the ellipse degenerates to a straight line or a circle. An alternative way of characterizing polarized light is by means of the Stokes parameters, named after a British physicist, George Gabriel Stokes, and defined as follows:

$$S_0 = \langle a_x^2\rangle + \langle a_y^2\rangle; \qquad S_1 = \langle a_x^2\rangle - \langle a_y^2\rangle;$$
$$S_2 = 2\langle a_x a_y \cos \varepsilon_{xy}\rangle; \qquad S_3 = 2\langle a_x a_y \sin \varepsilon_{xy}\rangle,$$

in which the polarized light is regarded as the resultant of two beams polarized with vectors *a*, and *a*, along the coordinates Ox and Oy, and ε_{xy} is the phase difference as in the section above. The brackets <> indicate time averages. If the light is completely polarized, then the square of S_0 is equal to the sum of the squares of the other three parameters. This relation was used by a French mathematician, Henri Poincairé, to produce an elegant representation of the properties of polarized light by means of a sphere, which is known as the Poincairé sphere. Each point on the sphere represents a different kind of polarized light; *e.g.*, the two poles represent right- and left-handed circularly polarized light, points on the equator represent plane polarized light; other points on the sphere represent different kinds of elliptically polarized light. The Stokes parameters constitute a matrix representation of polarized light. This kind of representation makes available certain powerful mathematical methods (which have been developed in other connections) for calculating how the state of a beam of polarized light changes on reflection or on passing through a crystal.

Colours of thin plates. When a parallel beam of white light (I_0) is passed through a thin slice of crystal placed between a polarizer and an analyzer, the intensity *I* of the emergent light may be expressed as the sum of two terms:

I = white term + colour term.

The white term represents the amount of light that would be transmitted if the crystal were not present. It is equal to I,, $\cos^2$ e, in which θ is the angle between the preferred directions of polarizer and analyzer. The colour term depends on the relation between the directions of the crystal axes and the preferred directions of polarizer and analyzer. It is also dependent on the retardation ($\varepsilon_{oe} = 2\pi d[n, - n_o]/\lambda$) of the plate. Because this retardation varies with the wavelength, the transmission depends on the colour. Some parts of the spectrum are transmitted more than others, and the emergent light is coloured. The first term, on the contrary, does not depend on the properties of the crystal, and it represents white light. It can be reduced to zero by setting the analyzer and polarizer so that their preferred directions are at right angles ($\theta = \pi/2$). The colour is then obtained most strongly, because any transmission of light results from anisotropy (*i.e.*, birefringence) in the slice. This provides a sensitive method of detecting strains in glass and may also be used to detect induced anisotropy when mechanical or electrical stress is applied. This method is sometimes used to detect regions of large strain in beams or girders. A model of the beam is made in plastic and placed between polarizer and analyzer. On applying a load, fringes appear in the regions of most strain. The Plate shows a picture obtained in this way. The example is chosen for simplicity. The useful application is to more complicated structures for which calculation is laborious.

A high-speed optical shutter called the Kerr shutter can be made by placing an isotropic material between crossed polaroids, one acting as a polarizer and the other as an analyzer, and applying an electric field. If a suitable material is used, the intensity of the transmitted light will reproduce the variation of electric field, even at frequencies over a megahertz. An improved shutter is produced by using the change of birefringence in some crystals.

The Kerr
shutter

Rings and brushes. The retardation of waves by a crystal plate depends on the relation between the perpendicular to the surface of the plate and the axes of the crystal from which it was cut. Observation of the colours of one plate with parallel light gives information in relation to one direction within the crystal. It is possible to obtain information about many directions within the crystal at one and the same time. This is done by taking the light that has passed through the polarizer and converging it strongly, using a microscope objective (reversed). It then passes through the crystal as a solid cone of light. It is rendered nearly parallel again by a second objective and passes through the analyzer. Finally it passes through an optical system that brings all rays that have passed through the crystal in one direction to a focus at a single point in a certain plane (a similar focussing is shown in Figure 12). Thus each point in this plane corresponds to a certain direction in the crystal and to a single value of retardation ε_{oe}. The differences in retardation ε_{oe} are caused partly by variation of (n_o — n,) with the direction in the crystal and, usually to a lesser extent, by a difference in the length of path within the crystal. This implies that, with monochromatic light, bright and dark fringes are observed. Each dark fringe is the locus of points for which the retardation is an odd number multiple of 180°—*i.e.*, ε_{oe} equals $p_0\pi$ (p_0 being an odd integer). If the slice is cut from a uniaxial crystal with its normal in the direction of the optic axis, the symmetry of the wave surface (Figure 21) requires that the fringes be circular rings (see Plate). The rings are interrupted at certain points for which the second term (in the expression of the intensity of the light transmitted by a crystal plate placed between polarizer and analyzer) is zero. This gives either a bright cross or a dark cross depending on the angle between the preferred directions of the polarizer and the analyzer; these crosses are known as brushes. The patterns obtained with a slice cut so that the normal is not in the direction of the optic axis (a crystal direction for $n_o = n_e$) or with biaxial crystals are complicated and sometimes beautiful (see Plate). Such patterns may be used to identify crystals present as fairly small inclusions in other materials.

ELECTROMAGNETIC-WAVE CHARACTER OF LIGHT

Maxwell's equations. Historically the theory of electricity and magnetism developed in the form of a number of empirical laws each of which was a generalization based on a series of experiments; *e.g.*, Coulomb's law dealt with the force between two stationary electric charges. Maxwell replaced all these laws by a single theory concisely stated in the form of a set of vector equations. It has been said that Maxwell's theory is Maxwell's equations, and indeed it is impossible to do justice to Maxwell's achievement without use of these equations. The content of these equations and their relevance to the theory of light will be described here in general terms. The reader may refer to standard texts on electromagnetic theory for the equations themselves.

Electric and magnetic fields are specified by means of the vectors E and H with which are associated the vectors D, B, and *J* (electric and magnetic induction and density of electric current). Maxwell's equations fall into two groups: (1) three constitutive equations and (2) four field equations.

Constitutive and
field
equations

All material bodies contain electrons. These are negative charges circulating around heavier nuclei that are positively charged. When an electric field is applied to a material body, the average positions of the negative charges relative to the positions of the positive charges are changed. This creates an internal electric field. Similarly the action of a magnetic field on a material changes the movement of the electrons and sets up an internal magnetic field. The constitutive equations state that effects within a material body are proportional to the applied fields so that the resultant fields within the body are proportional to the applied field. Certain constants are defined: E is the dielectric constant, μ is the magnetic permeability, and a is the electrical conductivity. There is no general agreement, however, concerning these constants, and therefore some authorities use a different nomenclature (for treatment of the constants in greater detail, see ELECTROMAGNETIC RADIATION and ELECTRICITY). But these are basic properties of the material: for free space the values are ε_0, μ_0, and zero respectively.

The first of the four field equations quantifies certain properties of the electric induction at the boundary of a volume that contains a net positive or negative charge. The second states that, since there are no free magnetic poles, a certain integral of magnetic quantities is zero. The third equation states that, when the magnetic flux through a surface changes, electrical voltages appear on the boundaries of the surface. The fourth states that electrical currents in conducting materials and changes of the electric induction in nonconducting materials produce magnetic effects.

The field equations (like the constitutive equations) are linear equations: they state that certain quantities are proportional to one another; *e.g.*, the third equation states that the electrical voltages are directly proportional to the rate of change of magnetic flux. No new constants (other than ε, μ, and σ), however, are introduced. In Maxwell's equations, electricity and magnetism are two aspects of one thing called electromagnetism. Maxwell's theory can indeed be stated in a way that does not mention electricity and magnetism separately.

Maxwell's new hypothesis

The three constitutive equations and the first three of the field equations are precise formulations of known empirical laws. In the fourth field equation Maxwell introduced a new hypothesis—that an electrical change in a nonconductor produces magnetic effects. This hypothesis—which can be verified by electrical experiments—leads to the theory of electromagnetic waves capable of being propagated through a vacuum.

Propagations of electromagnetic waves. When Maxwell's equations are combined, using standard mathematical methods, a new equation is obtained. This is similar in form to the wave equation (7) given above. It predicts the existence of electromagnetic waves, with well-defined properties which will now be described.

1. In free space (*vacuo*) electromagnetic waves are propagated with a phase velocity c $= (\varepsilon_0\mu_0)^{-1/2}$; the magnitude of c obtained from electrical measurements of $\varepsilon_0\mu_0$ is approximately equal to the measured velocity of light (see the Table). Plane waves are propagated without attenuation. Spherical waves have an amplitude inversely proportional to the distance from a small source.

2. For transparent nonconducting mediums such as water or glass, the phase velocity is b $= (\varepsilon\mu)^{-1/2}$, and the index of refraction is $n =$ c/b $= (\varepsilon_0\mu_0/\varepsilon\mu)^{1/2}$. This relation holds for radio waves and, with moderate accuracy, for infrared radiation. For visible light it holds moderately well for some mediums but not for others. The constants E and μ are associated with redistribution of charge in response to changes in the electromagnetic field. At low frequencies these movements follow the changes of the field in a simple way. At optical frequencies, when the field is reversing about 10^{14} times a second, the situation is more complicated. The effective value of μ at these frequencies is μ_0 and the effective value of E is less than the value measured with static fields, or fields that vary more slowly—apart from the possibility of resonance, which will be considered later.

3. In conducting mediums, the electromagnetic waves are absorbed as they are propagated. This absorption is exponential; *i.e.*, the fraction absorbed in a thin layer of thickness *d* is βd, in which β is a constant the value of which can be calculated when E and σ are known. For metals, β is very large so that a layer only a tenth of a micrometre in thickness absorbs about half of the incident light. This absorption is much stronger than that of nonconducting substances, which are normally regarded as opaque (such as ebony): these are usually quite transparent in thicknesses of a micrometre or so.

Although the simple theory is correct in predicting high absorption for metals in general, the values of β for different metals (calculated from E and σ) are not correct. This is because the effective value of n at high frequencies is not the same as that measured with direct current or low frequency alternating current.

4. The waves are transverse; the electric field vector (E) and the magnetic field vector (H) are perpendicular to one another and to the direction of propagation along the axis OZ as shown in Figure 23.

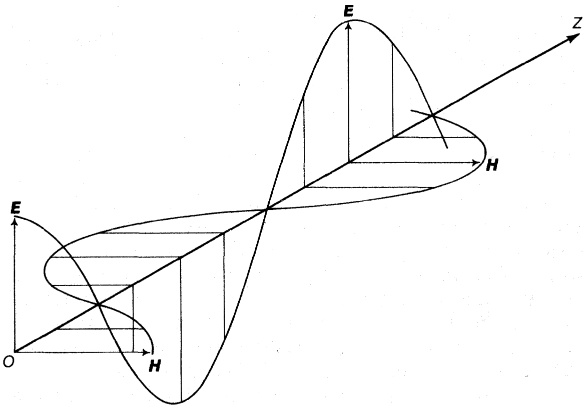

Figure 23: Electromagnetic wave, showing that electric field vector **E** and magnetic field vector **H** are in phase (see text).

5. The two quantities E and H, the magnitudes of vectors E and H, fluctuate in phase, so that when E is a maximum *H* also is a maximum (Figure **23**). This is implied in the equation

$$\varepsilon^{1/2}E = \mu^{1/2}H, \qquad (12)$$

which enables either E or H to be calculated when the other is known.

6. The electromagnetic field possesses energy, and the energy per unit volume (W) is equal to ½($\varepsilon E^2 + \mu H^2$). In view of equation (12) above, this implies that for electromagnetic waves,

$$W = \varepsilon E^2. \qquad (13)$$

The Poynting vector

7. The propagation of electromagnetic waves involves **a** transport of energy. A vector $S =$ E × H, called the Poynting vector (after an English physicist, John Henry Poynting), is used to describe this flow—*i.e.*, the energy flows in the direction of S (which is also the direction of wave propagation in an isotropic medium)—and the amount of energy crossing unit area (lying across the direction of flow) in unit time is equal to *S*—*i.e.*, to the magnitude of S. For electromagnetic waves S $= E \times$ H $= (\mu/\varepsilon)^{1/2} E^2$, and this relation, combined with equation (12), implies that $S = W/(\varepsilon\mu)^{1/2}$, or S $= bW$; thus, the mean value of *S* is b times the mean value of *W*—*i.e.*, the energy crossing unit area in unit time is equal to the velocity multiplied by the energy density.

The linearity of Maxwell's equations implies that the law of superposition applies to electromagnetic waves. The electromagnetic theory is therefore able to give a satisfactory account of all the simpler phenomena of interference and diffraction already described above. There are a few problems for which it is clearly superior to the "scalar-wave" theory that was described. These include the polarization of light transmitted through a slit the width of which is of the same order of magnitude as the wavelength and also the polarization of light scattered from microscopic particles. Calculations based on the electromagnetic theory are sometimes difficult mathematically, but the results are in agreement with experiment.

IV. The interaction of light with matter

REFLECTION AND REFRACTION

When light is incident in a perpendicular direction on the surface of a piece of glass, part is transmitted and part is reflected. This happens at any surface that forms the boundary between two transparent mediums of different refractive indices. For a particle theory of light, this phenomenon constitutes a serious difficulty. If a beam of light consists of a stream of particles all alike, because like causes produce like effects, there is no good reason why some should go through the surface and some be turned back. If the particles are not all the same (*e.g.*, if some have more energy and are therefore able to get through), then it would be expected that all those particles that do penetrate one surface would be able to pass through a second. This is never observed. In fact, the fraction of light transmitted at the second surface is the same as the fraction transmitted at the first (for light of one wavelength). Newton was aware of this fundamental difficulty and introduced the ad hoc hypothesis of particles with periodic oscillation between "fits of easy reflection" and "fits of easy transmission."

A wave theory of light, on the other hand, offers an explanation that follows in a natural and logical way from its premises. When a wave passes from one medium to another certain conditions must be fulfilled at the boundary. These conditions arise because the frequency of the transmitted wave must be the same as that of the incident wave. The velocities of light in the two mediums are different, and therefore, because velocity is the product of wavelength times frequency, the wavelength cannot be the same. By way of analogy, elastic waves can be imagined falling on a welded boundary between two solids—*e.g.*, steel and brass—with point P_1 just inside the first medium and P_2 extremely near P_1 and just inside the second medium. Then if P_1 and P_2 do not move exactly together the material at the boundary must tear. If the boundary is so strong that it does not tear, then the waves at the boundary must match each other in a most precise way. This match is possible only if there is a reflected wave as well as a transmitted wave: when the density and the elastic properties of the two mediums are known then the fraction reflected can be calculated.

For light, the fraction reflected can he calculated when the indices of refraction are known, and it is found that the fraction reflected when a beam of light is incident perpendicular to a boundary between air (refractive index nearly equal to 1) and a medium of refractive index n is $(n - 1)^2/(n + 1)^2$. Thus for glass (index 1.5) about 4 percent is reflected, but for diamond (index 2.42) 17 percent is reflected. This result is predicted by any reasonably self-consistent wave theory including the electromagnetic-wave theory. When light is incident on a surface at an angle other than perpendicularly, however, the calculation of the fraction of light reflected is more difficult. This fraction depends both on the direction of incidence and on the polarization of the light.

Fresnel relations

Fresnel derived certain expressions (known as Fresnel's relations) for the amount of light reflected under various conditions, using an elastic solid theory. To do this he assumed boundary conditions chosen ad hoc—*i.e.*, to produce the correct result. In the electromagnetic theory there is no choice in regard to the conditions that must be satisfied at the boundary of two dielectrics. The boundary conditions are fixed by the constitutive equations and by general principles such as the conservation of energy. They are derived from experiments on electricity, not from experiments on light.

These boundary conditions may be applied to electromagnetic waves with the following results.

1. The existence of a wave reflected so that the angle of reflection is equal to the angle of incidence and of a refracted wave the direction of which obeys Snell's law.
2. All the results that Fresnel had previously obtained for the amounts of light reflected and refracted under a variety of conditions, including Brewster's law.
3. The existence of total reflection and of certain observed results in regard to the change of polarization of light that has been totally reflected (when the incident light is polarized).
4. The amount of light reflected at the surfaces of metals (including the result that strong reflection is, in general, obtained with good conductors).
5. A detailed description of certain complicated results obtained when light is incident upon the surface of a transparent anisotropic crystal (*e.g.*, calcite).

DISPERSION AND SCATTERING

Oscillating dipoles. In electrostatics, a dipole consists of two equal and opposite charges situated a small distance apart. The line joining the charges is called the axis of the dipole, the dipole moment M is the name given to the product of one charge times separation. An oscillating dipole may be thought of as one in which charges move so that M fluctuates between $+M_0$ and $-M_0$ (*i.e.*, M = $M_0 \sin 2\pi\nu_t t$). Maxwell's theory shows that an oscillating dipole produces electromagnetic waves that are nearly spherical at distances large compared with the size of the dipole. The total energy emitted is proportional to the square of the ratio M_0/λ^2 (in which $A = c/\nu_t$).

Scattering by free electrons. When an electromagnetic wave (with an electric vector of amplitude E_0) operates on a free electron, it causes the electron to oscillate so as to produce an oscillating dipole with a moment proportional to E_0/h^2. This dipole emits waves in all directions. These waves are regarded as scattered light. The scattered light is strongest in directions perpendicular to the axis of the dipole, which is the same as the direction of the electric vector in the incident wave. It is polarized with its electric vector in the plane containing the dipole. The ratio of the energy scattered to the energy incident per unit area is: $k = (1/6\pi\epsilon_0^2)\ (e^4/m^2c^4)$, in which e is the charge and m is the mass of the electron. The energy scattered is equal to the amount of energy incident upon an area equal to k. For this reason k is called the scattering cross section or the scattering coefficient.

Dipole radiation

Scattering by bound electrons. A bound electron is subject to a restoring force when displaced from its equilibrium position, similar to a weight on the end of a spiral spring. An electron bound to an atom can oscillate with a natural frequency vo. Its motion produces an oscillating dipole and electromagnetic waves are emitted. Energy lost in this way constitutes damping, and the oscillation decays like the well-known damped harmonic oscillator of classical mechanics. The curve of decay is similar to the curve of a damped waye shown in Figure 14A. When a light wave is incident, a bound electron oscillates. The strength of the dipole produced and, hence, of the light scattered depends on the frequency (ν_t) of the light wave and also upon the frequency vo and the damping constant γ of the electron.

The scattering cross section (k') is found to be:

$$k' = \frac{\nu_t^4}{(\nu_0^2 - \nu_t^2)^2 + \gamma^2\nu_0^2}\,k; \qquad (14)$$

and it reaches a maximum value when v, is nearly equal to ν_0; *i.e.*, when the incident wave is in resonance with the natural frequency.

Molecular scattering. Because atoms and molecules contain bound electrons, they scatter light, but not just like single bound electrons. The scattered wave has an amplitude proportional to the amplitude (E_o) of the incident wave and inversely to the distance from the scattering centre; *i.e.*, the electric vector E_r of the scattered wave is $\eta E_o/r$, in which η is a constant. This value applies to the wave emitted at right angles to the electric vector of the incident light. The phase of the scattered wave is either the same as that of the incident wave or differs from it by an amount that is the same for each molecule. Figure 24 shows a beam of light incident upon a layer of gas at low pressure. The molecules are irregularly placed so that the light scattered from different molecules, such as M_1, M_2, M_r, M_i, etc., in any direction (except the forward direction) is incoherent. The law of photometric sammation (see above) applies, so that the total energy scattered by N molecules is just N times the energy scattered by one molecule.

A gas with N molecules per unit volume has an equivalent cross section (k_m),

$$k_m = \frac{8\pi}{3}\eta^2 N. \qquad (15)$$

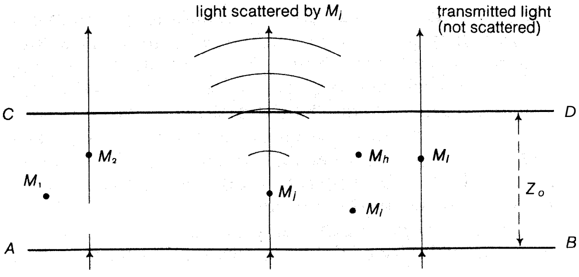

Figure 24: Scattering of light from molecules (see text).

In the forward direction the light scattered from different molecules is coherent because the total distance from the back edge of the gas layer (AB) to any molecule, such as M_j and M_l and thence to the front edge of the layer (*CD*) is equal to the thickness of the layer (z_0). Thus in the forward direction, the scattered waves can interfere with each other and with the wave representing the unscattered light. The resultant is a new wave in the forward direction but retarded—*i.e.*, with a phase lag $\eta\lambda N z_0$. In ordinary wave theory, however, the velocity of light in a medium of refractive index *n* is c/n and the phase lag due to passage through a layer of thickness z_0 is equal to $2\pi(n-1)z_0$. Equating these two estimates of the lag requires

$$2\pi(n-1) = \eta\lambda^2 N, \qquad (16)$$

and substituting for η from equation (16) into equation (15) implies that

$$k_m = \frac{32\pi^3}{3\lambda^4 N}(n-1)^2. \qquad (17)$$

This equation was derived by Rayleigh. He also showed that the brightness of the blue sky is about that to be expected if the light is produced only by molecular scattering, and it is not necessary to suppose that there is any appreciable scattering by dust particles—in the high atmosphere and on a clear day. The factor $1/\lambda^4$ implies that the scattering coefficient for blue light ($\lambda = 400$ nanometres) is about six times larger than that for red light ($\lambda = 640$ nanometres) and this accounts for the blue colour. Laboratory measurements of the amount of scattered light agree with that calculated from equation (17). For the rare gases (*e.g.*, argon) the scattered light is almost completely plane-polarized; but other gases show less complete polarization (*e.g.*, 90 percent for carbon dioxide) as would be expected if their molecules possess an electric dipole moment. The light of the blue sky is polarized but polarization is reduced because some of the light has been scattered more than once.

Dispersion. Equation (17) implies that (n − 1) may be calculated if η is known; *i.e.*, if the ratio of the amplitude of the scattered wave to that of the incident wave can be calculated. Dispersion formulas for gases have been obtained by assuming that the atoms or molecules contain bound electrons having a response that varies with frequency in the manner described above. The methods of calculation involve the properties of atoms and molecules rather than those of light and are not considered in this article. Certain general results are readily obtained—*e.g.*, that for most transparent mediums the refractive index increases regularly toward the blue end of the spectrum (this is called normal dispersion). It is also found that in a region in which there is a strong absorption, the index varies rapidly, and over part of this region the dispersion is anomalous (*i.e.*, the index increases in the direction of larger wavelengths). This derives from equations (14) and (17).

Normal and anomalous dispersion

Scattering of larger particles. **A** particle that contains N atoms but is small compared with the wavelength of light has a dipole moment approximately N times that for a single atom. The scattered energy is then proportional to N^2, or to V^2, or to R^6 (if V is the volume, and R is the radius). Thus a particle 20 nanometres in diameter scatters about as much light as 10^{12} separate atoms. For larger particles the scattering still increases though more slowly. When the particle is larger than a wavelength it must be considered as a diffraction object. The ratio of effective cross section for scattering to actual cross section fluctuates as the size increases. The theory of this variation, in relation to size, refractive index, and absorption has been worked out and verified experimentally.

Scattering by macroscopic solids and liquids. In crystalline solids the atoms are regularly arranged so that the wavelets scattered in a given direction have regularly varying phases. They interfere to give a small resultant except in the direction of the forward wave. Scattering of light is small in relation to the number of atoms per unit volume and results largely from crystal defects. For X-ray wavelengths smaller than the interatomic distance, the coherent waves scattered in certain directions reinforce one another.

For amorphous solids and liquids the number of atoms in any volume having a diameter of about one wavelength is large and the scattering per atom, although usually larger than in crystals, is still small in relation to the number of atoms involved.

The *Kramers–Kronig* relation. Any satisfactory theory of dispersion must comply with the condition that the scattered wave can never appear in advance of the incident wave that produces it. Physicists Hendrick Anthony Kramers of The Netherlands and Ralph de Laer Kronig of Germany showed that this basic causality condition implies that the dispersion (*i.e.*, the variation of refractive index with frequency) and the absorption are not independent. They derived equations enabling the absorption to be calculated when the dispersion is known (for all frequencies) and vice versa. It is not surprising that a relationship should exist, because dispersion and absorption are each related to the resonators described above in connection with scattering by bound electrons. The relationship has been found of great importance in many branches of pure and applied physics.

MECHANICAL EFFECTS OF LIGHT

When light is emitted or absorbed there are three mechanical effects: (1) an exchange of energy, (2) an exchange of linear momentum, and (3) an exchange of angular momentum. These are manifested as (1) heating (or cooling), (2) a pressure, and (3) a torque. If the conservation laws apply, then light must possess energy, momentum, and angular momentum. All these effects are predictable either from classical electromagnetic theory or from quantum theory. They can all be explored in relation to either exchanges between light and macroscopic pieces of matter or interaction between radiations and atoms. In this section the first will be treated, leaving the latter for the next section.

Light pressure

Equation (13) is an expression for light energy according to electromagnetic theory, and every detector of light is an energy transducer (converter). There is a general theorem, valid for light and sound, predicting that radiation must exert a pressure equal to W (the energy per unit volume) on a body that absorbs it. Twice this pressure is produced if the light is totally reflected at normal incidence. In electromagnetic theory, when light falls at normal incidence on a metal surface, a current (proportional to the field E) is produced in the metal; and, because this occurs in the magnetic field of the light, there is a reaction proportional to the vector product of the electric and magnetic field strengths (E × H) and normal to the surface—*i.e.*, a reaction proportional to the Poynting vector (*S*). For an insulator the induced current is the displacement current. Because the Poynting vector is proportional to W, the energy per unit volume, the pressure is proportional to W (further consideration shows that, in the usual units, it is equal to W).

The measurement of the linear momentum of light is difficult because, under normal experimental conditions, the pressure is less than 10^{-4} dyne per square centimetre. In Figure 25, light from powerful sources S_1 and S_2 falls on the mirror vanes A_1 and A_2 that are at the ends of a rod suspended by a quartz fibre. The pressure on the vanes produces a couple or twisting of the fibre and hence a rotation of the system that is measured by the usual

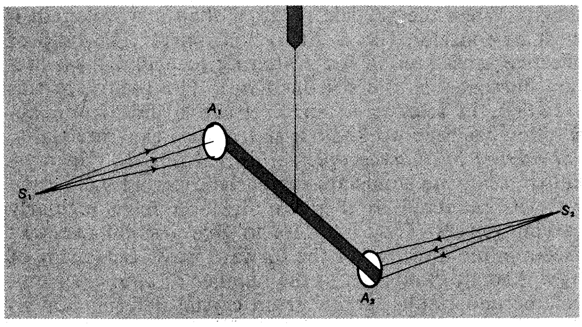

Figure 25: Apparatus for measurement of light pressure (see text).
From R.W. Ditchburn. *Light* (1963); Interscience Publishing, Inc., by permission of John Wiley & Sons, Inc.

mirror-and-scale method. The true radiation pressure can be measured only when a certain thermal action, called the radiometer effect, has been eliminated. In the radiometer effect, if radiation heats a surface, then molecules of gas that rebound from one side will move faster than those that rebound from the other, cooler side, and there will be a net pressure. In the period 1901 to 1905, when physicists were making the first accurate determination of light pressure, it was not possible to remove this effect by placing the system in a vacuum in which the number of molecules is at a minimum; instead, the effect was reduced by substituting the special cells for the vanes. Any radiometer effect within the cells produces no net force. The residual effects at outer surfaces are small and are the same whichever side of the cell is illuminated. The measured values (1) when radiation is absorbed and (2) when it is reflected agreed with theoretical values within 1 percent. By use of an alternative method of eliminating the radiometer effect, results in agreement with the theoretical values were also obtained.

It can be shown that a beam of circularly polarized light possesses angular momentum and thus should exert a torque upon a half-wave plate that reverses the rotation of polarization (*i.e.*, from left-handed to right-handed circularly polarized light or vice-versa). The experimental difficulties of measuring this torque (of about 10^{-11} dyne centimetre) are formidable and the overall error is about 10 percent. The result agrees with the theoretical value within this margin.

The density of radiation incident on the Earth's surface at its mean distance from the Sun is about 1.36 kilowatts per square metre (for a surface normal to the Sun's rays), and the corresponding light pressure is about 5×10^{-5} dyne per square centimetre. The total pressure on the Earth is about 6×10^{14} dynes, a minute fraction of the gravitational force exerted by the Sun.

Importance of the mechanical properties of light

The mechanical properties of light, difficult to measure in the laboratory, are important under certain astronomical conditions. Gravitational forces are proportional to the mass of a body and hence to the cube of its radius. For a body having large radius compared with the wavelength, the radiation pressure is proportional to the square of the radius. Whereas the attraction and repulsion may be equal and balanced for a medium size particle, for a smaller particle, the radiation pressure may be a large fraction of the whole force. For this reason, radiation pressure has a considerable effect in extending a comet's tail. In a star the outward flow of radiation from the centre produces a net force tending to expand the star, thus opposing the gravitational forces. Also, when radiation energy is transferred between two parts of a rotating star that are moving with different velocities, momentum transfers are involved. This produces an effect known as radiative viscosity because the resulting forces reduce the relative velocity of adjacent layers and so reduce the angular velocity of rotation.

V. Quantum theory of light

In the classical electromagnetic-wave theory, the absorption of light is a continuous process and there is no lower limit to the amount of energy that an atom can absorb from light of given frequency. Energy can be exchanged, in infinitesimal amounts between radiation and atoms, in an enclosure that is in thermal equilibrium. The total energy of the enclosure should, in equilibrium at temperature T, be distributed so that each degree of freedom has an equal amount, kT, in which k is Boltzmann's constant. The number of possible modes of vibration for transverse waves with frequencies between ν and $\nu + d\nu$ is $8\pi\nu^2 d\nu$ per unit volume. (In this section all frequencies are temporal frequencies and ν is used for pt). If $\rho(\nu)d\nu$ is the radiation energy per unit volume in this frequency range, and c is the velocity of light, then the radiation density is as shown in curve R–J of Figure 26. This law, derived by Rayleigh and Jeans, is the inevitable consequence of classical wave theory: It predicts that the radiation density increases without limit as the frequency increases, and this implies that, in equilibrium, all the energy in the universe is found in the high-frequency end of the electromagnetic spectrum and none is present in matter. This catastrophe may be avoided by assuming that there is some upper limit to the possible frequency of radiation, but the Rayleigh–Jeans law does'not agree with measurements of temperature radiation in the visible and ultraviolet regions of the spectrum (curve R–J, Figure 26). The experimental results are represented by curve P in Figure 26, and Planck suggested a formula, now called Planck's law, that fitted this curve. Originally this formula was probably an inspired guess, but Planck soon showed that it could be derived by assuming that a mode of frequency can change only by $h\nu$ (or by a multiple of hu) in which h is a new universal constant now called Planck's constant. The minimum "element of energy" (as Planck referred to it) is now called the quantum. For visible light the quantum is about 3.5×10^{-12} erg or 3.5×10^{-19} joule.

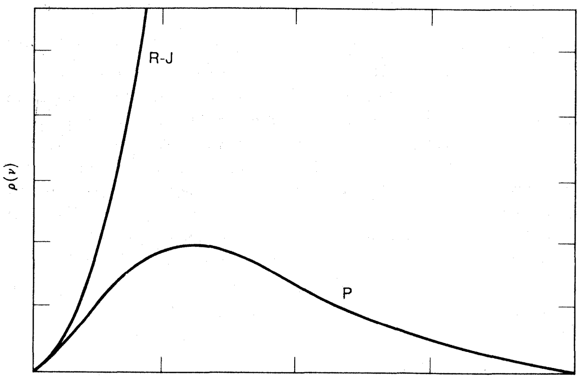

Figure 26: **Equilibrium** radiation density curve R–J (Rayleigh–Jeans); curve **P** (Planck; see text).

Properties of a photon

The theory in which Planck introduced the quantum was concerned with the interaction between radiation and matter. He expected that only minor modifications of the electromagnetic theory of light in free space and of the electron theory of matter would be needed. This expectation was not realized. Experiments, some of which will be described below, led Einstein to regard light as an assembly of entities, later called photons. A frequency ν, energy $h\nu$, momentum $h\nu/c = h/\lambda$, and angular momentum $h/2\pi$ are associated with a photon of circularly polarized light. In many situations the photons appear to be localized concentrations of energy and momentum—*i.e.*, to have the properties of particles. Yet the evidence that led to the rejection of a corpuscular theory in favour of a wave theory is still as valid and as compelling as it was in the time of Fresnel.

The theory, which includes logical descriptions both of those experiments that seem to require a corpuscular theory and those that support a wave theory, is known as quantum mechanics. This is a general theory of radiation and matter—not a special hypothesis about their interaction. The account given below of some aspects of quantum mechanics that are important in relation to experiments on light must be related to the general theory (see MECHANICS, QUANTUM).

PHOTONS

When light of suitable wavelength is incident upon the clean surface of a metal, electrons are emitted. If W_m is the maximum kinetic energy of one of those photoelectrons released by light of frequency ν, then it is found that the maximum kinetic energy is Planck's constant times the difference between two frequencies, or W, $=$ h(v $- \nu_0) = h\nu - W_0$, in which W_0 is written for $h\nu_0$. No electrons are emitted when ν is less than the critical frequency v,. It is known from other experiments that a minimum amount of energy called the work function is needed for an electron to escape from a surface. If W_0 is accepted as the work function for emission of a photoelectron, then it is easily understood that no electrons are emitted when frequency ν is less than the critical frequency and that the maximum energy of escape for an electron is $h\nu - W_0$. Some electrons may make collisions after absorption of energy $h\nu$ and either fail to emerge from the surface or else emerge with lower energy. Escape by gaining energy from two photons of frequency less than ν_0 is extremely improbable because the energy due to one absorption is almost always lost by collision before a second photon is absorbed.

The number of photons absorbed, and therefore the number of electrons released, are proportional to the energy density in the beam of light and to the time. The energy of individual electrons is independent of the energy density—*i.e.*, independent of the amplitude of the waves.

Bohr's postulate

Conservation of energy and **momentum.** Niels Bohr, a Danish physicist, postulated that an atom can exist only in one of a set of discrete stationary states of internal energy ($W_1, W_2, \ldots$). The frequency $h\nu_{nm}$ of light emitted in passing from state n to m is related to the energy difference by Bohr's frequency condition: that Planck's constant times the frequency is equal to the energy difference between two states; *i.e.*,

$$h\nu_{nm} = \text{Wn} - W_m.$$

For some pairs of states (W, $-$ W,) can be measured by experiments on collisions between electrons and atoms, and Bohr's condition is found to be satisfied within the limits of experimental error. Many other, less direct but more accurate, experiments are also in agreement with this equation.

In Bohr's theory, and subsequently in quantum mechanics, an angular momentum is associated with each atomic state. In the simplest situation, when polarized light is emitted in a magnetic field, the angular momentum about a known axis changes by $h/2\pi$. The changes are such that angular momentum is conserved if a photon of circularly polarized light has an angular momentum of $h/2\pi$ about the direction of propagation.

Compton scattering

It was shown by a United States physicist, Arthur Holly Compton, that when X-radiation is scattered by a nearly free electron, there is a wavelength change. A formula that gives the wavelength change as a function of the angle of scattering was derived by assuming that a "particle" of energy $h\nu$ and momentum $h\nu/c$ collides with a particle of mass m that is at rest, and that energy and linear momentum are conserved. The resting electron gains momentum and kinetic energy by changing its speed. The photon cannot change its speed, which is always c. It therefore must change its frequency when it changes energy and momentum. The measured change of frequency agrees with that calculated by Compton.

An atom that has absorbed a quantum of energy $h\nu_{mn}$ and changed from state m to state n may return to state m with emission of a photon of the same frequency (resonance radiation)—*i.e.*, $\nu_{mn} = \nu_{nm}$. If there is a state s intermediate in energy between states m and n, the return may be in two stages; n to s and s to m, with the emission of two photons. The sum of the two quanta $h\nu_{ns}$ and $h\nu_{sm}$ is then equal to a single quantum $h\nu_{nm}$ so that energy is conserved. In gases, these emissions usually follow the absorption in less than a microsecond, and the term fluorescence is used to include both resonance radiation and multistage processes. In solids and liquids there are sometimes intermediate states that are metastable so that emission occurs over much longer periods (phosphorescence; see LUMINESCENCE). In all these processes the frequency of the emitted radiation is not greater than that of the absorbed radiation in accord with an empirical law discovered in the 19th century. In quantum theory this law is a necessary consequence of conservation of energy.

Raman effect

In Rayleigh scattering, the frequency of the scattered light is equal to that of the incident light. The physicists Sir Chandrasekhara Venkata Raman of India and Leonid Isaakovich Mandelstamm of the Soviet Union independently discovered processes in which light is scattered by an atom or molecule that changes its state. There is a corresponding discrete change in the frequency of the scattered radiation. When the scattering atom or molecule is in its lowest state, the frequency of the unscattered radiation is always less than that of the incident light (Stokes lines). When light is scattered by a molecule that is not in its lowest state, photons of higher frequency may be found in the scattered radiation (anti-Stokes lines). The scattered photon then has more energy than the incident photon, but the molecule gives up energy by passing to a lower state. The Raman effect is observed when light is scattered by solids and liquids. There is also an additional kind of scattering in which photons exchange energy and momentum with the thermal vibrations of the solid or liquid (Brillouin scattering, named after a French physicist, Louis-Marcel Brillouin).

The experiments quoted are examples of a large number that are in accord with the view that, within the limits of measurement, energy and momentum are conserved in detail—*i.e.*, in each individual interaction between an atom and radiation.

Spontaneous and stimulated emission. Planck's theory gives the distribution of radiation energy with frequency in an assembly of atoms and radiation in thermodynamic equilibrium at a common temperature in an enclosure. An Austrian physicist, Ludwig Boltzmann, applying the same principles to the assembly of atoms, derived a formula that gives the distribution of atoms between different stationary states—*i.e.*, the ratio of the number N_n in any state n to the number N, in any other state m. In the enclosure now considered, Boltzmann's and Planck's laws must both be satisfied though each atom is changing its state frequently by emitting or absorbing a photon or by collision. Equilibrium can be maintained if, and only if, each individual reaction is balanced by its own reverse process. Einstein assumed that the equilibrium was maintained by the following process: (1) absorption of radiation at a rate $B_{mn}N_m\rho(\nu)$; (2) spontaneous emission at a rate $A_{nm}N_n$; and (3) stimulated emission at a rate $B_{nm}N_n\rho(\nu)$, in which A_{nm}, B_{mn}, and B_{nm} are constants, now known as Einstein coefficients. When the rate of absorption was equated to the rate of emission (*i.e.*, to the sum of spontaneous and stimulated emission), an equation of the same form as Planck's law was obtained. This equation became identical with Planck's law if

Einstein coefficients

$$B_{nm} = B_{mn} = \frac{c^3}{8\pi h\nu^3}A_{nm}. \tag{18}$$

If there were no stimulated emission (*i.e.*, if $B_{nm} = 0$), Planck's law and Boltzmann's law could not both be satisfied. Einstein postulated the existence of stimulated emission in 1905, but for more than 30 years it appeared to be only of theoretical interest. At the densities of radiation then available, the rate of stimulated emission was small compared with the rate of spontaneous emission. Equation (18) shows that in the microwave region of the electromagnetic spectrum (frequencies of a few thousand megahertz) the ratio $\mathbf{B}_{mn}/\mathbf{A}_{nm}$ is much larger than in the visible spectrum. Accordingly, it was much easier to develop microwave amplification by stimulated emission of radiation (maser) than the corresponding laser effect with radiation in or near the visible spectrum. The existence of stimulated emission can be fitted into a classical wave theory, like many other concepts that originated in relation to theories of photons.

Interference and diffraction of photons. It was at one time suggested that interference and diffraction phenomena are caused by collisions between photons considered as small particles, or at least to some kind of complex interaction between photons. A simple experiment performed by a British physicist, Geoffrey Ingram Taylor, in 1908 excludes this possibility. He photographed the diffraction pattern of a needle and reduced the illumination until long exposures were needed to obtain an image. When the chance of two or more energy quanta passing through the apparatus simultaneously was made extremely small, the diffraction pattern was exactly the same as that obtained with a strong source of light.

This experiment is supported by many later experiments, showing that interference and diffraction are to be associated with single photons. The discussion in the section on coherence above implies that when ordinary sources of light are used each photon can interfere only with itself and not with any other photon. An interference pattern can, of course, be photographed only by recording the effects of many photons because one photon can activate only one grain on the photographic plate, but it does not matter whether the photons all arrive over a time span of a microsecond or of several weeks.

The photograph of an interference pattern is both a wave phenomenon because it shows the characteristic spatial periodicity and a quantum phenomenon because the whole energy of a photon can be used to activate a single grain. It is not possible to trace the path of one photon (regarded as a particle) through the apparatus and, at the same time, obtain the interference pattern. In Young's experiment there is no way of finding out through which slit a given photon passes--except by covering one slit and thus losing the interference fringes.

THE WAVE–PARTICLE NATURE OF LIGHT

Uncertainty relations. Experiments with the photoelectric effect show that energy can be transferred from one atom to another in a way that suggests that photons are corpuscles—*i.e.*, localized concentrations of energy and momentum. Other experiments imply equally clearly that the light emitted from an atom, when it loses energy, must be represented by wave groups. Both of these sets of experiments are equally valid, and together they require that the photon must have both wave-group and particle properties at the same time.

It will now be assumed that the intensity of the waves gives the relative probability that a suitable detector will detect a photon at a given point. Experimentally, waves and particles are both abstractions, each describing the same physical system. Quantum mechanics does not seek a relationship such that particles are guided by waves according to the laws of classical physics—as in the theory of the English physicist J.J. Thomson, in which photons are pictured as closed tubes of electric force guided by Maxwellian waves. The waves and particles now to be considered do not have all the relevant properties of classical waves and particles. When a photon is absorbed, the whole of a wave group, possibly extending over a large volume, is annihilated. The position of a photon particle cannot be exactly specified. It is known only that it is within the wave group and most likely exists where the waves are most intense. Also the energy and momentum of the photon are determined by the frequency of the waves. Fourier analysis of wave groups shows that, when the wave group is short (so that the position of the photon is fairly well determined), the frequency of the waves and, hence, the energy and momentum of the photon are known only within a wide range. The product of the uncertainty in position and the uncertainty in momentum can never be less than a certain minimum value. It will now be shown how these relations appear in some experimental situations.

In one experiment a parallel beam of light is incident on a slit of width d, producing a diffraction pattern on a screen. The y-coordinate, at the moment when a photon passes through the slit, is known within an uncertainty $\Delta y = \pm d$. The direction of propagation when the photons emerge from the slit is uncertain because of diffraction, but most of the photons are observed within an angular range $\pm\theta$, in which $\sin\theta = \lambda/d$. There is therefore an uncertainty Δp_y in the y-component of the momentum (p) of about $\pm(h \sin\theta)/\lambda$, so that the product of the two uncertainties, Δp and Δy, is

$$\Delta p \Delta y \sim \frac{dh \sin\theta}{\lambda} \sim h,$$

in which the sign $\sim$ indicates is of the "order of magnitude of." In a second experiment, monochromatic light is passed through an optical shutter. The shutter is opened for a short time *At* so that a wave group of duration *At* and length $\Delta z = c\Delta t$ passes through the shutter. Then $c\Delta t$ is the length l of the wave train. This implies that the frequency ν varies within a range $\Delta\nu = 1/\Delta t$—*i.e.*, that the photon energy varies within a range $\Delta E \sim h/\Delta t$ so that $\Delta E\Delta t \sim h$. More detailed analysis shows that, if the uncertainties Δt and ΔE are the root mean square deviations of statistical theory, then their product is equal to or larger than $h/4\pi$; so that $\Delta E\Delta t \gtrsim h/4\pi$.

Uncertainty in energy of photons

Individual examples do not prove that the uncertainty relations are generally true any more than individual examples prove the general validity of the second law of thermodynamics. The fact that every example agrees, and that ingenious attempts to find exceptions all fail, constitutes a kind of proof by default, but the real proof is in the whole range of experimental work that demonstrates the equal status and inescapable association of wave and particle properties.

Maximum observations. The uncertainty relations show that precise measurement of both position and momentum are incompatible. It follows that a precise deterministic theory of particle dynamics is not appropriate because the precise initial condition of a particle is not observable. An extension of the uncertainty relations shows that the number of photons in a light beam and its phase cannot be simultaneously measured with precision, and thus a classical wave theory is also excluded.

In any experimental situation there are, in general, two or more observations that are compatible. Neither affects the other, and their results are independent of the order in which they are made. A complete assembly of such measurements is said to constitute a maximum observation. A state of a system is specified by giving the result of a maximum observation or in an equivalent way. The relative probabilities of future observations on a system can be calculated from the result of a maximum observation without reference to any previous results obtained on the system. For every system there is one certain prediction —that an immediate repetition of the maximum observation will give the same result.

Empirical questions. There is a certain type of question to which the quantum mechanics gives no direct answer because the question is not related to a possible observation. One may ask, for instance, what happens to a photon of right-handed circularly polarized light as it passes through a half-wave plate. It is known that the photon will emerge as a photon of left-handed circularly polarized light and that angular momentum is transferred to the plate. The wave theory gives an account of the progress of a wave through the plate. If, however, one tries to visualize the particle and asks for a mental picture of the way in which this particle alters as it goes through the plate, there is no ready answer. The theory has nothing to say unless an experiment is designed to determine what happens to the photon in passage through the plate. For example, a half-wave plate is split in two and the light is passed through the quarter-wave plate, which forms one half. It may subsequently be passed through a Nicol prism analyzer. There will be some orientation of the Nicol prism such that the photon will certainly pass through. If a Nicol prism is oriented at a to this direction, the probability for a single photon to pass through is $\cos^2$ a. This detailed theoretical prediction agrees with experiment. Thus the quantum mechanics correctly predicts the results of an experiment but leaves unanswered the original question about the way in which the photon, visualized as a particle, changes its angular momentum as it passes through the half-wave plate.

Assemblies of photons. The application of quantum mechanics to the electromagnetic field in an enclosure justifies a representation in terms of photons. These may be regarded as indistinguishable particles. Any number of these particles may exist simultaneously in the same energy state. The statistics of particles that obey these conditions is called Einstein–Bose statistics. The distribution of particles among different states may be calculated by the usual methods of statistical mechanics in which probability (or entropy) is maximized subject to certain limitations. In an assembly of material particles the total energy and also the number of particles are constants. With photons, the second condition is no longer valid because two photons of frequencies ν_{ns} and ν_{sm} may be replaced by one of frequency $\nu_{nm} = \nu_{ns} + \nu_{sm}$, thus decreasing the number of photons while conserving the total energy. The statistical calculation leads straightforwardly to Planck's law. It is found that for ordinary sources of light the probable number of photons in any given state is always much less than unity. For a laser source many photons are found in relatively few states, and, indeed, in an ideal single mode continuously operated laser, all photons would be in one state.

A considerable amount of experimental and theoretical work has recently been done on coincidences of photon detection in two or more detectors that are observing the same source. This kind of photon statistics measures the coherence of light from a star and hence the size of the star.

Assemblies of photons and atoms. In the Dirac theory of absorption and emission of radiation, quantum mechanics is applied to an enclosure that contains radiation and free atoms or molecules. Processes involving creation and annihilation of photons with corresponding atomic transitions must maintain equilibrium. The theory derives expression for the Einstein *A* and *B* coefficients of absorption and emission and for their ratios. It is also shown that, whereas spontaneous emission is random, stimulated emission is coherent with the radiation that excites it. The theory extends to include an account of Rayleigh scattering (and hence of dispersion) and of the Raman effect. All problems concerned with the absorption, emission, and scattering of light are, in principle, soluble, although the mathematical formulation, even of approximate formulas, is usually difficult.

Limitations of quantum mechanics

The quantum-mechanical theory is adequate at optical frequencies and at lower frequencies. It is also adequate at the higher frequencies associated with ultraviolet radiation and for X-ray scattering including the Compton effect. It is inadequate for photons of the still higher frequencies involved in the creation and annihilation of fundamental particles. It is to be expected that, in due course, a basic theory of electromagnetic forces and of their relation to gravitation and to the strong forces between nucleons will emerge. The present theory will then have the status of an approximation valid for a wide range of frequencies including the frequencies associated with visible light.

BIBLIOGRAPHY. A.C.S. VAN HEEL and C.H.F. VELZEL, *Wat is licht?* (1968; Eng. trans., *What Is Light?*, 1968), is a good book for the general reader; numerous illustrations are accompanied by a simple text. M. MINNAERT, *Licht en kleur in het landschap* (1937; Eng. trans., *The Nature of Light and Colour in the Open Air*, new ed., 1959), also recommended for the general reader, deals with optical effects such as rainbows, mirages, and many other effects of light and colour. MAX BORN and EMIL WOLF, *Principles of Optics*, 3rd rev. ed. (1965), is a comprehensive treatise on the wave theory of light, particularly strong on diffraction, scattering, polarization, and coherence—suitable for the reader with advanced mathematical knowledge. ROBERT W. DITCHBURN, *Light*, 2nd ed. (1963). is a text at the university level that includes both theory and experimental evidence in relation to wave phenomena and quantum optics. K.D. FROOME and LOUIS ESSEN, *The Velocity of Light and Radio Waves* (1969), is a critical review of modern methods of measuring the constant *c*. JOHN H. SANDERS, *The Velocity of Light* (1965), contains reprints of original papers by A.A. Michelson, F.G. Pease, F. Pearson, Louis Essen, A.C. Gordon-Smith, and E. Bergstrand, together with a review of other work on the subject. LEONARD I. SCHIFF, *Quantum Mechanics*, 2nd ed. (1955), is a systematic exposition of the physical concepts of quantum mechanics, including a description of the electromagnetic field and its interactions with matter. JOSEPH NEEDHAM, *Science and Civilisation in China*, vol. 4 (1962), includes an authoritative account of the study of light in ancient China and a detailed comparison with parallel developments due to Greek and Arab philosophers. EDMUND T. WHITTAKER, *A History of Theories of Aether and Electricity*, rev. ed., vol. 1 (1951), deals with the background to the development of the electromagnetic theory of light in the 19th century.

(R.W.Di.)

Light, Aberration of

Annual, diurnal, and planetary aberration

The term aberration in the context of this article refers to the various displacements in the apparent direction of a celestial body consequent on the finite speed of light in combination with transverse motions of the body and the observer. The displacement in apparent direction arises in much the same way as when a raindrop, falling straight down past the window of a moving automobile, seems to be falling in a direction slanted from front to back of the car. The fundamental aberration phenomenon with light results from the motion of the observer; the displacement, measured as an angle between the real and apparent directions of the light rays, is small and is in the direction of the observer's motion. The displacement due to the steady motion of the solar system, called secular aberration, is unobservable because it is constant in time, and it is usually disregarded. The displacement due to the orbital motion of the Earth around the Sun is the annual aberration, while the component due to the rotation of the Earth is the diurnal aberration. Motion of the body itself will produce an additional transverse displacement during the time that the light has taken to reach the Earth; this is called planetary aberration. The annual and diurnal aberrations have values of about 20 and 0.32 seconds of arc, respectively. The term stellar aberration was first used by James Bradley, later Astronomer Royal (1693–1762), who both discovered the phenomenon of annual aberration and explained it.

Discovery of aberration. The discovery of aberration resulted from a program of observations directed towards the solution of another problem, that of determining stellar parallax, the difference in direction of a stellar body observed from two diametrically opposite points in the Earth's orbit around the Sun. The possibility of computing the distance of a star by measuring the angles of the triangle formed by parallax (that is, by observing the slight and regular change in the star's direction due to the orbital motion of the Earth) had intrigued many astronomers from earliest times. It was not only a subject of great intrinsic interest, but it excited particular attention because it offered the possibility of a direct confirmation of the Copernican theory of the solar system. It is now realized that even the largest observed stellar parallax is extremely small, being less than one second of arc, and needs the greatest refinement for its observation. Nevertheless, some 17th-century astronomers did find comparatively large annual displacements that were sometimes ascribed to parallax. The method most frequently employed involved the measurement of the zenith distance of a star (that is, the angle between the zenith and the star) at intervals throughout one year. Robert Hooke observed the star Gamma Draconis in this way at his London observatory during 1669 and concluded from his observations that it has a parallax of about 30 seconds of arc. Jean Picard later observed Alpha Lyrae in a similar fashion but was unable to detect any parallax. John Flamsteed, from a subsequent study of the Pole Star over a period of eight years, supposed it to have a parallax of at least 40 seconds. That these large displacements are due to the phenomenon of aberration, and not at all to parallax, entirely escaped these earlier astronomers; and the way was open to Bradley to explain them correctly, and to make improved observations, during the following century.

Bradley's first program

In 1725 Bradley resolved to re-examine the problem of large anomalous annual displacements in star positions observed during the previous century, primarily in order to obtain the parallax of a star. His first program of work was done with his friend Samuel Molyneux, an amateur astronomer. They adopted the usual technique of observing the zenith distance of a star that culminates close to the zenith. A vertical telescope made for this purpose, 24 feet long with an aperture of 3% inches, was mounted against a chimney stack in Molyneux's house. The star Gamma Draconis was selected, and observations commenced on December 3, 1725. By December 21 Bradley and Molyneux had established that the star was apparently moving. Observations continued over a year showed that the star was apparently shifting position by about 20 seconds of arc, and that after a maximum of one year it returned to its original position. Bradley immediately realized that this effect could not be attributed to parallax because it bore the wrong phase relationship to the position of the Earth in its orbit. Bradley observed a maximum displacement when the Earth was in positions 1 and 3, as shown in Figure 1; but he realized that, had the displacements been due to parallax, the maximum displacements would have occurred at positions 2 and 4. As the telescope at Kew had only a small range of movement, it could observe only a small number of stars. Wishing to observe many more stars in a similar fashion, Bradley erected another shorter instrument in 1727. With this he was able to observe more than 200 stars, including Capella, and to establish the precise phase relation between the position of the Earth in its orbit and the displacement of the star. At this time he saw that his observations could be explained by supposing that the velocity of light could be combined in a vector diagram with velocity of the observer. The following demonstration of this combination is substantially that of Bradley.

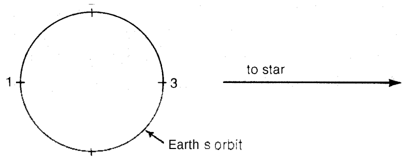

Figure 1: Orbit of the Earth. Maximum displacements of star's position are observed when the Earth is at positions 1 and 3, least at positions 2 and 4 (see text).

Development of theory. The nature of the aberration phenomenon is most easily understood if the celestial body is thought of as an emitter of photons of light, or packets of energy, rather than waves. In the diagram (Figure 2) the object is assumed to be emitting photons in all directions with velocity c. A stationary observer may obtain the direction of this object by sighting upon it through holes at A and B, distance *d* apart, which are so positioned that a photon entering at A may leave the sight at B. If the observer is also moving with velocity *V* transverse to the direction of the object, during the time that the photon has taken to move from hole A to hole B, hole B has moved a distance equal to d × V/c to one side; and the photon will miss it. But the photon could be caused to pass through both holes if the line joining them were to be tilted through an angle θ equal to V/c, because then hole B would have moved to the required position by the time that the photon reached it. This implies that the direction of the object is apparently displaced by an angle equal to V/c, measured in radians (a radian is that arc of a circle that is equal to the radius).

A small extension of this demonstration indicated that if the direction to the star is inclined at an angle θ to the line of sight the product of aberration ζ is equal to κ times sin θ, in which κ equals the fraction V/c radians (1 radian = 2.06264 X 1 0 seconds of arc). The value of κ found by Bradley was 20.25 seconds of arc (sec arc).

In spite of his careful work he never did achieve his original aim of measuring a parallax, but he remarked that if the parallax of one of his stars had been as much as one second of arc he could have detected it. His method was not a good one because the parallax appears as a small difference between two large quantities.

Bradley also noticed an apparently steady change in declination (an angular measurement of distance north or south of the celestial equator) that could not be attributed to aberration. He soon recognized that this effect is due to a rotation of the true pole of the Earth around the mean pole, caused by the attraction of the Moon upon the Earth's equatorial bulge. He continued his observations from 1727 to 1748 to confirm the explanation. This motion of the Earth's axis is called nutation (from the Latin "to nod" or "to rock"), and the circumstances of its discovery by Bradley illustrate the extreme care and the tenacity and patience that he applied to all his work.

Nutation

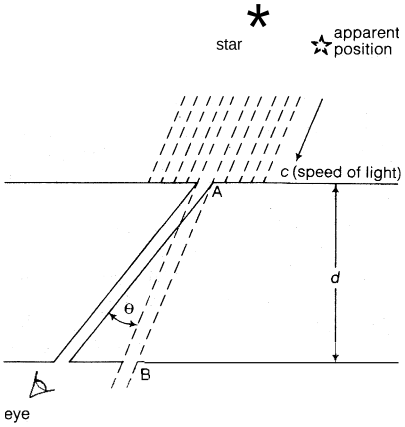

Figure 2: Idealized system of sighting on a star by alignment of two slits (A and B). The star's apparent direction is shifted because of the motion of the Earth (see text).

Although apparently simple in theory, the measurement of the constant of aberration is in practice one of the more difficult in astronomy because a comparison has to be made between star positions measured at a time interval of some six months. Since Bradley's measurements there have been many determinations. K.A. Kulikov, in his book *Fundamental Constants of Astronomy*, gives a tabulation of the results of 82 determinations up to 1951. Results of later measurements have been compiled. The value adopted by the International Astronomical Union in 1964, to be used to correct star places in ephemerides from 1968 onward, is 20.496 seconds of arc. The diurnal aberration, due to the Earth's rotation, has a maximum value of 0.319 seconds.

Constant of aberration

Astronomical effects. The annual aberration is one among several phenomena that affect the apparent position of a star in the sky. Other such phenomena are those of nutation, precession, and diurnal aberration. These effects require formal correction to star positions, and the full treatment is complex (see *Explanatory Supplement to the Ephemeris* [1961]); application of spherical trigonometry gives relations for the effect of aberration on the right ascension—angular measurement of east–west position in the sky—and declination of a star.

The planetary aberration is usually calculated on the assumption that both object and Earth move in straight lines during the time that the light takes to travel between the two. This assumption introduces an error of less than 0.001 second of arc for the outer planets. Although in the preparation of a star catalog corrections are made for nutation, precession, and aberration, no correction is made for the star's motion during the passage of light from it to the observer. An ephemeris for the Sun, however, includes the annual aberration.

The constant of aberration. The value of the constant of aberration, the direct measurement of which is discussed above, may also be calculated from the dimensions of the solar system. Taking into account the ellipticity of the Earth's orbit, the expected value of κ, which is related to the mean velocity of the Earth in its orbit, is given by the following equation:

$$\kappa = \frac{2\pi a}{cT\,(1 - e^2)^{\frac{1}{2}}} \text{ X } 2.06264 \times 10^5 \text{ sec arc,}$$

in which a is the semi-major axis of the Earth's orbit, e is its eccentricity, and T is the sidereal year expressed in mean solar seconds. If the equatorial radius of the Earth is denoted ρ, and the solar parallax is π_{Sun}, then these two quantities are related by the equation:

$$a = \frac{\rho}{\pi_{Sun}} \times 2.06264 \times 10^5.$$

Substituting for a in the equation for κ gives,

$$\pi_{Sun}\kappa = \frac{2\pi\rho}{cT\,(1 - e^2)^{\frac{1}{2}}} \times (2.06264 \times 10^5)^2.$$

Substitute the following values in this equation: $e = 0.01675$, $\rho = 6.378245 \times 10^3$ kilometres, $c = 2.997925 \times 10^8$ metres per second, then T = 3.155814954 X 10^7 seconds. The value for the velocity of light (above) is recommended by the XII General Assembly of the International Scientific Radio Union, which has assigned to it an uncertainty of ±0.0004 metre per second. This substitution leads to the following numerical relation between κ and π_{Sun}.

$$\pi_{Sun}\,\kappa = 180.245$$

Bradley was aware of such a relationship and used a similar one to verify his theory of aberration. Knowing the velocity of the Earth in its orbit, he was able to calculate: from his own observations, the time taken by light in its passages from the Sun to Earth. A comparison of this time with that deduced from the velocity of light, obtained from observations of the satellites of Jupiter, gave agreement to within 1 part in 493.

The relation may be used to deduce either the constant of aberration or the solar parallax. The solar parallax is now determined directly, knowing the velocity of light, by observing radar echoes from Venus. The accuracy of radar results greatly surpasses that obtainable by the best optical measurements. Probably the most accurate solar paraliax obtained by radar is that of D.O. Muhleman, who obtains 8.7941379 seconds of arc ± 0.0000015 second. Substituting this value into the previous relation gives $\kappa = 20.496$ seconds of arc. Note that this value for κ is independent of the velocity of light that is assumed.

Aberration, ether, and relativity. Although the phenomenon of aberration found a natural explanation in a particle theory of light, its explanation by a wave theory is not simple; and it was thought at the time that the amount of aberration might depend upon the thickness of glass or other transparent material in the telescope. Sir George Airy, then Astronomer Royal, remarked that this is "... a question which involves, theoretically, one of the most delicate points in the Undulatory Theory of Light." In order to test this point, Airy performed in 1871 a famous and far-seeing experiment. He filled a telescope with water and with it measured again the aberrational displacement, finding that use of the water-filled telescope gave the same result as before. At first sight, this is a rather surprising result, because in addition to refraction at the air–water interface, the light will pass more slowly between the slits if there is water between them, so that the tilt of the telescope should be increased. The magnitude of the expected effect can be readily calculated, if it is assumed that the water-filled telescope must be inclined at the new angle of aberration ξ. Because the light is refracted when it enters the telescope, it travels along the telescope inclined at an angle Ψ to its axis. As both ξ and Ψ are small angles, an approximate form of the refraction formula $\Psi \sim$ *3/12* (in which n is the refractive index of water) may be used to calculate * ▪. The velocity of light in the new telescope is equal to c/n, and the former condition for observation of the star must be modified to $\Psi = nv/c$. Hence, $\xi = n^2v/c$. Indeed, it should be possible to measure the absolute speed of the Earth, not just its orbital speed, by just such an experiment as this, for the change in angle of aberration on filling the telescope with water should be equal to

$$\xi - \zeta = \frac{n^2v}{c} - \frac{v}{c} = \frac{v}{c}(n^2 - 1).$$

The matter of why ξ should equal ζ can be resolved in a formal manner by following a suggestion first made by the French physicist Augustin-Jean Fresnel, that the water drags the light sideways with it at a velocity equal to fv, in which the factor f is called the Fresnel drag coefficient. A simple extension of the calculation given above shows that the null effect of filling the telescope with water can be accounted for if f is put equal to $1 - 1/n^2$. In 1871 the drag coefficient was already an established part of physics through the work of Armand-Hippolyte-Louis Fizeau, who had succeeded in demonstrating the effect quantitatively. Fizeau constructed an interferometer into the two beams of which were introduced tubes containing water. Interference fringes were obtained first with the water still, and then with the water in one tube following in the direction of the light, and in the other tube against the direction of the light. A small shift in the position of the fringes, increasing with the speed of the water, verified the expression for the drag coefficient.

The aberration experiment was not the only one to fail to give the absolute velocity of the Earth through the ether. Even more celebrated was that of Albert A. Michelson, and later Michelson and Edward E. Morley, who attempted to measure absolute velocity by using an interferometer to compare the speed of light in the direction of the Earth's motion with the speed at right angles to the motion; again the result was negative. Just as the aberration experiment apparently needed the drag coefficient for its understanding, so the Michelson–Morley experiment required the Lorentz–Fitzgerald contraction—a contraction of a moving body by a factor $1 - v^2/c^2$ in the direction of motion.

Theory of relativity

These facts found a natural expression in Einstein's special theory of relativity. For example, the Fresnel drag coefficient now emerges as the result of combining in a relativistic fashion the velocity of light in the medium, c/n, with the velocity of the medium. The aberrational effect can he calculated similarly by transforming the velocity components of a photon in a frame of reference, S, which might be the rest frame of the Sun, to the components in another frame of reference, S′, that of the Earth. If the velocity difference between the two frames of reference is V, then a velocity u_x in one system transforms into a velocity u_x' in the other, in which

$$u_{x'} = \frac{u_x + V}{1 + \frac{u_x \times V}{c^2}}.$$

Taking, as before, the angle between the line of sight to the star and the direction of the Earth's velocity as θ, so that $u_x = \cos\theta$, then the star appears at inclination θ' in frame S′ in which

$$\cos 8' = \frac{\cos\theta + V/c}{1 + V/c \cos 8'}$$

This is the relativistic form of the aberration formula, in which the change in direction of the star is equal to $\theta\text{-}\theta' = \xi$. The formula was derived by Einstein in his celebrated paper of 1905 on relativity. Putting, as is usual, $\beta = V/c$, and expanding this relation in terms of β, a second order is obtained in β, $\zeta = \beta \sin\theta - \beta^2 \sin 2\theta$.

As $\beta \sim 10^{-4}$, it is possible for practical purposes to neglect the term in β^2, when the formula reverts to the one obtained classically. If it is felt necessary, the calculation can be repeated for a telescope filled with water, with the same results. The Michelson–Morley experiment is technically an extremely difficult one to carry out, and it is satisfying that such a simple experiment as measuring the constant of aberration with a water-filled telescope can provide direct evidence for the theory of relativity.

BIBLIOGRAPHY. The discovery of aberration by Bradley is described in "A Letter from the Reverend Mr. James Bradley Savilian Professor Astronomy at Oxford, and F.R.S. to Dr. Edmond Halley Astronom. Reg. & c. Giving an Account of a New Discovered Motion of the Fix'd Stars," *Phil. Trans. R. Soc.*, 35:637–661 (1728). A general account of the circumstances of the discovery and of the life of Bradley is given by s . ~RIGAUD in his book, *Miscellaneous Works and Correspondence of James Bradley* (1832). The relativistic treatment of aberration was first given by EINSTEIN in his paper, "Zur Elektrodynamik bewegter Korper," *Annln. Phys.*, 17:891–921 (1905). The methods of correction of star places for aberration are given fully in the *Explanatory Supplement to the Astronomical Ephemeris and the American Ephemeris and Nautical Almanac* (1961); a full account of early work on aberration and a tabulation of early data is given by K.A. KULIKOV, *Fundamental Constants of Astronomy* (1964; orig.

pub. in Russian, 1956). An account of the 21st International Astronomical Union symposium, May 1963 is ***The System of Astronomical Constants,*** ed. by J. KOVALEVSKY (1965).

(D.E.Bl.)

Lighthouse

Lighthouses, the centuries-old function of which is to provide the mariner with an identifiable seamark by day and by night, giving him positional information and warning him of a hazard, have been influenced by the continuing advance of technology. More advanced and sophisticated aids, such as radio navigation systems, may be considered part of the subject treated in this article.

HISTORY

Lighthouses of antiquity. The forerunners of lighthouses proper were beacon fires, kindled on hilltops, the earliest references to which are contained in the *Iliad* and the Odyssey. The first authenticated man-made lighthouse was the renowned Pharos of Alexandria, which stood some 350 feet high. The Romans erected many lighthouse towers in the course of expanding their empire, and by AD 400 there were some 30 in service from the Black Sea to the Atlantic. These included a famous lighthouse at Ostia, the port of Rome, completed in AD 50, and lighthouses at Boulogne and Dover. A fragment of the original Roman lighthouse at Dover survived in the 1970s.

The Phoenicians, trading from the Mediterranean to Great Britain, marked their route with lighthouses, the present structure at La Coruña, Spain, being close to the site of an ancient Phoenician lighthouse (see Figure 1, right). These early lighthouses had wood fires or torches burning in the open, sometimes protected by a roof. After the 1st century AD, candles or oil lamps were used in lanterns with panes of glass or horn.

Medieval lighthouses. The decline of commerce in the Dark Ages halted lighthouse construction until the revival of trade in Europe about AD 1100. The lead in establishing new lighthouses was taken by Italy and France. By 1500, references to lighthouses became a regular feature of books of travel and charts. By 1600, at least 30 major beacons were established.

Lanterna of Genoa

These early lights were similar to those of antiquity, burning mainly wood, coal, or torches in the open, although oil lamps and candles were also used. A famous lighthouse of this period was the Lanterna of Genoa, probably established about 1139. It was rebuilt completely in 1544 as the impressive tower that remains a conspicuous seamark today. The keeper of the light in 1449 was Antonio Columbo, uncle of the Columbus who crossed the Atlantic. Another early lighthouse was built at Meloria, Italy, in 1157, which was replaced in 1304 by a lighthouse on an isolated rock at Leghorn. In France the Roman tower at Boulogne was repaired by the Emperor Charlemagne in AD 800. It lasted until 1644, when it collapsed due to undermining of the cliff. The most famous French lighthouse of this period was one on the small island of Cordouan in the estuary of the river Gironde, near Bordeaux. The original was built by Edward, the Black Prince, in the 14th century. In 1584 Louis de Foix, an engineer-architect, undertook the construction of a new light, which was one of the most ambitious and magnificent achievements of its day. It was 135 feet in diameter at the base and 100 feet high, with an elaborate interior of vaulted rooms, richly decorated throughout with a profusion of gilt, carved statuary, and arched doorways. It took 27 years to build, due to subsidence of the apparently substantial island. By the time the tower was completed in 1611, the island was completely submerged at high water. Cordouan thus became the first lighthouse to be built in the open sea, and the true forerunner of such rock structures as the Eddystone Lighthouse.

The influence of the Hanseatic League helped increase the number of lighthouses along the Scandinavian and German coasts. At least 15 lights were established by 1600, making it one of the best lighted areas of that time.

During this period there was a fairly extensive use of lights exhibited from chapels and churches on the coast as a substitute for lighthouses proper, particularly in Great Britain.

Winstanley's wooden tower at Eddystone

The beginning of the modern era. The development of modern lighthouses can be said to have started from about 1700, when improvements in structures and lighting equipment began to come more rapidly. In particular, that century saw the first construction of towers fully exposed to the open sea. The first of these was Henry Winstanley's 120-foot-high wooden tower on the notorious Eddystone Reef, off Plymouth. Although anchored by 12 iron stanchions laboriously grouted into exceptionally hard red rock, it lasted only from 1699 to 1703, when it was swept away without a trace in a storm of exceptional severity; its designer and builder, on the lighthouse at the time, perished with it. It was followed in 1708 by a second wooden tower, constructed by John Rudyerd, which was destroyed by fire in 1755. Rudyerd's lighthouse was followed by J. Smeaton's famous masonry tower in 1759. Smeaton, a professional engineer, embodied an important new principle in its construction whereby masonry blocks were dovetailed together in an interlocking pattern. He also devised the curved hyperbolic profile, which became the classic design for the world's lighthouse builders. It was later modified to include a solid cylindrical base to break the main force of the sea and reduce the tendency of waves to sweep up the sides.

Due to the undermining of the foundation rock, Smeaton's tower had to be replaced in 1882 by the present lighthouse, constructed on an adjacent part of the reef by Sir James Douglass, engineer in chief of Trinity House. The upper portion of Smeaton's lighthouse was dismantled and rebuilt on Plymouth Hoe, where it still stands as a monument; the lower portion or "stump" can still be seen on the Eddystone Reef. Following the Eddystone, masonry towers were erected in similar open sea sites, which include the Smalls, off the Welsh coast; Bell Rock in Scotland; South Rock in Ireland; and Minots Ledge off Boston, Massachusetts. The first lighthouse of the American continent, built in 1716, was on the island of Little Brewster, also off Boston. After about 1775, lighthouse construction spread rapidly. By 1820 there were an estimated 250 major lighthouses in the world.

MODERN LIGHTHOUSES

Construction. While masonry and brick continue to be used, particularly for shore lighthouses, concrete and steel are the most favoured forms of construction, particularly offshore.

Structurally well-suited and reasonably cheap, concrete lends itself to aesthetically pleasing designs for shore-based lighthouses. The new lighthouse erected at Dunge Ness, England, in 1961 is a notable example of how concrete can provide strength without great mass. The slender 135-foot tower, rising from a spiral base, is admirably proportioned architecturally (see Figure 1, left).

Submerged caisson construction

Modern construction methods have considerably facilitated the building of lighthouses in the open sea. On soft ground, the submerged caisson method is used, a system first applied in 1885 to the building of the Roter Sand Lighthouse in the estuary of the Weser River in Germany, and then to the Fourteen Foot Bank light in the Delaware Bay, Delaware. With this method, a steel caisson or open-ended cylinder, perhaps 40 feet in diameter, is positioned on the seabed. By excavation of sand, it is sunk into the seabed to a depth of possibly 50 feet. At the same time, extra sections are added to the top as necessary so that it remains above high water level. The caisson is finally pumped dry and filled with concrete to form a solid base on which the lighthouse proper is built.

Two other main types of construction are used for offshore lighthouses where the seabed is reasonably firm and level. The first utilizes concrete to build a "float out" lighthouse: a cylindrical tower on a large hollow concrete base, which can be 50 feet in diameter. The tower is constructed in a shore berth, towed out to position, and then sunk to the seabed where the base is finally filled with sand. Weighing 5,000 tons or more, these towers rely on their weight for stability and require a levelled, prepared seabed. For greater stability during towing, the cylindrical tower itself often consists of two or more telescopic sections, raised to full height by hydraulic jacks after being founded on the seabed. This design has been pioneered largely in Sweden, where at least eight have been constructed.

Texas Towers

The other form of construction, using open steelwork, is largely based on the design of offshore oil and gas wells, including the so-called Texas Towers. A typical lighthouse of this type has an upper deck containing the plant, the equipment, and personnel accommodation. It is usually about 60 square feet, with a short tower on one corner to support the light. The deck also can provide a helicopter landing platform. The accommodation deck is supported on four to eight tubular steel piles, about two feet in diameter, driven into the seabed to a penetration of 150 feet or more. Before the piles are driven, a tubular steel braced framework, known as a "jacket" or "template," is placed in position on the seabed. The piles are driven down through the vertical tubular members of the jacket, which act as guides. Concrete grout is then forced into the annular space between pile and jacket tube. The deck is usually fabricated on shore, taken out on a barge, lifted into position on the substructure by floating crane, and welded on. The U.S. has built about 15 light towers of this type to replace lightships. The most recent is Ambrose Light off New York.

Illurninants. Wood fires were not discontinued until 1800, though after c. 1550 coal, a more compact and longer burning fuel, was increasingly favoured, particularly in northwestern Europe. A lighthouse in those days could consume 300 tons or more of coal a year. In full blaze, the coal fire was far superior to other forms of lighting, preferred by mariners to oil or candles. The disadvantage of both coal fires and early oil lamps and candles was the prodigious amount of smoke produced, which resulted in rapid blackening of the lantern panes, obscuring the light.

The Argand lamp

In 1782 a Swiss scientist, Aimé Argand, invented an oil lamp whose steady smokeless flame revolutionized lighthouse illumination. The basis of his invention was a circular wick, with a glass chimney that ensured an adequate current of air up the centre and the outside of the wick for even and proper combustion of the oil. Eventually, Argand lamps with as many as ten concentric wicks were designed. These lamps originally burnt fish oil, later vegetable oil, and by 1860 mineral oil was in general use. The Argand lamp became the principal lighthouse illuminant for over 100 years. A few are still in use.

In 1901, Arthur Kitson invented the vaporized oil burner, which was subsequently improved by David Hood and others. This burner utilized kerosene vaporized under pressure, mixed with air, and burnt to heat an incandescent mantle. The effect of the vaporized oil burner was to increase six times the power of former oil wick lights. The principle is widely used for cooking stoves, pressure lamps, etc.

Early proposals to use coal gas at lighthouses did not meet with great success. A gas-making plant at the site was usually impracticable and most of the lights were too remote for a piped supply. The use of acetylene gas, generated in situ from calcium carbide and water, increased following the discovery of the dissolved acetylene process, which by dissolving the acetylene in acetone made it safe to compress for storage.

Use of acetylene gas

Acetylene gas as a lighthouse illuminant had a profound influence on the advancement of lighthouse technology, mainly through the work of Gustaf Dalén of Sweden, who pioneered its application between 1900 and 1910. Acetylene produced a light equal to that of oil, burnt either as an open flame or mixed with air in an incandescent mantle. Its great advantage was that it could be readily controlled; thus for the first time automatic unattended lights were possible. Dalén devised many ingenious mechanisms and burners, operating from the pressure of the gas itself, to exploit the use of acetylene. Most of the equipment he designed is still in general use today. One device is an automatic mantle exchanger that brings a fresh mantle into use when the previous one burns out. Another, economizing on gas, was the "sun valve," an automatic day–night switch capable of extinguishing the light during the day. The switch utilized the difference in heat-absorbing properties between a dull black surface and a highly polished one, producing a differential expansion arranged by suitable mechanical linkage to control the main gas valve.

The acetylene system facilitated the establishment of many automatic unattended lighthouses in remote and inaccessible situations, normally only requiring an annual visit to replenish the storage cylinders and overhaul the mechanism. Acetylene equipment is still widely used today because of its simplicity, robustness, and ease of maintenance. Liquefied petroleum gas, such as propane, is also used.

Electric illumination in the form of carbon arc lamps was first employed at lighthouses at an early date, even while oil lamps were still in vogue. The first of these was at Dunge Ness, England, in 1862, followed by a number of others. The majority of these, however, were eventually converted to oil, since the early arc lamps were difficult to control and costly to operate. In 1913, the Helgoland Lighthouse was equipped with arc lamps and searchlight mirrors to give a light of 38,000,000 candlepower, the most powerful lighthouse in the world at that time.

Electric-filament lamps

The electric-filament lamp, which came into general use in the 1920s, is the standard electric illuminant for lighthouses today. The light output is some ten times that of the vaporized oil burner. Electric lamps in common use range from a maximum of about three kilowatts down to as little as six watts or so for small buoy and beacon lights. When a specially powerful light is required, modern arc lamp equipment is employed. This is usually the compact type, with the arc enclosed in a glass bulb to make the lamp replaceable. While mercury arc lamps are used, they have a distinct bluish colour. The xenon arc lamp, originally developed for colour film work, is preferred for the intense white light it produces. The most powerful lighthouse in the world today, at Creach, Ile D'Ouessant, France, is a carbon arc installation. An augmented light, giving a beam of 500,000,000 candlepower, is brought into service only during fog or misty weather.

Various lighthouse authorities are currently experimenting with the electronic xenon flash tube, a novel type of lamp used in photography. This lamp produces a very short flash of a few millionths of a second duration of extremely high intensity, imparting a distinctive character to the light and making it particularly conspicuous against other background lights.

The catoptric system

Optical equipment. With the advent of the Argand lamp, a reliable and steady illuminant, it became possible to develop effective optical apparatus for increasing the intensity of the light. In the first equipment of this type, known as the catoptric system, paraboloidal reflectors concentrated the light into a beam. William Hutchinson of Liverpool in 1777 produced the first practical mirrors for lighthouses, consisting of a large number of small facets of silvered glass, set in a plaster cast molded to a parabolic form. More generally, shaped metal reflectors were used, silvered or highly polished. These were prone, however, to rapid deterioration from heat and corrosion; the glass facet reflector, although not as efficient, lasted longer. The best metallic reflectors available in 1820 were constructed of heavily silvered copper in the proportion of six ounces of silver to one pound of copper (compare one-half ounce of silver to one pound of copper commonly used for plated tableware of the period). The cleaning cloths were kept for subsequent recovery of the silver. These mirrors could increase the intensity of an Argand lamp, nominally about five candlepower, almost 400 times.

Although the mirror could effectively concentrate the light into an intense beam, it was necessary to rotate it to make it visible from any direction. This produced the now-familiar revolving lighthouse beam, with the light appearing as a series of flashes.

Mariners were not favourably disposed to these early flashing lights, contending that a fixed steady light was essential for a satisfactory bearing. However, the greatly increased intensity and the advantage of using the pattern of flashes to identify the light gradually overcame their objections. The first revolving beam lighthouse was at Carlsten, near Marstrand, Sweden, in 1781.

The Fresnel dioptric system

In 1828 Augustin Fresnel of France produced the first apparatus using the refracting properties of glass, now known as the dioptric system. On a lens panel he surrounded a central bull's-eye lens with a series of concentric glass prismatic rings. The panel collected light emitted by the lamp over a wide horizontal angle and also the light that would otherwise escape to the sky or to the sea, concentrating it into a narrow, horizontal pencil beam. With a number of lens panels rotating around the lamp, he was then able to produce several revolving beams from a single light source, an improvement over the mirror that produces only a single beam. To collect more of the light wasted vertically, he added triangular prism sections above and below the main lens, which both refracted and reflected the light. By doing this he considerably steepened the angle of incidence at which rays shining up and down could be collected and made to emerge horizontally. Thus emerged the full Fresnel catadioptric system, the basis of all lighthouse lens systems today. To meet the requirement for a fixed all-round light, Fresnel modified his principle by producing a cylindrical drum lens, which concentrated the light into an all-round fan beam. Although not as efficient as the rectangular panel, it provides a steady, all-round light. Small drum lenses, robust and compact, are widely used today for buoy and beacon work, eliminating the complication of a rotating mechanism.

Prior to Fresnel's invention the best mirror systems could produce a light of about 20,000 candles, using an Argand lamp. The Fresnel lens system increased this to 80,000 candles, roughly equivalent to a modern automobile head lamp; with the pressure oil burner, intensities of up to 1,000,000 candlepower could be achieved.

For a light of this order the burner mantle will measure four inches in diameter. The rotating lens system would have four large Fresnel glass lens panels, 12 feet high, mounted about four feet from the burner on a revolving lens carriage. The lens carriage would probably weigh five tons, about half of it being the weight of glass alone. The rotating turntable floats in a circular cast iron trough containing mercury. With this virtually frictionless support bearing, the entire assembly can be smoothly rotated by weight-driven clockwork. If the illuminant is acetylene gas, the lens rotation can be driven by gas pressure. Installations of this type are still in common use, although many have been converted to use an electric lamp with an electric-motor drive. Modern lens equipment of the same type is much smaller, perhaps 30 inches high, mounted on ball bearings and electric-motor driven. With a 250-watt lamp, illumination of several hundred thousand candlepower can be readily obtained. Lens panels are now moulded in transparent plastic (Perspex), which is lighter and cheaper. Drum lenses are also moulded in plastic. In addition, with modern techniques high-quality mirrors can be produced easily and cheaply.

Intensity, visibility, and character of lights. The candlepower of illumination is expressed in terms of the international unit, the candle (also called candela). Intensities of lighthouse beams vary from thousands to millions of candles. The range at which a light can be seen depends upon atmospheric conditions and elevation. Since the geographical horizon is limited by the curvature of the earth, it can be readily calculated for any elevation by standard geometrical methods. In lighthouse work the observer is always assumed to be at a height of 15 feet, although on large ships he may be 40 feet above the sea. Assuming a light at a height of 100 feet, the range to an observer at 15 feet above the horizon will be about 18 miles. This is known as the geographical range of the light. In clear weather a light of 10,000 candles will be visible at 18 miles.

Known as the luminous range of the light, this distance is the limiting range at which the light is visible, in the prevailing atmospheric condition, disregarding limitations due to its height and the earth's curvature. A very powerful light, low in position, could thus have a clear-weather luminous range greater than that when first seen by the mariner on the horizon. Powerful lights can usually be seen over the horizon because the light is scattered upward by particles of water vapour in the atmosphere; the phenomenon is known as the loom of the light.

Atmospheric conditions have a marked effect on the luminous range of lights and are defined in terms of a transmission factor expressed as a fraction or a percentage up to a maximum of unity or 100 percent, assuming a perfectly clear atmosphere, never attained in practice. Clear weather in the British Isles corresponds to about 80 percent transmission, but in tropical regions it can rise to 90 percent, increasing the luminous range of a 10,000-candle light from 18 to 28 miles. Conversely, in mist or haze at about 60 percent transmission, a light of 1,000,000 candles would be necessary to maintain a luminous range of 18 miles. In dense fog, with the visibility down to 100 yards, a light of 10,000,000,000 candles could scarcely be seen at one-half mile. Because average clear weather conditions vary considerably from one region of the world to another, luminous ranges of all lighthouses by international agreement are quoted in an arbitrary standard clear-weather condition corresponding to a daytime meteorological visibility of 10 miles, or 74 percent transmission. This is known as the nominal range of a light. Mariners use nautical conversion tables to determine the actual luminous range in the prevailing visibility.

Sector lights

Fixed lights are still used in port, harbour, and estuarial areas where they give the mariner directional information by showing red or green over sharply defined sectors. Known as range or sector lights, they are often shown as fixed lights subsidiary to the main flashing light of the lighthouse. Another range system, sometimes called leading lights, consists of two lights at different elevations, about a half-mile apart. The mariner steers to keep the two lights in line one above the other.

Most lighthouses rhythmically flash or eclipse their lights to provide an identification signal. The particular pattern of flashes or eclipses is known as the character of the light, and the interval at which it repeats itself is called the period. International agreement restricts the number of different characters that can be used, through the International Association of Lighthouse Authorities in Paris, to which the majority of maritime nations belong. The regulations are too lengthy to quote in full, but essentially a lighthouse may display a single flash, regularly repeated at perhaps 5-, 10-, or 15-second intervals. This is known as a flashing light. Alternatively, it may exhibit groups of two, three, or four flashes, with a short eclipse between individual flashes and a long eclipse of several seconds between successive groups. The whole pattern is repeated at regular intervals of 10 or 20 seconds. These are known as group flashing lights. In another category, "occulting" lights are normally on and momentarily extinguished, with short eclipses interrupting longer periods of light. Analogous to the flashing mode are occulting and group-occulting characters. A special class of light is the isophase, which alternates eclipses and flashes of exactly equal duration.

The daymark requirement of a lighthouse is also important; lighthouse structures are painted to stand out against the prevailing background. Shore lighthouses are usually painted white for this purpose, but in the open sea or against a light background conspicuous bands of contrasting colours, usually red or black, are utilized.

Sound signals. Periods of bad visibility led fairly early to the idea of a supplementary audible warning. At first, sound signals were explosive, created by a cannon, or bells, Both were being used in the 1970s.

The explosive can be heard up to four miles. Charges are attached to a jib arm above the lighthouse lantern and detonated electrically at regular intervals of from two to five minutes. Sometimes the charges incorporate magnesium to give a bright flare. Often bells up to one ton in weight are arranged to sound at predetermined intervals. At times this action is automatic, with the use of a piston-operated striker powered by a compressed gas cylinder.

Fog signals

Fog signals that depend upon compressed air for their operation and emit a continuous note are most effective. The Reed operates like a reed musical wind instrument. It emits a rather high-pitched note at about 500 hertz. Although efficient, it is limited in power and not much used. The Siren has a slotted revolving rotor and fixed slotted stator at the throat of a suitable horn. The rotor is driven by an electric motor, or by the compressed-air supply, which is chopped by the rotating member. The Diaphone works on the same principle but uses a reciprocating slotted piston in a cylinder with matching ports. The Tyfon has a vibrating metal diaphragm operated by a system of valves and differential air pressure. Sirens, Diaphones, and Tyfons produce a low note of about 150 hertz.

The larger sizes of Diaphones are the most powerful fog signals in existence, with ranges up to eight miles. They consume as much as 40 cubic feet of air a second during blast, however, and require a large and powerful compressing plant of 50 horsepower or more. The Tyfon is an efficient, compact unit with low air consumption. It is common practice to mount a number of emitters in a vertical column, which concentrates the propagation of the sound in a horizontal direction and minimizes wasteful dispersion of sound vertically. Such an array can have an audible range of four to five miles.

With fog signals capable of emitting a continuous note, the station is distinctly identified, as with lights, by a predetermined number of short blasts regularly repeated. The Diaphone is much favoured by mariners because it has a distinctive sound, with a short, low-pitched characteristic grunt at the end of each blast. A compressed-air fog signal installation at a lighthouse can involve a formidable amount of machinery such as air compressors and storage reservoirs for the air, valves, piping, etc. Operating air pressures range from 30 to 60 pounds per square inch.

Electric fog signals, sometimes called Nautophones, are of the vibrating diaphragm type. A metal plate between the pole pieces of a magnet vibrates because alternating current passes through windings around the magnet. Nautophones usually produce a note of about 300 hertz. The most powerful emitters can handle one kilowatt of power, supplied from special alternators or solid-state, electronic-drive units. It is common practice to arrange these emitters in vertical columns, as for the Tyfon. Typical installations have a total power of four to six kilowatts and a range of three to four miles.

The propagation of sound in the open air is somewhat haphazard due to the vagaries of atmospheric conditions, which greatly affect its acoustic properties. Humidity, turbidity, and temperature all have an effect, and layers of air of different temperature can deflect the sound up or down. Ranges of fog signals therefore can vary greatly from day to day and quoted figures must be treated with caution, as it is impossible to guarantee performance.

A useful system around 1930 relied on the transmission of sound waves through the water, giving greater range and consistency. Underwater fog signals of this type were virtually abandoned but they were again being seriously reconsidered in the light of the modern technology of sonar (*q.v.*).

Radio aids. Sophisticated and complex radio-navigation systems such as Decca and Loran are not properly within the field of lighthouses, though in some countries they are operated as part of the lighthouse administration (see NAVIGATION).

Radio and radar beacons

Two aids that are strictly complementary to a lighthouse are the radio and radar beacons. Many lighthouses are fitted with medium-frequency radio-beacon equipment operating around 300 kilohertz. These transmit a characteristic signal lasting one or two minutes, with the station identification repeated continuously in Morse Code. A long dash of 20–25 seconds during the transmission enables a ship to take a bearing with its radio direction finder. Depending on the sector of the world, transmissions vary from five minutes every hour to continuously in busy waters. In Europe where there are a large number of radio-beacons, they are arranged in groups of three on one frequency to avoid interference. Each station in a group transmits for one minute of every three. This enables the ship to take three bearings in quick succession and to obtain a fix by triangulation.

Radar beacons are known as racons. Their purpose is to increase the strength of the reflected radar pulse from a seamark such as a lighthouse, lightship, or buoy and to enhance its presentation on the ship's radar screen. They also identify it positively from other echoes on the radar picture. In the passive method, polyhedral clusters of metal sheets are arranged to reflect as much as possible of the radar pulse emitted by the ship's radar. The racon is an active device, consisting of a small microwave transmitter-receiver. The radar pulse is picked up by the receiver and retransmitted in an amplified form. It is also processed so that it appears in an unambiguous form on the radar screen, usually as a short bright line immediately behind the target that can be broken up into an arrangement of dots and dashes to provide better identification.

Lightships and buoys. *Lightships.* Lightships originated in the early 17th century, arising from the need to establish seamarks in positions where lighthouses were at that time impracticable. The first lightship, established in 1732 at Nore Sand in the Thames Estuary, was rapidly followed by others. These early vessels were small converted merchant or fishing vessels showing lanterns suspended from crossarms at the mast head. Not until 1820 were vessels built specifically as lightships.

A modern lightship is constructed of steel, measures about 120 feet in length, and has a 25-foot beam (see Figure 2, left). A crew of seven is usual. The lightship carries a full range of lighthouse aids, including a powerful light, a compressed air or electric fog signal, radio beacon, and racon. The light is usually revolving-mirror equipment to save weight, and intensities up to 500,000 candles are common. Since a lightship rolls and pitches in the sea, lighting equipment is gimbal-mounted on a pendulum-stabilized platform to keep the light beams horizontal. Light vessels do not usually carry any means of propulsion; they are moored by a single chain and anchor from the bow. There have been a number of unmanned lightships, usually in the form of a boat-shaped float fitted with automatic acetylene light and gas-operated bell that are adequate in sheltered waters and where high-powered illumination is not required. A recent development is a large 40-foot diameter unmanned buoy, originally developed for oceanographic purposes, that can survive the worst open-sea conditions (see Figure 2, right). It carries an automatic diesel-engine power plant for its powerful light and fog signal.

Buoys. Buoys delineate channels in estuaries; approaches to ports and harbours; and mark isolated dangers, wrecks, and local areas of special significance. Con-

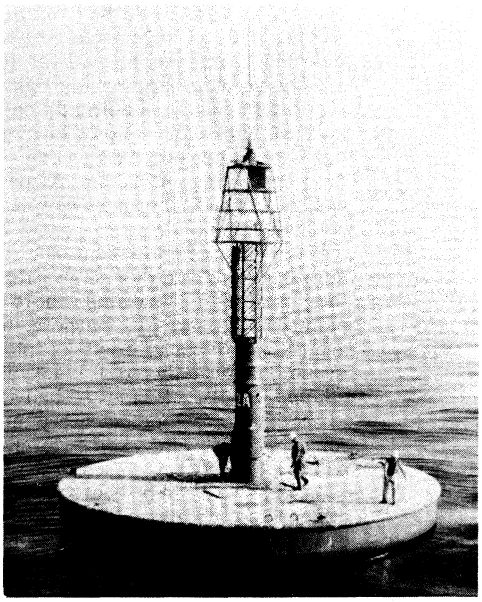

Figure 2: Modern *lightship* and *buoy*.

structed usually of ½-inch steel plate, they vary in size from five to ten feet in diameter and from one to nine tons in weight. Buoys are moored to a two- or three-ton concrete or cast-iron sinker by a single length of chain, which is ordinarily about three times as long as the depth of water at the mooring location. Smaller sized buoys recently have been manufactured in glass-reinforced plastic (glass fibre). Buoys are inspected at regular intervals and removed periodically for cleaning, painting, renewal of moorings, etc.

Cardinal and Lateral systems

Colour, shape, appearance of a buoy (*i.e.*, its daymark), and the character of the light, if fitted, convey information to the mariner. Buoys must conform to one of two internationally agreed systems of buoyage, drawn up by the League of Nations in 1936. Known as the Cardinal and Lateral systems, they designate specific shapes and colours for the various buoy positions. With the Cardinal system the form of the buoy indicates the bearing of the significant feature it marks; with the Lateral system buoys are laid along routes or channels to indicate on which side of the buoy the ship should pass.

In the more widely used Lateral system there are three main daymark shapes: conical, cylindrical or can, and spherical, and two main colours, black or red, alternated with white or plain. Lights are white, green, or red, showing specified characters. For additional differentiation, topmarks in the form of can, cone, sphere, diamond, tee, or cross can be mounted above the buoy. With unlighted buoys the body profile incorporates the daymark shape. The top mark, if any, is carried on a staff fixed to the top of the buoy. Lighted buoys have a cylindrical body with the daymark shape carried on a superstructure. The light and sometimes a radar reflector are mounted above the superstructure. The buoy measures about 14 feet from keel to top of superstructure, carrying the light about nine feet above the sea. In high focal plane buoys an extra high superstructure increases the range of the light. A long, cylindrical tail tube attached to the bottom of the hull promotes stability and makes the buoy about *36* feet from top to bottom.

Lights can be acetylene, propane, or electric. A small drum lens six to eight inches in diameter provides a light of 100 to 200 candles with a clear-weather range of five to six miles. With electric lights a 12-volt, 6- or 12-watt lamp is typical.

Gas-storage cylinders or electrical batteries, enclosed within the cylindrical hull, power the buoy lights for up to two years without attention. The light can be extinguished during the day by a photoelectric day-night switch or a "sunvalve," in the case of acetylene equipment. Buoys are sometimes fitted with small electric fog signals with a range of about a half-mile. Bells can be actuated in a random fashion by the motion of the buoy or regularly by a striker operated from compressed carbon dioxide. Bouys also can be fitted with whistles, actuated by the motion of the sea, which draws air into a central tube and expels it.

Automatic lighthouses. A fair degree of automation was first achieved with the acetylene-gas system. Today, with the increasing use of electrical equipment, modern industrial automation techniques are being applied. In the automatic lampchanger, from two to six electric lamps are carried on a rotating carriage. The lamps are arranged to bring a fresh replacement into position and focus when the filament of the lamp in use burns out. Lighthouses are costly to operate and maintain. If lightkeepers can be eliminated and maintenance visits reduced, considerable money can be saved.

Much effort has been devoted to the development of fog-detecting systems, capable of automatically starting the fog signal when the visibility falls. A number of satisfactory instruments are in use.

Lighthouses, lightships, and buoys are by their very nature located in remote or inaccessible situations where it may be difficult to provide electric power from a public supply. For lighthouses and lightships, power is often generated in situ from diesel generators. For buoys and minor lights replaceable electric batteries are used. Alternative power supplies are being developed to provide long periods of unattended service. Wind generators have been successfully used. Fuel cells and radioisotope generators, the latter offering 10 years' operation without refuelling, are also being investigated. Solar cells have been successfully used in a number of cases for small lights in extremely inaccessible positions. Electric generators that utilize the energy of the oscillating motion of the buoy in the sea have been tried with some success.

National lighthouse systems. *Lists of* **lights.** All lighthouse administrations publish Lists of Lights that are comprehensive catalogues of all lighthouses, lightships, buoys, and beacons under their control. These lists give the mariner the needed information regarding location and characteristics of the various lights. **The** major maritime countries publish light lists in several volumes, covering all the lights in the world. In the U.S. this is undertaken by the United States Coast Guard, and in Great

Britain by the Admiralty Hydrographic Department. These bodies also publish charts on a worldwide basis with similar information. Light lists and charts are kept up-to-date with information supplied by the lighthouse authority concerned. The latter publicize changes to lighthouses, lightships, and buoys by issuing Notices to Mariners, available to all ships' masters. Where a change occurs at short notice, for instance in the case of an emergency or breakdown, radio broadcasts notify mariners of the change.

Lighthouse administration. In most countries lighthouse administration comes under the appropriate department of the central government, financed as part of the government budget from taxation revenue. In many countries a number of lights, buoys, etc., are operated and maintained by dock and harbour authorities, often financed from harbour dues.

In the U.S., lighthouses and other aids are administered by the Aids to Navigation Division of the United States Coast Guard under the Federal Department of Transportation. Altogether the Coast Guard operates and maintains 500 lighthouses and nearly 40,000 other aids to navigation.

In Great Britain lighthouses in England and Wales are administered by the Corporation of Trinity House, a public corporation independent of the central government. The system is almost unique in that the service is financed by "light dues" levied on all shipping at every port in the United Kingdom based on the registered tonnage of the vessel. It evolved from the early medieval practice where lighthouses were operated by private individuals as a business enterprise under a dispensation purchased from the Crown, the granting of patents to erect and operate a lighthouse being vested in the Monarch of the day. Trinity House evolved from an early guild or fraternity of Pilots. In addition to its lighthouse activities it is also the United Kingdom Pilotage Authority.

The arrangement in its present form originated with the Merchant Shipping Act of Parliament in 1894, which abolished all privately owned lighthouses. It converted Trinity House into a public corporation with responsibility for all seamarks. Annual revenue from light dues is about £6,000,000; the Corporation maintains about 90 lighthouses, 34 lightships, and 600 buoys. Lighthouses in Scotland and Ireland are separately administered by the Northern Lighthouse Board and the Commissioners of Irish Lights. These are semi-autonomous bodies, financed from the same fund of light dues as Trinity House, which remains the ultimate approving authority for all United Kingdom sea marks. In nearly all other countries the lighthouse administration is either a government body in its own right or operates as part of or in association with a main department or ministry, as follows: West Germany—Ministry of Marine; France—Lighthouse Service in association with the Ministry of Public Buildings and Works; Sweden—National Administration of Shipping and Navigation; Norway—Directorate of Lighthouse Services; Canada—Aids of Navigation Division, Department of Transport; Japan—Navigational Aids Department, Maritime Safety Agency; and Italy—Inspectorate of Lights in conjunction with the Public Works Department and Ministry for the Mercantile Marine and General Navigation.

BOWEN, *British Lighthouses* (1947), a short but usefully comprehensive summary of British lighthouse practice from the early 19th century to 1947; G.R. PUTNAM, *Lighthouses and Lightships of the United States,* rev. ed. (1933), an historical survey of most of the major lighthouses and lightships of the U.S.; D.A. STEVENSON, *World's Lighthouses before 1830* (1959), and an edited version of a detailed journal kept by Robert Stevenson during a tour of English lighthouses, *English Lighthouse Tours of Robert Stevenson* (1946), classic works by a member of the famous family of Scottish lighthouse engineers; F. MAJDALANY, *The Red Rocks of Eddystone* (1959), a readable description of the building of the four Eddystone lighthouses, emphasizing the human and dramatic aspects of the work rather than the technical; H.P. MEAD, *Trinity House* (1947), a discussion of the origins and history of Trinity House, the lighthouse authority for England and Wales; UNITED STATES COAST GUARD, *Historically Famous Lighthouses* (1950), and *Coast Guard History* (1949), two pamphlets that provide a brief insight into the work of the U.S. Coast Guard and some of its more famous lighthouses.

(I.C.C.)

Lighting and Lighting Devices

Lighting in modern times derives almost entirely from electric light sources; lamps with a wire filament in an evacuated glass bulb or long fluorescent tubes. A building is lighted throughout to levels comparable with daylight, and selectively placed light is focussed on work of special difficulty. Lighting devices of many kinds have been used through the long ages since man learned to control fire. Evidence of torches has been found at archaeological sites; the cave paintings at Altamira in Spain and the Dordogne in France are perhaps the oldest.

From its beginnings, artificial light has had two distinct purposes: to permit visibility in natural darkness and to create visual effects. The development of lighting technology has been characterized by invention of light sources with greater output and efficiency. With the introduction of each light source, technology for its control has advanced. The candle produced the candelabra that enhances light with prismatic glass adornments. The oil lamp brought in its train the development of various reflectors to concentrate the light. The gas mantle gave rise to the first efforts at precise optical control with prisms and reflectors, the principles of which were later applied to the electric light bulb, which, in turn, because of its safety and cleanliness, permitted the first designs of decorative and architectural lighting fittings and lampshades. The last major advance in light sources, the fluorescent tube, gave rise to the luminous ceiling, a characteristic feature of modern buildings.

Two important aspects of the development of lighting technology in recent years can be identified. First, lighting technologists and specialists in human vision have collaborated, and a science of lighting and seeing has grown up, based on the idea that artificial lighting must be not only decorative but efficient and comfortable in terms of human sight, as well. Second, the lighting technologist has learned from the architect, who has always concerned himself with natural lighting in buildings but rarely with its artificial counterpart. The lighting engineer has learned about the flow of light, modelling of people and objects, and the active creation of beauty by the interplay of light, form, and colour. Perhaps to these could be added a third development, the tardy recognition by building designers and engineers that large amounts of artificial light give off heat, which ignored can cause discomfort but controlled can heat a building. Understanding the relationship between light and heat has given rise to the concept of total environmental design. (For information on the physics of light, see LIGHT, and OPTICS, PRINCIPLES OF. The principles of human vision are covered in EYE AND VISION, HUMAN.)

Development of lighting technology

THE BEGINNINGS OF ARTIFICIAL LIGHTING

Until the development of electric lighting in the 19th century, all artificial lighting was based on some form of incandescence brought about by burning fossil fuels. Wood brands could give massive amounts of light but were dangerous and difficult to control. The introduction of vegetable and animal oils, waxes, and fats and the wick to control the rate of burning represented a major advance, gradually refined in a number of ways. There are numerous examples from every ancient civilization of lamps designed for utility, decoration, or both. Improvements were made in design and fabrication of light sources but little in their efficiency. In 18th-century England, for example, the labourers in the countryside still made artificial lighting from rushes and pork fat.

Rush light

Nonelectrical lighting devices. *Oil lamps.* During the 18th and 19th centuries, however, useful improvements were made in the design of oil lamps as a result of a better understanding of the physics of combustion. More reliable and powerful than its predecessors, the Argand oil lamp of 1784 used a cotton wick with a controlled current of air to obtain maximum oxygen for efficient combustion together with glass cylinders with or without simple optical control (bull's-eye lens) of the light output. The discovery of massive reserves of petroleum fuel, particularly in the United States, and of refining methods that produced an oil (kerosene or paraffin) that burned efficiently in an oil lamp, but without any danger of spontaneous combustion, made cheap, reliable, and safe lamps widely available and rendered the wax candle obsolete except for decorative purposes.

Gas light. Unquestionably the major development in artificial lighting during the 19th century was the introduction of methods for generating and distributing coal gas to all buildings in an urban community. The subsequent discovery of natural gas, again in the United States and Canada, reduced the cost to the fortunate citizens within reach of the natural-gas fields but did not materially alter the design of lighting equipment. The first development of coal-gas illumination is credited to William Murdock, a Scottish engineer working in Cornwall, who, in the tradition of many British inventors, tried his experiments on his own family first by lighting his own home by gas in full knowledge of the risk of explosion. No explosion occurred, and, a few years later, at the turn of the century, Murdock was commissioned to install gas lighting in London. The gas lighting in Pall Mall, installed in 1820, is reputed to be one of the oldest extant street-lighting installations in the world. For several decades, gas lighting made use of a simple burner in which the yellow light of the flame itself was the source of illumination. During the 1820s a new form of burner was introduced in which a controlled amount of air was admitted to the gas current, producing a high-temperature but nonluminous flame that heated a refractive, noncombustible material to a very high temperature. This became the source of light: the higher the temperature of the material, the whiter the colour and the greater the light output.

Welsbach gas mantle

The search for an optimum material that would be durable, infusible, and capable of being repeatedly heated to white heat, culminated, during the 1880s, in the development of the Welsbach mantle, which, in its final form, consisted of a network woven in cotton, of spherical, cylindrical, or linear form, impregnated with the salts of thorium and cerium. By suitable treatment these mantles could be made sufficiently strong to be transported and retailed. Once they were fitted to the lighting appliance, however, the material which gave them stability burnt off. and a slight jar could destroy the mantle. In spite of this disadvantage, the introduction of the Welsbach gas mantle resulted in gas lighting being employed everywhere within reach of the distributive network of coal- or natural-gas supply. The incandescent light from the thorium–cerium salts in the mantle was not truly white but was tinged a greenish colour with the luminous emissions of these salts, giving rise to the somewhat garish and ghostly appearance characteristic of gaslight. This was unfavourably contrasted with the pleasant, warm glow of the candle, and, as a result, the introduction of the gas mantle was also responsible for a revival in the use of candlelight as a luxury to be indulged in by the wealthy. Improvements in gas lighting itself, particularly by the use of pressure boosted above the safe level for the distribution mains, gave a considerable increase in lighting efficiency.

Coal gas was used only in urban areas in which the cost of distribution was low. This gave rise to the development of forms of local gas generation to confer the advantages of gas lighting in rural areas. Acetylene gas, generated by the dripping of water on calcium carbide, was a particularly valuable development, although its unpleasant smell gave rise to ventilation problems when used in domestic interiors. The natural acetylene flame, however, had a high luminous efficiency and a colour closely approximating natural daylight, which rendered it specially valuable in industrial processes requiring a high standard of fidelity to natural colours.

Electric lighting devices. *The* electric *lamp.* Despite the successful history of gaslight, modern lighting owes very little to anything that happened before the invention of the incandescent electric lamp about 1870. The incandescent lamp was not the first electric lamp; lighting devices employing an electric arc struck between electrodes of carbon had been developed and were in use earlier. Arc lamps were massive and complicated pieces of equipment that could be installed and maintained only by a skilled engineer. Used for street lighting, arc lamps had advantages, including reasonable reliability, high efficiency, and, above all, a pleasant colour, closely approximating natural sunlight. The light of the arc lamp was particularly kind to the colour of the human complexion and the stone of historic buildings. Partly for this reason, these devices were retained in dignified city settings—for example, in the City of London—long after more modern light sources had come into wide use.

Arc lamps

The importance attached to the invention of the incandescent filament lamp can be gauged by the degree of controversy which has arisen over attribution of its invention. Arguments and claims on both a national and individual basis have been made. While it is true that early lamps of a kind were made in France and Russia and that Sir Joseph Swan of England demonstrated and manufactured carbon-filament lamps of a sophisticated kind before anybody else, the true invention of electric lighting should be credited to Thomas Edison in the United States. To Swan, the lamp was an important technical and scientific development with a utilitarian purpose. To Edison, it was part of a grand scheme of electric lighting, which included the generation and distribution of electric power. The first incandescent lamps, both of Swan and Edison, consisted of a filament of carbon wire in an evacuated glass bulb, two ends of the wire being brought out through a sealed cap and thence to the electric supply. When the supply was connected, the filament glowed and by virtue of the vacuum, did not oxidize away quickly as it would have done in air. The commercial success of the lamps depended upon the production of a high degree of vacuum, and strength great enough for them to be transported without damage. Though these problems were solved by both Swan and Edison, it was Edison who made the major commercial development. Edison's firm arranged a historic demonstration of electric lighting in Menlo Park in 1879 and received contracts for generating plant, distribution networks, lamp outlets, and bulbs. It is important to realize that the whole of this concept, not merely the invention of the light bulb, was Edison's contribution. In particular, Edison employed the system of parallel rather than series installation, so that when a bulb failed, as often happened in early days, the rest of the installation did not go out as would have been the case with the series operation first used by Swan. In fact, the distribution system of electric lighting in use today is nothing more than a highly sophisticated version of Edison's original concept. Among early electric lighting installations was that at the Savoy Theatre in London, built for the Gilbert and Sullivan operas.

Edison's distribution system

Of the major improvements in electric lighting that followed Edison's first installations, the most important was development of metallic filaments, particularly the tungsten filament, now used almost exclusively in filament lamps. Tungsten was known to be particularly suitable for use in electric lamps, because, of all materials suitable for drawing into filament wires, it had the highest melting point. This meant that lamps could run at a higher temperature and therefore emit both whiter light and more light for the same electrical input than was possible with the less durable and less refractory carbon filament. Tungsten could not be used, however, until a process had been invented for drawing it into thin wire filaments; this development took place in the early 1900s.

From this time forward, light-bulb manufacture became a major industry; much money was spent on research in the physics of light production in the incandescent lamp in order to increase its efficiency, sturdiness, and life in use. Some of the leading technical physicists of the day were engaged by manufacturers, who profited considerably as steady improvements were introduced. The early tungsten lamps, like the carbon lamps, suffered from migration of filament molecules to the glass bulb, causing a blackening of the bulb, a loss in light output, and progressive thinning of the filament until it broke. The introduction of a small amount of inert gas (argon) reduced migration and enabled the filament to be run at a higher temperature, giving a whiter light, higher efficiency, and longer life. Further improvements, such as the development of the coiled filament and then the coiled-coil filament, improved tungsten-filament lamps to the point at which the manufacturer had to decide whether to market a lamp with almost infinite life, but low light output, running at a low colour temperature, or to sell the consumer a brighter and more efficient lamp with a relatively short life. The manufacturers settled the matter between themselves by agreeing to market a lamp that would last for an average of 1,000 hours, producing a light of colour considerably yellower than that of natural daylight but still whiter than that of an oil lamp or candle. This was judged to be the most acceptable compromise for the consumer, and in spite of occasional demands for lamps of longer life, little change has taken place over the past 40 years. The most recent development is the introduction of the tungsten–halogen-filament lamp, in which the presence of a small amount of iodine reduces the migration of tungsten, permitting a higher running temperature. Because of the chemical effect of the iodine on glass, the filament must be placed in a quartz rather than a glass bulb, increasing initial cost. Though these lamps have whiter colour and longer life, they have not yet been used for general domestic lighting. They are rapidly coming into universal use for automobile headlamps and other forms of light projectors calling for maximum light output from bulbs of minimum size.

Neon lights

Vapour-tubs **devices.** During the late 19th century, many physicists, particularly Sir William Crookes in England, experimented with methods of generafing radiation by striking an arc between electrodes in an evacuated tube to which small amounts of elemental vapour had been admitted. The physicist Georges Claude in Paris developed such a tube with neon gas as the filling; when a high voltage was applied to the two electrodes at either end of the tube, it emitted a deep red light whose value for decorative and advertising purposes was quickly recognized. Neon signs soon decorated the exteriors of commercial buildings in the cities of the world; experiments with other vapour fillings—particularly mercury vapour, which gave a blue light--enabled a variety of colours to be produced. The discharge tube, however, had little application in interiors until the development in the 1930s of the fluorescent tube, a long tube with a mercury-vapour filling, the inner wall of which was coated with a material which fluoresced white or near white when subjected to the radiation of the mercury discharge, and the quantity of light was multiplied a hundredfold. The lamp became a practical possibility for the illumination of interiors.

Somewhat before the fluorescent tube came into use, lamps with much shorter arcs, in which the vapour operated at a higher pressure, were introduced, including the high-pressure mercury-vapour-discharge lamp and the sodium-discharge lamp. Neither of these found much use for interior lighting, however, because of their colour rendering. They made people look like ghosts, and it was only for street lighting, where safety arguments could be advanced, that the mercury- or the sodium-discharge lamp was accepted. Application of these lamps for exterior lighting developed so rapidly that within 20 years almost all principal streets in cities of the world (excepting the United States) were lit by sodium-discharge lamps. The ghostly rendering of the human complexion was balanced by the pleasant appearance of the brick and stone facades of buildings. In the early 1950s, the pattern of lighting seemed clear: filament and fluorescent lamps for interiors, neon and similar strips for exterior advertising and signs, and sodium-discharge lamps for streets.

By the 1970s, however, developments suggested that this pattern might change radically. The mercury-discharge lamp, which, after a brilliant start, rapidly gave way to the sodium lamp, had undergone extensive development; new forms, becoming commercially available, suffered from fewer of the disadvantages of the parent. Such lamps may eventually find both internal and external use. Yet the day of the sodium lamp was not over, because equally new developments, particularly the high-pressure sodium lamp, had overcome to some extent the unpleasant colour rendering, and it was difficult to predict whether the mercury or the sodium lamp or both together would prevail. Lamp manufacturers continued to experiment with new devices, sometimes in the laboratory and sometimes with a commercial product. In this category might be included the xenon-discharge lamp, a high-powered source with colour almost identical to natural sunlight. The electroluminescent lamp, by virtue of which walls and ceilings could be made self-luminous, was once believed to be the lighting of the future, but has made little recent progress.

Optic fibres

Not all lamp development is concerned with general lighting on a massive scale. So much is now known about the physics of incandescent lighting, of discharge lighting, and of other forms of generating light, that any particular requirement can almost certainly be met by a lamp tailored to the purpose. Great lamps of massive light output have been made, using the arc principle, the vapour-discharge principle, and the incandescent-filament principle for lighthouses, searchlights, and the floodlighting of large areas, such as airport landing runways. Microscopic filament lamps have been created for insertion in the body to enable the surgeon, aided by suitable optical equipment, to make visual inspection to supplement other methods of diagnosis. The development of flexible optic fibres, thin wires of transparent plastic that "conduct" light by internal reflection from a suitable lamp at one end to the target at the other, have also been used for medical and other purposes. Other lamps for special uses include highly actinic lamps (*i.e.*, radiating energy in the visible and ultraviolet spectral regions and producing chemical changes thereby) for photography, colour television, and cinematography or lamps with emission in selected parts of the spectrum for industrial uses, infrared lamps for paint drying, and both infrared and ultraviolet lamps for therapeutic use. There are probably few branches of applied physics in which progress has been so rapid during the past 50 years as in the development of artificial light sources.

MODERN ADVANCES IN LIGHTING TECHNOLOGY

Lighting as an applied science was founded during the 1890s and 1900s when—with development of the incandescent-filament lamp, the carbon arc, and the maintenance for some years of the supremacy of the Welsbach mantle—the extension of the working day into the hours of darkness became feasible. A massive expansion in artificial-lighting technology resulted.

Lighting technology was advanced partly by unskilled and semiskilled inventors and mechanics, and partly by trained physicists and engineers who explored basic principles. The first group produced rapid results, while the second developed the theoretical knowledge upon which subsequent technology could be based.

Edison screw

Fixtures and voltage. The first requirement was to accommodate the light bulb where it was required on the ceiling, desk, or wall. The Edison-screw lamp terminal (male) and power outlet (female) probably had as important an effect upon the development of lighting for domestic and industrial use as any other single invention. All that was required to install electric lighting was for an electrician to affix the Edison-screw power outlet to the appropriate wall or ceiling surface with the necessary twin wires back to the supply terminal and then for the householder to screw into it a light bulb with an Edison-screw cap. Installation was safe, simple, and reliable. The various electric-power companies, Edison's being the pioneer, steadily refined and introduced new methods of power distribution that simplified electric lighting and made its use more safe and reliable. Individual light switches for each room and each lamp soon became sufficiently inexpensive to be universal. Controversy arose, not yet settled today, over the best method of distribution to avoid accident by electrocution. The same amount of light can be generated by a lamp carrying a small current (amperes) but subjected to a high electrical pressure (voltage), as would be given by a different lamp carrying a much heavier current but subjected to a lower voltage. It is much cheaper to distribute electricity at a high voltage, because the current can be less and hence the amount of expensive copper in the conductors can be reduced. On the other hand, the risk of death by electrocution is greater at the higher voltage and experience unfortunately showed that, in spite of instructions, people would occasionally touch the two terminals of the electrical supply together and subject themselves to the full electrical pressure. In the United States a decision was taken to supply households at no more than 110 volts. This meant that the distribution network had to be heavier and therefore more expensive. The United Kingdom, on the other hand, decided to use about 200 volts, thereby approximately halving the cost of domestic distribution but considerably increasing the risk. Over 70 years, neither country has seen fit to make a change. After a period of uncertainty, the whole of Europe followed the British rather than the American lead.

Safety devices. All forms of electric lamps are liable to failure, sometimes gradual, sometimes immediate, sometimes catastrophic. Gradual failure only results in loss of light which may often be imperceptible over a period. Modern discharge lamps, for example, last indefinitely but slowly lose their light output. Immediate failure, such as the breaking of the filament of an incandescent lamp, causes no more than temporary inconvenience. Sometimes, however, a filament lamp or a discharge lamp may fail, probably due to a manufacturing flaw, in such a way as to give rise to a surge of current against which the distribution system must be protected. Every circuit must have some form of fuse or contact breaker to cut off the current if it exceeds safe levels. With a fuse, one need only detect the cause of the fault, remedy it, and replace the fuse. The contact breaker is a switch which is tripped by an excess of current; it can be reset at once without providing another fuse. The past pattern was to use fuses in domestic circuits and contact breakers in larger installations where a professional electrician was available to detect the cause of failure before resetting the contact breaker. Modern usage relies on the circuit breaker. (For power generation and transmission, see ELECTRIC POWER.)

Directing light. The next stage in the development of lighting devices was to provide means by which the light from the electric lamp could be directed where it was wanted. At this point, the technology of lighting for seeing and lighting for effect parted company. In the first type of lighting, it is not desirable for the light source to be visible. Instead, maximum light is directed onto the work and none allowed to escape elsewhere. In lighting for effect, however, it is sometimes desirable to see the source for its brilliance; in particular, the light is directed to create effects, modelling, shadows, reflections, and high spots without considering whether people can see to read or work. The lighting in a church, for example, may be designed to enhance the appearance of the architecture.

Lighting for seeing and for effect

To achieve lighting for seeing, two principles of optics—reflection and refraction—were used, either separately or in combination. Light, when received at a smooth, polished surface, is reflected in a predictable and calculable way. Likewise, light received at the (incident) surface of a transparent medium, such as glass, is changed in direction (refracted), and, if the other (emergent) surface of the glass is not parallel to the first surface, the emergent ray of light is changed in direction. Thus, by suitable choice of incident and emergent surface, light can be refracted into any desired direction. The principle of lighting devices employing reflection or refraction is therefore to wrap such a reflecting device (mirror) or refracting device (lens or prism) around as much of the light source as possible, collecting all the light emitted in unwanted directions and redirecting it where desired.

Both forms of device can be used for a multiplicity of purposes. The searchlight reflector and the lighthouse refractor are both designed to concentrate the maximum intensity in the desired angle but for different purposes. The searchlight concentrates the light in order to illuminate and make visible a distant object. The lighthouse, on the other hand, concentrates the beam to permit the maximum visibility of the source itself from the greatest possible distance.

In the home, factory, or office, on the other hand, a narrow, concentrated beam is rarely required. The purpose is to illuminate the whole of a writing desk or an entire working area. Such lighting devices, therefore, must produce a wide but uniform beam, since it is irritating and fatiguing to work where light is bright at one point and dull at another. The lighting engineer aims at uniformity of illumination and uses reflector contours that calculation and experience indicate will give the most satisfactory result.

High skills were soon brought to bear on the design of optical controls for light, particularly in such areas as hospital operating theatres, where the maximum amount of entirely shadowless lighting is directed onto the surgeon's task; or in street lighting, in which light emitted from a small source is directed along a narrow band of street and sidewalk with perhaps 200 feet or 60 metres between adjacent lampposts. Street-lighting equipment in particular has made use of refraction as the controlling principle, in part because of its greater accuracy but chiefly because the refractor units could be made in the form of glass bowls or dishes that could be tightly sealed to the lamp-holding device to keep out weather and insects.

For interior lighting, however, the need for precise optical control progressively diminished as light became cheaper and more plentiful because of the more efficient generation and distribution of electric power, and because lamps became more efficient in producing light rather than heat. Interior lighting is now a matter of lighting the whole environment instead of only the working task. Fixtures have employed new methods of controlling light, such as the use of optical diffusion. Special techniques were developed, first in central Europe and subsequently elsewhere, that permitted a white opal glass to be blown into attractive shapes, such as spheres and cylinders, in which the lamp could be placed as part of the fixture and its light diffused to give a uniform white-light source of large size and pleasant appearance. The Bauhaus School of Architecture and Design in Germany under Walter Gropius combined with the skill of the central European glassmakers revolutionized interior lighting design during the 1930s. Other diffusing materials have since supplanted glass, and hence there exists an immense range of plastic diffusing light fixtures of all possible shapes and sizes. The reflecting light fixture still has its uses in general room lighting. A contemporary fashion among architects is to inset lighting into the ceiling and direct it through small holes, almost invisible during the day; this has led to development of ceiling-inset spotlights, which use all the old skills of the light-reflector designer.

Diffusing light

The lighting designer. The most essential tasks of the lighting designer are to spread adequate light on the work for efficient and comfortable seeing, and to light the environment so that people can see well and enjoy what they see. The determination of the amount of light for efficient and comfortable seeing is a matter for the specialist in physiological optics and in the relation between lighting and seeing. Experimental work in England, Germany, and the United States showed that visual performance could be analyzed into three basic factors: sharpness of vision (visual acuity), detection of contrast, and detection of movement. International agreement was eventually reached on a method by which necessary levels of lighting for specific tasks could be prescribed. By breaking down a visual task—for example, that of threading a needle—into its component parts, the amount of light necessary for efficient and comfortable seeing could be prescribed. This prescription forms the basis of the codes of recommended lighting practice that have been adopted in most countries.

The factors governing discomfort from bright light sources are also known and a glare prescription can be written, called a visual comfort index in the United States and a glare index in most other countries. Codes of lighting practice can therefore lay down the glare index based on the levels of tolerable brightness of lighting devices in their particular environment in order to avoid discomfort from glare.

Although this article is intended to be concerned primarily with the physical aspects of lighting design, in other words lighting technology or illuminating engineering, it is notable that lighting is concerned with human sensations; that is, human vision. It must be kept in mind that the eye can adapt to the kind of lighting in which it finds itself. The level of lighting by moonlight, for example, is one-1,000,000th of that by sunlight, and yet the human eye can adapt sufficiently to moonlight to perform many tasks.

Apparent brightness

This adaptation to light not only affects the range of brightness but also has a profound effect upon the sensation given by any particular physical amount of light. A surface of a certain brightness (luminance) seen in a dimly lit street at night, for example, will appear very bright, whereas a surface of the same brightness (luminance) seen in daylight looks like a very dark shadow. Lighting design must take this into account. Thus it is not physical brightness, but apparent brightness that determines the subjective effect. Though apparent brightness is the ultimate criterion for the designer, experience and existing technology let him undertake almost the whole of his lighting design in terms of physical measures.

Current lighting practice

The brief summary of current lighting practice below attempts to strike a balance among practices in different countries and by different schools of design. This is difficult; there is the "illuminating engineering" school of lighting, and there is the "architects or interior decorators" school, quite different in approach and results and almost irreconcilable. They accord most closely in Britain and are farthest apart in the United States.

INTERIOR LIGHTING

Interior lighting in most countries tends to follow similar patterns, dictated by the availability of light sources, by architectural fashion, and by the special lighting requirements of the task or the environment or both. The amounts of light now considered necessary for efficient and comfortable vision are very much higher than they were even ten years ago. Lighting levels have in fact increased up to 50-fold in the last 50 years. This is not because human sight has deteriorated. Ample evidence indicates that in spite of the fact that more people now wear spectacles than ever before, human sight remains much what it was in the past, and there is certainly no deterioration due to the use of artificial light. It is simply that people demand perfect vision and thus wear correcting glasses for minor visual defects that were previously neglected. In the same way, people want to be able to see excellently everywhere, whereas previously they were satisfied to move closer to the candle or other light source to read or perform other tasks.

Dwellings. Light installed by a skilled lighting designer and interior decorator can do much to create the character of an interior environment. In modest homes a central pendant fitting supplemented by one or two wall fittings or desk lamps, or lamp standards, remained in the 1970s the best way of achieving good lighting on sound visual principles with the greatest economy.

The eye functions most efficiently (with greatest visual acuity and comfort) when the task is lit to a slightly higher brightness than the immediate surroundings, which in turn should be slightly brighter than the general environment. This standard is usually achieved in a home when a moderate level of general lighting is provided from a central fixture and a high level of working light from a desk or floor lamp. Less satisfactory is the use of a desk lamp alone in a room, because this leaves the room too dark and gives rise to visual fatigue.

Recognizing this, the Illuminating Engineering Society of the United States, as long ago as the 1930s, designed a study lamp which provided both working light on the desk and general light in the room; this unit is probably still the most efficient lighting fixture for the economic lighting of working rooms in dwellings.

Fluorescent lighting has not yet found its way into homes to a great extent, apart from utility areas, such as kitchens and bathrooms. This is partly due to the large size of the lamp, which is out of scale with normal rooms in small houses, and partly to the fact that the light which it emits is less compatible with the social character of dwellings than the warmer, yellower filament lamp. People apparently do not want to prolong the colour of daylight into their social lives after dark.

Lighting for television viewing

Lighting for television viewing has been a source of some controversy, but it has been demonstrated that people with normal sight can light television-viewing rooms as they please without harming their eyes, though eye muscles may become fatigued more quickly in a darkened room. The colours of a colour-television screen are adulterated by too much white light falling upon the screen, and so, for watching colour television, the level of light should preferably be somewhat less than that for watching black-and-white. Lighting for television is more a matter of common sense and setting the light as the viewers want it, avoiding annoying reflections. Persons, with subnormal sight, however, may need care in the prescription of lighting for television viewing.

Schools. With changes in education that have taken place over the past 20 years, schools have been made more attractive and welcoming than ever before. This development has been most marked in England where school building and school lighting corresponds much more closely to that in homes than it does in other countries. In continental Europe and the United States, emphasis is still placed primarily on lighting the task. American schools are almost always lit by fluorescent lighting, inset in the ceiling or in the form of an overall luminous ceiling, providing shadowless lighting to a high level over the whole working space. In England, on the other hand, the emphasis is on the lighting of the environment. Continental Europe, with the exception of Scandinavia, tends to follow the American pattern.

Offices. Ceiling-mounted fluorescent lighting is used in offices to create a uniform level of light over the whole of the working area, allowing maximum flexibility in office arrangement. The levels provided range from about one fifth to one tenth of the light from a natural sky. This appears to be about the optimum required for work on white paper. Improvements in the colour of fluorescent lighting are constantly being made, and the distortions in the appearance of the human complexion have been largely overcome.

The concept of office landscaping, created in West Germany, has emphasized the need for a uniform level of lighting over the whole working space. The essence of the office-landscaping principle is to permit every task to be placed anywhere in the office space and planned in relation to the flow of work demanded, and, for this, uniform lighting is essential.

Lighting practice in offices nowadays sometimes makes use of the principle of permanent supplementary artificial lighting of interiors (PSALI) originating at the Building Research Station in England, in which the light from the windows and the light from the artificial-lighting system are planned together as part of an integrated whole. Before this, the artificial lighting was planned primarily for operation after dark, while the windows provided the working light during the daytime and had to be very large if light was to penetrate into a large deep office. PSALI means that windows no longer must provide all the working light during the daytime but are important simply because they provide a view and an awareness of the world outside. PSALI has been developed primarily in Britain and the Scandinavian countries and, to a lesser extent, in continental Europe. In the United States the contrary tradition has developed, of working by artificial lighting entirely, by day as by night, and even drawing blinds over the windows by day to eliminate glare.

Hospitals. Here, again, different approaches have been taken. American hospitals tend to be much more "institutional" in character, making little use of colour on the walls and hangings and providing high levels of uniform fluorescent lighting from ceiling-mounted fixtures and from fixtures placed immediately above the bedheads. British practice, on the other hand, employs much lower levels of light, on the theory that sick people often want to rest; colour is used extensively both on walls and in draperies. Until quite recently there was a strong prejudice in England against the use of fluorescent lighting in hospitals, and many modern hospitals are still lighted by filament bulbs. Hospital day spaces are designed to resemble a home both in the use of light and of colour, as are visitors' waiting rooms. The essential requirement in an operating theatre is that high-intensity light should be concentrated upon the operating area so that, no matter where the surgeon places his hands, no shadows are cast. For shadow-free lighting, one very large source is needed, which may either be a suspended lighting unit (the least costly solution) or a luminous ceiling as developed in France. A luminous ceiling may be an enormous elliptical reflector, with the light source at one focus and the operating area at the other, or it may consist of a multiplicity of small projectors concentrated on the operating area, possibly with an array of push buttons at the surgeon's control to change the direction and distribution of the light. It is important to light the whole theatre as well as the operating area, both to enable the assistant staff to work efficiently and to minimize visual fatigue on the part of the surgeon.

Lighting the operating theatre

Factories. In industrial processes, the prime requirement is to light the task efficiently, since people are concentrating on their work and are less concerned with the environment. Factory lighting is provided almost universally by ceiling-mounted fluorescent equipment to a high level of illumination, ranging from one tenth to one fourth that given by the natural sky on a bright day. It is important to bear in mind that the factory-lighting problem is different from that of offices. Most office work is concerned with white paper, whereas most factory processes are concerned with objects which reflect much less light than white paper; therefore, the same degree of visual comfort results from a very much higher level of illumination. The higher level of illumination assists acuity and contrast and colour discrimination, thereby improving visual performance. Experience over the years has shown that higher levels of lighting give rise to higher productivity and that good lighting pays for itself.

Some critical visual tasks demand additional lighting, both to reduce visual fatigue and to give added visual efficiency. Assembly of fine instruments, watches, and cameras demands light on the work approximating that given by the bright sky, which is better achieved by selective lighting. Similarly, in drawing offices, many draftsmen like to have a high level of general illumination in the office, plus an individual desk lamp for selective lighting on the work.

Factory light fixtures

The factory-lighting designer often must choose between using totally enclosed and open fixtures. Though the totally enclosed fixture may be readily cleaned and maintained, open fittings can be so designed that the heat of the lamp creates an upward draft through the fitting, which carries dirt with it and so reduces the amount which settles on the reflecting and transmitting surface of the fixture. Thus, open fixtures are said to require less maintenance than enclosed ones. With the increasing tendency to build factories as totally enclosed artificial environments—with heat supplied from high levels of lighting, from machinery and industrial processes, and from the workers' bodies—the use of the open-type fixture is indicated, coupled with efficient filtering of the recirculated air. A further disadvantage of the enclosed fixture is that in a factory it may overheat, and, since fluorescent lamps rapidly drop in light output with increase of temperature, the light output from the fixture will fall.

The building lighting in a factory is usually arranged either as high-bay lighting, in which the fixtures are symmetrically positioned at maximum height from the floor, or as continuous-run lighting, in which fixtures are placed end to end across the width of the factory. The high-bay lighting system is better suited to spaces like aircraft hangars because it gives a uniform distribution of illumination with minimum interference with the volume of the space. The continuous-run system can be related directly to an assembly line or row of benches. Furthermore, it can be closely integrated with the daylighting, the continuous run of fluorescent lighting fittings being set along the same lines as the continuous run of glazing in the roof, either to replace it after dark, or to act as a permanent supplement during the daytime. Luminous ceilings are also employed in factories, particularly in those that demand a very close control over the interior climate. The luminous ceiling may consist of an uninterrupted plastic surface behind which the fluorescent lamps are arranged at regular intervals to give a uniform distribution of brightness and to help maintain a uniform temperature in the space below. In certain specialized manufacturing operations, such as the assembly of delicate watch mechanisms or submarine repeaters, in which avoiding dust is important, the overall sealed ceiling lighting system has obvious advantages.

Few factories are lighted today by uncorrected mercury-vapour or sodium-discharge lamps. During the 1930s and 1940s many such installations were made and some still remain, but they are being rapidly replaced by fluorescent lighting. The two main complaints against the use of mercury vapour and sodium were the unpleasant colour and the fact that flicker and stroboscopic effects were marked. Such effects could cause dangerous misjudgments of speed with rotating machinery. Modern fluorescent lighting gives less trouble, but, from the nature of the method of light production in the lamp, on alternating current some residual flicker, greater than that from filament lighting, is present. In poorly engineered lighting installations, lamp flicker may be acutely annoying. Fluorescent lamps near the end of their useful life also tend to flicker. Flicker can be reduced by use of special circuits or special lamps with a long "afterglow."

Flicker in fluorescent lighting

EXTERIOR LIGHTING

While much interior lighting, particularly in nonindustrial buildings, can be undertaken, with some technical assistance, by the architect or interior designer, most exterior lighting demands the services of the specialized lighting engineer. Lighting an airfield, for example, is recognized as a highly specialized and skilled job that would be dangerous to leave to any but an experienced professional. Not only must the airstrip itself be illuminated so the incoming pilot can judge his position and distance accurately, but the approach lighting must be designed so that the pilot can orient himself on to the right flight path with great accuracy from a great distance. The principles of central and peripheral vision have been studied in order to understand how people orient themselves in space and time with no other visual clues than points of light arranged in patterns in space. Despite great advances in instrumented landing equipment, airfield lighting promises to continue indefinitely to be an important field for the lighting engineer.

The lighting engineer also has a special role in such public places as streets, sports arenas, and parks and in the decorative floodlighting of buildings. All these forms of exterior lighting call upon the use of specialized equipment more or less tailored to the job.

Streets. Artificial lighting was perceived at an early date as a potential crime deterrent. The first installations of gas street lighting were made in London and Paris in the early 19th century with this purpose in mind. Toward the end of the century large cities began to recognize the prestige value of street lighting in the centre of their cities and developed more sophisticated street lighting, with ornate cast-iron lampposts housing fixtures mounted 25 to 30 feet (eight to nine metres) above the roadway with powerful filament lamps or arc lamps lighting not only the roadway but the prestigious buildings around. This phase of street lighting lasted approximately up to World War I.

With the development of the internal-combustion engine and the increase of traffic on the roads at night, street lighting acquired new importance. Levels of illumination were considerably increased with the aid of mercury- and sodium-vapour-discharge lamps. At this stage practice in the United States, in Great Britain, and in continental Europe diverged. The United States were most backward in the development of fixed street lighting, relying more upon the light from automobile headlamps and from shop windows, so that by the end of the 1930s the United States was at least ten years behind Europe. In Great Britain silhouette vision formed the basis for street-lighting design, the principle being that light from the street lamps was reflected off the "sheen" of the road surface to provide a background brightness against which objects were seen black in silhouette. Objections that this was an unnatural way to see things were largely overruled by the fact that far better revealing power could be achieved this way for the same expenditure of electrical power than by any other method. Continental Europe, on the other hand, adhered to the principle of natural vision, lighting the object preferentially and trying to keep the background dark. Revealing power by the continental system, however, was far less. The disadvantage of the British system was that it required by its very nature a high level of light to reach the observer's eye because the optical system of the lantern could not be controlled with sufficient precision to confine the light to the road surface alone. The continental system, on the other hand, because it did not depend upon reflection, was far more comfortable and less glaring.

Silhouette vision

After World War II, work undertaken in a number of laboratories showed that one of the major causes of street accidents was skidding and that much could be done to minimize this by the better design of road surfaces combined with tire-tread improvements. The road surfaces with best skid-resistance characteristics had exactly the wrong reflection characteristics for the silhouette principle of street lighting. Attention was therefore directed everywhere to the further development of the continental street-lighting system of illuminating the objects directly. With greater affluence, the much higher levels of lighting necessary for the proper operation of the continental system could be afforded. The silhouette principle, of immense value at its time, has now been abandoned, although in practice, much vision on the streets at night is still by silhouette.

Street lighting today employs sodium-discharge equipment almost universally for traffic routes because of its high luminous efficiency and relative ease of optical control, and fluorescent-tube lighting or colour-corrected mercury-vapour-discharge lamps in the centres of cities. Filament lighting, like gas-lighting, has been almost entirely abandoned. The use of fluorescent lighting necessarily gives rise to very large lighting fixtures, which may be mounted on standards or hung over the roadway, of a size and proportion that would not have been tolerated in the early part of the century.

Sports fields and arenas. Lighting of these installations has developed rapidly since World War II. As soon as lighting engineers could demonstrate that the cost of lighting a large arena to the levels necessary for games or athletic performances was economically feasible, sports-ground lighting developed rapidly. The basic principle is almost always that of employing massive banks of light projectors around the periphery of the ground, floodlighting the arena, rather than suspending lighting units above the arena itself. This has led to the development of powerful projectors based on the searchlight principle, and, for this, the development of the tungsten–halogen projector lamp, with its high light output and relatively long life, has been crucial to success. Arc lamps, the basis of earlier searchlight design, have been almost entirely supplanted, though the development of new forms of colour-corrected mercury-vapour-discharge lamps or the further development of the xenon-discharge lamp may prove eventually to be of value in sports-arena lighting.

Floodlighting of buildings. This field has also been transformed by the availability of filament lamps of high light output and long life. As with the lighting of sports arenas, the principle is to project light onto the facade of the building from powerful projectors located sufficiently far from the building not to impede circulation around it. The aim in floodlight design is to distribute the light, in amount and direction, so that all parts of the facade are adequately illuminated and the sculpture and form of the building are modelled either as they are in daylight or in such a way that other aspects of the design make themselves apparent. These principles have also been applied to the lighting of the interior of monumental buildings, such as cathedrals.

Measurement and calculation of lighting

FUNDAMENTALS OF LIGHT MEASUREMENT AND CONTROL

Lighting engineering is based on a few simple principles of the physics of radiation. A light source is said to radiate light because part of its emitted radiation causes a particular sensation when it strikes the retina of the human eye. Said to be outside the visible spectrum, radiation, which does not give rise to a sensation of light, may have short wavelengths (ultraviolet radiation) or longer wavelengths (infrared radiation).

The name light flux is given to the rate of emission from the source; the unit of light flux is the lumen. The light output from any lighting fixture is expressed in lumens. A wax candle emits about 13 lumens, a 100-watt filament lamp about 1,200 lumens, and a five-foot (1.5-metre) fluorescent tube about 5,000 lumens.

The lumen

Illuminance, reflectance, and utilance. The lighting level—that is, the amount of light spread over the area receiving the light—is called the illuminance (sometimes the illumination) and is expressed in lumens per unit area. One lumen per square foot is the amount of illuminance of a surface one foot (30 centimetres) from the light of one ordinary wax candle. (Hence, in the United States the unit of illumination is the footcandle, identical with the lumen per square foot.) Unobstructed daylight from a bright, overcast sky gives about 1,000 lumens per square foot. The unit of illuminance in metric units is the lux—one lumen per square metre. One lumen per square foot equals 10.76 lux. Unobstructed daylight from a bright, overcast sky gives about 10,000 lux. Overall fluorescent lighting to the standard required for factory work is about 1,000 lux.

Light falling on a surface is reflected off it according to the ability of the surface to reflect light. This reflection factor, or reflectance, relates the light falling on the surface as seen by the observer. A white surface has a reflectance of nearly 100 percent, while a black surface has a reflectance of about 2 percent and a medium-gray surface about 40 percent. If the surface diffuses light equally in all directions (*e.g.*, a matte surface paint or a dull velvet), the brightness of the surface will be related directly to the illumination falling upon it. The physicist and engineer use the word luminance to express the physical measure of brightness. The unit of luminance used in the United States is the footlambert. Luminance, illuminance, and reflectance are related by the equation: Luminance (footlamberts) equals illuminance (footcandles) times reflectance. Thus a diffusing off-white surface of 50 percent reflectance receiving ten footcandles will have a luminance of five footlamberts. Illuminance to a level of 100 footcandles falling on a desk top of reflectance of 30 percent on which is a white paper of reflectance of 80 percent would thus give a luminance of 80 footlamberts to the paper and 30 footlamberts to the desk top.

In order to calculate the amount of light necessary to produce a certain level of illuminance in a room, the concept of utilance, or coefficient of utilization, must be introduced. This is the proportion of light that is actually received on the surface under consideration. If in the room the total light from all the lighting fixtures in the installation is directed onto the working reference surface and nowhere else, the illuminance would obviously be given by the density of light flux in lumens over the area of the reference surface; that is, illuminance equals total flux (lumens) divided by area of reference plane (square feet or metres).

Calculating the utilance

Much of this light flux from the fixtures is, however, lost in various ways. Some light is absorbed in the fixtures themselves, while more light falls on the ceilings, walls, furniture, and elsewhere and is absorbed there and never reaches the reference surface. The coefficient of utilization, or utilance, is the measure of the ratio of the light flux actually reaching the reference plane to the light flux initially emitted by the lamps of the installation. It is determined by the loss of light by absorption at the surfaces of the room, the absorption of light in the fixtures, and the effect of the proportions of the room. Calculation of the utilance is a complicated process, but it is made easy by the publication of tables of utilance. Computer programs for its calculation are also available. In practice, the utilance varies from about 0.15 for totally indirect lighting (which hits the ceiling first and is reflected downward onto the working surface) through about 0.3 or 0.4 for general lighting (emitted in all directions) to about 0.6 for direct lighting (directed by means of reflectors or refractors directly on to the working surface).

If, for example, the required average level of illuminance in a factory 100 × 30 feet (30 × 9 metres) is to be 100 footcandles, and the coefficient of utilization has been found from tables for the particular space, the reflection characteristics of the walls, floor, and ceiling to be 0.3, then the total amount of light flux in lumens required from the lighting installation will be: required light flux (lumens) equals illuminance times area utilance, equals $\frac{100 \times 3000}{0.3}$ equals 1,000,000 lumens.

If the installation is to use five-foot (1.5-metre) fluorescent tubes, each giving 5,000 lumens, 200 tubes will be needed. These might be arranged in continuous trunking along the length of the factory, 20 tubes per line, requiring ten lines across the width of 30 feet (nine metres), or, more economically, the tubes might be twinned giving 40 tubes per line and hence five lines spaced, say, five feet (1.5 metres) apart, across the width of the factory.

This calculation does not allow for the fact that the light output will drop during the life of the installation, due to the inevitable accumulation of dirt and to the fall-off in light output as the lamps get older. It is usual in lighting calculations to step up the light output by about 25 percent to allow for depreciation losses.

The above calculation is very simple and does not require the skills of the lighting engineer. It is no more than a first attempt to indicate how much lighting is required. More often the lighting designer must direct light specifically where it is wanted for efficient and comfortable seeing. The light from bare lamps must be controlled according to his plans. In order to design a fixture that will, when correctly mounted, direct the light to where it is wanted, he must first know the light output of the source (the bare lamp) in all directions. This directional light output must be expressed in terms of the amount of light flux (lumens) being emitted by the source within a given cone (solid angle). Light flux per unit solid angle is expressed in candelas (formerly candlepower) and is called the intensity of the light source. An ordinary wax candle has an intensity of approximately one candela.

The intensity distribution of the bare lamp must be measured in order to determine where the light from the lamp is going and, thence, to redirect it where it is wanted. The intensity distribution is measured by placing a light receptor at a fixed distance from the lamp and in all necessary directions. The amount of light received on the receptor surface will then enable the intensity of the source in the particular direction to be calculated by means of the inverse-square law.

Inverse-square law

The inverse-square law of radiation states that the illuminance, E, at a point varies directly with the intensity, I, of the source and inversely as the square of the distance, D, between the source and the point. If the surface at the point is normal to the direction of the incident light, the inverse-square law gives: E = 1/02.

This is true if the source is a point and is approximately true if the distance, D, is great compared with the dimensions of the source. If, therefore, in measuring the intensity distribution of a point source of light, the illuminance at a given point at a given distance from the source is obtained, the light receptor being perpendicular to the direction of the source, the intensity I is given by: $I = E \times D^2$.

If the light receptor is moved around the light source on, for example, a rotating arm so that it is always at the same distance from the light source and always normal to it, the intensity in any given direction will therefore be proportional to the illuminance of the receptor, which can then be calibrated directly in units of intensity (candelas). Such an instrument employed in this way is called a light-distribution photometer.

Light distribution. The light distribution from a source can be expressed in different ways. If it is known that the light source is symmetrical about an axis (an ordinary general service pearl bulb, for example, is to all intents and purposes symmetrical about the vertical axis through the cap of the lamp, and a fluorescent tube is to all intents and purposes symmetrical about an axis along the centre line of the tube), the light distribution can be expressed in two dimensions in the form of a polar curve, a graph on circular coordinates. The light output can equally be expressed on a graph in rectangular coordinates, but the polar distribution curve gives a better visualization of the light-output characteristics of the lamp.

Light output of a complete fixture

The same procedure is used for measuring the light output of the complete fixture. After the fixture has been designed to direct light where required, the light output from the complete fixture must be measured in order to proceed with the next stage of lighting design. Here, again, if the light output from the fixture is symmetrical, a simple polar curve in two dimensions will give all the necessary information. If, however, the light output is not symmetrical—as would be the case, for example, in a street-lighting fixture where the purpose is to direct light in two directions only—it is then necessary to express the light output of the fixture in three dimensions. This is often done by means of a special graph based on principles of trigonometry and called an isocandle diagram. The information in the polar-curve intensity diagram, for a symmetrical fixture, or in the isocandle intensity diagram, for a nonsymmetrical fixture, gives all that is necessary to proceed on lighting design.

If, for example, the requirement is to produce an illuminance of 10 footcandles on a surface normal to the fixture and distant 100 feet (30 metres) from it, the inverse-square law will give the necessary intensity as being: 10 × (100 × 100) = 100,000 candelas in the direction of the surface. The intensities in other directions can be found in the same way. Hence, the required light distribution of the fixture can be determined from the illuminance requirements. Equally, in reverse, if a given fixture is available for the job, the illuminance values in significant directions and at given distances from the fixture can be found and compared with requirements.

Light distribution categories

This type of point-by-point lighting design is necessary when it is required to find or to provide specific illuminance at a specific point. A great deal of lighting design, however, particularly of interiors and also of large areas out-of-doors—such as a building facade—is more concerned with average illumination over a whole area. For this determination, it is better to know the light distribution from the fixture in broad zones. Thus the average intensity may be tabulated for a symmetrical fixture in zones. Even more simply, the light-output distribution of the fixture may be classified into three distribution categories—direct, general, and indirect distributions. In a direct distribution, all the light is concentrated downward onto the working surface. In indirect distribution, the light is directed upward onto the ceiling and reflected back to the working surface. A general distribution is one with equal intensities in all directions, so that some light reaches the working surface directly and the rest reaches it only after reflection.

These different distributions not only determine the calculation of the lighting design but also in large measure the character of the lighting. Totally direct lighting on the working surface, while concentrating the attention on the job, gives a dark ceiling often considered unpleasant and believed to lead to visual fatigue. It is a type of lighting formerly characteristic of industrial areas when light was expensive and had to be directed exclusively onto the work.

Indirect lighting

Indirect lighting is pleasant and restful and has often been advocated as the ideal form of lighting since it essentially imitates the diffuse light from the sky. It is not entirely satisfactory for work lighting, however, because the eyes tend to be drawn upward to the bright ceiling. It also lacks life and tends to be soporific. Indirect lighting, provided with a little sparkle from, for example, small reflecting surfaces and supplemented by local lighting on the work, can provide a very pleasant illumination. The best lighting, however, is usually provided by some form of general lighting combined with some direct lighting on special areas.

Glare, or visual comfort, index. Glare control, a recent development in lighting technology, takes two forms, one very simple, one very complex. The simplest means of glare control limits the perceived luminance of the fixture in the directions of view most likely to cause trouble. A typical example of such control is in the regulations for school buildings in England and Wales, where it is required that the luminance over an angle up to 45° above the line of sight should not on the average exceed 1,000 footlamberts. Otherwise it is necessary to determine the glare index for the whole environment.

Precalculated tables of glare index are published in Great Britain, similar to the tables of utilance, which enable the lighting engineer to find the glare index for his installation, provided he knows the light output and light distribution of his fixtures, as well as their number, position and mounting height, and the dimensions and reflectance characteristics of the room surfaces. Computer programs also exist.

Light-measuring instruments. The commonest photometric devices are based on the changes that occur in the electrical properties of certain substances when light strikes them. Simple measurements of illuminance made by the lighting engineer usually employ a photoelectric photometer with a light receptor such as a selenium photocell, connected to a suitable instrument that measures the current generated by the cell when light falls upon it.

Another light-sensitive material, cadmium sulfide, has been used in photometers: the change in its electrical conductivity upon illumination causes a change in the current produced by a battery. The instrument is calibrated at a standardizing laboratory in terms of the international standard of light.

Recommended Lighting Values*

class	examples	recommended illuminance		limiting glare index
		lux	footcandles	
Visual task				
Little difficulty	stores	200	20	—
Ordinary tasks	general offices	400	40	—
Some difficulty	business machines	600	60	—
Fine detail	tailoring	900	90	—
Very fine detail	gem cutting	local, up to 3,000	300	—
Environment				
Glare of little consequence	boiler houses	—	—	28
Secondary consequence	machine shops	—	—	25
Limited glare	shops	—	—	22
Close control	general offices	—	—	19
Closer control	school rooms	—	—	16
Minimum	hospital wards	—	—	13
No glare tolerable	art galleries	—	—	10

*Values taken from current lighting codes in Great Britain.

Very simple light meters, which can be carried in the pocket, are of use to the lighting engineer as a rough guide. They cannot, however, match in accuracy a precision instrument.

STANDARDS OF LIGHTING

Standards of lighting as laid down in regulations are in terms of illuminance (footcandles) and glare index, and these standards vary from one visual task to another and from one type of environment to another.

The Table gives a very brief selection of recommended values taken from current lighting codes in Great Britain.

American recommendations are at present higher than those for other countries. Differences in actual practice in the different countries are narrowing, however. America sets a high target, while European countries tend to set a lower target, which is often surpassed.

So far as the control of glare is concerned, there has not yet been international agreement on the method of specifying glare, and it is only in the United Kingdom that a universal and comprehensive generally used system of glare control is available. Typical values of recommended maximum, limiting glare index on the British system only, are therefore given.

BIBLIOGRAPHY. There are two quite different kinds of books written about lighting, those written by architects and interior decorators who use light as a tool to create atmosphere and character, and those written by illuminating engineers. Occasionally, as in DEREK PHILLIPS, *Lighting in Architectural Design* (1964), and R.G. HOPKINSON and J.D. KAY, *The Lighting of Buildings* (1969), the attempt has been made to marry the two different aspects of lighting, the former by an architect who practices as a lighting consultant and the latter a collaborative effort by an illuminating engineer and an architect working together. Generally, however, the architectural lighting books say relatively little about the hardware, and the illuminating engineering books say very little about the effects of light. Probably the two most useful reference books are the ILLUMINATING ENGINEERING SOCIETY, *Lighting Handbook* (issued every five years); and the ILLUMINATING ENGINEERING SOCIETY OF GREAT BRITAIN, *Recommendations for Good Interior Lighting.* The former is a compendium of every aspect of lighting and also includes a mass of useful trade material, whereas the latter is a brief summary and probably the best introduction to the subject for both the specialist and nonspecialist.

The best books on illuminating engineering were written some time ago, when the subject was a major discipline in schools of electrical engineering. The *Theory and Design of Illuminating Engineering Equipment,* by L.W. JOLLEY, J.M. WALDRAM, and G.H. WILSON (1930), is a "lighting engineer's bible" so far as principles and design are concerned. So are H.H. HIGBIE, *Lighting Calculations* (1934); and D.H. JACOBS, *Fundamentals of Optical Engineering* (1943). More recent books on the hardware of lighting are S.T. HENDERSON and A.M. MARSDEN (eds.), *Lamps and Lighting,* 2nd ed. (1972), and J.M. WALDRAM, *Street Lighting* (1952); J.W.T. WALSH, *Photometry* (1958), gives not only the fundamentals of photometry but also the basis of lighting engineering insofar as this relates to the measurement of light.

Later books on lighting and seeing are H.C. WESTON, *Sight, Light and Work* (1962); and a short book written primarily for the informed layman, R.G. HOPKINSON, *Lighting and Seeing* (1969). There are a great many specialist books about particular aspects of lighting—the NUFFIELD PROVINCIAL HOSPITALS TRUST, *Studies in the Function and Design of Hospitals* (1965), is of particular value to architects in showing the relation between natural and artificial lighting and building design. Much of the most recent work on lighting, however, has not been gathered between hard covers yet, and so it is necessary to refer to the original papers. These appear particularly in *Illuminating Engineering,* published by the Illuminating Engineering Society of New York; and *Lighting Research and Technology,* published by the Illuminating Engineering Society of Great Britain.

(R.G.H.)

Lightning

A natural electrical discharge within the atmosphere is called a lightning flash. Such flashes are usually associated with cumulonimbus clouds (thunderclouds) but also occur in nimbostratus clouds, snow and dust storms, and sometimes in the erupting gas of an active volcano. The flash occurs because separate regions of net positive and net negative electric charge are formed. This separation produces an electrical potential, and when the potential exceeds the dielectric strength (insulator strength) of air, a lightning flash occurs. Within a thunderstorm, the flash can occur between clouds (cloud-to-cloud discharges), within a cloud (intracloud discharges), between a cloud and air (air discharges), or from a cloud to the ground (ground discharges).

Cloud-to-ground discharges are composed of one or more strikes that frequently can be perceived by the eye as a flicker. Although these discharges represent only about 20 percent of the lightning flashes, such occurrences cause approximately 150 deaths, $20,000,000 of property damage, and set 10,000 forest fires destroying $30,000,000 worth of marketable timber each year in the United States alone.

Dangers to man

A direct or nearby lightning strike frequently causes death to man, but medical evidence indicates that prompt cardiopulmonary resuscitation and prolonged artificial respiration sometimes can revive a person who apparently has been "killed" by lightning. The effect of direct strikes to man-made objects can range from no damage to extensive destruction, depending upon the physical characteristics of the lightning flash and the degree to which the object struck provides a safe electrical conducting path to the ground. The same range of damage is experienced by trees, although some species show characteristic damage. Conifers, for example, usually have their barks split with a shallow furrow a few inches wide that spirals along the trunk, exposing the outermost layers of sapwood.

Intracloud discharges occur more frequently than ground discharges and almost always expend their energy in a harmless way. Strikes that pass through airplanes are not unusual and cause little or no damage. An exception, however, was the loss of a Boeing 707 in December 1963 that was attributed to lightning from an unseasonable thunderstorm. The most famous lightning flash in modern times was the strike to Apollo 12 on November 14, 1969, as the Saturn/Apollo space vehicle passed through clouds above Cape Kennedy. Fortunately, there was no serious damage.

Lightning is becoming less mysterious as it becomes better understood. The cloud-to-ground lightning flash is the simplest type of lightning to study because it is unobscured by its source, the cloud. Light emitted by the components of the flash can be subjected to photographic and spectroscopic examination to determine physical properties of the flash, such as velocity, temperature, and pressure. High currents flowing within the flash produce time-varying electric and magnetic fields whose characteristic signatures (patterns) reveal the movement of electric charge. Direct strikes to instrumented towers permit measurement of the magnitude of lightning currents; and the subsequent thunder has an acoustical energy spectrum that can be related to the energy per unit length in the flash. All of these measurements, combined with laboratory data on analogous electrical sparks, yield information that reveals the physical characteristics of lightning. Such knowledge, in turn, helps to reduce the deaths and damage due to lightning.

This article treats the physical properties of the several types of lightning, the ways in which these properties are determined, and the occurrence and distribution of lightning strikes. For additional information on electrical phenomena in the atmosphere, see CLOUDS; THUNDERSTORMS; ATMOSPHERE; and AURORAS. See also ELECTRICITY for basic information on the nature and propagation of electric charges and on electrical potential and allied topics.

KINDS OF LIGHTNING

A lightning flash occurs because regions of net charge are produced by charge separation processes within clouds to give an electrical dipole structure (like the magnetic dipole of the earth, with one end positive relative to the other) to the cloud. A South African authority, D.J. Malan, has proposed a cloud charge distribution that can schematically represent the distribution in a typical mid-latitude cumulonimbus cloud (see Figure 1). **A** net positive charge is located at an altitude of ten kilometres (where the temperature is about −45° C) and a net negative charge at five kilometres (−15°C); both charges are of the same magnitude, usually 40 coulombs (an absolute coulomb = 0.1000 electromagnetic unit). A smaller positive charge is located at an altitude of two kilometres (+5° C). The electrical potential between the cloud and ground is on the order of 10^8 volts. At this time the charge resides on ice particles or water drops or both. Discharges can occur between any of the oppositely charged regions or between the cloud and the surrounding air.

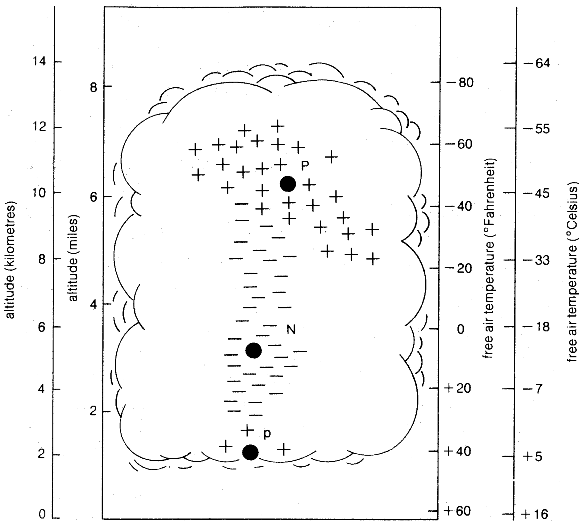

Figure 1: Probable distribution of the thundercloud charges P, N, and p (according to D.J. Malan). Point charges are indicated by solid black circles.

Cloud-to-ground lightning. The flash of cloud-to-ground lightning is initiated by electrical breakdown between the small positive charge region and the negative charge region. On a time scale measured in fractions of a second, high-speed cameras can record luminous events in the flash (see Figure 2). A faint luminous process in regular distinct steps, typically of 50-metre length, at time intervals of 50 microseconds, descends in a downward branching pattern toward the ground. Carrying currents on the order of hundreds of amperes, this stepped leader or initial stroke propagates at a typical velocity of 1.5×10^5 metres per second, or about one two-thousandth the speed of light. Diameter estimates for the stepped leader range from a few centimetres to a few metres. The current carrying core is on the order of one or two centimetres, and photographic measurements indicate that a sheath of

electric charge (corona sheath) with a diameter of one to ten metres exists around the core. As the branching process nears the ground, approximately five coulombs of charge have been deposited on the channel, inducing an opposite charge on the ground and increasing the electric field between the leader and the point to be struck. An upward discharge occurs from the ground, church steeple, house, or other object to meet the stepped leader about 50 metres above the surface. At this moment of junction the cloud is short-circuited to the ground and a highly luminous return stroke of high current occurs. Stepped leaders that have not reached the ground become the branches of the return stroke, and charge on the branches flows into the main channel. The five coulombs of charge typically deposited on the stepped leader flow to ground in a few hundred microseconds to produce peak currents that are usually on the order of 20,000 amperes but may range from a few thousand to 200,000 amperes. Temperatures in the channel are on the order of 30,000" K (50,000" F). Due to the junction process occurring near the ground, the time to peak current measured at the ground is typically ten microseconds. As the charge avalanches toward the ground, the luminosity (return stroke) propagates toward the cloud base at 5×10^7 metres per second, or approximately one-tenth the speed of light, and the high current carrying core expands to a diameter of a few centimetres. Laboratory experiments suggest that when pressure equilibrium is attained between the channel and the surrounding air, the channel approximates a high-current arc characterized by a current density of 1,000 amperes per square centimetre. In the rapid passage from ground to cloud the luminous return stroke is observed to pause at points where the branches join the main channel, and the channel is observed to brighten as charge from the branch flows into the channel. The stroke then continues its upward propagation, reaching the cloud base in about 70 microseconds; the downward propagating stepped leader traverses the same distance in 20 milliseconds.

Strokes and energy dissipation

At this moment there is a pause for tens of milliseconds and the channel cools to a few thousand degrees Kelvin. If a second stroke occurs it begins with the appearance of a dart of light, perhaps 50 metres in length, propagating down the channel of the return stroke. At a speed of 2×10^6 metres per second (about one one-hundredth the speed of light) the dart leader carries a current of the order of 1,000 amperes toward the ground. Once again a charge centre in the cloud is short-circuited to the ground and the return stroke occurs. This sequence of dart leader–return stroke typically occurs three to four times, although a flash to the ground that had 26 strokes and lasted two seconds has been reported. When a flash does have more than one stroke the subsequent return strokes draw charge from successively higher charge centres in the cumulonimbus clouds.

During the return stroke stage approximately 10^5 joules (1 joule $= 9.482 \times 10^{-4}$ BTU) of energy per metre are dissipated within the lightning channel. This energy is divided among the dissociation, ionization, excitation, and kinetic energy of the particles, the energy of expansion of the channel, and radiation. Spectroscopic measurements reveal that the air particles, principally nitrogen, oxygen, and water molecules, are split into their respective atoms and that, on the average, one electron is removed from each atom. The conversion from air molecules to a singly ionized plasma occurs in a few microseconds. At this time the temperature of the plasma is at least 30,000" K and the pressure is greater than ten at-

Velocities of Lightning Components and Related Data

	minimum*	representative	maximum*

Charge transferred including continuing current (coul)	3	25	90

*The words maximum and minimum are used in the sense that most measured values fall between these limits. †Velocities of propagation are generally determined from photographic data and thus represent "two-dimensional" velocities. Since many lightning flashes are not vertical, values are probably slight underestimates of actual values. ‡First return strokes have slower average velocities of propagation, slower current rates of increase, longer times to current peak, and generally larger charge transfer than subsequent return strokes in a flash. §Current measurements are made at the ground.

mospheres. The high pressure greatly exceeds the ambient (surrounding) pressure. The return stroke channel expands at a supersonic rate, and the shock wave decays to a sound wave that is eventually heard as thunder. Because it is estimated that 1 percent of the input energy is stored in the particles and less than 1 percent emitted as radiation in the visible and infrared region (4,000 to 11,000 A, where $A = 10^{-8}$ centimetres), it is probable that most of the energy dissipated goes into the energy of channel expansion, a process requiring no more than 10 to 20 microseconds.

A small percentage of discharges between the cloud and ground are actually initiated at the ground and propagate upward to a charged region in the cloud. These discharges often are initiated (or triggered) by tall structures or by towers on hilltops. These discharges have branching in the upward direction, giving the impression of a cloud-to-ground lightning flash that is upside down.

Some physical properties of cloud-to-ground lightning are summarized in the Table. The words maximum and minimum are not absolute but refer to the fact that most measured values occur within these limits.

Occurrence, duration, and current flow of intracloud lightning

Cloud-to-cloud and intracloud lightning. True cloud-to-cloud lightning is rare because most lightning flashes occur within the cloud. Of the total number of flashes occurring, South African studies report that the majority were intracloud, English records indicate 40 percent were intracloud, and studies in Sweden reported 20 percent were intracloud. The lower percentage of intracloud discharges may be associated with lower cloud bases. The first lightning flash in a thundercloud is typically an intracloud discharge. When an intracloud discharge occurs the cloud becomes luminous for approximately 0.2 second. The discharge is initiated by a leader that propagates between charge centres. The 0.2-second illuminosity is continuous and has several pulses of higher luminosity of one-millisecond duration superimposed upon it. This situation suggests minor return strokes as the leader contacts pockets of charge, but the similarity ends there. During the 0.2 second, the amount of the charge transfer is probably similar to the amount involved in a ground discharge: 20 coulombs, with a range from 0.3 to 100 coulombs. The mean velocity of propagation of the intracloud flash is $1 \times 10'$ to 2×10^4 metres per second. Electrical currents associated with the luminous brightening are probably in the range of 1,000 to 4,000 amperes. Strikes to aircraft indicate peak currents of only a few thousand amperes, an order of magnitude less than currents in ground flashes. Rise times to peak currents are measured in milliseconds, three orders slower than rise times in return strokes. The energy of intracloud flashes is unknown.

AURAL AND VISUAL PHENOMENA

Thunder. When air is crossed by a spark or a lightning flash, the air is heated rapidly and the cylindrical column expands at supersonic speed. Within a metre or two the shock wave decays to a sound wave. The sound heard as thunder comes from the entire channel length and is modified by the intervening medium. The result is a series of sounds that are variously described as peals, claps, rolls, and rumbles. These can conveniently be condensed into claps, which are sudden loud sounds, and rumbles, which are all other sounds of thunder. At short distances of a few hundred metres the thunder begins with a sudden clap followed by a long rumble. At extended distances the thunder begins with a rumble. Because light travels at 186,000 miles per second and sound travels at about 1,100 feet per second, observation of the time of arrival of thunder permits calculation of the distance to the flash; the sound will travel one mile in five seconds. For close lightning the elapsed time until the beginning of the thunderclap gives the minimum distance to the flash and the time duration to the rumble is a minimum estimate of the channel length. A thunderclap heard two seconds after the flash, followed by a rumble of 20 seconds, for example, indicates a distance to the flash of approximately 2,000 feet and a channel length at least four miles long. For reasons that include the atmospheric temperature lapse rate, wind shear, and terrain features, thunder is rarely heard at distances greater than 15 miles. The energy spectrum of thunder has been recorded and shows that most of the energy is in the low-frequency audible range with a maximum at 50 hertz (cycles per second).

Types of lightning flashes. Lightning types have been discussed thus far according to a scientific classification. Before the components of the lightning flash were known or studied. however, man devised his own method of classifying the bright flashes. Names such as forked, streak, sheet, heat, hot and cold, ribbon, and bead lightning all have their explanations in terms of ground or intracloud flashes.

Forked lightning refers to a many-branched cloud-to-ground lightning flash; the forked part is just the extensive branching created by numerous stepped leaders that propagate toward the ground until one fortuitously contacts the earth. The stepped leaders that have not reached the ground become the branches of the first return stroke. If there are very few branches, the flash is referred to as streak lightning.

An intracloud discharge, the most frequent type of lightning, usually illuminates a cloud without the channel being visible. The cloud has the brief appearance of a white sheet, hence the origin of the term sheet lightning.

Heat lightning is a type of distant cloud-to-ground discharge that occurs on warm summer evenings and is characteristically red or orange. All colours of the visible spectrum are emitted by the lightning channel, from the short-wave blue radiation to the long-wave red radiation. Blue light is scattered more efficiently than red so that relatively more red light propagates to the distant observer to give the impression of red lightning. (For this same reason the setting sun appears red.) Thunder cannot be heard because this type of lightning occurs at a great distance from the observer.

Hot and cold lightning refer to the observation that some ground discharges cause forest fires and others do not. Although the nature of the material struck is important, the return current characteristics of the return stroke are more important. Flashes containing strokes with a continuing current of a few hundred amperes and lasting for milliseconds after the high current phase have been shown to set forest fires and are consequently termed hot lightning. Flashes to trees without a continuing current usually cause only explosive damage and are called cold lightning.

Several rare forms of lightning include ribbon and bead lightning. These are also a form of ground discharge. If a flash consists of several strokes and a strong wind is blowing perpendicular to the line of sight, the channel is blown sideways and subsequent strokes are displaced. Due to the residual image on the retina of the eye, the flash appears to be a ribbon of several strokes. The same effect can be photographically recorded by slowly moving a camera from side to side, producing a slow time resolution of the component strokes in a flash. It was in this manner, in fact, that the stroke components of the flash were first identified around 1900. Bead lightning has been photographed on several occasions; the main lightning flash breaks into luminous sections, or beads, as the light intensity of the channel decays. The time-extended luminosity of the section can be caused by sections of the channel being viewed end-on or by sections that intrinsically have a larger diameter and, therefore, take longer to cool.

Ball lightning

The most rare and mysterious form of lightning is ball lightning, a ball of luminosity that usually occurs near the impact point of a flash, moves horizontally at a few metres per second, can penetrate closed windows, usually is accompanied by a hissing sound, has a diameter of about 20 centimetres, and has a lifetime of several seconds. The colour is quite variable, and the ball often ends with an explosion, leaving an odour of smoke. Ball lightning theories can be classified into those that propose an external energy source and those that propose an internal energy source. Unfortunately, none of the theories has succeeded in explaining the mobility of the ball or why the ball does not rise, as a hot plasma gas in pressure equilibrium should. An authentic photograph of ball lightning has never been published, but considerable research has been devoted to this phenomenon.

THE STUDY OF LIGHTNING

Problems and techniques of measurement. The transient, unpredictable nature of the lightning flash makes it one of the most difficult atmospheric phenomena to study. Occurring in a time scale measured in millionths of a second, the discharge strikes without warning, carries currents from a few tens to a few hundred thousand amperes, and has components that emit light with intensities varying over several orders of magnitude. Despite the harsh experimental conditions existing during the thunderstorms that produce lightning, it is possible to obtain data using photographic and spectroscopic techniques, electric and magnetic field measurements, current measurements, and acoustical measuring techniques.

Photography is the easiest and perhaps the most used process for recording the lightning flash. A time exposure at night during a thunderstorm invariably yields a few photographs. If the camera is moved slowly from side to side, it is possible to time resolve a ground flash into its component return strokes. Investigators in South Africa in the 1930s used high-speed photographic techniques, principally a rotating film drum and stationary optics, to obtain microsecond resolution. This procedure was sufficient to record successfully the faint stepped leader process, dart leaders, and return strokes. These data, when analyzed, yielded the two-dimensional velocities of the leaders and return strokes and the relative intensities of the same components.

Magnetic and electric measurements

The amount of electric charge involved in the entire flash and its polarity are determined by monitoring the electric field produced by the net charges in the cloud and the charges of the opposite sign induced on the ground, The motion of the charges within the cloud and between the cloud and ground constitutes an electric current; this, in turn, produces a magnetic field that can be measured at the ground. From this measurement the amount of current in the lightning channel can be deduced. A direct strike to an instrumented tower, on the other hand, will allow the current to flow through a known resistance. If the voltage versus time is measured and Ohm's law (voltage = current × resistance) holds, the current in the lightning channel can be directly calculated at the ground. This value, however, is not necessarily the lightning current in the channel above the tower. The simplest current measurement to perform, and probably the most difficult to interpret, is the experiment using magnetic links. Because the residual magnetism induced by the unidirectional magnetic field in the magnetic links depends on the maximum current, it is possible to measure peak flash current by placing the links around transmission towers.

The rapid rise of current in the flash produces a large variation in charge and current in a short time interval; the result is a time-varying electromagnetic field. Measurements of these fields are correlated with the visible part of the flash. Leaders emit primarily higher frequencies in the ten-megahertz range, and radiation in the one–ten-kilohertz range is predominantly from the return stroke. Studies of the microwave radiation from lightning show that the dart leader is the main source of this radiation.

At the other end of the electromagnetic frequency scale, the emission in the ultraviolet, visible, and infrared spectral regions provides a source for detailed recording and analysis. The simplest procedure for recording these emissions is to use a transmission diffraction grating (a ruled optical grating that transmits light according to wavelength) in front of a camera lens. If colour film is used, the spectrum will be recorded in colour in addition to the white image of the flash. The most intense lines are from singly ionized nitrogen atoms (atoms that have lost one electron), which are ions in an excited state from which light is emitted. A strong red line, the characteristic H-alpha line of the hydrogen atom, is derived from the dissociation of water vapour in the path of the lightning flash. Just as time-resolving cameras reveal the luminous components of a flash, time-resolving spectrographs reveal the spectral features of the flash components. Analysis of the recorded relative line intensity produced by emissions from singly ionized nitrogen atoms indicates that the return stroke temperature is at least 30,000" K, or five times hotter than the surface of the sun. A measurement of the H-alpha line width reveals that the electron density in the channel is 10^{24} m^{-3}, while the density of the channel is about one-hundredth of the normal atmospheric value. Ionization within the channel is approximately 100 percent, implying that every atom has lost one electron. In tens of microseconds the channel expands and cools. The rapidly expanding channel produces the sound wave with an acoustical spectrum that can be recorded. Analysis of the spectrum reveals the dominant peak in the acoustical spectrum of thunder: 50 cycles per second. Furthermore, theory relates this value to the energy deposition per unit length within the channel.

Occurrence and distribution of lightning. Lightning occurs throughout the world, and it is estimated that 1,800 storms producing 100 flashes per second are in progress at any given moment. On a per day basis the earth experiences 44,000 thunderstorms, which produce over 8,000,000 lightning flashes. Most of the flashes occur in the equatorial regions between 30° N and 30° S. The relative frequency of thunderstorms over land and ocean is not well-known, but initial satellite observations in the equatorial region at night suggest that ten times as many thunderstorms occur over land areas as over the sea.

Most of the estimated 8,000,000 flashes occur harmlessly, but others damage airplanes, kill and injure people, set fires, and cause accidents. Although lightning does not usually strike objects more than once, once is usually sufficient. Associated with a ground strike are voltage, heating, and pressure phenomena. A strike to a transmission line with a current rise of 60 kiloamperes per microsecond will produce a voltage difference in the transmission line of 100 kilovolts per metre.

Strikes to sand, on the other hand, will sometimes cause the sand particles to fuse along the path of the channel, forming a fulgurite, a permanent record of the lightning's path in sand. Large pressures are generated when the lightning strikes objects, instantly evaporating water in cracks to split trees or cause explosions. At 100,000 amperes, blocks of stone weighing five tons may be torn loose and rocks weighing 50 pounds may be thrown 20 yards or more:

Direct lightning strikes to humans usually cause death, and in fact do cause more deaths than any other weather phenomenon. Seventy percent of the deaths are single events and hence receive little publicity. Outdoor recreation activities, however, are increasing so that the number of deaths each year can be expected to increase. Common safety precautions during thunderstorms include staying off the water in small boats, staying inside cars, not standing under trees. A number of golfers have been killed or injured because their shoes were equipped with metal cleats, making their bodies more effective lightning rods. The telephone is considered by many people to be safe, yet lightning strikes during calls produced telephone casualties of four killed and 36 injured between 1959 and 1965.

Evidence indicates that lightning strikes to people need not be fatal if prompt cardiopulmonary resuscitation and prolonged artificial respiration are applied. A person struck by lightning is rendered unconscious, and heart action and breathing cease. Recovery can be complete, however, except for possible impairment or loss of sight or hearing.

Protection of structures

A satisfactory building protection system involves lightning rods to intercept the lightning flash, down conductors to transfer the charge safely to the earth electrode, and a grounding system to provide a safe conducting path into the ground. The lightning rod, invented by Benjamin Franklin in 1752, has undergone remarkably little change. Its purpose is to intercept a lightning discharge before it can contact a building and pass the lightning current safely to ground. A commercial proposal to increase the effective height of a lightning rod by using radioactive material to ionize the air is scientifically unsound. The additional ionization created by the radioactivity is several orders of magnitude less than the natural ionization produced by a natural lightning rod in the presence of a thunderstorm electric field. No artificial means are known to increase the range of protection afforded by a lightning conductor. Furthermore, the acceptance of a fixed value for the area protected by a lightning rod is not justified. The area protected is approximated by a circle whose radius is the height of the rod. This is only a statistical quantity as there are reports of strikes within the presumed area of protection.

(R.E.Or.)

Li Hung-chang

Li Hung-chang (in Pin-yin romanization Li Hongjang) was a Chinese statesman under the Manchu (Ch'ing) dynasty (1644–1912) who exemplified many Confucian ideals and in some ways symbolized Confucian China's inability to adjust to the modern world. He rose through the Confucian examinations to the highest offices and seemed to be omnicompetent, excelling in both civil and military affairs. But he added new elements. For long periods he was virtually in charge of relations with the Westerners, who had forced a new era of treaties on China; equally unprecedented for a Confucian official were his enterprises in commerce and industry.

Charles Phelps Cushing

Li Hung-chang.

Early life and career

Li was born on February 15, 1823, at Hofei, Anhwei Province. Both his father and Tseng Kuo-fan, who became his mentor, took terminal degrees in the examinations. Li started on his official career in 1844 under Tseng's guidance in Peking, the capital; in 1847 he earned his terminal degree.

In 1850 the Taiping Rebellion, a great national religious–political upheaval, broke out and threatened to topple the dynasty. When their homeplace was threatened, Li and his father organized a local militia. Li became so involved that he stayed (unofficially) at his post even when his father died in 1855, in defiance of the traditional Confucian mourning retirement. He earned a judgeship in 1856.

Tseng Kuo-fan, in 1860 governor general of the Liang-kiang provinces (central China), was organizing irregular anti-Taiping forces, and Li later joined his staff. In 1862 he was made acting governor of Kiangsu Province and travelled to Shanghai with his own troops in rented steamers. Hitherto, steamers had given the West a great advantage in two China wars (1839–42 and 1856–60), from which came the so-called unequal treaties, whereby China unilaterally surrendered such things as tariff autonomy and extraterritorial jurisdiction.

At just under 40 years of age, Li enjoyed high civil provincial rank and independent military power, a combination that had been forced on the central government by the exigencies of the rebellion.

For the next few years, Li worked partly with foreigners and their weapons in the anti-Taiping effort around Shanghai. Best known of these Westerners was Charles ("Chinese") Gordon, then a 30-year-old English army officer who led the "Ever-Victorious Army," a force, later put at Li's disposal, made up of foreign mercenaries. Although Westerners tended to credit this alien force with putting down the rebellion, it was really Tseng Kuo-fan and subordinates such as Li. The immediate director of the 1864 campaign against Nanking, the Taiping capital, was a brother of Tseng Kuo-fan, but Li disregarded his orders to assist in that terminal action because he felt that jealousies might arise—a delicacy that hinted at Li's own eminence.

Between 1865 and 1870, Li was heavily involved in various high official assignments in central, north, and west China, mostly to suppress other rebellions. He kept his interest in the Western-style arsenals he had established in Nanking and Shanghai, because he wanted to strengthen China against the West—or encroachment by Japan, whose modernization in the late 1860s was increasingly alarming to Li.

Appointment as governor general of Chihli

In 1870 came appointment as governor general of the capital province, Chihli. Li was also a grand secretary (a central government post), and superintendent of trade for the north, responsible for supervising Western trade out of the so-called treaty ports north of the Yangtze River. Although there was a new Peking agency for China's Western diplomatic relations, the Tsungli Yamen, Li became the Chinese negotiator most familiar to foreigners. Thus, he had positions in both the central and the provincial structures, military forces at his disposal, growing prestige abroad, and, it developed, an unprecedented 25-year term of office in Chihli.

During this long tenure, Li interested himself in several major modernizing projects: another arsenal at Tientsin and improved fortifications there, the sending of young Chinese to the United States to learn new skills, a commercial steamship line, Western-built warships, a coal mine, a railroad, a telegraph line, a cotton mill, a military academy, a modern mint, and two modern naval bases. He even talked about change in the procrustean Confucian examinations. There were few other Chinese officials interested in such projects.

During these years, Li also engaged heavily in negotiations with the Japanese, the British, the French, and other treaty powers. If his efforts were not in sum successful, this was largely a reflection of China's continuing relative military weakness, of which Li, throughout his "self-strengthening" efforts, was acutely aware. China sent a mission of apology to Great Britain in 1876 after the murder of a British official; in the same year, Japan made a treaty with Korea that ignored China's traditional suzerainty over the peninsula, and Li was not able, in a later treaty of commerce between the United States and Korea that he tried to manipulate, to get American recognition of the old relationship; in 1879 China lost to Japan her suzerainty over the Liuchiu (Ryukyu) Islands; Li sought French acceptance of Chinese suzerainty over Annam, but the result of the Sino-French War (1884–85) was that French suzerainty was substituted for it; Li's efforts to recover China's prestige in Korea were undercut by Japan, and, in 1885, Li and the leading Japanese statesman, It6 Hirobumi, in effect agreed to a joint protectorate over the contested peninsula. Indeed, in 1894 Japan went to war with China over Korea.

In this war, Li's northern fleet bore the brunt; virtually no assistance came from China's two other modem fleets. Again China lost a modem naval war and had to cede Formosa and the Liaotung Peninsula to Japan, to recognize Korean independence, to open new treaty ports, to pay a large indemnity to Japan, and to grant to the Japanese all of the advantages hitherto pre-empted by Westerners under the unequal treaties. Li had tried to avoid this war, but his influence, nonetheless, suffered because of it. He personally opened peace negotiations in Japan in March 1895 but was wounded by a Japanese fanatic—and. ironically, it was this attack, which excited Japanese sympathy, that somewhat ameliorated the harsh peace terms. (Certain Western powers, including Russia, forced the retrocession of the Liaotung Peninsula—which Russia in effect appropriated in 1898 anyway.)

State visits abroad

Still, to many Westerners, Li was the leading Chinese. In 1896, he attended the Tsar's coronation, and, while in Russia, negotiated a secret alliance, China's first equal treaty. Although he journeyed in state through western Europe and was received in Washington, D.C., by President Cleveland, his homecoming was chilly; probably the Empress Dowager had to use her influence to protect him (it was said that he bribed her for the favour). He kept his trade superintendency and in 1899 was made acting governor general of the Liangkwang provinces. His prestige was still such that he was selected to negotiate with the aggrieved Western powers after the 1900 Boxer Rebellion fiasco. Again Li had to preside at a national humiliation. He died on November 7, 1901.

Li Hung-chang did not exemplify all of the Confucian virtues. He did not have the reputation for financial disinterest enjoyed by Tseng Kuo-fan, and much of his innovating enterprise was made with an eye to personal profit. But the terminal crisis of the dynastic Confucian system in China cannot be explained thus. Li and a few contemporaries modernized parts of China's forces to protect the old system, but within that system, with its peculiar values and organization, the modern devices could not give full service. Li saw something of this contradiction; he hoped that examination reform would give prestige to the scientific modes, but his proposals were truncated, and he was nearly alone in making them. He did support the education mission noted above, but, when conservatives at court decried it as subversive to Confucian norms, Li did not stake his reputation on it, and in 1881 it was terminated. Li was adroit in manipulating the system and was unquestionably loyal to it.

Liliales

The order Liliales is a vast assemblage of plants whose flowers usually have three petals and three sepals—the sepals usually resembling the petals in shape and colour—and whose leaves are generally linear or strap-shaped with the veins running parallel. These characteristics—along with one leaf in the embryo—are common to most monocotyledonous plants. Within this large order, exemplified by the lily, are more than 400 genera and 8,000 species, including erect perennial herbs, climbers, shrubs, and a few trees. The group contains many common garden plants and vegetables, such as lily, hyacinth, narcissus, amaryllis, asparagus, onion, and yam. Other economically important members include the agaves, fibre crop plants; *Colchicum,* from which the drug colchicine is extracted; and Smilax, from which the flavouring sarsaparilla is derived.

Contemporary authorities recognize from five to 20 families in the Liliales, an indication of the lack of consensus among botanists as to what constitutes the order. In this article 20 families are recognized, according to a recent classification scheme; the validity of this outlook is critically appraised in the last section.

GENERAL FEATURES

Diversity. Species of the Liliales are usually perennial herbs, with fleshy stems arising from various kinds of underground stems. Herbaceous climbers are found in the yam family (Dioscoreaceae) and in the families Alstroemeriaceae and Alliaceae. Climbing shrubs are known from the families Smilacaceae and Petermanniaceae. The order also contains succulents such as the Aloe and Agave species. Agaves include some of the largest members of the Liliales: the flower stalk of the so-called century plants (several Agave species) may attain six metres (about 20 feet) in height. Yucca and Dracaena species are often woody and treelike, such as the Joshua tree (Yucca brrvifolia) and the dragon tree (Dracaena draco).

Aquatic Liliales are rare. They include erect or floating herbs in the family Pontederiaceae, particularly in *Pontederia* species and the water hyacinth (*Eichhornia crassipes*), and rarely in the Amaryllidaceae, notably *Crinum thaianum*, native to Thailand.

Distribution. The lily order is cosmopolitan in distribution, although most of its members are found in temperate and subtropical regions. The extreme range is as far north as northern Greenland (*Tofieldia* coccinea) and as far south as the southern tip of South America and New Zealand (Luzuriaga *marginata*). In numbers of species and individuals the order is best represented in southern Africa, North America, western Asia, and Australia.

Among the widest in distribution are the families Liliaceae. Amaryllidaceae, and Pontederiaceae. The lily family is worldwide in distribution, but is most abundant in temperate and subtropical regions. The amaryllis family ranges from southern Africa to Asia and the Western Hemisphere; and the family Pontederiaceae, common in tropical freshwaters, ranges as far north as southern Canada.

Importance. The lily order is notable for its important food and industrial plants, on the one hand, and its many showy cultivated ornamental plants, on the other.

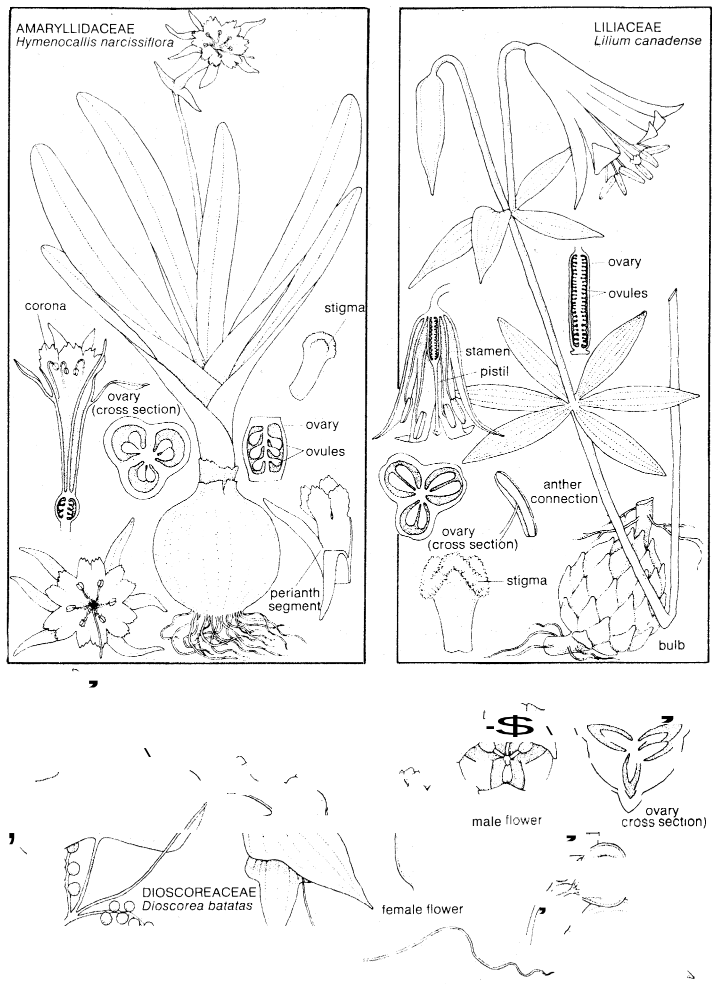
Edible products. Among food crops, the outstanding ones are onion (*Allium* cepa), garlic (*A.* sativum), leek (A. *porrum*), chive (A. *schoenoprasum*), rakkyo, or *ch'iao* (A. chinense), and Chinese chive (*A. tuberosum*). The most important of these is the onion, the others being grown mostly for local consumption or in limited quantities.

Other edible crops of the lily order are asparagus (*Asparagus officinalis*), of the family Liliaceae, and various species of Dioscorea, of the family Dioscoreaceae, of which white yam (D. *alata*), negro yam (*D. cayennen*sis) and cush-cush, or yampi (D. *trifolia*), are considered among the best. Used locally as important starchy food crops throughout the tropics, they are twining plants that produce tubers rich in starch and containing poisonous alkaloids; the latter are easily destroyed by boiling.

Elephant's-foot, or Hottentot bread (*Testudinaria ele*plzantipes), of the family Dioscoreaceae, produces a very large edible rhizome (rootlike structure) used as a food locally in Africa. Black bryony, or black bindweed (*Tamus* conzmunis), a perennial vine of the family Dioscoreaceae, is occasionally cultivated and consumed as a vegetable from southern and western Europe to Kurdistan in Asia. The roots are also used medicinally. Another source of starch is arrowroot, from Tacca *pinnatifida*, of the family Taccaceae. It is used locally in the South Sea islands as food. Starch from the tuberous roots of *Alstroemeria* species, of the family Alstroemeriaceae, is used locally as a food by the Andean Indians of South America.

Sarsaparilla, the flavouring extract, is obtained from the dried roots of several species of *Smilax* native to South America. The elongated berries of species of *Gethyllis* and *Apodolirion*, of the Amaryllidaceae, known as *kukumakrankas*, are collected and consumed locally in South Africa. In China and elsewhere, the buds of daylilies (*Hemerocallis* species) are harvested and used as a vegetable.

Industrial products. The 300 species of Agave, ranging from the United States to tropical South America, and the related 30 species of Furcraea provide important commercial fibres, obtained by processing the leaves. Sisal hemp is obtained from Agave *sisalana*, native to Yucatán; henequen from Agave fourcroydes, Mexico; mauritius hemp or flax from Furcraea *gigantea*, the tropics; and Ceylon bowstring hemp, from *Sansevieria* zeylanica, Ceylon.



Representative plants from three major families of the order **Liliales.**

Drawing by M. Moran

Many other Agave species are cultivated or harvested from native stands mostly for local fibre needs or for fermented beverages. Several species are used in making pulque, the national drink of Mexico; the alcoholic liquor mescal is distilled from pulque.

The water hyacinth, with its bladderlike leaf bases, has been recommended as a source of cellulose for papermaking and other uses.

Dracaena cinnibari, a tree native to the island of Socotra, in the Indian Ocean, is the source of a red resin called dragon's blood, or Socotra resin, which is used in varnishes and also as an astringent and to stop hemorrhage. *Dracaena draco*, a tree native to the Canary Islands, is the source of a red resin, also known as dragon's blood, which is used in the varnish industry, for pigment in papermaking, and in medicine.

Drug products. Drug products include many crude drugs used locally. Aloe juice, obtained from various Aloe species, is used as a purgative. The flowers of lily of the valley (*Convallaria majalis*) are used as a cardiac tonic in place of digitalis; squill, from the bulbs of *Urgirzea scilla*, is, among other things, a cardiac stimulant. White hellebore (*Veratrum album*), *min-mun-tung*, from the tubers of *Ophiopogon japonicus*, and China root, from the dried rhizomes of *Similax* china, have been used medicinally in China since ancient times. The seeds and corms of the meadow saffron (Colchicum *autumnale*) are used to treat rheumatism and also as a diuretic. The active chemical is the alkaloid colchicine, which is one of the most efficient chemicals yet discovered for causing the doubling of chromosomes in cells; it has played an important role in plant and animal science since 1937.

Ornamental plants. The lily order is outstanding for its many ornamental plants, cultivated from most of the 20 families; the more important ones, however, are found in the following families: Liliaceae (*e.g.*, tulip, hyacinth, crocus, lily, daylily, aloe); Amaryllidaceae (*e.g.*, *Amaryllis*, Narcissus, Lycoris); and Agavaceae (*e.g.*, Agave, Yucca, *Hosta,* Dracaena, Cordyline, Sansevieria).

In The Netherlands there is a considerable export business based on certain bulbous and cormous plants of the Liliales. In the United States, particularly in Oregon, lily (Lilium) breeding for the domestic and export trade has developed into a considerable industry. Locally, the growing of plants of the lily order is active in season, particularly the forcing and marketing of lilies, tulips, hyacinths, narcissus, amaryllis, and others for holidays.

NATURAL HISTORY

The life cycle of members of the Liliales is similar to that of other monocotyledonous plants (plants with one seed leaf). Pollination is usually by insects or by other small animals, but cleistogamy, a condition in which self-fertilization takes place within unopened flowers, occurs in the genera *Heteranthera* and Hydrothrix, of the Pontederiaceae.

Food and water storage. One of the outstanding features of a large number of the Liliales is the manner in which they have adapted to the seasonal peculiarities in different parts of the world. The most primitive Liliales are usually herbaceous perennials having short rhizomes with fibrous roots; they are adapted to humid climates. Organs for moisture and food storage have been evolved to carry the plant over unfavourable periods when growth is inhibited by dry or cold weather. These include creeping rhizomes, specialized thickened stems on or just below the ground surface, as in daylilies (Hemerocallis), and lily of the valley (Convallaria); bulbs, as in Lilium, Allium, and *Amaryllis;* corms, swollen bases of the stem, as in Biodiaea, *Milla*, and Tecophilaea; tubers, short underground stems, as in Gloriosa; and tuberous roots with buds at the stem end, as in Alstroemeria and Dioscorea.

In the agaves and aloes, the problem of surviving in a dry desert climate has been successfully solved by the evolution of tough, thick succulent leaves and a tough, thick stem for food and moisture storage. The American Agave species, family Agavaceae, have assumed the outward shape, within limits, of the thick succulent-leaved African Aloe and allied genera of the family Liliaceae. It is interesting to note that the related genera, *Hosta*, native to humid parts of China and Japan, and Polianthes (tuberose), native to Trinidad and humid Mexico, have not developed the succulent habit.

Extreme drought resistance is exhibited by such amaryllids as Leucocoiyne, native to the extremely dry Atacama Desert of Chile, where scant rainfalls occur years apart. When limited rains do occur after prolonged droughts, the bulbs, dormant for years, quickly sprout, come into flower, and produce seed. Another interesting adaptation to an arid climate is found in certain species of Vellozia, in which the upper parts of the stems are covered with fibrous sheaths of the leaves, and the lower parts with a covering of aerial roots inches deep. When water falls on the aerial roots, it disappears as if into a sponge. The plant is thus able to supply itself with moisture in the form of dew and occasional light rainfall as well as from moisture condensed on the aerial roots.

Reproductive adaptations. In many species of the Amaryllidaceae, the seeds soon lose their viability, but some, such as Chlidanthus boliviensis and C. *fragrans*, which grow in dry mountain habitats, retain their germinating power over a period of years. Amaryllis petiolata, native to the forests on the river banks in southern South America, produces no viable seeds but has evolved a novel means of dispersal. The parent bulb produces many small, nearly round bulblets on the bulb scales. They remain dormant almost a year. During the spring floods they are carried long distances.

Apogamous reproduction

Apogamy, a form of parthenogenesis (reproduction in which seeds are developed without fertilization), occurs in such genera of the Amaryllidaceae as *Habranthus* and Zephyranthes. Copious seed production by such means has allowed certain species of these genera to spread over very large areas of Texas and northern Mexico.

Vivipary, in the sense of bulblets sprouting from buds in a flower cluster (inflorescence) almost to the total exclusion of the regular florets in the inflorescence, is found in some Allium species. European wild garlic (Allium *vineale*) by such means has been naturalized as a noxious weed over wide areas in North America and elsewhere. Protandry, the maturing of the stamens before the pistil, is found to a slight degree in many Alliaceae and Amaryllidaceae and to an extreme degree in *Alstroemeria* species, of the family Alstroemeriaceae, in which the stamens mature and shed their pollen before the pistil begins to enlarge and mature. These processes favour cross-pollination.

Miscellaneous adaptations. The Pontederiaceae are adapted for life in an aquatic habitat. In *Eichhornia crassipes*, for instance, the swollen petioles enable the plant to float; and floating has led to very wide distribution of this species. In species of the family Smilacaceae, the prickly shrubs and climbers are protected to some extent against animals. Seeds of many species in the order Liliales are winged, enabling them to be carried by the wind.

FORM AND FUNCTION

The rootstock varies from creeping rhizomes, bulbs, corms, and tubers, all of which are modifications of the stem, to thickened storage roots with buds at the stem end. The plants are usually perennials, very rarely annuals, ranging from herbs to shrubs and climbers or very rarely to types with a woody stem that is branched and treelike. The leaves are usually linear or strap-shaped, with longitudinal veins; rarely, the leaves are broader, and with stalk petiole, with longitudinal veins separated by netted venation. Latex-bearing vessels (laticifers) are present in the Alliaceae.

Floral variations

The flower varies from small and in loose clusters to large, solitary, and showy, with the showy perianth (petals and sepals collectively) usually six-parted, rarely three-parted or less; the perianth segments are similar, and are sometimes united below into a tube. Occasionally there is a floral structure called the paraperigone, consisting of inward extensions of the lower part of the perianth tube; or scales or bristles may be present at the base of the filaments. The stamens usually number six, rarely are there three or less; each stamen consists of an anther—in which pollen is produced—and a filament, or stalk. The filaments may be variously modified, united into a tube below or into a conspicuous staminal cup. The pistil—usually one to a flower—consists of a three-parted ovary formed of three greatly modified leaves (carpels) and a stalk (style) capped by a pollen-receptive tip (stigma). Pollination is accomplished by small animals, including birds, insects, and arachnids. Fertilization—the union of a sperm cell and the egg cell—follows pollination. Most of the Liliales depend on cross-pollination, and thus fertilization follows flower opening; rarely are the flowers cleistogamous, a condition in which there is fertilization without opening of the flowers. The fruit is usually a dry, three-parted (rarely a one-celled) capsule, sometimes a fleshy berry, very rarely a nut; the seeds are sometimes winged.

EVOLUTION

In the absence of a fossil record, any estimate of the evolutionary relationships must be based on the characteristics of the living species. The evolutionary course within the Liliales, as well as in the superorder Lilianae, including several orders as well, is only partly understood; enough is known, however, so that the general evolutionary course may be described to a limited extent on the basis of gross morphology, chromosomal complement, anatomy, and biochemistry.

Morphological evidence. The general evolutionary course of some prominent morphological features in the Liliales, is listed in the accompanying table.

Evolutionary Course in the Liliales

organ	original form	evolved form
Stem	stem with taproot and fibrous secondary roots	rhizome, bulb, corm, tuber, or storage root with buds at the stem end
	herbaceous	shrubby or climbing, rarely woody, rarely treelike and branched
Leaves	linear, with longitudinal veins (originally evolved from petiolate leaves)	secondary petiolate leaves, with longitudinal veins, and reticulate veins between
Flower	perianth segments six, free	perianth segments three or fewer; perianth segments united below into a tube, with six or three segments above
	perianth tubular	perianth tubular with accessory structure (paraperigone)
	carpels free	carpels partially or fully united
	ovary three-parted	ovary with single compartment or two
	ovary superior	ovary inferior
	stigma three-parted	stigma three-lobed, capitate, or pointed
	stamens six, free	functional stamens four or fewer, filaments modified in various ways

Chromosomal evidence. Evidence from the chromosomal makeup of the cells has helped to solve difficult problems in phylogeny. The basic chromosome set, with a few large and many small chromosomes, in the *Yucca-Agave* group is very stable. The chromosome complement in *Hosta* is similar, on which basis it has been suggested that *Hosta* be recognized as the type of a separate tribe, Hosteae, to be placed next to the tribe Yucceae (*Yucca* and its allies) in the family Agavaceae. The evolutionary course is irreversible, and the chances that such a unique chromosome complement originated a second time are remote. The suggestion is therefore valid, indicating that these two tribes originated from the same ancestral stock. The difference in gross morphology can be attributed to differences in habitat: *Hosta* evolved in humid parts of China and Japan; *Yucca* and its allies in the arid parts of southwestern North America. Later, apparently a few species of *Yucca* spread to the more humid southern United States and the West Indies, but only after leathery leaves and other characters had evolved in the arid climate.

The presence of lacticifers in the Alliaceae indicate the distinctness of this family and its presumed early evolutionary divergence from the rest of the Liliales.

The significance of saponins

Biochemical evidence. Biochemistry and other scientific disciplines have yielded evidence that suggests relationships among the flowering plants. On the basis of the presence of one substance—saponin—the Liliales may be divided into two groups:

1. Families in which the plants usually contain saponin compounds, including the Liliaceae and its allies, Xanthorrhoeaceae, Alphyllanthaceae, Philesiaceae, Smilacaceae, and Asparagaceae; the Dioscoreaceae and its allies, Stemonaceae, and Taccaceae; the Agavaceae; and the Alliaceae.
2. Families in which the plants lack saponins, including the Pontederiaceae and its ally Philydraceae; and the Amaryllidaceae and its allies, Alstroemeriaceae, Haemodoraceae, Hypoxidaceae, and Velloziaceae.

Chelidonic acid is present in many families of the Liliales. Alkaloids are present in a number of families, including the Amaryllidaceae. Thus, this group is singled out as a very distinct entity. Alkaloids have also been reported for *Dioscorea* species, *Tacca chantrieri*, and *Stemona* species. Colchicine has been extracted from *Colchicum, Merendera,* and *Gloriosa* species of the Liliaceae. The occurrence of these and other distinct biochemical compounds in Liliales suggest the potential value of this approach in solving outstanding phylogenic problems.

Most authorities on the monocotyledons place the order Liliales in a central position from which other orders have arisen. A hypothetical, now extinct, group with nutritive tissue (endosperm) in the seeds, two-celled pollen grains, and separate or partially united carpels and numerous stamens presumably gave rise to three main lines.

The Liliales, Iridales, Zingiberales, and Orchidales are derived directly from the Liliales ancestral stock. The order Iridales is probably derived from the subfamily Melanthioideae of the Liliaceae. The order Zingiberales was probably derived directly from the Liliales and is claimed to have much in common with the Amaryllidaceae and the subfamily Asphodeloideae of the Liliaceae. The order Orchidales shows closest connections with the family Hypoxidaceae of the Liliales, especially the genera *Hypoxis* and *Curculigo*. The connecting link between these and the Orchidaceae is the most primitive subfamily of the Orchidaceae, the Apostasioideae. The Liliales stock may have given rise to two additional superorders, the Juncanae and Commelinanae.

CLASSIFICATION

The shift in diagnostic features

Distinguishing taxonomic features. In the past, the position of the ovary with respect to the perianth was considered very important in distinguishing groups within the Liliales but is no longer considered as reliable in delimiting larger groups. Currently, the number of chromosomes, the presence of such internal features as laticifers (vessels bearing latex), and the presence of chemical compounds such as saponins and alkaloids are considered of greater significance in grouping of families within the Liliales.

Annotated classification. A currently considered classification lists 20 families in the order Liliales.

ORDER LILIALES

Monocotyledonous plants usually with storage rootstocks. Herbs to trees. Leaves often clustered at base. Flowers usually showy and bisexual (having male and female parts); components in 6 (3 petals, 3 sepals) or 3 parts. The order includes 20 families, about 430 genera, and 8,000 species; distribution is worldwide, but members are concentrated in temperate and subtropical regions.

Family Liliaceae

Erect or climbing, herbs, rarely soft-wooded shrubs, with rootstock a rhizome, bulb, corm, or tuber. Flowers usually bisexual and regular, flower segments 6, rarely 4 or more, often tubular below, with petals and sepals similar. Stamens usually 6, sometimes fewer, rarely more; anthers with 2 compartments (locules). Ovary superior (rarely semi-inferior), usually with 3 locules, style (stalk) entire or divided (rarely free); ovules usually numerous per locule, rarely solitary; fruit a capsule or fleshy berry; seeds with copious nutritive tissue (endosperm). One of the largest families of flowering plants, with 250 genera and 3,700 species, most abundant in temperate and subtropical regions.

Family Xanthorrhoeceae

Perennials with thick rhizomes. Stem when present woody and sometimes tall, single, or somewhat branched. Leaves often sheathing, usually linear. Flowers usually small and in clusters (rarely solitary and larger); flower segments 6, free or shortly united below. Stamens 6, anthers with 2 locules. Ovary superior, with 1 to 3 locules; fruit a capsule or rarely a 1-seeded nut; seeds with hard endosperm. Includes 8 genera and 66 species, in Australia, New Caledonia, and New Zealand.

Family Aphyllanthaceae

Perennial herbs, with short rhizomes. Leaves reduced to sheaths. Flowers bisexual, 1 to 3 in short terminal spike; flower segments 6. Anthers united at bases. Ovary with 3 locules; ovules solitary; fruit a capsule. Consists of a single species, mostly in the western Mediterranean region.

Family Alliaceae

Rootstock usually a bulb or corm. Leaves usually basal, long and thin. Stem leafless (scapose). Flowers in clusters (umbel), subtended by 1 or more spathe-valves; flower bisexual, flower segments 6, usually similar, free or united below into a tube; paraperigone (corona), inner petallike appendages, may be present. Stamens 6 (rarely 3 or 2); filaments sometimes united into a staminal cup. Ovary superior, with 3 (rarely 2) locules; style entire or 3-lobed; fruit a capsule; seeds with fleshy endosperm. About 30 genera and 670 species, worldwide except for tropical regions, Australia, and New Zealand.

Family Agavaceae

Rootstock usually a rhizome. Stem short, often woody and arborescent. Leaves basal, narrow, lancelike, often thick or fleshy (succulent), sometimes with prickly teeth on the margin. Flowers regular or somewhat irregular, in clusters, with the floral branches suhtended by bracts; flowers segments 6, united into a tube below. Stamens 6, inserted at the base of the segments or on the tube; anthers with 2 locules. Ovary with 3 locules; ovules numerous or solitary in each locule; fruit a capsule or berry; seeds with fleshy endosperm. Encompasses about 20 genera and 720 species; especially prevalent in the tropics and subtropics and ranging into the temperate zone.

Family Amaryllidaceae

Perennial herbs, with bulbs or rhizomes. Leaves few to several, sometimes solitary, from the base of the stem, or apex of the bulb; linear, usually strap-shaped, lanceolate. Flowers usually showy, bisexual, regular or somewhat irregular, in clusters (sometimes 2 or 1 by reduction); usually each floret subtended below by a bracteole, and the entire inflorescence subtended below by *2* or more, rarely 1, spathe-valves; fiower segments 6, in 2 series, usually similar, often united below into a tube; paraperigone sometimes present. Stamens 6 (rarely more and rarely reduced to 3), opposite the segments, filaments free, or variously modified, or joined to form a staminal cup; anthers with 2 locules. Ovary inferior, with 1 to 3 locules, style slender, stigma capitate, 3-lobed or 3-parted; ovules usually numerous per locule; fruit a capsule or, rarely, a berry; seeds with copious endosperm. About *65* genera, including about 835 species, worldwide in distribution, mostly in the tropics and subtropics.

Family Alstroemeriaceae

Rootstock a rhizome. Stems usually erect, often climbing, leafy. Leaves crowded or scattered, the petiole usually twisted and thus reversing the surfaces. Flowers bisexual, irregular, in terminal clusters, or in irregular racemes, rarely solitary; segments 6, often narrowed to the base or spoon-shaped, in 2 series. Stamens 6, inserted on top of the ovary, filaments free. Ovary infer·ior, with 1 to 3 locules, style threadlike (filiform), shortly 3-lobed, usually maturing after the anthers; ovules numerous per locule; fruit a capsule; seeds small with copious endosperm. Four genera, including 200 species, ranging from Central America to southern South America, mostly in the Andes mountains.

Family Haemodoraceae

Herbs with short rhizomes, or rounded tubers and fibrous roots. Leaves clustered at the base, linear, or sword-shaped, sheathing at the base; stem leaves reduced or absent. Flowers bisexual, segments 6, regular or somewhat irregular, in clusters, often hairy. Stamens 6 to 3, filaments free, anthers with 2 locules. Ovary with 3 locules; style usually filiform; ovules 1 to many in each locule; fruit a capsule; embryos small with copious endosperm. About 15 genera, including 75 species, ranging from South Africa and Australia to tropical America.

Family Hypoxidaceae

Herbs with tuberous rhizomes or corms. Leaves usually basal, mostly with prominent veins, often with long hairs. Flowers bisexual, segments 6, regular or somewhat irregular, in clusis short or in the form of a long beak on top of the ovary; segments 6, similar in shape and colour. Stamens 6, rarely 3; anthers with 2 locules, entire or 2-lobed at the base. Ovary inferior, with 3 locules; single short style or 3 separated styles; ovules numerous per locule; fruit a capsule; seeds small; with copious endosperm. Includes 7 genera and 120 species, common except in Europe and northern Asia.

Family Velloziaceae

Arborescent and shrubby plants. Leaves tufted at the end of branches, narrow, often sharply pointed. Flowers bisexual, solitary, regular; flower tube absent or very short, segments 6, equal. Stamens 6, or numerous in 6 groups of 2 to 6; anthers linear and joined at their bases. Ovary inferior, with 3 locules; style slender; stigmas capitate or shortly trifid; ovules numerous per cell; fruit a capsule; seeds with abundant endosperm. Two genera, including 170 species, ranging from the Arabian Peninsula, tropical and southern Africa, and Madagascar to tropical South America.

Family Philesiaceae (including **Petermanniaceae)**

Rootstock a slender branched rhizome, supporting shrubs or tall woody climbers, rarely semi-epiphytic. Leaves without stipules, oblong or ovate. Flowers bisexual, regular; flower segments 6. Stamens 6. Ovary superior, with 1 to 3 locules; style slender; stigma 3-lobed or capitate; ovules numerous or a few per locule; fruit a berry. Consists of 8 genera, including 10 species, ranging in the Southern Hemisphere from New Guinea, the Pacific Islands, New Caledonia, Australia, and New Zealand to temperate South America and southeast Africa.

Family Tecophilaeaceae

Upright herbs, with tunicated corms or thick, flattened tubers. Leaves basal. or near the base of the flowering stems. Flowers bisexual, regular or slightly irregular. in clusters; perianth segments 6, free or sometimes united below. Stamens 6 or 4 (or 2 functional); anthers with 2 locules. Ovary semi-inferior, with 3 locules; style awl-shaped to filiform; stigma more or less 3-lobed; ovules numerous per locule; fruit a capsule; seeds with fleshy endosperm. Seven genera, including 25 species, ranging in a scattered pattern from Africa to southern California.

Family Cyanastraceae

Rootstock a tuber or a tuberous rhizome. Leaves basal, linear. Flowers bisexual, regular; solitary or in clusters, flower segments 6. Stamens 6, filaments free. Ovary partly inferior, with 3 locules; 2 ovules in each locule; fruit I-seeded. One genus, 6 species, confined to tropical Africa.

Family Asparagaceae (including Ruscaceae)

Rootstock a rhizome. Stems herbaceous or woody, erect or climbing. Leaves reduced to very small scales, bearing in their axils green, needlelike modified branchlets that function as leaves. Flowers solitary or in clusters; flower segments free or united into a tube below. Anthers 2-lobed. Ovary with 1 to 3 locules; ovules 2 or more in each locule; fruit a globose berry; seeds solitary, or few in each locule. Four genera, including about 310 species, ranging over Asia, Europe, and Africa to the Azores, Madeira Islands, and Canary Islands.

Family Smilacaceae

Rootstock a rhizome, supporting climbing shrubs. Stems and branches prickly, often with tendril-like petioles. Flowers usually unisexual (rarely bisexual), small, in cluster; flower segments 6, free (rarely united below into a tube). Stamens 6; anthers with 1 locule. Ovary superior, with 3 locules; ovules 1 or 2 in each locule; fruit a 1- to 3-seeded berry; endosperm hard. Comprises 4 genera, including 375 species, ranging from the tropics to temperate regions.

Family Stemonaceae (**including** Croomiaceae)

Erect or climbing perennial herbs, with rhizomes or tubers. Leaves often smilax-like, with parallel main nerves and closely parallel cross veins. Flowers in clusters, bisexual, regular, sometimes unpleasantly scented; flower segments 4. Stamens 4, resembling petals or sepals; filaments free or nearly so; anthers with 2 locules. Ovary superior to semi-inferior, with 1 locule; style simple, ovules numerous to 2 per locule; fruit a capsule; seeds with copious endosperm. Three genera, including 30 species, ranging from northern Australia, India, and Japan to the southeastern United States.

Family Dioseoreaceae

Rootstock thick and woody or a tuberious rhizome, usually supporting climbing stems, or sometimes shrubs. Leaves net-veined, often arrow-shaped or heart-shaped, usually alternate. Flowers regular, 6-lobed, inconspicuous, and in clusters. Stamens 6 (sometimes only 3 functional); filaments free or shortly united below; anthers with *2* locules. Ovary inferior, with 3 locules; styles 3, sometimes 3-winged; ovules 2, rarely numerous per locule; fruit a capsule or a berry; seeds with endosperm, often winged. Consists of 6 genera, including 750 species, confined to the tropics and warm temperate regions.

Family Taccaceae

Perennial herbs, with tubers or rhizomes. Leaves basal, broad- or much-lobed, often long-stalked. Flowers bisexual, regular, in clusters; flower in the form of a tube, with 6 lobes above. Stamens 6, inserted on the fiower tube; filaments short; anthers with 2 locules. Ovary inferior, with 1 locule; style short; the 3 stigmas often petallike and reflexed over the style; ovules numerous; fruit a berry, opening by 3 valves; seeds with abundant endosperm. Two genera, 31 species, ranging from China to tropical Asia.

Family Pontederiaceae

Freshwater plants, floating or rooted and erect. Leaves with floating or emmersed blades. Flowers bisexual, mostly regular, in clusters subtended by a spathelike leaf sheath, bracts minute or absent; flower 6-lobed. Stamens 6 or 3 (rarely 1), inserted on the blossom, filaments free; anthers with 2 locules. Ovary superior, with 3 locules and numerous ovules, or with 1 locule and a single ovule; style entire or 3-parted. Flowers sometimes cleistogamous. Fruit a capsule, seeds with abundant endosperm. Six genera and 30 species, in the Old World and in the American tropics and subtropics.

Family Philydraceae

Erect herbs with short rhizomes. Leaves narrow, basal, 2-ranked. Flowers bisexual, irregular, solitary in the axil of bracts; flower segments 4, corolla-like, free. Stamen 1; filament flattened; anther with 2 locules. Ovary superior, with 1 to 3 locules; style slender; ovules numerous; fruit a capsule. Four genera, 5 species, ranging from China and New Guinea to eastern and southwestern Australia.

Critical appraisal. The classification presented above is the product of several contemporary botanists, prominent among them being A. Cronquist, an American, and A. Takhtajan, a Soviet citizen. It is the nature of a taxonomic system that it can be improved, and, as new and more critical data are amassed, it is expected that changes will be made in the disposition of the families.

Dissenting opinions

The inter-relationships of the families listed above are determined to a considerable extent on the basis of gross morphology, as offered by earlier workers (see in the *Bibliography* the works of Engler and Prantl, Hutchinson, and others). This approach has yielded important results but is now being enlarged by data from other disciplines, including (1) chromosome number and morphology, such as the presence of a unique and stable basic chromosome complement in the Agavaceae; (2) evidence from anatomy, such as the presence of laticifers in the Alliaceae, and (3) evidence from biochemistry, such as the presence or absence of saponins, alkaloids, and other compounds.

In view of these data, the twenty families listed above may be accommodated as follows (see also in the *Bibliography* the works of Traub, Sterling and Huang, and others): the families Tecophilaeaceae and Cyanastraceae have been placed under the new order Tecophilaeales, which is transferred to the subclass Iridae, leaving 18 families—plus two new families under the new order Alliales—again making twenty families to be accommodated under subclasses Liliidae (saponin containing) and Amaryllidae (saponin free).

Subclass Liliidae: Order Liliales, laticifers absent, chromosomes not of *Yucca-Agave* type; families Liliaceae, Xanthorrhoeaceae, Aphyllanthaceae, Philesiaceae, Smilacaceae, and Asparagaceae. Order Dioscoreales, laticifers absent, unique alkaloids present; families Stemonaceae, Discoreaceae, and Taccaceae. Order Agavales, laticifers absent, unique and stable basic chromosome complement of *Yucca-Agave* type present; family Agavaceae. Order Alliales, laticifers present, and unique alliaceous scent usually present; families Hesperocallaceae, Milulaceae, and Alliaceae.

Subclass Amaryllidae: Order Pontederiales; families Pontederiaceae and Philydraceae Order Amaryllidales; families Amaryllidaceae (unique alkaloids present), Alstroemeriaceae, Haemodoraceae, Hypoxidaceae, and Velloziaceae.

TRAUB (1970), a still valid classic of the Amaryllidaceae in the wider sense; J. HUTCHINSON, *The Families of Flowering Plants*, vol. *2, Monocotyledons*, 2nd ed. (1959), a definitive grouping of the Monocotyledons, including the Liliales, on the basis of gross morphology; A TAKHTAJAN, *Flowering Plunts: Origin and Dispersal* (1969; Eng. trans. from the 2nd Russian ed., 1961), an important modern book on the grouping of flowering plants, including Liliales, similar to that of Cronyuist (above), but developed independently; H.P. TRAUB, "The Tribes and Genera of the Agavaceae," *Pl. Life*, 9:134–137 (1953) and 28:137–138 (1972), the grouping of *Hosta* with the Agavaceae; *The Genera of Arnaryllidaceae* (1963), a late revision of the family Amaryllidaceae with information also on the Alliaceae; "The Subgenera, Sections and Subsections of *Allium* L.," *Pl. Life*, 24:147–163 (1968) and 28:132–137 (1972), grouping of the species of *Allium* into subgenera and sections; "The Order *Alliales*," *ibid.*, 28:129–132 (1972); and "Class Liliida, of Superclass Monocotyidra," *ibid.*, vol. 30 (1974), disposition of 20 families formerly grouped under order Liliales; T.W. WHITAKER, "Chromosome Constitution in Certain Monocotyledons," J. *Arnold Arbor.*, 15:135–143 (1934), an important paper on the chromosome complement of nine species of the Agavaceae and *Hosta*.

(H.P.Tr.)

Lima

Lima, the national capital of the Republic of Peru, is also the country's commercial and industrial centre. It is located on the south bank of the Rio Rimac, just inland from the Pacific Ocean port of Callao. Its name is a corruption of the Quechua Indian name Rimac, meaning Talker. A vast concentration of individual towns, greater Lima houses a population of more than 3,000,000 (1971). The city forms a modern oasis, surrounded by the Peruvian coastal desert and overshadowed by the neighbouring Andes mountains.

Lima, a focus for the wealth of contemporary Peru, is a centre of attraction for the country's rural population. Provided with a reserve of inexpensive labour, a nearby ocean port, and good transportation links to the interior, the city's industrial strength is assured. It is also, however, beset with the problems of overcrowding, air pollution, economic and social stratification, and inadequate public utilities. The gravest difficulty attends the provision of adequate food and water supplies for an ever growing population. Such supplies must be obtained from distant sources in the Andes and from the coastal valleys, and it may be difficult to meet future demands.

Spanish origins

History. Lima was founded in 1535 by the Spanish explorer Francisco Pizarro. It replaced Cuzco as the capital of the new Spanish kingdom of Peru because its coastal location facilitated communications with Spain. The city, walled in during the 1680s, was defended from incursions by pirates by the fortress-port of Callao.

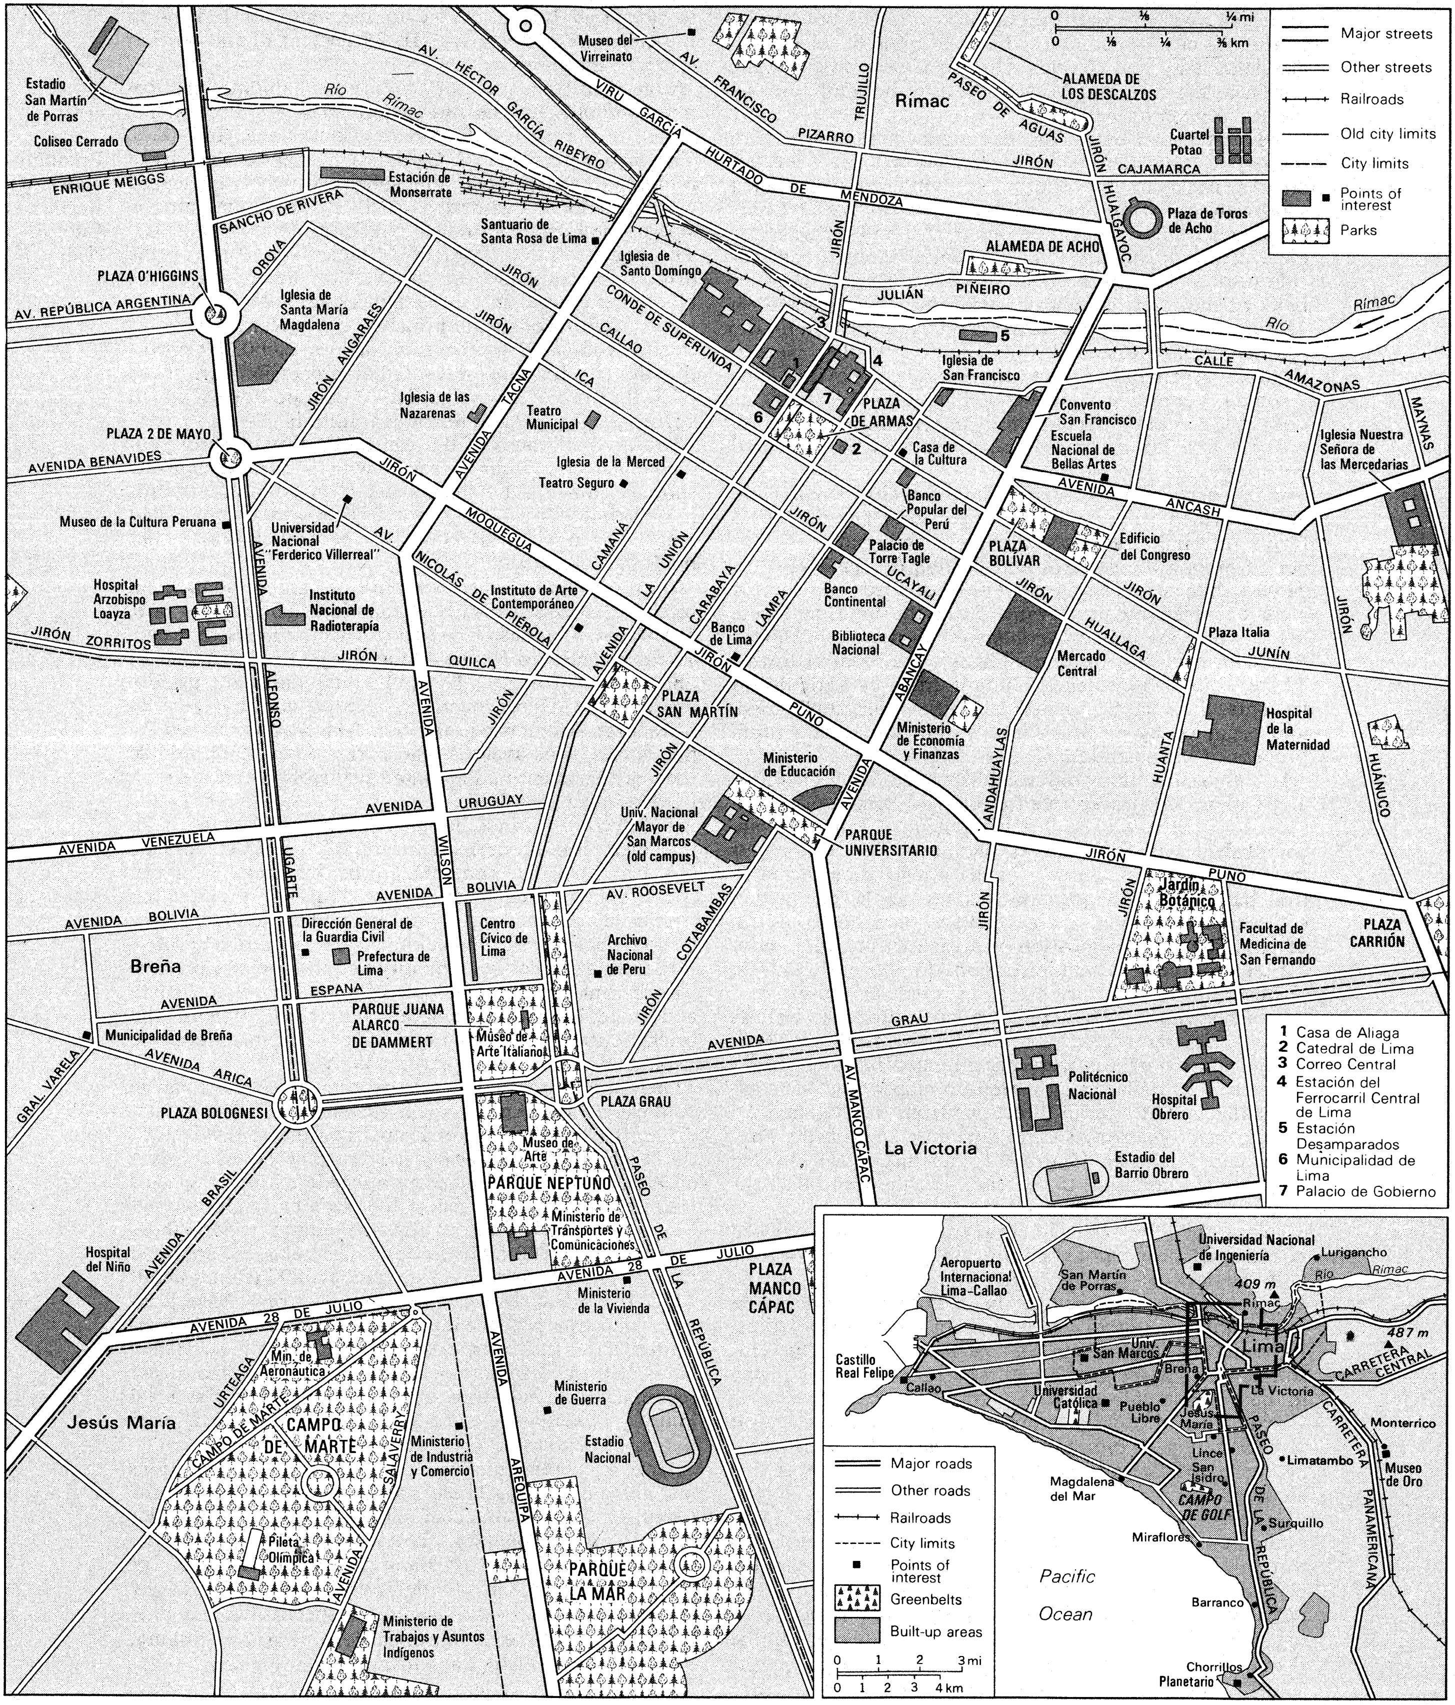
In planning the city, squares or blocks of 4,500 square yards were drawn, resulting in a checkerboard pattern. The founders set aside about 530 acres for the governor's house, for churches, and for the mansions of the colonists. In 1614 the city covered 776 acres and housed more than 25,000 inhabitants. The population grew steadily, reaching 54,000 in 1775; 64,000 in 1812; and 100,000 in 1876. By 1940 Lima had over 528,000 inhabitants and covered 5,560 acres.

During the 19th century, railways were built linking the city to Callao and to La Oroya in the Andes. The modern city then began to emerge as the major administrative, commercial, and industrial centre of Peru.

The contemporary city. Lima is located on the central Peruvian coast about eight miles inland from its Pacific port at Callao, at an elevation of 466 feet (154 metres) above sea level. Suburbs extend in all directions except to the east, where city growth is limited by the Andes. The city proper and the old suburbs cover an area of 27 square miles (70 sq km), while the province of Lima extends over 1,005 square miles (2,604 sq km).

The environment. Although Lima is in the tropical zone, the cooling effect of the offshore Peru (Humboldt) Current creates a temperate climate. The average temperature is between about 60" to 64" F (16" to 18° C) in the winter months from May to November and between about 70° to 80° F (21" to 27° C) in the summer months of December to April. Precipitation does not occur as rain but as a result of a condition known as Garúa, or vaporization of the atmosphere. The air is laden with constant mists that obliterate the sun during most of the winter. Annual precipitation averages between one and two inches. There are no strong winds, but light breezes blow from the sea during the day and from the Andes at night.

The cloud cover, the excessive humidity, the lack of winds, and the lack of direct sunlight combine to produce a high degree of air pollution. This condition is further complicated by exhaust fumes from vehicles.



Central Lima and (inset) its metropolitan area.

There is a paucity of plant and animal life in the vicinity. The plants are characteristic of deserts, while there is scanty vegetation on the river banks. There is, however, an extraordinary amount of animal and vegetable wealth found in the Pacific Ocean. The Peru Current has given the Peruvian sea quantities of plant and animal plankton that provide the ecological basis for plentiful marine life, which includes anchovies, flounder, shrimp, lobster, seals, and whales.

The city plan. The old city retains its original checkerboard pattern, and the streets have retained their original names; many have also acquired unofficial names relating to events that have occurred along them. The boundaries of the old city—once marked by the ruins of its walls—are defined by the avenues Alfonso Ugarte to the west, Unión to the east, and Miguel Grau to the south, and by the Rio Rimac to the north.

The first urban extension was made in the early 19th century to Magdalena Vieja (now Pueblo Libre), located on the coast to the southwest. Settlement continued southward to Miraflores and Barranco, ending at Chorrillos, where the river valley, the desert, and the seashore meet. These towns are both residential suburbs and seaside resorts. The northern suburb of Rimac, on the right bank of the river, is opposite old Lima. During the 20th century, the city expanded greatly to the west along the old seven-mile horse and wagon route to Callao. Named Colonial Avenue, it is now the Avenida Benavides. The Avenida Venezuela runs parallel to it to the south, as does the Avenida Argentina to the north. The first industrial and large commercial operations were located between Lima and Callao.

In the open country surrounding the city, small rural towns formed around chapels or parishes. The numerous farms or small tracts of cultivated land that were dispersed among the suburbs and barren, dry land also became urbanized. They were either divided into lots or were occupied by immigrants from the interior. These areas, which are called *barriadas* (slum neighbourhoods) or *pueblos jóvenes* (young villages), are squatter towns. There were also clusters of huts lived in by agricultural workers. Sixty large ranches were, however, subdivided, and occupied by *pueblos jóvenes*, thus initiating a rapid process of urbanization.

Although the industrial establishments between Lima and Callao are concentrated along Argentina and Benavides avenues, the overall development of Lima was accomplished without integral planning. The pattern of land use has given rise to a haphazard location of industrial buildings in inappropriate zones, to the occupation of green and productive areas without plan, and to a lack of planning in the allocation of areas for recreation, education, and central administration. In the early 1970s, however, the city was being zoned for industrial use.

Transportation. The Lima–Callao railroad as well as the electric tramway connecting Lima, Miraflores, Barranco, and Chorrillos were discontinued in 1963. These systems were replaced by a well-developed highway network that radiates in all directions from the old city. To the north the highway system is connected with the Pan-American Highway (Carretera Panamericana), to the south with Chorrillos, to the east with the Central Highway, and to the west with Callao.

During the 1960s, the internal traffic of Lima reached unexpected proportions, complicated by narrow streets and the lack of parking space. The congestion in the city's streets was relieved by the opening of the Paseo de la República (Republic Drive) from Lima to Chorrillos.

The international airport is located at Callao. The Central Railway of Peru, the highest standard-gauge railway in the world, climbs the Andes from Lima northeast to La Oroya. The railway line from the city to Callao was built in 1850 and is the oldest in South America. There is also a northern coastal railway to Paramonga and a short line south to Lurín.

The people. In 1971 the population of greater Lima numbered 3,130,000. The inhabitants were distributed throughout 32 contiguous districts, as well as in satellite towns separated from the principal urban nucleus. The population density varies from district to district. It is high along the main roads in such areas as Comas in the northwest, Agustino in the east, and Atocongo in the south. When migrants first arrive in Lima, however, they move to the centre of the city and accumulate in the districts of Surquillo, La Victoria, and Rimac, which now have up to 129,500 inhabitants per square mile. The average density in the city as a whole is 31,000 inhabitants per square mile.

Almost 75 percent of the population is classified as either white or mestizo. (In Peru the term mestizo applies to those of mixed white and Indian parentage as well as to urbanized Indians.) Due to the influx of Indians to the cities since World War II, 25 percent of the population is of Incan origin.

Predominance of Roman Catholicism

More than 97 percent of the city's inhabitants are Roman Catholic. Of the remainder, most are Protestants; there are a very few Buddhists, Confucians, and Jews. The high percentage of Catholics has given the city a traditional, conservative atmosphere, which is evidenced by large religious gatherings such as the annual procession of the Lord of Miracles (El Señor de los Milagros). The image of the "Lord of Miracles"—a copy of the original fresco painted on the wall of the church of the Nazarenes more than three centuries ago by a black slave—is carried through the principal city streets. The enormous accompanying procession of over 2,000,000 people fills the city for three days. Other processions are those of Santa Rosa of Lima and San Martin de Porras, which perpetuate the colonial religious tradition.

Housing. Because of the constant influx of rural people to the city, Lima is faced with a chronic housing shortage. Since 1960 there have been attempts to promote building in, and to supply services to, overcrowded areas. The unplanned nature of the city, however, has made the task difficult.

In the *barriadas,* houses are built of bamboo mats, mud brick, or collapsed oil tins. Sanitation facilities are rare, and water often has to be brought to the areas by truck. There are also *callejones*—long alleys lined with small one-story apartments. The individual units are usually overcrowded. Upper income residential suburbs—such as Miraflores, Monterrico, and San Isidro—are marked by fine homes, wide avenues, and parks. Since 1965, middle income apartment buildings and two-story dwellings with gardens have been built.

Architecture. Lima has blended colonial styles with the advances of modern architecture. The rainless climate has permitted the construction of buildings with flat roofs, while the frequency of earthquakes in the area has precluded the building of multistoried structures. Large enclosed balconies in the colonial style often offer protection from the excessive humidity and the cool sea breezes. The ancient building materials of adobe, bamboo thatch, and wood have been replaced with steel, cement, and bricks; structural innovations have been introduced to avoid disasters caused by earthquakes.

There are many buildings remaining from the Spanish colonial period. Among them are the Cathedral (Catedral), the temples of San Francisco, and the Palace of the Tagle Tower (Palacio de Torre Tagle). The Paseo de Aguas and the tree-lined promenade of the Descalzos (barefoot priests) also reflect the city's early elegance.

Commerce and industry. At the end of 1965 there were almost 2,800 industrial establishments in Lima and Callao. The labour force of about 500,000 includes about 125,000 workers engaged in manufacturing. The principal industries produce textiles, plastics, timber, pharmaceutical products, chemicals, and synthetic fibres. Heavy industry is also important. Food processing and drink manufacturing industries are numerous. The fish-meal industry in Callao is of considerable national and international importance.

Banks are represented by both state credit institutions and private capital. There are 22 banks, including the Continental Bank (Banco Continental) and the Popular Bank (Banco Popular). The Lima Bank (Banco de Lima), the National City Bank, and the Credit Bank of Peru (Banco de Crédito del Perú) are supported by French, U.S., and Italian capital, respectively. The state banks encourage agriculture, cattle raising, and mining. There are many finance and insurance companies.

The cooperative system is well developed in Lima, having 12 corporations engaged in construction; there are also numerous mutual benefit and savings associations.

The main commercial districts are Limatambo, Miraflores, and San Isidro. There are over three dozen food markets and a wholesale produce market. The itinerant food markets, or *paraditas,* which sell at retail prices, are characteristic of Lima. Meat and milk are often of short supply and must be rationed.

Water supply

Public utilities. Lima consumes 850,000 quarts of water daily. Local supplies are, however, inadequate because the Rio Rimac is low nine months of the year. To augment the water supply a six-mile tunnel was built under the cordillera of the Andes to obtain water from the lakes located in the high sierra east of Lima. It is estimated that, by 1980, Lima will lack water if other sources, such as the Rio Montaro to the east, are not utilized.

Water is also needed for the generation of electricity. In 1966 the installed capacity for the city was about 200,000 kilowatts. By 1971 the capacity installed for public service had a potential of 605,000 kilowatts.

Health, safety, and education. In 1969, health facilities included 22 hospital centres, 18 state and social security hospitals (caring for those covered by social security), and 22 private clinics.

Service in the fire brigades that man the city's 14 fire stations is honorary and voluntary. The state subsidizes the acquisition of fire-fighting equipment.

Public order is maintained by the police or civil guard and to a smaller degree by the municipal police. Schools, which include some religious establishments, include about 2,800 primary schools, a number of state technical schools, and more than 700 private schools. There are about 1,240,000 children of school age.

University City

There are five national and seven private universities attended by 120,000 students. The most important is the National University of San Marcos (Universidad Nacional Mayor de San Marcos de Lima); founded in 1551, it has a new campus outside Lima in the University City. The agrarian and engineering universities also have extensive campuses awaiting development.

Cultural life. The Academies of Language and of History are the principal cultural centres. The government's House of Culture (Casa de la Cultura del Perú) encourages the intellectual, literary, and artistic elements in national life. Other institutions are the National School of Fine Arts (Escuela Nacional Superior de Bellas Artes), the National Symphonic Orchestra (Orquesta Sinfónica Nacional), the National Conservatory of Music (Conservatorio Nacional de Música), and the National Theatre.

There are about 40 museums in the Lima metropolitan area. These include the Museum of Gold (Museo de Oro); the Museum of Art; the Museum of Italian Art; the Archaeological Museum (Museo Arqueologico "Rafael Larco Herrera"); the National Historical Museum; and the Museum of the Viceroys. The restored castle of Real Felipe in Callao is also a museum. There is also an astronomical observatory and planetarium, a botanical garden, and the "Park of Legends," which contains examples of Peru's varied animal and plant life. The Convent of San Francisco, with its catacombs and its gardens with tiled patios and fountains, is now open to the public after four centuries. It has a valuable library of incunabula, as well as works of religious art dating from the time of the viceroys. Numerous restored houses containing valuable furnishings and artwork are open to the public. The House of Aliaga contains the sword of the conquistador Francisco Pizarro and historical objects dating back to the time of the city's founding.

The National Library, founded by José de San Martin, the liberator of Peru, contains copies of the first printed works in Peru. The National Archives of Peru (Archivo Nacional de Perú) include judicial and historical collections. There are libraries attached to the universities, government ministries, and private associations, as well as 40 public libraries.

There are a dozen daily newspapers. *El Comercio,* founded in 1839, is Peru's oldest paper. *Ojo,* a morning paper, has the largest circulation. *El Peruano* is the official state gazette, while *Expreso* is the leading opposition daily. The headquarters of the foreign press agencies in Peru are located in Lima. There are also numerous periodicals and reviews covering cultural affairs, economics, and current events.

Lima is served by more than 30 radio stations. Most of them are commercial stations, two are government stations, and eight are cultural. Television programs are broadcast by five commercial stations.

Recreation. Recreational facilities include the racetrack, the bullfight plaza, cockpits, and the football (soccer) stadiums. There are three principal theatres, as well as numerous experimental university theatres, drama centres, and dramatic schools. Among these, the Theater of the University of San Marcos (Teatro Universitario de San Marcos) has a high reputation.

Favourite sports include football, golf, tennis, polo, swimming, and surfing. The popular spectator sports are bullfighting, cockfighting, and horse racing. There are more than 100 cinemas.

In addition to some of the most luxurious dining rooms in Latin America, there are also many popular Oriental restaurants, as well as those that serve typically Peruvian meals to the accompaniment of music and folk dances. The taste for folk music is evidenced by the existence of large coliseums in which national music and dance programs are attended by huge numbers of spectators.

BIBLIOGRAPHY. JUAN BROMLEY, *La fundación de la ciudad de los reyes* (1935); and with JOSE BARBAGELATA, *Evolución urbana de Lima* (1945), are the most important works on the foundation and growth of the city of Lima—they summarize Spanish-language historical works of the mid-20th century. Other features of the city are discussed in RAUL PORRAS BARRENECHEA (comp.), *Pequeña antologia de Lima (1535–1935)...* (1935); JOSE GALVEZ, *Calles de Lima y meses del año* (1943); JOSE MATOS MAR, *Estudio de las barriadas limeñas* (1955); and ALLAN G. AUSTIN and SHERMAN LEWIS, *Urban Government for Metropolitan Lima* (1970). JOSE CARLOS MARIATEGUI, *7 ensayos de interpretación de la realidad peruana* (1928), contains a chapter on the "centralism" of Lima that argues that the centralization of Peruvian politics benefits the city to the detriment of the rest of the nation; EMILIO ROMERO, *Geografía económica del Perú,* new ed. (1939), argues that the prosperity of Lima is founded in its geographic and economic background rather than in its privileged political situation.

(Em.R.)

Limestones and Dolomites

Limestones and dolomites are sedimentary rocks (those formed by the accumulation of sediment in air or water) that consist of more than 50 percent carbonate minerals, mainly calcite (calcium carbonate, $CaCO_3$) and dolomite (calcium magnesium carbonate, $CaMg(CO_3)_2$). For this reason, they are commonly referred to as carbonate rocks.

Although their distinction is based on their rather uniform mineralogical composition, limestones and dolomites are formed by a wide variety of processes. A limestone may be produced by the cementation of carbonate sand grains derived by erosion of a former carbonate landform (*e.g.*, island, hill, plateau); in this case it is a clastic rock, a sandstone, whose grains have been transported and deposited in accord with the laws of hydraulics. On the other hand, a limestone might result from direct precipitation in seawater, in which case it is a chemical rock, like salt, whose formation has been governed by such factors as water temperature and pressure, and the concentration of the solution. In still another category are carbonate bodies, such as reefs, that have been constructed principally by sedentary organisms; in this case the rock-forming process is skeletal secretion by physiological means. Since the three types of carbonate sediments may be mixed while they are still in the depositional environment or may be modified by various postdepositional changes, the final product may be a rock with a very complicated history.

Significance and use of carbonate rocks

Limestones and dolomites have long fascinated geologists and paleontologists because of their rich fossil content. Much existing knowledge of the Earth's chronology and evolution has been derived from study of fossils included in carbonate rocks. They represent about 20% of all sedimentary rocks and occur in all continents, in strata of every age—from Precambrian to Quaternary.

In the last few decades enormous petroleum reservoirs have been discovered in carbonate rocks in the Middle East, the Canadian Rockies, west Texas, and many other parts of the world. Some of these oil fields are localized in fossil reefs, such as Norman Wells (northern Canada), Leduc (Alberta), the Permian Basin of Texas, New Mexico, and the Tampico area (Mexico).

Carbonates have a large variety of economic uses. As building stone, limestones and dolomites are used for monuments, exterior and interior facings, and flooring of several kinds. Crushed rock is used for railroad ballast, riprap fill (broken rock used to protect structures from natural processes of erosion) around the bases of dams and piers, filter beds in sewage treatment, and surfacing for airports. The heating of limestones and magnesian limestones to temperatures of 900°–1,000° C (1,650"–1,800" F) will dissociate calcium carbonate and yield carbon dioxide and lime for commercial use. Lime has major applications in the construction industries, for the manufacture of glass, and for agricultural purposes. Carbonate rocks are also common host rocks for many ore deposits, because they are easily attacked by high-temperature solutions that precipitate ore minerals.

Treated in this article are the composition of limestones and dolomites and their textures, structures, origin, and geological significance. For further information on the mineral constituents see CARBONATE MINERALS; and for a discussion of the relation of limestones and dolomites to sedimentary rocks in general see SEDIMENTARY ROCKS. See also CAVES AND CAVE SYSTEMS; CORAL ISLANDS, CORAL REEFS, AND ATOLLS; DURICRUSTS; and EVAPORITES for the occurrence of carbonate rocks in natural environments, and OCEANS AND SEAS and ELEMENTS, GEOCHEMICAL DISTRIBUTION OF for treatment of carbonate geochemistry.

PHYSICAL AND CHEMICAL CHARACTERISTICS

Mineral and chemical composition. The most important rock-forming carbonate minerals are calcite, aragonite, and dolomite. Other carbonate minerals of the calcite family are magnesite ($MgCO_3$), rhodochrosite ($MnCO_3$), and siderite ($FeCO_3$); these occur in restricted environments and are quantitatively of limited importance.

Calcareous sediments forming today in tropical and subtropical shallow seas consist predominantly of aragonite and magnesium-rich calcite. Both minerals are metastable, however, and change quickly with geological time. All limestones of Precambrian to Tertiary age (*i.e.*, older than 2,500,000 years) consist of normal calcite; that is, calcite with a low magnesium content. This is because the rocks have undergone diagenetic (postdepositional) processes that changed their original mineralogical character. Only limestones formed in deep or cold marine environments have undergone no transformation; they were made of normal, low-magnesium calcite from the outset.

Minor constituents

Minor constituents also are commonly present in limestones and dolomites. These may be finely disseminated throughout the rock (*e.g.*, clay minerals, iron oxides, bituminous matter), present as individual grains (*e.g.*, glauconite, pyrite, quartz, and feldspar), or segregated into large nodules (*e.g.*, chert or flint). Compositional gradations are common, and many classification schemes have been used. In the chemical sense, however, carbonate rocks are rather simple because they reflect their mineralogical composition. Calcium and magnesium oxides and carbon dioxide are the most important constituents, forming more than 95 percent of the rock in many cases. When impure carbonates are involved, other constituents, such as silica, alumina, iron oxides, phosphorus, and sulfides, may contribute notably to the bulk composition.

Depositional textures. The two main classes of carbonate rocks are mechanically deposited carbonates, those with particulate texture, and carbonates grown in place, either by biological activity (reefs) or chemically accreted (tufa, travertine, caliche, and speleothems, or cave deposits). The mechanically deposited carbonates constitute the most important group; the other types are of more limited extent.

The particulate material consists of a mixture of various particles (grains) immersed in a finer matrix (lime mud). The rigid grain framework creates a pore system that permits the transmission and storage of fluids. Subsequently, this pore system may become partially or completely filled by a chemical precipitate (cement). The particles and their matrix produce varying rock textures, depending upon their arrangement, and the textures of limestones and dolomites exert a controlling influence on porosity and permeability and, in turn, on rock suitability as a reservoir for oil or water (see further PETROLEUM; GROUNDWATER). Five major types of grains are recognized in carbonates; namely, skeletal, detrital, pellets, lumps, and coated grains.

Skeletal *grains.* Grains consisting of whole and fragmented skeletons of marine plants and animals are called skeletal grains. Unlike other kinds of grains, they usually have a precise internal structure resulting from a regular crystal arrangement. A wide variety of marine organisms (mollusks, algae, corals, echinoderms, sponges, and foraminifera) of quite different character contribute their skeletal remains. Accordingly, different kinds of skeletal sediments may form. The skeletal grains can be studied and classified according to their environmental occurrence or to their mineralogy, biology, or sedimentological character. In this last case they are treated as grains and not as organisms or fossils; their shape, hydraulic behaviour, and relative resistance to breakdown of the whole skeleton are important factors. Six varieties of skeletal grains can be distinguished: (1) sheets and spicules, formed by disintegration of green algae (*Penicillus* species), sponges, and alcyonarians; (2) segments, formed by disintegration of segmented organisms such as green and red algae (*Halimeda* species), crinoids, and asteroids after their death; (3) branches, formed by mechanical or biogenic breakage of branched animals and plants, such as some species of red algae, corals, and bryozoans; (4) chambers, formed from hollow or partly hollow skeletons of gastropods, brachiopods, pelecypods, and foraminifera; (5) crusts formed on surfaces by such plants and animals as red algae, bryozoans, foraminifera, and annelid worms; and *(6)* massive grains—that is, those formed by colonial corals and coralline algae.

Varieties of skeletal grains

Detrital grains. Grains made of debris derived from pre-existing rocks are called detrital grains. They may originate during deposition as pieces broken from poorly consolidated sediments (intraclasts) or as pieces broken from rigid rocks (lithoclasts). Detrital grains usually have sharp angular corners, may show an internal texture derived from the source rock, and a single specimen may be essentially of one or of varied rock types.

Intraclasts form after the sediment becomes sufficiently coherent if there is an agent able to break it; they are abundant where erosion, dynamic energy—generally in the form of waves and currents—and burrowers occur. Intraclasts can be formed from carbonate mud when it is compacted or when it dries out, but in carbonate sands, rapid cementation (filling of the pores by a chemical precipitate) must occur. It is easier for sediments to become compacted or desiccated than cemented; thus, intraclasts usually have a fine-grained (mud) texture.

Lithoclasts form when carbonate rocks are exposed and eroded. They usually are related to land areas, such as a carbonate tropical island. They may represent minor unconformities, or interruptions in the depositional sequence.

Pellets. Grains of mud lacking significant internal structure are called pellets; they usually have an ovoidal or subspherical shape. They are a polygenetic group of grains, because some of them are of fecal origin (fecal pellets); whereas others (grains of matrix) may represent processes of physical accretion, diagenetic (postdepositional) alterations of skeletal grains, and recrystallization; and still others may represent bits of lime mud torn from the sea floor and rolled around before coming to rest. Genetically, the latter should belong to the intraclast category, but because of their small size it is impossible to recognize their detrital origin.

Fecal pellets, which are the most important type, range in size from tens of microns (one micron equals 0.001 millimetre) to a few millimetres. Their shape may be ovoidal, spherical, cylindrical, or discoidal, and some exhibit external sculpture. The smallest are spherical and the largest rodlike. Fecal pellets are produced by animals that eat bottom sediments (worms, holothurians, sea stars) and by filter feeders (oysters, tunicates, sponges,

some gastropods, and some worms). Their consistency covers a wide spectrum, from gelatinous to compact to very hard, almost lithified.

Significance of pellets

These grains are of considerable geologic importance, because they are very abundant in sequences of carbonate strata. In making them, the animals change the size of the original sediment: sand is produced from mud through biological elaboration.

Lumps. These are composite grains (*i.e.*, aggregates of particles, generally pellets), in which the single element protrudes from the principal body and gives it a characteristic lobate outline. In Recent sediments (those formed during the last 10,000 years) various forms can be distinguished (grapestones — forms resembling bunches of grapes — botryoidal lumps, friable aggregates); in ancient carbonates they are regarded as a single group. Lumps form in environments in which grains lying on the sea bottom tend to cement together; they occur in carbonate sand tongues controlled by tidal currents that flow through inter-key channels and are frequently associated with oolitic sands described below.

Coated ***grains.*** Grains having concentric or enclosing layers of calcium carbonate around a central nucleus are called coated; the most common types are oolites, pisolites, and algae-encrusted grains. Oolites (from the Greek *don,* "egg," and *lithos,* "stone") are subspherical grains less than two millimetres in size; if bigger, they are called pisolites. The nucleus is generally a skeletal grain, a pellet, or, more rarely, a quartz grain; some oolites may display a radial structure.

Origin of oolites

There are various theories of the origin of oolites. The first, introduced a century ago, is called the "snowball" theory. According to this theory, seawater is presumed to be crowded with suspended aiagonite crystallites in a particular place; as they roll on the bottom or float in the water, particles of whatever origin, possibly coated with adhesive mucilaginous organic material, capture the crystallites, which adhere to their surfaces. As a result of the continuous movement caused by waves and tidal currents, the small grains grow just like a snowball rolling downhill. **A** second theory explains oolite growth by chemical precipitation producing crystals perpendicular to the grain surface; as the grain rolls, these crystals break and lie on the surface, trapped by the organic mucilage. A third theory attributes oolite origin to the presence of proteinic matter that supposedly controls precipitation and orientation of crystals.

Matrix material. This is generally a very fine lime mud, now almost universally called micrite (originally from the contraction of the words microcrystalline calcite). Micrite, which applies to both consolidated and unconsolidated carbonate mud, is the carbonate analogue to the mud that occurs between the framework grains of many land-derived sands. There is considerable controversy over the size limit that is to distinguish matrix (micrite) from grains; four, 20, 30, 60, and 125 microns (one micron equals 0.001 millimetre) have been proposed. The origin of micrite also is controversial; two different interpretations exist. According to the first, lime mud is derived from the production of aragonite needles by precipitation from waters of abnormally high salinity and carbonate saturation. According to the second, micrite is essentially derived from the skeletal parts of marine organisms (corals, mollusks, calcareous algae, foraminifera, nannoplankton), mainly as a result of: (1) production of aragonite needles by postmortem disintegration of calcified green algae (*Penicillus* species); (2) production of mud-sized skeletal debris by predominantly physical processes of particle-size reduction in agitated environments; (3) production of mud-sized skeletal debris other than aragonite needles by predominantly biological processes of particle-size reduction in quiet-water environments (activity of boring micro-organisms, mastication and ingestion by the vagrant benthos); (4) production of lime ooze by accumulation of microscopic organisms.

Although direct chemical precipitation from saturated waters cannot be excluded, much research indicates that lime mud is largely of skeletal origin.

Stromatolites, bioherms, and reefs

Structures in carbonate rocks. Mechanically deposited carbonate rocks show the same structures that are present in terrigenous (land-derived) rocks: cross-bedding (inclined and intersecting layers), graded bedding (the grain size changes from coarse to fine, vertically), ripple marks, mud cracks, laminations (very thin sedimentary layers), and cut-and-fill structures (pockets formed by erosion and subsequently filled with sediment) may be well displayed in many limestones. There are some structures that are peculiar to carbonate rocks, however; stromatolites (fossil algae), stylolites (columns or veins that are inclined to the beds), nodular bedding, and various solution features are a few examples. Stromatolites are organic-sedimentary structures composed of flat, undulated, or cabbage-like laminations; these are built by dense mats consisting primarily of blue-green algae, which selectively trap and bind sediment particles among their mucilaginous filaments. Stromatolites range in age from the early Precambrian (perhaps 2,500,000,000 years old) to the Recent, although they are most abundant in the Precambrian and Lower Paleozoic (about 400,000,000 to 570,000,000 years ago). Recent stromatolites are forming in littoral (near shore) environments in south Florida and in the Bahamas; spectacular examples are those of Shark Bay (Western Australia), where stromatolitic columns more than one metre tall occur. These have an elliptical cross section, the long axis being oriented with the prevailing current. Similar current-oriented stromatolites have been discovered in the Precambrian of the Northwest Territories, in Canada.

Biohermal and reef structures are other typical structures of carbonate rocks. Bioherms are domelike, moundlike, or otherwise circumscribed masses built exclusively or mainly by sedentary organisms and enclosed in a normal rock of a different lithologic character. They vary in size and shape and may be as small as a few centimetres or impressive structures several kilometres across and hundreds of metres thick. Algae, stromatoporoids, coral, crinoids, and mollusks are among the most common constituents.

ORIGIN OF LIMESTONES AND DOLOMITES

Source material and its transportation. Limestones originate mainly through lithification (transformation to rock) of loose carbonate sediments. Exceptions are deposits like travertine or reefs, which are lithified in their original state. The primary origin of most limestones is attributable to biochemical or physicochemical processes.

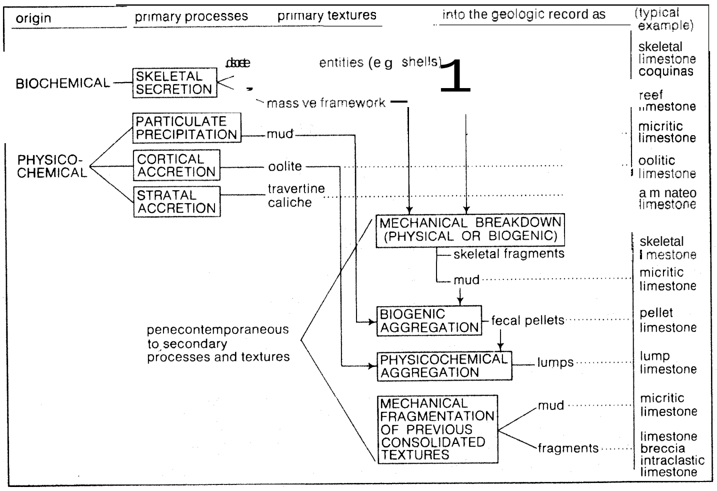

Figure 2: The origins of limestones.

Skeletons of marine plants and animals are produced biochemically, through skeletal secretions. If cemented, these skeletal sediments may be transferred directly into the geologic record as skeletal limestones, reefs, or bioherms. Otherwise, they may undergo early diagenetic processes like biogenic breakdown or biogenic and physicochemical aggregation. In this way, muds, fecal pellets, and lumps can be produced from carbonate matter of biochemical origin, and such rocks as micritic limestones, pellet limestones, and lump limestones will be formed.

Lime muds, oolites, and travertine are produced physicochemically, through particulate precipitation and layered accretion, although travertine may also be controlled by algal activity. These carbonate deposits may become micritic limestones, oolitic limestones, and laminated limestones, respectively.

Both biochemically derived and physicochemically derived carbonate sediments may be mechanically fragmented after early consolidation, and clastic sediments and rocks such as limestone breccias, intraclastic limestones, and carbonate mudstones may be produced.

The dolomite problem

Poor knowledge of the origin of ancient dolomites, which are widespread, together with the apparent lack of dolomite in Recent sediments, created the "dolomite problem," which has been debated for many years. The greater frequency of occurrence of dolomites in Lower Paleozoic and Precambrian strata had led at one time to the hypothesis of ancient "dolomitic seas" that were presumably quite different from modern ones. All of this was abruptly changed by the development of X-ray diffraction techniques. In the last few years dolomite has been discovered in Recent sediments, and an understanding of its origin and occurrence in the geologic record has been gained.

All the Recent dolomite occurs in a particular environment; namely, hypersaline lakes or lagoons, and supratidal areas (Persian Gulf, Bahamas, Florida, The Netherlands Antilles). Hypersalinity is the hallmark.

Hypersalinity in marginal marine environments and in intermontane basins may result because of excess of evaporation over rainfall; interstitial waters in the sediments transpire upward and evaporate at the sediment–air interface. This process is common in intertidal and supratidal flats in the tropics. Hypersalinity may also result when evaporation exceeds precipitation plus runoff, thus increasing the concentration and density of the waters in lagoons and shallow coastal seas. The heavy brine that is formed sinks and flows seaward down the sloping shelf. If, however, this reflux to the sea is prevented by natural barriers such as reefs or sills, the brine migrates to the lowest possible topographic depressions and seeps slowly through the underlying sediments, which are progressively dolomitized.

Hypersaline brines are also responsible for a subsurface process by which older calcareous rocks can be transformed into dolomites. Volcanic activity, faults, and special subsurface traps or other conditions control the migration of the brines and the dolomitization process.

Two major categories of dolomites, recognizable by their petrographic characters, are present in the geological record. Primary (syngenetic) dolomites are formed by chemical precipitation or substitution of originally calcareous sediments at the time of deposition. They retain their original texture (micrite, pellets, skeletal grains, and intraclasts) and structures (laminations, desiccation features), are poorly fossiliferous (ostracods, foraminifera, algae) and usually fine grained. Secondary (diagenetic) dolomites have a crystalline texture and are caused by replacement of former calcareous rocks or by recrystallization of primary dolomites. They are generally coarsely crystalline, porous, structureless, and massive and are often related to faults and volcanic activity. Relict textures (those originally present in the rocks) are frequently recognizable.

A third kind of dolomite that is petrographically recognizable is a chemical precipitate that partially or totally fills cavities in primary dolomites. It has crystalline texture and forms quite early in the genetic history of the rock. Cavities in primary dolomites may be lined by rounded masses of dolomite (colloform texture).

Carbonate sediments, unlike terrigenous sediments (*i.e.*, silicate muds, silts, and sands), usually form entirely within a local sedimentary basin—they are deposited and accumulated in the same area in which they are produced. In contrast with the terrigenous sediments, there is relatively little net lateral transportation, because of irregular physiography (shoals, islands, reefs) and, especially, the low gradient of the shallow-water carbonate platforms. Sometimes in the presence of steep submarine slopes or scarps, which occur along Recent and ancient carbonate platforms, shallow-water carbonate sands may be carried into other environmental regimes (oceanic bottoms) by turbidity currents (density currents that flow along the bottom by reason of their high sediment concentration). These displaced deposits are known from Recent deposits (Tongue of the Ocean, Bahamas) and from the Jurassic (136,000,000 to 190,000,000 years ago) troughs of the Mediterranean area.

High-energy and low-energy environments

Depositional environments. The hydrodynamic significance of the texture of carbonate sediments is that lime mud accumulation depends upon local conditions of water agitation. In a particular rock, the relative proportion of mud matrix to cement is an index of water agitation or mechanical energy. Depositional areas of "high energy" are inferred to produce clean, well-sorted, coarse-grained carbonate sediments, whereas areas of "low energy" are held to be responsible for muddy deposits. High-energy sites are beaches, surf zones, dunes, and tidal channels. Carbonate muds generally accumulate in protected areas such as lakes, lagoons, deep-sea basins, and areas on the lee side of major islands situated on oceanic banks.

Textural studies of Recent carbonate sediments indicate that the size, shape, and sorting of skeletal sands are greatly influenced by the nature of the skeletons. Even in quiet-water environments such as the lagoons of many Pacific atolls, for example, the green calcareous alga *Halimeda* can produce very coarse sand because it is segmented; when the alga dies the various segments are released. If the same coarse skeletal sand were made of mollusk fragments, however, it would be considered to represent a high-energy deposit—a beach, for example.

Carbonate rocks form in various environments; namely, continental, marine, or transitional. Most of them are formed in shallow marine and transitional zones of the tropical seas. Criteria that help to distinguish different environments of deposition may be found in grain types, sedimentary structures, geometry of sedimentary bodies, fossil content, and stratigraphic relationships with the rocks that are adjacent, both laterally and vertically. Diagnosis usually is achieved by the association of various distinctive elements.

Continental environments. Carbonate rocks such as crusts or soils may form in a semi-arid climate in which the predominant direction of movement of soil moisture is upward, because of the excess of evaporation over rainfall. Caliche, well known in the southwestern United States, is a limestone that precipitated from evaporating soil moisture; similar deposits are known in the Mediterranean region, where they are called nari and calcrete. Caliche-like deposits, containing pisolites and concretions formerly thought to be algal in origin, have been recognized in Mesozoic and Paleozoic carbonate sequences.

Spring, cave, and dune sand deposits

Another carbonate rock of continental origin is travertine, the genetic term for all organic or inorganic, nonmarine limestone accumulations that formed in lakes, rivers, springs, and caves; it is colloform (in rounded masses) or accretionary in individual layers, and highly porous.

Dunes composed of carbonate sands are abundant along the tropical coasts, where beaches may consist of skeletal fragments, oolites, and other carbonate grains. If cemented, these eolian deposits form eolianites, which display spectacular cross-bedding. Many famous islands, such as Bermuda and the greater part of the Bahamas, consist entirely of calcareous dune deposits.

Transitional and shallow marine environments. Knowledge of these particular and very important environments has been gained from studies made in tropical regions such as the Indo-Pacific islands, the Australian coasts, the Persian Gulf, the Bahama Banks, southern Florida, and other areas of the Caribbean and Gulf of Mexico. There is a vast range of subenvironments that all fit into the general pattern of an open sea with relatively deep water on one side; a marginal zone of high energy with turbulent and shallow water, where waves break on a reef, barrier beach, or sandy shoals; and a sheltered lagoon of variable width and depth that passes to the mainland through tidal marshes, mangrove swamps, or rocky shores. Sometimes there is no mainland but only a wide shallow bank or lagoon that grades into a turbulent marginal zone and beyond that into deep water on all sides.

In the high-energy marginal belt, oolitic and skeletal sands are the typical sediments, the latter being frequently associated with barrier reefs. The sands, kept continuously in motion by waves and tidal currents, accumulate in bars and submerged dunes that form elongated shoals. These are cut perpendicularly to the bank edge by tidal channels, and the bars and dunes surface in places during low tide. The sands are very clean, with no micritic matrix; abundant current structures such as ripple marks and cross-bedding occur. The infauna—animals living in the bottom sediments—is very scarce or absent because the sand is continuously in motion and migrating.

Oolites form on the edge of the platform where the open ocean water is slightly warmed as it flows up on the shallow banks; the increase in temperature produces the supersaturation of carbonate necessary for precipitation, and the movement of the bottom sediments produces the specific oolitic form. All Recent oolitic sediments are found in shallow water, less than 15 metres (50 feet) deep, and within range of exchange with deeper water areas nearby. Elevated salinity, however, is not required for the formation of oolites.

Deposition in the lagoon environment

Toward the internal lagoon the dynamic energy decreases considerably, and the lime mud, whatever its origin, collects in the most sheltered places. Bottom sediments are quiet and are stabilized by organic films, algae, or grass; organic activity is therefore abundant, and animals burrowing and feeding on the bottom continuously rework the sediments. In these environments micritic, pellet–micritic, and micritic–skeletal deposits will form; current structures will be absent, and traces of burrowing activity are quite common. In areas that are intermediate between oolitic shoals and lagoons, physicochemical conditions (supersaturation and quietness) may favour the development of lump sediments.

Farther toward land the lagoon grades into the littoral belt. When the shore is rocky, skeletal and intraclastic sands occur on the surf zone and on the beach. These sediments are beautifully laminated and may present very low-angle cross-bedding. On the shore, cross-bedded calcareous dunes may develop. When the shore is flat, tidal flats, tidal marsh, and mangrove swamps may occur. Tidal flats reveal a great variety of textures and structures because of the peculiar situation of intermittent exposure and submergence. They receive sediments mainly during storms, and these sediments are largely pelletiferous and muddy, though coarse skeletal sediments occur in the main channels as lag deposits or bars; stromatolitic laminations, mud cracks, and intraclastic sands and breccias (rocks consisting of coarse angular fragments) are quite common.

Open-sea environments. Open-sea environments are also the sites of distinctive associations of carbonate sediments. Depth and distance from land are the main controlling factors; life is precluded for many organisms, and the physical effects of current and waves are extremely limited.

Open-sea carbonate deposits may result from the exclusive vertical sedimentation of planktonic organisms or from the combined operation of such vertical sedimentation with the lateral effects of gravity displacement.

Pelagic carbonate deposits consist of the tests (hard coverings or internal supporting structures) of planktonic invertebrates or plants and the skeletal remains of swimming organisms that have sunk to the bottom. Recent deep-sea calcareous oozes consist of tests of foraminifera, pteropods, and nannoplankton. Ancient analogues of these pelagic carbonates occur in the Alpine geosynclines (depositional basins that serve as loci for subsequent mountain building).

Material of shallow-water origin may be introduced into deep-water depositional sites by submarine slumps, slides. and turbidity currents. The deposits, composed of skeletal sands, oolites, and intraclasts, become graded and are interbedded with the pelagic sediments. They occur near submarine scarps and slopes of carbonate banks, platforms, and islands.

Solution of carbonate and the compensation depth

The mineralogical composition of deep-sea sediment is controlled partly by the composition of the planktonic skeletal remains that are the chief component and partly by dissolution of magnesium-rich calcite and aragonite. ***Globigerina*** tests and coccoliths, for example, which are among the most important planktonic sources of deep-sea sediments, consist of magnesium-poor calcite. Under deep-sea conditions, as a result of the lower temperature and higher pressure, all the carbonates are removed by dissolution. The depth beyond which no carbonates are present is called the "compensation depth," and it occurs at 4,000–5,000 metres (13,000–16,000 feet). Aragonite and magnesium-rich calcite are less stable than magnesium-poor calcite and go into solution at shallower depths; magnesium-poor sediments prevail to the "compensation depth." This phenomenon explains why many deep oceanic basins are barren of carbonate oozes, even though the calcareous plankton sinks continuously to the bottom.

Diagenetic changes. The carbonate rocks observed in the geologic record have undergone diagenetic processes over long periods of time, altering them partially or even completely. The late diagenetic changes occurring in a sediment are a response to pressure, temperature, the nature of the fluids moving through the pores, and the physical and chemical properties of the original sediment.

The first change occurs in grain mineralogy when magnesium-rich sediments pass to magnesium-poor calcareous rocks. The result is a complete change of mineralogy of the grains, but with retention of their original depositional texture. The exact mechanism by which removal of magnesium takes place is not yet fully understood.

Cement is the most important textural diagenetic element and the most important single element in the lithification (rock-forming) process. It consists of a chemical precipitate that fills voids within the sediment. The pore space may have existed originally between the grains or may have been created by desiccation or selective dissolution of the lime mud matrix. The most common mineral cement is calcite, but dolomite, anhydrite, and siliceous cements also occur. Cement appears as a clear, coarse mosaic and commonly begins as euhedral (well-formed) crystals that grow radially outward from the grains or from the cavity walls. Sometimes cementation is incomplete, and the available space may be filled with finer diagenetic sediment, called "crystal silt."

Recrystallization is another important diagenetic process that is responsible for the obliteration of the original depositional textures; a mass of large interlocking crystals, which may strongly resemble cement, is the final product. The process, which consists of grain or crystal enlargement, may operate in either fine-grained or coarse-grained sediments, and it may be selective, involving only parts of the material, or complete. Apparently, lime mud matrix is the textural element most sensitive to recrystallization.

SIGNIFICANCE OF CARBONATE ROCKS IN THE GEOLOGIC RECORD

Geochemical evolution. Carbonate rocks represent a natural response to the geochemical evolution of the Earth and to major steps in the course of biological evolution. A first milestone in the carbonate history is the appearance of the first organisms that began to use carbon dioxide and to liberate oxygen as a by-product of sugar synthesis. This removal of carbon dioxide from solution in seawater must have increased the alkalinity and led to the precipitation of calcium carbonate. The first carbonate fossils, stromatolitic algal structures, are found all over the world in Precambrian rock formations, the oldest of which are more than 2,700,000,000 years old.

Paleozoic and Mesozoic occurrences

During Paleozoic and Early Mesozoic times (from 570,000,000 to about 200,000,000 years ago), limestones and dolomites were deposited in a belt extending from North America through western Europe and the Soviet Union to Australia. These carbonates were largely the product of sedimentation in shallow seas. In the Late Mesozoic (65,000,000 to 150,000,000 years ago), pelagic carbonate organisms burst out in an immense biological explosion all over the world. This great biological event changed the Earth's carbonate economy and shifted a large part of the carbonate deposition from the continental shelves to the oceanic depths. The earlier, shallow-water limestones were likely to be recycled—destroyed by erosion and solution during regressions of the sea and then redeposited during transgressions—whereas the pelagic carbonates are oceanic and almost permanently withdrawn from surface circulation. The range of marine carbonates today reflects conditions that have been valid only since Cretaceous times, and the earlier distribution requires a quite different standard for appraisal.

Paleoclimates. Current opinion holds that carbonate rocks record warm climatic conditions and, consequently, the ancient distribution of land and sea with respect to the Equator. This paleoclimatological significance of carbonates assumes, however, that the climatic conditions of the geologic past were similar to present conditions. This is not exactly true: the "normal" geological paleoclimate was warmer than the present climate by about 3°–5° C (5°–9° F) in equatorial latitudes and more than 20" C (36" F) in polar latitudes.

Some types of carbonate rocks can be considered climate indicators, however, because they are precisely restricted to a climatic range of occurrence. These rocks include (1) marine oolites, with a bimodal (doubly peaked) distribution at latitudes 25° north and south, water temperature of 20"–30" C (68°–86° F) and normal salinity; (2) skeletal limestones whose organisms have living representatives with distinctive climatic ranges; (3) calcareous soils and crusts that indicate temperate climates with moderate winter precipitation and strong seasonality; (4) calcareous eolian dunes, whose origin requires a warm (15"–30" C, or 59°–86° F), shallow sea with vigorous productivity of carbonate-shelled organisms, suitable beach conditions, and a relatively long dry season to aid dune building; and (5) beachrock, a skeletal sand rapidly cemented on beaches in the intertidal belt by inorganic aragonite; the formation of beachrock occurs between 30" and 40" north and south, with water temperatures of 15°–30° C and normal salinity.

Paleogeography. The changing water levels that coincided with the formation and subsequent retreat of extensive shallow seas during the geologic past provided favourable marine environments for the accumulation of carbonates. High sea levels favoured the carbonates, whereas low sea levels did not. The causes of sea level change include (1) major episodes of mountain building and uplift of the Earth's surface; (2) slowly pulsating movements that produce broader, regional uplift of the Earth's surface, and (3) eustatic changes, those changes of sea level that result from glaciations and deglaciations.

Influence of tectonism

Tectonism (movements of the Earth's crust) exerts a strong effect on carbonate sedimentation. With increasing tectonic activity the relief becomes more pronounced, continental shelves tend to be narrower, and the shelves are smothered by continental sediments transported to the sea by rivers. Moreover, the turbidity of the waters may eliminate organisms capable of rapid carbonate secretion. Carbonate sedimentation is generally restricted to areas of tectonic stability, such as stable interior platforms and shelves. Carbonates occur in these environments together with some continental sediments. The most common groups include stromatolitic limestones and dolomites, biostromes and bioherms, and skeletal, pellet, and oolitic limestones; pebble conglomerates and mud-cracked micrites are also quite common. Carbonate sediments generally are restricted to the early stages of the geosynclinal (mountain-building) cycle, when the relief is not yet pronounced and the main influx of continental sediments has not yet started. Cherty micritic limestones with planktonic fossils are typical in the geosynclinal troughs, and carbonate sediments affected by slumping and turbidity currents may also occur,

Lincoln, Abraham

The 16th president of the United States, Abraham Lincoln preserved the Union during the Civil War and brought about the emancipation of the slaves. Among American heroes, Lincoln continues to have a unique appeal for his fellow countrymen and also for people of other lands. This charm derives from his remarkable life story—the rise from humble origins, the dramatic death—and from his distinctively human and humane personality as well as from his historical role as saviour of the Union and emancipator of the slaves. His relevance endures and grows especially because of his eloquence as a spokesman for democracy. In his view, the Union was worth saving not only for its own sake but also because it embodied an ideal, the ideal of self-government, which was of interest to the people of the entire world. Hence the universality of his continuing appeal.

Lincoln, 1863.

LIFE

Born on Feb. 12, 1809, in a backwoods cabin three miles south of Hodgenville, Kentucky, Lincoln was two years old when he was taken to a farm in the neighbouring valley of Knob Creek. His earliest memories were of this home and, in particular, of a flash flood that once washed away the corn and pumpkin seeds he had helped his father plant. The father, Thomas Lincoln, was descended from a weaver's apprentice who had migrated from England to Massachusetts in 1637. Though much less prosperous than some of his Lincoln forebears, Thomas was a sturdy pioneer. On June 12, 1806, he married Nancy Hanks. The Hanks genealogy is difficult to trace, but Nancy appears to have been of illegitimate birth. She has been described as "stoop-shouldered, thin-breasted, sad," and fervently religious. Thomas and Nancy Lincoln had three children: Sarah, Abraham, and Thomas (died in infancy).

Childhood and youth. In December 1816, faced with a lawsuit challenging the title to his Kentucky farm, Thomas Lincoln moved with his family to southwestern Indiana. There, as a "squatter" on public land, he hastily put up a "half-faced camp"—a crude structure of logs and boughs with one side open to the weather—in which the family took shelter behind a blazing fire. Soon he built a permanent cabin, and later he bought the land on which it stood. Abraham helped to clear the fields and to take care of the crops but early acquired a dislike for hunting and fishing. In afteryears he recalled the "panther's scream," the bears that "preyed on the swine," and the poverty of Indiana frontier life, which was "pretty pinching at times." The unhappiest period of his boyhood followed the death of his mother in the autumn of 1818. As a ragged nine year old, he saw her buried in the forest, then faced a winter without the warmth of a mother's love. Fortunately, before the onset of a second winter, Thomas Lincoln brought home from Kentucky a new wife for himself, a new mother for the children. Sarah Bush Johnston Lincoln, a widow with two girls and a boy of her own, had energy and affection to spare. She ran the household with an even hand, treating both sets of children as if she had borne them all; but she became especially fond of Abraham, and he of her. He afterward referred to her as his "angel mother."

Mother's death

This stepmother doubtless encouraged Lincoln's taste for reading, yet the original source of his desire to learn remains something of a mystery. Both of his parents were almost completely illiterate, and he himself received little formal education. He once said that, as a boy, he had gone to school "by littles"—a little now and a little then—and his entire schooling amounted to no more than one year's attendance. His neighbours later recalled how he used to trudge for miles to borrow a book. According to his own statement, however, his early surroundings provided "absolutely nothing to excite ambition for education. Of course, when I came of age I did not know much. Still, somehow, I could read, write, and cipher to the rule of three; but that was all." Apparently the young Lincoln did not read a large number of books but thoroughly absorbed the few that he did read. These included Parson Weems's *Life and Memorable Actions of George Washington* (with its story of the little hatchet and the cherry tree), *Robinson Crusoe*, *Pilgrim's Progress*, and Aesop's *Fables*. From his earliest days he must have had some familiarity with the Bible, for it doubtless was the only book his family owned.

Migration to Illinois

In March 1830 the Lincoln family undertook a second migration, this one to Illinois, with Lincoln himself driving the team of oxen. Having just reached the age of 21, he was about to begin life on his own. Six feet four inches tall, he was rawboned and lanky but muscular and physically powerful. He was especially noted for the skill and strength with which he could wield an ax. He spoke with a backwoods twang and walked in the long-striding, flat-footed, cautious manner of a plowman. Good-natured though somewhat moody, talented as a mimic and storyteller, he readily attracted friends. He was yet to demonstrate whatever other abilities he possessed.

After his arrival in Illinois, having no desire to be a farmer, Lincoln tried his hand at a variety of occupations. As a "rail splitter" he helped to clear and fence his father's new farm. As a flatboatman, he made a voyage down the Mississippi River to New Orleans. (This was his second visit to that city, his first having been made in 1828, while he still lived in Indiana.) On his return he settled in New Salem, a village of about 25 families on the Sangamon River. There he worked from time to time as storekeeper, postmaster, and surveyor. With the coming of the Black Hawk War (1832), he enlisted as a volunteer and was elected captain of his company. Afterward he joked that he had seen no "live, fighting Indians" during the war but had had "a good many bloody struggles with the mosquitoes." Meanwhile, aspiring to be a legislator, he was defeated in his first try and then repeatedly re-elected to the state assembly. He considered blacksmithing as a trade but finally decided in favour of the law. Already he had taught himself grammar and mathematics, and now he began to study lawbooks. In 1836, having passed the bar examination, he began to practice law.

Prairie lawyer. The next year he moved to Springfield, Illinois, the new state capital, which offered many more opportunities for a lawyer than New Salem did. At first he was a partner of John T. Stuart; then of Stephen T. Logan; and finally, from 1844 on, of William H. Herndon. Nearly ten years younger than Lincoln, Herndon was more widely read, more emotional at the bar, and generally more extreme in his views. Yet this partnership seems to have been as nearly perfect as such human arrangements ever are. Lincoln and Herndon kept few records of their law business, and they split the cash between them whenever either of them was paid. It seems they had no money quarrels.

Early legal career

Within a few years after his removal to Springfield, Lincoln was earning from $1,200 to $1,500 annually, at a time when the governor of the state received a salary of $1,200 and circuit judges only $750. He had to work hard. To keep himself busy he found it necessary not only to practice in the capital but also to follow the court as it made the rounds of its circuit. Each spring and fall he would set out by horseback or buggy to travel hundreds of miles over the thinly settled prairie, from one little county seat to another. Most of the cases were petty and the fees small.

The coming of the railroads, especially after 1850, made travel easier and practice more remunerative. Lincoln served as a lobbyist for the Illinois Central Railroad to assist it in getting a charter from the state, and thereafter he was retained as a regular attorney for that railroad. After successfully defending the company against the efforts of McLean County to tax its property, he received the largest single fee of his legal career—$5,000. (He had to sue the Illinois Central in order to collect the fee.) He also handled cases for other railroads and for banks, insurance companies, mercantile and manufacturing firms. In one of his finest performances before the bar, he saved the Rock Island Bridge, the first to span the Mississippi River, from the threat of the river transportation interests that demanded the bridge's removal. His business included a number of patent suits and criminal trials. One of his most effective and famous pleas had to do with a murder case. A witness claimed that, by the light of the moon, he had seen Duff Armstrong, an acquaintance of Lincoln's, take part in a killing. Referring to an almanac for proof, Lincoln argued that the night had been too dark for the witness to have seen anything clearly, and with a sincere and moving appeal he won an acquittal.

By the time he began to be prominent in national politics, about 20 years after launching upon his legal career, Lincoln had made himself one of the most distinguished and successful lawyers in Illinois. He was noted not only for his shrewdness and practical common sense, which enabled him always to see to the heart of any legal case, but also for his invariable fairness and utter honesty.

Private life. While residing in New Salem, Lincoln was acquainted with Ann Rutledge. Apparently he was fond of her, and certainly he grieved with the entire community at her untimely death, in 1835, at the age of 19. Afterward stories were told of a grand romance between Abraham and Ann, but these stories lack the support of sound historical evidence. A year after the death of Miss Rutledge, Lincoln was carrying on a halfhearted courtship with Mary Owens. Miss Owens concluded that Lincoln was "deficient in those little links which make up the chain of woman's happiness." She turned down his proposal.

Marriage to Mary Todd

So far as can be known, the first and only real love of Lincoln's life was Mary Todd. High-spirited, quick-witted and well-educated, Miss Todd came from a rather distinguished Kentucky family, and her Springfield relatives belonged to the social aristocracy of the town. Some of them frowned upon her association with Lincoln, and from time to time he too had doubts whether he ever could make her happy. Nevertheless, they became engaged. Then, on a day in 1841 that Lincoln recalled as the "fatal first of January," they broke the engagement, apparently on his initiative. For some time after that, he was overwhelmed by a mood of terrible depression and despondency. Finally the two were reconciled and on Nov. 4, 1842, were married.

Four children, all boys, were born to the Lincolns. Robert Todd, the eldest and only one to survive to adulthood, was never very close to his father. Edward Baker was nearly 4 when he died, and William Wallace was 11. Thomas, affectionately known as "Tad," outlived his father; Tad, who had a cleft palate and a lisp, was Lincoln's favourite. Lincoln left the upbringing of his sons largely to their mother, who was alternately strict and lenient in her treatment of them.

The Lincolns had a mutual affectionate interest in the doings and welfare of their boys, were fond of one another's company, and missed each other when apart, as existing letters show. Like most married couples, the Lincolns also had their domestic quarrels, which sometimes were hectic but which undoubtedly were exaggerated by contemporary gossips. Mrs. Lincoln suffered from recurring headaches, fits of temper, and a sense of insecurity and loneliness that was intensified by her husband's long absences on the lawyer's circuit. After his election to the presidency, she was afflicted in spirit by the death of her son Willie, by the ironies of war that made enemies of Kentucky relatives and friends, and by the unfair public criticisms of her as mistress of the White House. She lost all money sense and ran up embarrassing bills. She also put on some painful scenes of wifely jealousy. At last, in 1875, she was officially declared insane, but that was after she had undergone the further shock of seeing her husband murdered at her side. During their earlier married life, Mrs. Lincoln unquestionably encouraged her husband and served as a prod to his own ambition. During their later years together she probably strengthened and tested his innate qualities of tolerance and patience.

Religious views

With his wife, Lincoln attended Presbyterian services in Springfield and in Washington but never joined any church. He once explained:

> When any church will inscribe over its altar, as its sole qualification for membership, the Saviour's condensed statement of the substance of both Law and Gospel, "Thou shalt love the Lord thy God with all thy heart, and with all thy soul, and with all thy mind, and thy neighbor, as thyself," that church will I join with all my heart and all my soul.

Early in life he had been something of a skeptic and freethinker. His reputation had been such that, as he once complained, the "church influence" was used against him in politics. When running for Congress in 1846, he issued a handbill to deny that he ever had "spoken with intentional disrespect of religion." He went on to explain that he had believed in the doctrine of necessity—"that is, that the human mind is impelled to action, or held in rest by some power over which the mind itself has no control." Throughout his life he also believed in dreams and other enigmatic signs and portents. As he grew older, and especially after he became president and faced the soul-troubling responsibilities of the Civil War, he developed a profound religious sense, and he increasingly personified necessity as God. He came to look upon himself quite humbly as an "instrument of Providence" and to view all history as God's enterprise. "In the present civil war," he wrote in 1862, "it is quite possible that God's purpose is something different from the purpose of either party—and yet the human instrumentalities, working just as they do, are of the best adaptation to effect His purpose."

Lincoln was fond of the Bible and knew it well. He also was fond of Shakespeare. In private conversation he used many Shakespearean allusions, discussed problems of dramatic interpretation with considerable insight, and from memory recited long passages with rare feeling and understanding. He liked the essays of John Stuart Mill, particularly the famous one on liberty, but disliked heavy or metaphysical works.

Though he enjoyed the poems of Lord Byron and Robert Burns, his favourite piece of verse was the work of an obscure Scottish poet, William Knox. Lincoln often quoted Knox's lines beginning: "Oh! why should the spirit of mortal be proud?" He liked to relax with the comic writings of Petroleum V. Nasby, Orpheus C. Kerr, and Artemus Ward, or with a visit to the popular theatre.

Early politics. When Lincoln first entered politics, Andrew Jackson was president. Lincoln shared the sympathies that the Jacksonians professed for the common man, but he disagreed with the Jacksonian view that the government should be divorced from economic enterprise. "The legitimate object of government," he was later to say, "is to do for a community of people whatever they need to have done, but cannot do at all, or cannot do so well, for themselves, in their separate and individual capacities." He most admired Henry Clay and Daniel Webster among the prominent politicians of the time. Clay and Webster advocated using the powers of the federal government to encourage business and develop the country's resources by means of a national bank, a protective tariff, and a program of internal improvements for facilitating transportation. In Lincoln's view, Illinois and the West as a whole desperately needed such aid to economic development. From the outset, he associated himself with the Clay and Webster party, the Whigs.

Member of Illinois State Legislature

As a Whig member of the Illinois State Legislature, to which he was elected four times from 1834 to 1840, he devoted himself to a grandiose project for constructing with state funds a network of railroads, highways, and canals. Whigs and Democrats joined in passing an omnibus bill for these undertakings, but the Panic of 1837 and the ensuing business depression brought about the abandonment of most of them. While in the legislature he demonstrated that, though opposed to slavery, he was no abolitionist. Resolutions were introduced, in 1837, in response to the mob murder of Elijah Lovejoy, an antislavery newspaperman of Alton. Instead of denouncing lynch law, these resolutions condemned abolitionist societies and upheld slavery within the Southern states as "sacred" by virtue of the federal Constitution. Lincoln refused to vote for the resolutions. Together with a fellow member he drew up a protest against them. This maintained, on the one hand, that slavery was "founded on both injustice and bad policy" and, on the other, that "the promulgation of abolition doctrines tends rather to increase than to abate its evils."

During his single term in Congress (1847–49), Lincoln, as the lone Whig from Illinois, gave little attention to legislative matters as such. He proposed a bill for the gradual and compensated emancipation of slaves in the District of Columbia, but the bill was to take effect only with the approval of the "free white citizens" of the district. It displeased abolitionists as well as slaveholders and never was seriously considered.

Involvement in presidential politics

Much of his time Lincoln devoted to presidential politics, to unmaking one president, a Democrat, and making another, a Whig. He found an issue and a candidate in the Mexican War. With his "spot resolutions" he challenged the statement of Pres. James K. Polk that Mexico had started the war by shedding American blood upon American soil. Along with other members of his party, Lincoln voted to condemn Polk and the war while voting supplies for carrying it on. At the same time he laboured for the nomination and election of the war hero Zachary Taylor. After Taylor's success at the polls, Lincoln expected to be named commissioner of the general land office as a reward for his campaign services, and he was bitterly disappointed when he failed to get the job. His criticisms of the war, meanwhile, had not been popular among the voters in his own congressional district. At the age of 40, frustrated in politics, he seemed to be at the end of his public career.

For about five years he took little part in politics, and then a new sectional crisis gave him a chance to re-emerge and rise to statesmanship. In 1854 his political rival Stephen A. Douglas manoeuvred through Congress a bill for reopening the entire Louisiana Purchase to slavery and allowing the settlers of Kansas and Nebraska (with "popular sovereignty") to decide for themselves whether to permit slaveholding in those territories. The Kansas–Nebraska Act provoked violent opposition in Illinois and the other states of the old Northwest. It gave rise to the Republican Party while speeding the Whig Party on the way to disintegration. Along with many thousands of other homeless Whigs, Lincoln soon became a Republican (1856). Before long, some prominent Republicans in the East talked of attracting Douglas to the Republican fold, and with him his Democratic following in the West. Lincoln would have none of it. He was determined that he, not Douglas, should be the Republican leader of his state and section. In their basic views, he and Douglas were not quite so far apart as they seemed in the heat of political argument. Neither was an abolitionist, neither a proslavery man. But Lincoln, unlike Douglas, insisted that Congress must exclude slavery from the territories. He disagreed with Douglas' belief that the territories were by nature unsuited to the slave economy and that no congressional legislation was needed to prevent the spread of slavery into them. He declared (1858): *"A house divided against itself cannot stand. I* believe the government cannot endure permanently half slave and half free." He predicted that the country eventually would become "all one thing, or all the other." Again and again he insisted that the civil liberties of every U.S. citizen, white as well as black, were at stake. The territories must be kept free, he further said, because "new free states" were "places for poor people to go and better their condition." He agreed with Thomas Jefferson and other founding fathers, however, that slavery should be merely contained, not directly attacked. In the Lincoln–Douglas debates of 1858, while contesting for Douglas' seat in the United States Senate, he drove home the inconsistency between Douglas' "popular sovereignty" principle and the Dred Scott decision (1857), in which the U.S. Supreme Court held that Congress could not constitutionally exclude slavery from the territories. Though he failed to obtain the Senate seat, Lincoln gained national recognition and soon began to be mentioned as a presidential prospect for 1860.

Lincoln–Douglas debates

On May 18, 1860, after Lincoln and his friends had made skillful preparations, he was nominated on the third ballot at the Republican Convention in Chicago. He then put aside his law practice and, though making no stump speeches, gave his full time to the direction of his campaign. His "main object," he had written, was to "hedge against divisions in the Republican ranks," and he counselled party workers to "say nothing on points where it is probable we shall disagree." With the Republicans united, the Democrats divided, and a total of four candidates in the field, he carried the election on November 6. No one in the Deep South voted for him and no more than 40 out of 100 in the country as a whole. Still, the popular votes were so distributed that he won a clear and decisive majority in the electoral college.

President Lincoln. After Lincoln's election and before his inauguration, the state of South Carolina proclaimed its withdrawal from the Union. To forestall similar action by other Southern states, various compromises were proposed in Congress. The most important, the Crittenden Compromise, included constitutional amendments (1) guaranteeing slavery forever in the states where it already existed and (2) dividing the territories between slavery and freedom. Though Lincoln had no objection to the first of these amendments, he was unalterably opposed to the second and indeed to any scheme infringing in the slightest upon the free-soil plank of his party's platform. "I am inflexible," he privately wrote. He feared that a territorial division, by sanctioning the principle of slavery extension, would only encourage planter imperialists to seek new slave territory south of the American border and thus would "put us again on the highroad to a slave empire." From his home in Springfield he advised Republicans in Congress to vote against a division of the territories. The proposal was killed in committee. Six additional states then seceded and, with South Carolina, combined to form the Confederate States of America.

Secession of the Confederate states

So, before Lincoln took office, a disunion crisis was upon the country. Attention, North and South, focussed in particular upon Ft. Sumter, in Charleston Harbor. This fort, still under construction, was garrisoned by U.S. troops under Maj. Robert Anderson. The Confederacy claimed it and, from other harbour fortifications, threatened it. Foreseeing trouble, Lincoln, while still in Springfield, confidentially requested Winfield Scott, general in chief of the U.S. Army, to be prepared "to either *hold*, or ***retake***, the forts, as the case may require, at, and after the inauguration." In his inaugural address (March 4, 1861), besides upholding the Union's indestructibility and appealing for sectional harmony, Lincoln restated his Sumter policy as follows:

> The power confided to me, will be used to hold, occupy, and possess the property, and places belonging to the government, and to collect the duties and imposts; but beyond what may be necessary for these objects, there will be no invasion—no using of force against, or among the people anywhere.

Then, near the end, addressing the absent Southerners: "You can have no conflict, without being yourselves the aggressors."

No sooner was he in office than Lincoln received word that the Sumter garrison, unless supplied or withdrawn, would shortly be starved out. Still, for about a month, Lincoln delayed to act. He was beset by contradictory advice. On the one hand, General Scott, Secretary of State William H. Seward, and others urged him to abandon the fort; and Seward, through a go-between, gave a group of Confederate commissioners to understand that the fort would in fact be abandoned. On the other hand, many Republicans insisted that any show of weakness would bring disaster to their party and to the Union. Finally Lincoln ordered the preparation of two relief expeditions, one for Ft. Sumter and the other for Ft. Pickens, in Florida. (He afterward said he would have been willing to withdraw from Sumter if he could have been sure of holding Pickens.) Before the Sumter expedition, he sent a messenger to tell the South Carolina governor:

> I am directed by the President of the United States to notify you to expect an attempt will be made to supply Fort-Sumpter with provisions only; and that, if such attempt be not resisted, no effort to throw in men, arms, or ammunition, will be made, without further notice, or in case of an attack upon the Fort.

Without waiting for the arrival of Lincoln's expedition, the Confederate authorities presented to Major Anderson a demand for Sumter's prompt evacuation, which he refused. On April 12, 1861, at dawn, the Confederate batteries in the harbour opened fire.

Attack on
Ft. Sumter:
Civil War

"Then, and thereby," Lincoln informed Congress when it met on July 4, "the assailants of the Government, began the conflict of arms." The Confederates, however, accused him of being the real aggressor. They said he had cleverly manoeuvred them into firing the first shot so as to put upon them the onus of war guilt. Though some historians have repeated this charge, it appears to be a gross distortion of the facts. Lincoln was determined to preserve the Union; to do so he thought he must take a stand against the Confederacy, and he concluded he might as well take this stand at Sumter.

Lincoln's primary aim was neither to provoke war nor to maintain peace. In preserving the Union, he would have been glad to preserve the peace also, but he was ready to risk a war that he thought would be short.

After the firing on Ft. Sumter, Lincoln called upon the state governors for troops (Virginia and three other states of the upper South responded by joining the Confederacy). He then proclaimed a blockade of the Southern ports. These steps—the Sumter expedition, the call for volunteers, and the blockade—were the first important decisions of Lincoln as commander in chief of the army and navy. He still needed a strategic plan and a command system for carrying it out.

General Scott advised him to avoid battle with the Confederate forces in Virginia, to get control of the Mississippi River, and by tightening the blockade to hold the South in a gigantic squeeze. Lincoln had little confidence in Scott's comparatively passive and bloodless "Anaconda" plan. He believed the war must be actively fought if it ever was to be won. Overruling Scott, he ordered a direct advance on the Virginia front, which resulted in defeat and rout for the Federal forces at Bull Run (July 21, 1861). After a succession of more or less sleepless nights, Lincoln produced a set of memorandums on military policy. His basic thought was this: the armies should advance concurrently on several fronts and should move in such directions as to hold and use the support of Unionists in Missouri, Kentucky, western Virginia, and eastern Tennessee. He later explained:

Lincoln's
strategy
as
commander
in chief

> I state my general idea of this war to be that we have the *greater* numbers, and the enemy has the *greater* facility of concentrating forces upon points of collision; that we must fail, unless we can find some way of making *our* advantage an over-match for *his;* and that this can only be done by menacing him with superior forces at *different* points, at the *same* time.

This, with the naval blockade, comprised the essence of Lincoln's strategy.

From 1861 to 1864, while hesitating to impose his ideas upon his generals, Lincoln experimented with command personnel and organization. Accepting the resignation of Scott (November 1861), he put George B. McClellan in charge of the armies as a whole. After a few months, disgusted by the slowness of McClellan, he demoted him to the command of the Army of the Potomac alone. He questioned the soundness of McClellan's plans for the peninsular campaign, repeatedly compelled McClellan to alter them, and, after the Seven Days' Battles before Richmond (June–July 1862), ordered him to give them up. Then he tried a succession of commanders for the army in Virginia—John Pope, McClellan again, Ambrose E. Burnside, Joseph Hooker, and George Gordon Meade—but was disappointed with each of them in turn. Meanwhile, he had in Henry W. Halleck a general in chief who gave advice and served as a liaison with field officers but who shrank from making important decisions. For nearly two years the Federal armies had no very effective unity of command. President Lincoln, General Halleck, and War Secretary Edwin M. Stanton acted as an informal council of war. Lincoln, besides transmitting official orders through Halleck, also communicated directly with the generals, sending personal suggestions in his own name. To generals opposing Robert E. Lee, he suggested that the object was to destroy Lee's army, not to capture Richmond or to drive the invader from Northern soil.

Finally Lincoln looked to the West for a top general. He admired the Vicksburg Campaign of Ulysses S. Grant. Nine days after the Vicksburg surrender (which occurred on July 4, 1863), he sent Grant a "grateful acknowledgment for the almost inestimable service" he had done the country. Lincoln sent also an admission of his own error. He said he had expected Grant to bypass Vicksburg and go on down the Mississippi, instead of crossing the river and turning back to approach Vicksburg from the rear. "I feared it was a mistake," he wrote in his letter of congratulations. "I now wish to make the personal acknowledgment that you were right, and I was wrong."

Choice of
Grant as
commander
of Federal
armies

In March 1864 Lincoln promoted Grant to lieutenant general and gave him command of all the Federal armies. At last Lincoln had found a man who, with such able subordinates as William T. Sherman, Philip Sheridan, and George H. Thomas, could put into effect those parts of Lincoln's concept of a large-scale, coordinated offensive that still remained to be carried out. Grant was only a member, though an important one, of a top-command arrangement that Lincoln eventually had devised. Overseeing everything was Lincoln himself, the commander in chief. Taking the responsibility for men and supplies was Stanton, the secretary of war. Serving as a presidential adviser and as a liaison with military men was Halleck, the chief of staff. And directing all the armies, while accompanying Meade's Army of the Potomac, was Grant, the general in chief. Thus Lincoln pioneered in the creation of a high command, an organization for amassing all the energies and resources of a people in the grand strategy of total war. He combined statecraft and the overall direction of armies with an effectiveness that year by year increased. His achievement is all the more remarkable in view of his lack of training and experience in the art of warfare. This lack may have been an advantage as well as a handicap. Unhampered by outworn military dogma, Lincoln could all the better apply his practical insight and common sense—some would say his military genius—to the winning of the Civil War.

Lincoln and the slavery question

There can be no doubt of Lincoln's deep and sincere devotion to the cause of personal freedom. Before his election to the presidency he had spoken often and eloquently on the subject. In 1854, for example, he said he hated the Douglas attitude of indifference toward the possible spread of slavery to new areas. "I hate it because of the monstrous injustice of slavery itself," he declared. "I hate it because it deprives our republican example of its just influence in the world: enables the enemies of free institutions with plausibility to taunt us as hypocrites. . . ." In 1855, writing to his friend Joshua Speed, he recalled a steamboat trip the two had taken on the Ohio River 14 years earlier. "You may remember, as I well do," he said, "that from Louisville to the mouth of the Ohio there were, on board, ten or a dozen slaves, shackled together with irons. That sight was a continual torment to me; and I see something like it every time I touch the Ohio, or any other slave-border."

Yet, as president, Lincoln was at first reluctant to adopt an abolitionist policy. There were several reasons for his hesitancy, He had been elected on a platform pledging no interference with slavery within the states, and in any case he doubted the constitutionality of federal action under the circumstances. He was concerned about the possible difficulties of incorporating nearly 4,000,000 Negroes, once they had been freed, into the nation's social and political life. Above all, he felt that he must hold the border slave states in the Union, and he feared that an abolitionist program might impel them, in particular his native Kentucky, toward the Confederacy. So he held back while others went ahead. When Gen. John C. Frémont and Gen. David Hunter, within their respective military departments, proclaimed freedom for the slaves of disloyal masters, Lincoln revoked the proclamations. When Congress passed confiscation acts (in 1861 and 1862), he refrained from a full enforcement of the provisions authorizing him to seize slave property. And when Horace Greeley in the *New York Tribune* appealed to him to enforce these laws, Lincoln patiently replied (Aug. 22, 1862):

> My paramount object in this struggle is to save the Union, and is not either to save or to destroy slavery. If I could save the Union without freeing any slave I would do it; and if I could save it by freeing all the slaves I would do it; and if I could save it by freeing some and leaving others alone, I would also do that.

Meanwhile, in response to the rising antislavery sentiment, Lincoln came forth with an emancipation plan of his own. According to his proposal, the slaves were to be freed by state action, the slaveowners were to be compensated, the federal government was to share the financial burden, the emancipation process was to be gradual, and the freedmen were to be colonized abroad. Congress indicated its willingness to vote the necessary funds for the Lincoln plan, but none of the border slave states were willing to launch it, and in any case few Negro leaders desired to see their people sent abroad.

Emancipation Proclamation and the antislavery amendment

While still hoping for the eventual success of his gradual plan, Lincoln took a quite different step by issuing his preliminary (Sept. 22, 1862) and his final (Jan. 1, 1863) Emancipation Proclamation. This famous decree, which he justified as an exercise of the president's war powers, applied only to those parts of the country actually under Confederate control, not to the loyal slave states nor to the Federally occupied areas of the Confederacy. Directly or indirectly the proclamation brought freedom during the war to fewer than 200,000 slaves. Yet it had great significance as a symbol. It indicated that the Lincoln government had added freedom to reunion as a war aim, and it attracted liberal opinion in England and Europe to increased support of the Union cause.

Lincoln himself doubted the constitutionality of his step, except as a temporary war measure. After the war the slaves freed by the proclamation would have risked re-enslavement, had nothing else been done to confirm their liberty. Something else was done: the Thirteenth Amendment was added to the Constitution, and Lincoln played a large part in bringing about this change in the fundamental law. Through the chairman of the Republican National Committee he urged the party to include a plank for such an amendment in its platform of 1864. The plank, as adopted, stated that slavery was the cause of the rebellion, that the President's proclamation had aimed "a death blow at this gigantic evil," and that a constitutional amendment was necessary to "terminate and forever prohibit" it When Lincoln was re-elected on this platform and the Republican majority in Congress was increased, he was justified in feeling, as he apparently did, that he had a mandate from the people for the Thirteenth Amendment. The newly chosen Congress, with its overwhelming Republican majority, was not to meet until after the lame duck session of the old Congress during the winter of 1864–65. Lincoln did not wait. Using his resources of patronage and persuasion upon certain of the Democrats, he managed to get the necessary two-thirds vote before the session's end. He rejoiced as the amendment went out to the states for ratification, and he rejoiced again and again as his own Illinois led off and other states followed one by one in acting favourably upon it. (He did not live to rejoice in its ultimate adoption.)

Lincoln deserves his reputation as the Great Emancipator. His claim to that honour, if it rests uncertainly upon his famous proclamation, has a sound basis in the support he gave to the antislavery amendment. It is well founded also in his greatness as the war leader who carried the nation safely through the four-year struggle that brought freedom in its train. And, finally, it is strengthened by the practical demonstrations he gave of respect for human worth and dignity, regardless of colour. During the last two years of his life he welcomed Negroes as visitors and friends in a way no president had done before. One of his friends was the distinguished former slave Frederick Douglass. Afterward Douglass wrote: "In all my interviews with Mr. Lincoln I was impressed with his entire freedom from prejudice against the colored race."

Wartime politics

To win the war, President Lincoln had to have popular support. The reunion of North and South required, first of all, a certain degree of unity in the North. But the North contained various groups with special interests of their own. Lincoln faced the task of attracting to his administration the support of as many divergent groups and individuals as possible. So he gave much of his time and attention to politics, which in one of its aspects is the art of attracting such support. Fortunately for the Union cause, he was a president with rare political skill. He had the knack of appealing to fellow politicians and talking to them in their own language. He had a talent for smoothing over personal differences and holding the loyalty of men antagonistic to one another. Inheriting the spoils system, he made good use of it, disposing of government jobs in such a way as to strengthen his administration and further its official aims.

The opposition party remained alive and strong. Its membership included war Democrats and peace Democrats, often called "Copperheads," a few of whom collaborated with the enemy. Lincoln did what he could to cultivate the assistance of the war Democrats, as in securing from Congress the timely approval of the Thirteenth Amendment. So far as feasible, he conciliated the peace Democrats. He gave heed to the complaints of one of them, Gov. Horatio Seymour of New York, in regard to the draft quota for that state. He commuted the prison sentence of another, Congressman Clement L. Vallandigham of Ohio, to banishment within the Confederate lines. In dealing with persons suspected of treasonable intent, Lincoln at times authorized his generals to make arbitrary arrests. He justified this action on the ground that he had to allow some temporary sacrifice of parts of the Constitution in order to maintain the Union and thus preserve the Constitution as a whole. He let his generals suspend several newspapers, but only for short periods, and he promptly revoked a military order suppressing the hostile *Chicago Times*. In a letter to one of his generals he expressed his policy thus:

> You will only arrest individuals and suppress assemblies or newspapers when they may be working palpable injury to the

> military in your charge, and in no other case will you interfere with the expression of opinion in any form or allow it to be interfered with violently by others. In this you have a discretion to exercise with great caution, calmness, and forbearance.

Considering the dangers and provocations of the time, Lincoln was quite liberal in his treatment of political opponents and the opposition press. He was by no means the dictator critics often accused him of being.

Within his own party he confronted factional divisions and personal rivalries that caused him as much trouble as did the activities of the Democrats. True, he and most of his fellow partisans agreed fairly well upon their principal economic aims. With his approval, the Republicans enacted into law the essentials of the program he had advocated from his early Whig days—a protective tariff; a national banking system; and federal aid for internal improvements, in particular for the construction of a railroad to the Pacific Coast. The Republicans disagreed among themselves, however, on many matters regarding the conduct and purposes of the war. Two main factions arose: the "radicals" and the "conservatives." Lincoln himself inclined in spirit toward the conservatives, but he had friends among the radicals as well, and he strove to maintain his leadership over both. In appointing his cabinet, he chose his several rivals for the 1860 nomination and, all together, gave representation to every important party group. Wisely he included the outstanding conservative, Seward, and the outstanding radical, Salmon P. Chase. Cleverly he overcame cabinet crises and kept these two opposites among his oflicial advisers until Chase's resignation in 1864.

Reconstruction of the South

He had to deal with even more serious factional uprisings in Congress. The big issue was the "reconstruction" of the South. The seceded states of Louisiana, Arkansas, and Tennessee having been largely recovered by the Federal armies, Lincoln late in 1863 proposed his "ten percent plan," according to which new state governments might be formed when 10 percent of the qualified voters had taken an oath of future loyalty to the United States. The radicals rejected Lincoln's proposal as too lenient, and they carried through Congress the Wade–Davis Bill, which would have permitted the remaking and re-admission of states only after a majority had taken the loyalty oath. When Lincoln pocket vetoed that bill, its authors published a "manifesto" denouncing him.

Already he was the candidate of the "Union" (that is, the Republican) party for re-election to the presidency, and the Wade–Davis manifesto signalized a movement within the party to displace him as the party's nominee. He waited quietly and patiently for the movement to collapse, but even after it had done so, the party remained badly divided. A rival Republican candidate, John C. Frémont, nominated much earlier by a splinter group, was still in the field. Leading radicals promised to procure Frémont's withdrawal if Lincoln would obtain the resignation of his conservative postmaster general, Montgomery Blair. Eventually Frémont withdrew and Blair resigned. The party was reunited in time for the election of 1864.

In 1864, as in 1860, Lincoln was the chief strategist of his own electoral campaign. He took a hand in the management of the Republican Speakers' Bureau, advised state committees on campaign tactics, hired and fired government employees to strengthen party support, and did his best to enable as many soldiers and sailors as possible to vote. Most of the citizens in uniform voted Republican. He was re-elected with a large popular majority (55 percent) over his Democratic opponent, General McClellan.

Lincoln's second term

In 1864 the Democratic platform called for an armistice and a peace conference, and prominent Republicans as well as Democrats demanded that Lincoln give heed to Confederate peace offers, irregular and illusory though they were. In a public letter, he stated his own conditions:

> Any proposition which embraces the restoration of peace, the integrity of the whole Union, and the abandonment of slavery, and which comes by and with an authority that can control the armies now at war against the United States will he received and considered by the Executive government of the United States, and will be met by liberal terms on other substantial and collateral points.

When conservatives protested to him against the implication that the war must go on to free the slaves, even after reunion had been won, he explained: "To me it seems plain that saying reunion and abandonment of slavery would be considered, if offered,is not saying that nothing *else* or *less* would be considered, if offered." After his re-election, in his annual message to Congress, he said: "In stating a single condition of peace, I mean simply to say that the war will cease on the part of the government, whenever it shall have ceased on the part of those who began it." On Feb. 3, 1865, he met personally with Confederate commissioners on a steamship in Hampton Roads. He promised to be liberal with pardons if the South would quit the war, but he insisted on reunion as a precondition for any peace arrangement. In his second inaugural address he embodied the spirit of his policy in the famous words "with malice toward none; with charity for all." His terms satisfied neither the Confederate leaders nor the radical Republicans, and so no peace was possible until the final defeat of the Confederacy.

Policy toward the South

At the end of the war, Lincoln's policy for the defeated South was not clear in all its details, though he continued to believe that the main object should be to restore the "seceded States, so-called," to their "proper practical relation" with the Union as soon as possible. He possessed no fixed and uniform program for the region as a whole. As he said in the last public speech of his life (April 11, 1865), "so great peculiarities" pertained to each of the states, and "such important and sudden changes" occurred from time to time, and "so new and unprecedented" was the whole problem that "no exclusive and inflexible plan" could "safely be prescribed." With respect to states like Louisiana and Tennessee, he continued to urge acceptance of new governments set up under his 10 percent plan during the war. With respect to states like Virginia and North Carolina, he seemed willing to use the old rebel governments temporarily as a means of transition from war to peace. He was on record as opposing the appointment of "strangers" (carpetbaggers) to govern the South. He hoped that the Southerners themselves, in forming new state governments, would find some way by which whites and Negroes "could gradually live themselves out of their old relation to each other, and both come out better prepared for the new." A program of education for the freedmen, he thought, was essential for preparing them for their new status. He also suggested that the vote be given immediately to some Negroes—"as, for instance, the very intelligent, and especially those who have fought gallantly in our ranks."

On the question of reconstruction, however, Lincoln and the extremists of his own party stood even farther apart in early 1865 than a year before. Some of the radicals were beginning to demand a period of military occupation for the South, the confiscation of planter estates and their division among the freedmen, and the transfer of political power from the planters to their former slaves. In April 1865 Lincoln began to modify his own stand in some respects and thus to narrow the gap between himself and the radicals. He recalled the permission he had given for the assembling of the rebel legislature of Virginia, and he approved in principle—or at least did not disapprove—Stanton's scheme for the military occupation of southern states. After the cabinet meeting of April 14, Attorney General James Speed inferred that Lincoln was moving toward the radical position. "He never seemed so near our views," Speed believed. What Lincoln's reconstruction policy would have been, if he had lived to complete his second term, can only be guessed at.

Assassination

On the evening of April 14, 1865, John Wilkes Booth shot Lincoln as he sat in Ford's Theatre in Washington, and early the next morning Lincoln died.

REPUTATION AND CHARACTER

"Now he belongs to the ages," Stanton is supposed to have said as Lincoln breathed his last. Many thought of him as a martyr. The assassination had occurred on Good Friday, and on the following Sunday, memorable as "Black Easter," hundreds of speakers found a sermon in the event. Some of them saw more than mere chance in the fact that assassination day was also crucifixion day. One declared: "Jesus Christ died for the world; Abraham Lincoln died for his country." Thus the posthumous growth of his reputation was influenced by the timing and circumstances of his death, which won for him a kind of sainthood.

Among the many who remembered Lincoln from personal acquaintance, one was sure he had known him more intimately than any of the rest and influenced the world's conception of him more than all the others put together. That one was his former law partner Herndon. When Lincoln died, Herndon began a new career as Lincoln authority, collecting reminiscences wherever he could find them and adding his own store of memories. Though admiring Lincoln, he objected to the trend toward sanctifying the man. He saw, as the main feature of Lincoln's life, the far more than ordinary rise of a self-made man, a rise from the lowest depths to the greatest heights—"from a stagnant, putrid pool, like the gas which, set on fire by its own energy and self-combustible nature, rises in jets, blazing, clear, and bright." To emphasize this point, Herndon gave his most eager attention to evidences of the dismal and sordid in Lincoln's background. An extremely significant event in Lincoln's development, as Herndon viewed it, was a "romance of much reality" with Ann Rutledge. Lincoln loved no one but Ann and, after her death, never ceased to grieve for her. His memory of her both saddened and inspired him. As for his wife, Mary Todd, she married him out of spite, then devoted herself to making him miserable. So Herndon would have it, and after him countless biographers and novelists and playwrights elaborated upon his views, which persist as accepted knowledge about Lincoln despite their refutation by historical scholarship.

Lincoln has become a myth as well as a man. The legendary is to be found in imaginative literature and in folklore, in poems, plays, novels, anecdotes, and the like. It is also to be found in ostensibly factual productions, including footnoted biographies and histories.

The Lincoln of legend has grown into a protean god who can assume a shape to please almost any worshipper. He is Old Abe and at the same time a natural gentleman. He is Honest Abe and yet a being of superhuman shrewdness and cunning. He is also Father Abraham, the wielder of authority, the support of the weak; and he is an equal, a neighbour, and a friend.

The greatness of Lincoln

Lincoln the man has a reputation that may be considered apart from that of Lincoln the myth. While he was still alive, his reputation began to grow, and before his death his qualities of greatness already were widely recognized. In the midst of the Civil War, for instance, the *Washington Chronicle* found a resemblance between him and George Washington in their "sure judgment"; "perfect balance of thoroughly sound faculties"; and "great calmness of temper, great firmness of purpose, supreme moral principle, and intense patriotism." The *Buffalo Express* referred to his "remarkable moderation and freedom from passionate bitterness," then added: "We do not believe that Washington himself was less indifferent to the exercise of power for power's sake." An English newspaper, the *Liverpool Post,* suggested that "no leader in a great contest ever stood so little chance of being the subject of hero worship as Abraham Lincoln," if one were to judge only by the way he looked. His long arms and legs, his grotesque figure, made him too easy to caricature and ridicule. "Yet," this newspaper concluded, "a worshiper of human heroes might possibly travel a great deal farther and fare much worse for an idol than selecting this same lanky American." His inner qualities—his faithfulness, honesty, resolution, insight, humour, and courage–would "go a long way to make up a hero," whatever the man's personal appearance.

Lincoln's best ideas and finest phrases were considered and written and rewritten with meticulous revisions. Some resulted from a slow gestation of thought and phrase through many years. One of his recurring themes—probably his central theme––was the promise and the problem of self-government. As early as 1838, speaking to the Young Men's Lyceum of Springfield on "The Perpetuation of Our Political Institutions," he recalled the devotion of his Revolutionary forefathers to the cause, and went on to say:

> Their ambition aspired to display before an admiring world, a practical demonstration of the truth of a proposition, which had hitherto been considered, at best no better, than problematical; namely, *the capability of a people to govern themselves.*

Again and again he returned to this idea, especially after the coming of the Civil War, and he steadily improved his phrasing. In his first message to Congress after the fall of Ft. Sumter, he declared that the issue between North and South involved more than the future of the United States.

> It presents to the whole family of man, the question, whether a constitutional republic, or a democracy—a government of the people, by the same people—can, or cannot, maintain its territorial integrity, against its own domestic foes.

And finally at Gettysburg he made the culminating, the supreme statement, concluding with the words:

> . . . that from these honored dead we take increased devotion to that cause for which they gave the last full measure of devotion—that we here highly resolve that these dead shall not have died in vain—that this nation, under God, shall have a new birth of freedom—and that government of the people, by the people, for the people, shall not perish from the earth.

BIBLIOGRAPHY. For the general reader, the most usable and valuable guide is PAUL M. ANGLE, A *Shelf of Lincoln Books* (1946). Practically all the known writings of Lincoln himself are available in *The Collected Works of Abraham Lincoln,* ed. by ROY P. BASLER, 9 vol. (1953–55). A judicious selection from these volumes is reprinted in *The Living Lincoln,* ed. by PAUL M. ANGLE and EARL S. MIERS (1955).

Classic multivolume biographies are JOHN G. NICOLAY and JOHN HAY, *Abraham Lincoln: A History,* 10 vol. (1890; abridged ed., 1 vol., 1966); ALBERT J. BEVERIDGE, *Abraham Lincoln, 1809–1850,* 2 vol. (1928); CARL SANDBURG, *Abraham Lincoln: The Prairie Years,* 2 vol. (1926), and *The War Years,* 4 vol. (1939); and JAMES G. RANDALL, *Lincoln the President,* 4 vol. (1945–55). The best of the one-volume lives is BENJAMIN P. THOMAS, *Abraham Lincoln* (1952).

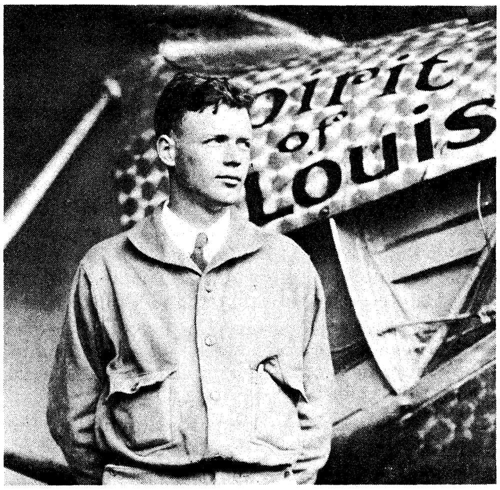
Matters of controversy and conflicting interpretation are discussed by DAVID DONALD in *Lincoln Reconsidered,* 2nd ed. (1961); and by RICHARD N. CURRENT in *The Lincoln Nobody Knows* (1958). Important works dealing with aspects of Lincoln's statesmanship are DON E. FEHRENBACHER, *Prelude to Greatness: Lincoln in the 1850's* (1962); DAVID M. POTTER, *Lincoln and His Party in the Secession Crisis* (1942); WILLIAM B. HESSELTINE, *Lincoln and the War Governors* (1948); KENNETH M. STAMPP, *And the War Came* (1950); and T. HARRY WILLIAMS, *Lincoln and the Radicals* (1941) and *Lincoln and His Generals* (1952). RUTH PAINTER RANDALL writes authoritatively of Lincoln's family life in *Mary Lincoln: Biography of a Marriage* (1953) and *Lincoln's Sons* (1955). Mrs. Randall effectively refutes the views of William H. Herndon, which may most conveniently be found in *Herndon's Life of Lincoln,* ed. by PAUL M. ANGLE (1930). An able and realistic treatment of Lincoln's legal career is JOHN J. DUFF, A. *Lincoln, Prairie Lawyer* (1960).

(R.N.C.)

Lindbergh, Charles A.

Probably the best known but least understood figure in aeronautical history, Charles Lindbergh heightened worldwide interest in aviation by his dramatic nonstop solo flight across the Atlantic in May 1927. That flight brought him fame, wealth, and a great personal tragedy. Its immediate aftermath also generated in him a great antipathy toward any form of personal publicity, and not until the mid-1960s did the self-generated screen covering his and his family's activities begin to dissipate.

Lindbergh was born in Detroit on February 4, 1902. His early years were spent mostly in Little Falls, Minnesota, and in Washington, D.C., where for ten years his father represented the 6th district of Minnesota in the Congress. His formal education ended during his second year at the University of Wisconsin, in Madison, when his growing interest in aviation led to enrollment in a flying school in Lincoln, Nebraska, and the purchase of a World War I Curtiss Jenny, with which he made stunt-flying tours through Southern and Midwestern states. After a year at the army flying schools in Texas (1924–25), he became an airmail pilot (1926), flying the route from St.



Lindbergh, 1927.
By courtesy of the Library of Congress, Washington. D.C.

Louis, Missouri, to Chicago. During this period he obtained financial backing from a group of St. Louis businessmen to compete for the $25,000 prize offered for the first nonstop flight between New York and Paris. In the monoplane "Spirit of St. Louis" he made the flight in 33½ hours on May 20–21, 1927. Overnight Lindbergh became a folk hero on both sides of the Atlantic and a well-known figure in most of the world. There followed a series of goodwill flights in Europe and America.

First nonstop New York–Paris flight

In Mexico, Lindbergh met Anne Morrow, daughter of the United States ambassador, Dwight Morrow. They were married in May 1929 and together made flights that took them to many countries of the world. During this period, Lindbergh acted as technical adviser to two airlines, Transcontinental Air Transport and Pan American Airways, personally pioneering many of their routes.

In March 1932 Lindbergh's two-year-old son, Charles Augustus, Jr., was kidnapped from the Lindberghs' home near Hopewell, New Jersey, and murdered. Partly because of Lindbergh's worldwide popularity, this became the most celebrated crime of the 1930s, and it was a major subject of newspaper attention until April 1936, when Bruno Richard Hauptmann was executed after being convicted of the kidnap-murder. The publicity was so distasteful to the Lindberghs that they took refuge in Europe. After 1936, when he visited German centres of aviation, Lindbergh repeatedly warned against the growing air power of Nazi Germany. His decoration by the German government in 1938 led to considerable criticism, as did the speeches advocating American neutrality in World War II he made in 1940–41 after his return to the United States. Criticism of his public statements by Pres. Franklin D. Roosevelt led Lindbergh to resign his Air Corps Reserve commission in April 1941.

When the United States entered the war, however, Lindbergh, as a civilian, threw himself unobtrusively into the war effort, serving as a consultant to the Ford Motor Company and to the United Aircraft Corporation. In the latter capacity he flew 50 combat missions during a tour of duty in the Pacific; and later, after the end of the war in Europe, he accompanied a navy technical mission in Europe investigating German aviation developments.

Following World War II, Lindbergh and his family lived quietly in Connecticut and then in Hawaii. He continued as consultant to Pan American World Airways and to the U.S. Department of Defense. He was a member of the National Advisory Committee for Aeronautics and served on a number of other aeronautical boards and committees. He received many honours and awards, in addition to the Medal of Honor that had been awarded to him by special act of Congress in 1927. For his services to the government he was appointed brigadier general in the Air Force Reserve by Pres. Dwight D. Eisenhower in 1954. His book *The Spirit of St. Louis,* describing the flight to Paris, was published in 1953 and gained him a Pulitzer Prize. He was also the author of *We* (1927), *Of Flight and Life* (1948), and, with the French surgeon and biologist Alexis Carrel, *The Culture of Organs* (1938), concerning researches on which he and Carrel had collaborated.

His *Wartime Journals* (1970) is a record (not initially intended for publication) that was handwritten as time permitted during the years 1938–45. Lindbergh died at his home on the island of Maui, Hawaii, on August 26, 1974.

BIBLIOGRAPHY. Lindbergh describes his nonstop airplane flight from New York to Paris in *The Spirit of St. Louis* (1953). An earlier volume in which he tells the story of his youth and his famous flight is *We* (1927). See also *The Wartime Journals of Charles A. Lindbergh* (1970), which covers the period from March 1938 to June 1945. Two biographies are KENNETH S. DAVIS, *The Hero* (1959); and WALTER S. ROSS, *The Last Hero: Charles A. Lindbergh* (1967).

Linguistics

Linguistics is the scientific study of language. The word was first used in the middle of the 19th century to emphasize the difference between a newer approach to the study of language that was then developing and the more traditional approach of philology. The differences were and are largely matters of attitude, emphasis, and purpose. The philologist is concerned primarily with the historical development of languages as it is manifest in written texts and in the context of the associated literature and culture. The linguist, though he may be interested in written texts and in the development of languages through time, tends to give priority to spoken languages and to the problems of analyzing them as they operate at a given point in time, without reference to their history. The linguist, in principle, is interested in all languages and not merely in the great literary languages of the world.

Synchronic and diachronic linguistics

The field of linguistics may be conveniently divided in terms of three dichotomies: synchronic versus diachronic, theoretical versus applied, microlinguistics versus macrolinguistics. A synchronic description of a language describes the language as it is at a given time; a diachronic description is concerned with the historical development of the language and the structural changes that have taken place in it between successive points in time. The goal of theoretical linguistics is the construction of a general theory of the structure of language or of a general theoretical framework for the description of languages (there is some controversy as to the difference between these two conceptions of the subject); the aim of applied linguistics is the application of the findings and techniques of the scientific study of language to a variety of practical tasks, especially to the elaboration of improved methods of language teaching. The terms microlinguistics and macrolinguistics are not yet well established, and they are, in fact, used here purely for convenience. The former refers to a narrower and the latter to a much broader view of the scope of linguistics. According to the microlinguistic view, languages should be analyzed for their own sake and without reference to their social function, to the manner in which they are acquired by children, to the psychological mechanisms that underlie the production and reception of speech, to the literary and the aesthetic or communicative function of language, and so on. In contrast, macrolinguistics embraces all of these aspects of language. A number of areas within macrolinguistics have been given terminological recognition: psycholinguistics, sociolinguistics, anthropological linguistics, dialectology, mathematical and computational linguistics, and stylistics. Macrolinguistics should not be identified with applied linguistics. The application of linguistic methods and concepts to language teaching may well involve other disciplines in a way that microlinguistics does not. But there is, in principle, a theoretical aspect to every part of macrolinguistics, no less than to microlinguistics.

About half of this article is devoted to theoretical, synchronic microlinguistics, which is generally acknowledged as the central part of the subject; it will be abbreviated henceforth as theoretical linguistics.

EARLIER HISTORY

Greek naturalists and conventionalists

Greek contributions. Western linguistic theory originated in Greece in the 5th century BC and was, at first, dominated by mainly philosophical issues, the most famous of which was whether language is of natural or conventional origin. According to the naturalists, the relationship between the form of a word and its meaning was, in the original state of language at least, of the kind exemplified by such onomatopoeic English words as "splash," "cuckoo," and so forth. Words whose form was no longer "naturally" related to their meaning in this way were traced back to what was assumed to have been their original "natural" state by the application of ad hoc and often quite fanciful etymological principles. The conventionalists argued that there were very few onomatopoeic forms, that they varied from language to language, and that they could be removed from the vocabulary without affecting the efficiency of the language as a vehicle of communication. The controversy endured for centuries and is still encountered in discussions of the origin of language. For the history of linguistics, its importance lies in the fact that it concentrated the attention of scholars upon the forms of words and grammatical patterns in their language.

The second great linguistic controversy of antiquity, that between the analogists and the anomalists, had a more direct and specific effect upon the development of traditional grammar. This concerned the grammatical structure of language—whether it is basically regular or irregular. Aristotle was an analogist, and the Alexandrian scholars followed him; the Stoics were, for the most part, anomalists. Both the Stoics and the Alexandrians contributed in roughly equal measure to the development of Greek grammatical theory, the former to the identification of the major grammatical categories, the latter to the establishment of the main patterns of inflection.

It was in Alexandria, one of the great centres of Hellenistic literary scholarship, that the grammar of Classical Greek was first codified. The so-called *Technē grammatikē* ("Art of Grammar") of Dionysius Thrax (c. 100 BC) was regarded as definitive for more than a thousand years, and it exerted a tremendous influence upon the grammars of the language written by Western scholars right down to modern times. The ***Technd*** of Dionysius dealt mainly with the accidence, or inflection, of Greek words. Greek syntax was described more than three centuries later, also in Alexandria, by Apollonius Dyscolus (2nd century AD). The grammar of Greek, as it is presented today in the standard handbooks, was fixed in all but relatively minor respects by the works of Dionysius and Apollonius.

Grammars of Donatus and Priscian

Roman practice. Roman grammarians were heavily dependent upon Greek models, and the fact that Greek and Latin were very similar in grammatical structure meant that Latin could be described in terms of the Greek grammatical categories without much difficulty. The Latin grammatical tradition, at first more strongly influenced by the Stoics than by the Alexandrians, later drew heavily from the grammars of Dionysius and Apollonius and, later, from those of Donatus (*c.* 400 AD) and Priscian (*c.* 500 AD). They were used not only for teaching Latin until well after the Renaissance, but they served as models for the description of many of the vernacular languages of Europe.

Medieval views on language. Though a number of advances were made in grammatical theory by medieval scholars, in general they were content to work with the grammar of Priscian. The most important development in the Middle Ages, as far as the history of linguistics is concerned, was the rise of what is usually called speculative grammar in the 13th and 14th centuries, when, dissatisfied with the mere description of the facts, scholastic grammarians set out to explain the structure not only of Latin but in principle of all languages in terms of the alleged congruence of grammatical, metaphysical, and epistemological categories. This interest in a universal grammar was revived in 17th-century France by the so-called rational grammar (*grammaire raisonnée*) of the Port Royal Abbey, on the basis, however, of Cartesian rather than scholastic philosophy.

Post-Renaissance work. Even during the Middle Ages there had been some sporadic concern with languages other than Latin. After the Renaissance this increased considerably and during the Reformation was further promoted by the Protestants' belief in the importance of translating the Bible into vernacular languages. With the expansion of Europe there evolved an increased appreciation of the range and diversity of the world's languages. By the 17th century, grammars of certain of the major indigenous languages of South America were being published, and some knowledge of Chinese, Vietnamese, Sanskrit, and other languages of the Far East, Southeast Asia, and India had been acquired, mainly as a result of the efforts of the Jesuit missionaries. All of this was to contribute to the formation of an intellectual climate in which linguistic research could set forth on a new and vigorous course of development in the 19th century.

THE 19TH CENTURY

Discovery of the Indo-European language family

Development of the comparative method. It is generally agreed that the most outstanding achievement of linguistic scholarship in the 19th century was the development of the comparative method, which comprised a set of principles whereby languages could be systematically compared with respect to their sound systems, grammatical structure, and vocabulary and shown to be "genealogically" related. As French, Italian, Portuguese, Romanian, Spanish, and the other Romance languages had evolved from Latin, so Latin, Greek, and Sanskrit as well as the Celtic, Germanic, and Slavic languages and many other languages of Europe and Asia had evolved from some earlier language, to which the name Indo-European or Proto-Indo-European is now customarily applied. That all the Romance languages were descended from Latin and thus constituted one "family" had been known for centuries; but the existence of the Indo-European family of languages and the nature of their genealogical relationship was first demonstrated by the 19th-century comparative philologists. (The term philology in this contest is not restricted to the study of literary languages.)

The main impetus for the development of comparative philology came toward the end of the 18th century, when it was discovered that Sanskrit bore a number of striking resemblances to Greek and Latin. An English orientalist, Sir William Jones, though he was not the first to observe these resemblances, is generally given the credit for bringing them to the attention of the scholarly world and putting forward the hypothesis, in 1786, that all three languages must have "sprung from some common source; which perhaps no longer exists." By this time, a number of texts and glossaries of the older Germanic languages (Gothic, Old High German, and Old Norse) had been published, and Jones realized that Germanic as well as Old Persian and perhaps Celtic had evolved from the same "common source." The next important step came in 1822, when the German scholar Jacob Grimm, following the Danish linguist Rasmus Rask (whose work, being written in Danish, was less accessible to most European scholars), pointed out in the second edition of his comparative grammar of Germanic that there were a number of systematic correspondences between the sounds of Germanic and the sounds of Greek, Latin. and Sanskrit in related words. Grimm noted, for example, that where Gothic (the oldest surviving Germanic language) had an *f*, Latin, Greek, and Sanskrit frequently had a *p* (*e.g.*, Gothic *fotus*, Latin *pedis*, Greek *podós*, Sanskrit *padás*, all meaning "foot"); when Gothic had a *p*, the non-Germanic languages had a *b;* when Gothic had a *b*, the non-Germanic languages had what Grimm called an "aspirate" (Latin *f*, Greek *ph*, Sanskrit *bh*). In order to account for these correspondences he postulated a cyclical "soundshift" (*Lautverschiebung*) in the prehistory of Germanic, in which the original "aspirates" became voiced unaspirated stops (*bh* became b, etc.), the original voiced unaspirated stops became voiceless (b became p, etc.), and the original voiceless (unaspirated) stops became "aspirates" (*p* became f). Grimm's term, "aspirate," it will be noted, covered such phonetically distinct categories as aspirated stops (*bh*, *ph*), produced with an accompanying audible puff of breath, and fricatives (f), produced with audible friction as a result of incomplete closure in the vocal tract.

The **Neogrammarians** and sound laws

In the work of the next 50 years the idea of sound change was made more precise, and, in the 1870s, a group of scholars known collectively as the *Jurzggramrnatiker* ("young grammarians," or Neogrammarians) put forward the thesis that all changes in the sound system of a language as it developed through time were subject to the operation of regular sound laws. Though the thesis that sound laws were absolutely regular in their operation (unless they were inhibited in particular instances by the influence of analogy) was at first regarded as most controversial, by the end of the 19th century it was quite generally accepted and had become the cornerstone of the comparative method. Using the principle of regular sound change, scholars were able to reconstruct "ancestral" common forms from which the later forms found in particular languages could be derived. By convention, such reconstructed forms are marked in the literature with an asterisk. Thus, from the reconstructed Proto-Indo-European word for "ten," **dekm*, it was possible to derive Sanskrit *daśa*, Greek *déka*, Latin *decem*, and Gothic *taihun* by postulating *a* number of different sound laws that operated independently in the different branches of the Indo-European family. The question of sound change is dealt with in greater detail in the section entitled *Historical Linguistics.*

The role of analogy. Analogy has been mentioned in connection with its inhibition of the regular operation of sound laws in particular word forms. This was how the Neogrammarians thought of it. In the course of the 20th century, however, it has come to be recognized that analogy, taken in its most general sense, plays a far more important role in the development of languages than simply that of sporadically preventing what would otherwise be a completely regular transformation of the sound system of a language. When a child learns to speak he tends to regularize the anomalous, or irregular, forms by analogy with the more regular and productive patterns of formation in the language; *e.g.*, he will tend to say "comed" rather than "came," "dived rather than "dove," and so on, just as he will say "talked," "loved," and so forth. The fact that the child does this is evidence that he has learned or is learning the regularities or rules of his language. He will go on to "unlearn" some of the analogical forms and substitute for them the anomalous forms current in the speech of the previous generation. But in some cases, he will keep a "new" analogical form (*e.g.*, "dived" rather than "dove"), and this may then become the recognized and accepted form.

Ideas of Wilhelm von Humboldt

Additional 19th-century theories **and development.** *Inner and outer form.* One of the most original, if not one of the most immediately influential, linguists of the 19th century was the learned Prussian statesman, Wilhelm von Humboldt (died 1835). His interests, unlike those of most of his contemporaries, were not exclusively historical. Following the German philosopher Johann Gottfried von Herder (1744–1803), he stressed the connection between national languages and national character: this was but a commonplace of romanticism. More original was Humboldt's theory of "inner" and "outer" form in language. The outer form of language was the raw material (the sounds) from which different languages were fashioned; the inner form was the pattern, or structure, of grammar and meaning that was imposed upon this raw material and differentiated one language from another. This "structural" conception of language was to become dominant, for a time at least, in many of the major centres of linguistics by the middle of the 20th century. Another of Humboldt's ideas was that language was something dynamic, rather than static, and was an activity itself rather than the product of activity. A language was not a set of actual utterances produced by speakers but the underlying principles or rules that made it possible for speakers to produce such utterances and, moreover, an unlimited number of them. This idea was taken up by a German philologist, Heymann Steinthal, and, what is more important, by the physiologist and psychologist Wilhelm Wundt, and thus influenced late 19th- and early 20th-century theories of the psychology of language. Its influence, like that of the distinction of inner and outer form, can also be seen in the thought of Ferdinand de Saussure, a Swiss linguist. But its full implications were probably not perceived and made precise until the middle of the 20th century, when the U.S. linguist Noam Chomsky re-emphasized it and made it one of the basic notions of generative grammar (see below).

Development of phonetics

Phonetics and dialectology. Many other interesting and important developments occurred in 19th-century linguistic research, among them work in the areas of phonetics and dialectology. Research in both these fields was promoted by the Neogrammarians' concern with sound change and by their insistence that prehistoric developments in languages were of the same kind as developments taking place in the languages and dialects currently spoken. The development of phonetics in the West was also strongly influenced at this period, as were many of the details of the more philological analysis of the Indo-European languages, by the discovery of the works of the Indian grammarians who, from the time of the Sanskrit grammarian Pāṇini (5th or 6th century BC), if not before, had arrived at a much more comprehensive and scientific theory of phonetics, phonology, and morphology than anything achieved in the West until the modern period.

THE 20TH CENTURY

Structuralism. The term structuralism has been used as a slogan and rallying cry by a number of different schools of linguistics, and it is necessary to realize that it has somewhat different implications according to the context in which it is employed. It is convenient to draw first a broad distinction between European and American structuralism and, then, to treat them separately.

Structural linguistics in Europe. Structural linguistics in Europe is generally said to have begun in 1916 with the posthumous publication of the *Cours de Linguistique Générale (Coume in General Linguistics)* of Ferdinand de Saussure. Much of what is now considered as Saussurean can be seen, though less clearly, in the earlier work of Humboldt, and the general structural principles that Saussure was to develop with respect to synchronic linguistics in the *Cours* had been applied almost 40 years before (1879) by Saussure himself in a reconstruction of the Indo-European vowel system. The full significance of the work was not appreciated at the time. Saussure's structuralism can be summed up in two dichotomies (which jointly cover what Humboldt referred to in terms of his own distinction of inner and outer form): (1) *langue* versus *parole* and (2) form versus substance. By *langue*, best translated in its technical Saussurean sense as language system, is meant the totality of regularities and patterns of formation that underlie the utterances of a language; by *parole*, which can be translated as language behaviour, is meant the actual utterances themselves. Just as two performances of a piece of music given by different orchestras on different occasions will differ in a variety of details and yet be identifiable as performances of the same piece, so two utterances may differ in various ways and yet be recognized as instances, in some sense, of the same utterance. What the two musical performances and the two utterances have in common is an identity of form, and this form, or structure, or pattern, is in principle independent of the substance, or "raw material," upon which it is imposed. "Structuralism," in the European sense then, refers to the view that there is an abstract relational structure that underlies and is to be distinguished from actual utterances—a system underlying actual behaviour—and that this is the primary object of study for the linguist.

European sense of structuralism

Two important points arise here: first, that the structural approach is not in principle restricted to synchronic linguistics; second, that the study of meaning, as well as the study of phonology and grammar, can be structural in orientation. In both cases "structuralism" is opposed to "atomism" in the European literature. It was Saussure who drew the terminological distinction between synchronic and diachronic linguistics in the *Cours*; despite the undoubtedly structural orientation of his own early work in the historical and comparative field, he maintained that, whereas synchronic linguistics should deal with the structure of a language system at a given point in time, diachronic linguistics should be concerned with the historical development of isolated elements—it should be atomistic. Whatever the reasons that led Saussure to take this rather paradoxical view, his teaching on this point was not generally accepted, and scholars soon began to apply structural concepts to the diachronic study of languages. The most important of the various schools of structural linguistics to be found in Europe in the first half of the 20th century have included the Prague school, most notably represented by Nikolay Sergeyevich Trubetskoy (died 1938) and Roman Jakobson (born 1896), both Russian émigrés, and the Copenhagen (or glossematic) school, centred around Louis Hjelmslev (died 1970). John Rupert Firth (died 1960) and his followers, sometimes referred to as the London school, were less Saussurean in their approach, but, in a general sense of the term, their approach may also be described appropriately as structural linguistics.

Structural linguistics in America. American and European structuralism shared a number of features. In insisting upon the necessity of treating each language as a more or less coherent and integrated system, both European and American linguists of this period tended to emphasize, if not to exaggerate, the structural uniqueness of individual languages. There was especially good reason to take this point of view given the conditions in which American linguistics developed from the end of the 19th century. There were hundreds of indigenous American Indian languages that had never been previously described. Many of these were spoken by only a handful of speakers and, if they were not recorded before they became extinct, would be permanently inaccessible. Under these circumstances, such linguists as Franz Boas (died 1942) were less concerned with the construction of a general theory of the structure of human language than they were with prescribing sound methodological principles for the analysis of unfamiliar languages. They were also fearful that the description of these languages would be distorted by analyzing them in terms of categories derived from the analysis of the more familiar Indo-European languages.

The work of Sapir, Bloomfield, and Whorf

After Boas, the two most influential American linguists were Edward Sapir (died 1939) and Leonard Bloomfield (died 1949). Like his teacher Boas, Sapir was equally at home in anthropology and linguistics, the alliance of which disciplines has endured to the present day in many American universities. Boas and Sapir were both attracted by the Humboldtian view of the relationship between language and thought, but it was left to one of Sapir's pupils, Benjamin Lee Whorf, to present it in a sufficiently challenging form to attract widespread scholarly attention. Since the republication of Whorf's more important papers in 1956, the thesis that language determines perception and thought has come to be known as the Whorfian hypothesis.

Sapir's work has always held an attraction for the more anthropologically inclined American linguists. But it was Bloomfield who prepared the way for the later phase of what is now thought of as the most distinctive manifestation of American "structuralism." When he published his first book in 1914, Bloomfield was strongly influenced by Wundt's psychology of language. In 1933, however, he published a drastically revised and expanded version with the new title Language; this book dominated the field for the next 30 years. In it Bloomfield explicitly adopted a behaviouristic approach to the study of language, eschewing in the name of scientific objectivity all reference to mental or conceptual categories. Of particular consequence was his adoption of the behaviouristic theory of semantics according to which meaning is simply the relationship between a stimulus and a verbal response. Because science was still a long way from being able to give a comprehensive account of most stimuli, no significant or interesting results could be expected from the study of meaning for some considerable time, and it was preferable, as far as possible, to avoid basing the grammatical analysis of a language on semantic considerations. Bloomfield's followers pushed even further the attempt to develop methods of linguistic analysis that were not based on meaning. One of the most characteristic features of "post-Bloomfieldian" American structuralism, then, was its almost complete neglect of semantics.

Another characteristic feature, one that was to be much criticized by Chomsky, was its attempt to formulate a set of "discovery procedures"—procedures that could be applied more or less mechanically to texts and could be guaranteed to yield an appropriate phonological and grammatical description of the language of the texts. Structuralism, in this narrower sense of the term, is represented, with differences of emphasis or detail, in the major American textbooks published during the 1950s.

More recent developments. The most significant development in linguistic theory and research in recent years was the rise of generative grammar, and, more especially, of transformational–generative grammar, or transformational grammar, as it came to be known. Two versions of transformational grammar were put forward in the mid-1950s, the first by Zellig S. Harris and the second by Noam Chomsky, his pupil. It is Chomsky's system that has attracted the most attention so far. As first presented by Chomsky in Syntactic Structures (1957), transformational grammar can be seen partly as a reaction against post-Bloomfieldian structuralism and partly as a continuation of it. What Chomsky reacted against most strongly was the post-Bloomfieldian concern with discovery procedures. In his opinion, linguistics should set itself the more modest and more realistic goal of formulating criteria for evaluating alternative descriptions of a language without regard to the question of how these descriptions had been arrived at. The statements made by linguists in describing a language should, however, be cast within the framework of a far more precise theory of grammar than had hitherto been the case, and this theory should be formalized in terms of modern mathematical notions. Within a few years, Chomsky had broken with the post-Bloomfieldians on a number of other points also. He had adopted what he called a "mentalistic" theory of language, by which term he implied that the linguist should be concerned with the speaker's creative linguistic competence and not his performance the actual utterances produced. He had challenged the post-Bloomfieldian concept of the phoneme (see below), which many scholars regarded as the most solid and enduring result of the previous generation's work. And he had challenged the structuralists' insistence upon the uniqueness of every language, claiming instead that all languages were, to a considerable degree, cut to the same pattern—they shared a certain number of formal and substantive universals.

The work of Harris and Chomsky

The effect of Chomsky's ideas has been phenomenal. It is hardly an exaggeration to say that there is no major theoretical issue in linguistics today that is debated in terms other than those in which he has chosen to define it, and every school of linguistics tends to define its position in relation to his. Among the rival schools are tagmemics, stratificational grammar, and the Prague school. Tagmemics is the system of linguistic analysis developed by the U.S. linguist Kenneth L. Pike and his associates in connection with their work as Bible translators. Its foundations were laid during the 1950s, when Pike differed from the post-Bloomfieldian structuralists on a number of principles, and it has been further elaborated since then. Tagmemic analysis has been used for analyzing a great many previously unrecorded languages, especially in Central and South America and in West Africa. Stratificational grammar, developed by a U.S. linguist, Sydney M. Lamb, has been seen by some linguists as an alternative to transformational grammar. Not yet fully expounded or widely exemplified in the analysis of different languages, stratificational grammar is perhaps best characterized as a radical modification of post-Bloomfieldian linguistics, but it has many features that link it with European structuralism. The Prague school has been mentioned above for its importance in the period immediately following the publication of Saussure's ***Cours.*** Many of its characteristic ideas (in particular, the notion of distinctive features in phonology) have been taken up by other schools. But there has been further development in Prague of the functional approach to syntax (see below). The work of M.A.K. Halliday in England derived much of its original inspiration from Firth (above), but Halliday provided a more systematic and comprehensive theory of the structure of language than Firth had, and it has been quite extensively illustrated.

Prague school

II. Methods of synchronic linguistic analysis

STRUCTURAL LINGUISTICS

This section is concerned mainly with a version of structuralism (which may also be called descriptive linguistics) developed by scholars working in a post-Bloomfieldian tradition.

Phonology. With the great progress made in phonetics in the late 19th century, it had become clear that the question whether two speech sounds were the same or not was more complex than might appear at first sight. Two utterances of what was taken to be the same word might differ quite perceptibly from one occasion of utterance to the next. Some of this variation could be attributed to a difference of dialect or accent and is of no concern here. But even two utterances of the same word by the same speaker might vary from one occasion to the next. Variation of this kind, though it is generally less obvious and would normally pass unnoticed, is often clear enough to the trained phonetician and is measurable instrumentally. It is known that the "same" word is being uttered, even if the physical signal produced is variable, in part, because the different pronunciations of the same word will cluster around some acoustically identifiable norm. But this is not the whole answer, because it is actually impossible to determine norms of pronunciation in purely acoustic terms. Once it has been decided what counts as "sameness" of sound from the linguistic point of view, the permissible range of variation for particular sounds in particular contexts can be measured, and, within certain limits, the acoustic cues for the identification of utterances as "the same" can be determined.

What is at issue is the difference between phonetic and phonological (or phonemic) identity, and for these purposes it will be sufficient to define phonetic identity in terms solely of acoustic "sameness." Absolute phonetic identity is a theoretical ideal never fully realized. From a purely phonetic point of view, sounds are more or less similar, rather than absolutely the same or absolutely different. Speech sounds considered as units of phonetic analysis in this article are called phones, and, following the normal convention, are represented by enclosing the appropriate alphabetic symbol in square brackets. Thus [p] will refer to a p sound (*i.e.,* what is described more technically as a voiceless, bilabial stop); and [pit] will refer to a complex of three phones—a p sound, followed by an *i* sound, followed by a *t* sound. A phonetic transcription may be relatively broad (omitting much of the acoustic detail) or relatively narrow (putting in rather more of the detail), according to the purpose for which it is intended. A very broad transcription will be used in this article except when finer phonetic differences must be shown.

Phones: speech sounds

Phonological, or phonemic, identity was referred to above as "sameness of sound from the linguistic point of view." Considered as phonological units—*i.e.*, from the point of view of their function in the language—sounds are described as phonemes and are distinguished from phones by enclosing their appropriate symbol (normally, but not necessarily, an alphabetic one) between two slash marks. Thus /p/ refers to a phoneme that may be realized on different occasions of utterance or in different contexts by a variety of more or less different phones. Phonological identity, unlike phonetic similarity, is absolute: two phonemes are either the same or different, they cannot be more or less similar. For example, the English words "bit" and "pit" differ phonemically in that the first has the phoneme /b/ and the second has the phoneme /p/ in initial position. As the words are normally pronounced, the phonetic realization of /b/ will differ from the phonetic realization of /p/ in a number of different ways: it will be at least partially voiced (*i.e.,* there will be some vibration of the vocal cords), it will be without aspiration (*i.e.*, there will be no accompanying slight puff of air, as there will be in the case of the phone realizing /p/), and it will be pronounced with less muscular tension. It is possible to vary any one or all of these contributory differences, making the phones in question more or less similar, and it is possible to reduce the phonetic differences to the point that the hearer cannot be certain which word, "bit" or "pit," has been uttered. But it must be either one or the other; there is no word with an initial sound formed in the same manner as /p/ or /b/ that is halfway between the two. This is what is meant by saying that phonemes are absolutely distinct from one another —they are discrete rather than continuously variable.

Classifying phones or phonemes

How it is known whether two phones realize the same phoneme or not is dealt with differently by different schools of linguists. The "orthodox" post-Bloomfieldian school regards the first criterion to be phonetic similarity. Two phones are not said to realize the same phoneme unless they are sufficiently similar. What is meant by "sufficiently similar" is rather vague, but it must be granted that for every phoneme there is a permissible range of variation in the phones that realize it. As far as occurrence in the same context goes, there are no serious problems. More critical is the question of whether two phones occurring in different contexts can be said to realize the same phoneme or not. To take a standard example from English: the phone that occurs at the beginning of the word "pit" differs from the phone that occurs after the initial /s/ of "spit." The "*p* sound" occurring after the /s/ is unaspirated (*i.e.*, it is pronounced without any accompanying slight puff of air). The aspirated and unaspirated "*p* sounds" may be symbolized rather more narrowly as [pʰ] and [p] respectively. The question then is whether [pʰ] and [p] realize the same phoneme /p/ or whether each realizes a different phoneme. They satisfy the criterion of phonetic similarity, but this, though a necessary condition of phonemic identity, is not a sufficient one.

The next question is whether there is any pair of words in which the two phones are in minimal contrast (or opposition); that is, whether there is any context in English in which the occurrence of the one rather than the other has the effect of distinguishing two or more words (in the way that [pʰ] versus [b] distinguishes the so-called minimal pairs "pit" and "bit," "pan" and "ban," and so on). If there is, it can be said that, despite their phonetic similarity, the two phones realize (or "belong to") different phonemes—that the difference between them is phonemic. If there is no context in which the two phones are in contrast (or opposition) in this sense, it can be said that they are variants of the same phoneme—that the difference between them is nonphonemic. Thus, the difference between [pʰ] and [p] in English is nonphonemic; the two sounds realize, or belong to, the same phoneme, namely /p/. In several other languages—e.g., Hindi—the contrast between such sounds as [pʰ] and [p] is phonemic, however. The question is rather more complicated than it has been represented here. In particular. it should be noted that [p] is phonetically similar to [b] as well as to [pʰ] and that, although [pʰ] and [b] are in contrast, [p] and [b] are not. It would thus be possible to regard [p] and [b] as variants of the same phoneme. Most linguists, however, have taken the alternative view, assigning [p] to the same phoneme as [pʰ]. Here it will suffice to note that the criteria of phonetic similarity and lack of contrast do not always uniquely determine the assignment of phones to phonemes. Various supplementary criteria may then be invoked.

Free variation and complementary distribution

Phones that can occur and do not contrast in the same contest are said to be in free variation in that context, and, as has been shown, there is a permissible range of variation for the phonetic realization of all phonemes. More important than free variation in the same context, however? is systematically determined variation according to the contest in which a given phoneme occurs. To return to the example used above: [p] and [pʰ], though they do not contrast, are not in free variation either. Each of them has its own characteristic positions of occurrence, and neither occurs, in normal English pronunciation, in any context characteristic for the other (e.g., only [pʰ] occurs at the beginning of a word, and only [p] occurs after s). This is expressed by saying that they are in complementary distribution. (The distribution of an element is the whole range of contexts in which it can occur.) Granted that [p] and [pʰ] are variants of the same phoneme /p/, it can be said that they are contextually, or positionally, determined variants of it. To use the technical term, they are allophones of /p/. The allophones of a phoneme, then, are its contextually determined variants and they are in complementary distribution.

The post-Bloomfieldians made the assignment of phones to phonemes subject to what is now generally referred to as the principle of bi-uniqueness. The phonemic specification of a word or utterance was held to determine uniquely its phonetic realization (except for free variation), and, conversely, the phonetic description of a word or utterance was held to determine uniquely its phonemic analysis. Thus, if two words or utterances are pronounced alike, then they must receive the same phonemic description; conversely, two words or utterances that have been given the same phonemic analysis must be pronounced alike. The principle of bi-uniqueness was also held to imply that, if a given phone was assigned to a particular phoneme in one position of occurrence, then it must be assigned to the same phoneme in all its other positions of occurrence; it could not be the allophone of one phoneme in one context and of another phoneme in other contexts.

A second important principle of the post-Bloomfieldian approach was its insistence that phonemic analysis should be carried out prior to and independently of grammatical analysis. Neither this principle nor that of bi-uniqueness was at all widely accepted outside the post-Bloomfieldian school, and they have been abandoned by the generative phonologists (see below).

Phonemes of the kind referred to so far are segmental; they are realized by consonantal or vocalic (vowel) segments of words, and they can be said to occur in a certain order relative to one another. For example, in the phonemic representation of the word "bit," the phoneme /b/ precedes /i/, which precedes /t/. But nonsegmental, or suprasegmental, aspects of the phonemic realization of words and utterances may also be functional in a language. In English, for example, the noun "import" differs from the verb "import" in that the former is accented on the first and the latter on the second syllable. This is called a stress accent: the accented syllable is pronounced with greater force or intensity. Many other languages distinguish words suprasegmentally by tone. For example, in Mandarin Chinese the words **haò** "day" and **haǒ** "good" are distinguished from one another in that the first has a falling tone and the second a falling–rising tone: these are realized, respectively, as (1) a fall in the pitch of the syllable from high to low and (2) a change in the pitch of the syllable from medium to low and back to medium. Stress and tone are suprasegmental in the sense that they are "superimposed" upon the sequence of segmental phonemes. The term tone is conventionally restricted by linguists to phonologically relevant variations of pitch at the level of words. Intonation, which is found in all languages, is the variation in the pitch contour or pitch pattern of whole utterances, of the kind that distinguishes (either of itself or in combination with some other difference) statements from questions or indicates the mood or attitude of the speaker (as hesitant, surprised, angry, and so forth). Stress, tone, and intonation do not exhaust the phonologically relevant suprasegmental features found in various languages, but they are among the most important.

Suprasegmental phonemes

A complete phonological description of a language includes all the segmental phonemes and specifies which allophones occur in which contexts. It also indicates which sequences of phonemes are possible in the language and which are not: it will indicate, for example, that the sequences /bl/ and /br/ are possible at the beginning of English words but not /bn/ or /bm/. A phonological description also identifies and states the distribution of the suprasegmental features. Just how this is to be done, however, has been rather more controversial in the post-Bloomfieldian tradition. Differences between the post-Bloomfieldian approach to phonology and approaches characteristic of other schools of structural linguistics will be treated below.

Morphology. The grammatical description of many, if not all, languages is conveniently divided into two complementary sections: morphology and syntax. The relationship between them, as generally stated, is as follows: morphology accounts for the internal structure of words, and syntax describes how words are combined to form phrases, clauses, and sentences.

Distinction between morphology and syntax

There are many words in English that are fairly obviously analyzable into smaller grammatical units. For example, the word "unacceptability" can be divided into un-, accept, abil-, and -ity (abil- being a variant of -able). Of these, at least three are minimal grammatical units, in the sense that they cannot be analyzed into yet smaller grammatical units—un-, abil-, and -ity. The status of accept, from this point of view, is somewhat uncertain. Given the existence of such forms as accede and accuse, on the one hand, and of except, excede, and excuse, on the other, one might be inclined to analyze accept into ac- (which might subsequently be recognized as a variant of ad-) and -cept. The question is left open. Minimal grammatical units like urt-, abil-, and -ity are what Bloomfield called morphemes; he defined them in terms of the "partial phonetic-semantic resemblance" holding within sets of words. For example, "unacceptable," "untrue," and "ungracious" are phonetically (or, phonologically) similar as far as the first syllable is concerned and are similar in meaning in that each of them is negative by contrast with a corresponding positive adjective ("acceptable," "true," "gracious"). This "partial phonetic-semantic resemblance" is accounted for by noting that the words in question contain the same morpheme (namely, un-) and that this morpheme has a certain phonological form and a certain meaning.

Bloomfield's definition of the morpheme in terms of "partial phonetic-semantic resemblance" was considerably modified and, eventually, abandoned entirely by some of his followers. Whereas Bloomfield took the morpheme to be an actual segment of a word, others defined it as being a purely abstract unit, and the term morph was introduced to refer to the actual word segments. The distinction between morpheme and morph (which is, in certain respects, parallel to the distinction between phoneme and phone) may be explained by means of an

Plural morphs in English

example. If a morpheme in English is posited with the function of accounting for the grammatical difference between singular and plural nouns, it may be symbolized by enclosing the term plural within brace brackets. Now the morpheme (plural) is represented in a number of different ways. Most plural nouns in English differ from the corresponding singular forms in that they have an additional final segment. In the written forms of these words, it is either -*s* or -es (*e.g.*, "cat" : "cats"; "dog" : "dogs"; "fish" : "fishes"). The word segments written -*s* or -es are morphs. So also is the word segment written -en in "oxen." All these morphs represent the same morpheme. But there are other plural nouns in English that differ from the corresponding singular forms in other ways (*e.g.*, "mouse" : "mice"; "criterion" : "criteria"; and so on) or not at all (*e.g.*, "this sheep" : "these sheep"). Within the post-Bloomfieldian framework no very satisfactory account of the formation of these nouns could be given. But it was clear that they contained (in some sense) the same morpheme as the more regular plurals.

Morphs that are in complementary distribution and represent the same morpheme are said to be allomorphs of that morpheme. For example, the regular plurals of English nouns are formed by adding one of three morphs on to the form of the singular: /s/, /z/, or /iz/ (in the corresponding written forms both /s/ and /z/ are written -*s* and /iz/ is written -*es*). Their distribution is determined by the following principle: if the morph to which they are to be added ends in a "sibilant" sound (*e.g.*, *s, z, sh, ch*), then the syllabic allomorph /iz/ is selected (*e.g.*, fish-es /fiš-iz/, *match-es* /mač-iz/); otherwise the nonsyllabic allomorphs are selected, the voiceless allomorph /s/ with morphs ending in a voiceless consonant (*e.g.*, cat-s /kat-s/) and the voiced allomorph /z/ with morphs ending in a vowel or voiced consonant (*e.g.*, flea-s /fli-z/, *dog-s* /dog-z/). These three allomorphs, it will be evident, are in complementary distribution, and the alternation between them is determined by the phonological structure of the preceding morph. Thus the choice is phonologically conditioned.

Past participle morphs in English

Very similar is the alternation between the three principal allomorphs of the past participle ending. /id/, /t/, and /d/, all of which correspond to the -*ed* of the written forms. If the preceding morph ends with /t/ or /d/, then the syllabic allomorph /id/ is selected (*e.g.*, wail-ed /weit-id/). Otherwise, if the preceding morph ends with a voiceless consonant, one of the nonsyllabic allomorphs is selected—the voiceless allomorph /t/ when the preceding morph ends with a voiceless consonant (*e.g., pack-ed* /pak-t/) and the voiced allomorph /d/ when the preceding morph ends with a vowel or voiced consonant (*e.g.,* row-ed /rou-d/; tarne-d /teim-d/). This is another instance of phonological conditioning. Phonological conditioning may be contrasted with the principle that determines the selection of yet another allomorph of the past participle morpheme. The final /n/ of show-n or *see-n* (which marks them as past participles) is not determined by the phonological structure of the morphs *show* and see. For each English word that is similar to "show" and "see" in this respect, it must be stated as a synchronically inexplicable fact that it selects the /n/ allomorph. This is called grammatical conditioning. There are various kinds of grammatical conditioning.

Alternation of the kind illustrated above for the allomorphs of the plural morpheme and the /id/, /d/, and /t/ allomorphs of the past participle is frequently referred to as morphophonemic. Some linguists have suggested that it should be accounted for not by setting up three allomorphs each with a distinct phonemic form but by setting up a single morph in an intermediate morphophonemic representation. Thus, the regular plural morph might be said to be composed of the morphophoneme /Z/ and the most common past-participle morph of the morphophoneme /D/. General rules of morphophonemic interpretation would then convert /Z/ and /D/ to their appropriate phonetic form according to context. This treatment of the question foreshadows, on the one hand, the stratificational treatment and, on the other, the generative approach, though they differ considerably in other respects.

An important concept in grammar and, more particularly, in morphology is that of free and bound forms. A bound form is one that cannot occur alone as a complete utterance (in some normal context of use). For example, -*ing* is bound in this sense, whereas wait is not, nor is waiting. Any form that is not bound is free. Bloomfield based his definition of the word on this distinction between bound and free forms. Any free form consisting entirely of two or more smaller free forms was said to be a phrase (*e.g.*, "poor John" or "ran away"), and phrases were to be handled within syntax. Any free form that was not a phrase was defined to be a word and to fall within the scope of morphology. One of the consequences of Bloomfield's definition of the word was that morphology became the study of constructions involving bound forms. The so-called isolating languages, which make no use of bound forms (*e.g.*, Vietnamese), would have no morphology.

Inflection and derivation

The principal division within morphology is between inflection and derivation (or word formation). Roughly speaking, inflectional constructions can be defined as yielding sets of forms that are all grammatically distinct forms of single vocabulary items, whereas derivational constructions yield distinct vocabulary items. For example, "sings," "singing," "sang," and "sung" are all inflectional forms of the vocabulary item traditionally referred to as "the verb to sing"; but "singer," which is formed from "sing" by the addition of the morph -er (just as "singing" is formed by the addition of -*ing*), is one of the forms of a different vocabulary item. When this rough distinction between derivation and inflection is made more precise, problems occur. The principal consideration, undoubtedly, is that inflection is more closely integrated with and determined by syntax. But the various formal criteria that have been proposed to give effect to this general principle are not uncommonly in conflict in particular instances, and it probably must be admitted that the distinction between derivation and inflection, though clear enough in most cases, is in the last resort somewhat arbitrary.

Bloomfield and most linguists have discussed morphological constructions in terms of processes. Of these, the most widespread throughout the languages of the world is affixation; *i.e.*, the attachment of an affix to a base. For example, the word "singing" can be described as resulting from the affixation of -*ing* to the base sing. (If the affix is put in front of the base, it is a prefix; if it is put after the base, it is a suffix; and if it is inserted within the base, splitting it into two discontinuous parts, it is an infix.) Other morphological processes recognized by linguists need not be mentioned here, but reference may be made to the fact that many of Bloomfield's followers from the mid-1940s were dissatisfied with the whole notion of morphological processes. Instead of saying that -*ing* was affixed to *sing* they preferred to say that sing and -*ing* co-occurred in a particular pattern or arrangement, thereby avoiding the implication that *sing* is in some sense prior to or more basic than -*ing*. The distinction of morpheme and morph (and the notion of allomorphs) was developed in order to make possible the description of the morphology and syntax of a language in terms of "arrangements" of items rather than in terms of "processes" operating upon more basic items. Nowadays, the opposition to "processes" is, except among the stratificationalists, almost extinct. It has proved to be cumbersome if not impossible to describe the relationship between certain linguistic forms without deriving one from the other or both from some common underlying form, and most linguists no longer feel that this is in any way reprehensible.

Bloomfield's theory of syntax

Syntax. Syntax, for Bloomfield, was the study of free forms that were composed entirely of free forms. Central to his theory of syntax were the notions of form classes and constituent structure. (These notions were also relevant though less central in the theory of morphology.) Bloomfield defined form classes, rather imprecisely, in terms of some common "recognizable phonetic or grammatical feature" shared by all the members. He gave as examples the form class consisting of "personal substantive expressions" in English (defined as "the forms that, when spoken with exclamatory final pitch, are calls for a person's presence or attention"; *e.g.*, "John," "Boy," "Mr. Smith"); the form class consisting of "infinitive expressions" (defined as "forms which. when spoken with exclamatory final pitch, have the meaning of a command"; *e.g.*, "run," "jump," "come here"); the form class of "nominative substantive expressions" (*e.g.*, "John," "the boys"); and so on. It should be clear from these examples that form classes are similar to though not identical with the traditional parts of speech, and that one and the same form can belong to more than one form class.

What Bloomfield had in mind as the criterion for form class membership (and therefore of syntactic equivalence) may best be expressed in terms of substitutability. Form classes are sets of forms (whether simple or complex, free or bound) any one of which may be substituted for any other in a given construction or set of constructions throughout the sentences of the language.

Constituents and immediate constituents

The smaller forms into which a larger form may be analyzed are its constituents, and the larger form is a construction. For example, the phrase "poor John" is a construction analyzable into, or composed of, the constituents "poor" and "John." Because there is no intermediate unit of which "poor" and "John" are constituents that is itself a constituent of the construction "poor John," the forms "poor" and "John" may be described not only as constituents but also as immediate constituents of "poor John." Similarly, the phrase "lost his watch" is composed of three word forms, "lost," "his," and "watch," all of which may be described as constituents of the construction. Not all of them, however, are its immediate constituents. The forms “his” and "watch combine to make the intermediate construction "his watch"; it is this intermediate unit that combines with "lost" to form the larger phrase "lost his watch." The immediate constituents of "lost his watch" are "lost" and "his watch; the immediate constituents of "his watch" are the forms "his" and "watch." By the constituent structure of a phrase or sentence is meant the hierarchical organization of the smallest forms of which it is composed (its ultimate constituents) into layers of successively more inclusive units. Viewed in this way, the sentence "Poor John lost his watch" is more than simply a sequence of five word forms associated with a particular intonation pattern. It is analyzable into the immediate constituents "poor John" and "lost his watch," and each of these phrases is analyzable into its own immediate constituents and so on, until, at the last stage of the analysis, the ultimate constituents of the sentence are reached. The constituent structure of the whole sentence is represented by means of a tree diagram in Figure 1.

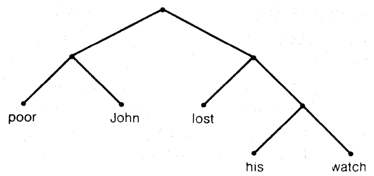

Figure 1: The constituent structure of a simple sentence (see text).

Each form, whether it is simple or composite, belongs to a certain form class. Using arbitrarily selected letters to denote the form classes of English, "poor" may be a member of the form class *A*, "John" of the class B, "lost" of the class *C*, "his" of the class *D*, and "watch" of the class E. Because "poor John" is syntactically equivalent to (*i.e.*, substitutable for) "John," it is to be classified as a member of A. So too, it can be assumed, is "his watch." In the case of "lost his watch" there is a problem. There are very many forms—including "lost," "ate," "stole"—that can occur, as here, in construction with a member of A and can also occur alone; for example, "lost" is substitutable for “stole the money," as "stole" is substitutable for either or for “lost his watch." This being so, one might decide to classify constructions like "lost his watch" as members of C. On the other hand, there are forms that—though they are substitutable for "lost," "ate," "stole," and so on when these forms occur alone—cannot be used in combination with a following member of A (cf. "died," "existed"): and there are forms that, though they may be used in combination with a following member of A, cannot occur alone (*cf.* "enjoyed"). The question is whether one respects the traditional distinction between transitive and intransitive verb forms. It may be decided, then, that "lost," "stole," "ate" and so forth belong to one class, *C* (the class to which "enjoyed" belongs), when they occur "transitively" (*i.e.*, with a following member of A as their object) but to a different class, *F* (the class to which "died" belongs), when they occur "intransitively." Finally, it can be said that the whole sentence “Poor John lost his watch" is a member of the form class *G*. Thus the constituent structure not only of "Poor John lost his watch" but of a whole set of English sentences can be represented by means of the tree diagram given in Figure 2. New sentences of the same type can be constructed by substituting actual forms for the class labels.

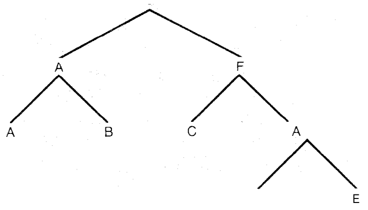

Figure 2: The constituent structure of a class of simple sentences with arbitrary letters used to represent the form class of each constituent (see text).

Endocentric and exocentric constructions

Any construction that belongs to the same form class as at least one of its immediate constituents is described as endocentric; the only endocentric construction in the model sentence above is "poor John." All the other constructions, according to the analysis, are exocentric. This is clear from the fact that in Figure 2 the letters at the nodes above every phrase other than the phrase A + B (*i.e.*, "poor John," "old Harry," and so on) are different from any of the letters at the ends of the lower branches connected directly to these nodes. For example, the phrase D + E (*i.e.*, "his watch," “the money," and so forth) has immediately above it a node labelled A, rather than either *D* or E. Endocentric constructions fall into two types: subordinating and coordinating. If attention is confined, for simplicity,-to constructions composed of no more than two immediate constituents. it can be said that subordinating constructions are those in which only one immediate constituent is of the same form class as the whole construction, whereas coordinating constructions are those in which both constituents are of the same form class as the whole construction. In a subordinating construction (*e.g.*, "poor John"), the constituent that is syntactically equivalent to the whole construction is described as the head, and its partner is described as the modifier: thus, in "poor John," the form "John" is the head, and "poor" is its modifier. An example of a coordinating construction is "men and women," in which, it may be assumed, the immediate constituents are the word “men” and the word "women," each of which is syntactically equivalent to "men and women." (It is here implied that the conjunction "and" is not a constituent, properly so called, but an element that, like the relative order of the constituents, indicates the nature of the construction involved. Not all linguists have held this view.)

Ambiguous constructions

One reason for giving theoretical recognition to the notion of constituent structure is that it helps to account for the ambiguity of certain constructions. A classic example is the phrase "old men and women," which may be interpreted in two different ways according to whether one associates "old" with "men and women" or just with "men." Under the first of the two interpretations, the immediate constituents are "old and "men and women"; under the second, they are "old men" and “women.” The difference in meaning cannot be attributed to any one of the ultimate constituents but results from a difference in the way in which they are associated with one another. Ambiguity of this kind is referred to as syntactic ambiguity. Not all syntactic ambiguity is satisfactorily accounted for in terms of constituent structure.

Semantics. Bloomfield thought that semantics, or the study of meaning, was the weak point in the scientific investigation of language and would necessarily remain so until the other sciences whose task it was to describe the universe and man's place in it had advanced beyond their present state. In his textbook *Language* (1933), he had himself adopted a behaviouristic theory of meaning, defining the meaning of a linguistic form as "the situation in which the speaker utters it and the response which it calls forth in the hearer." Furthermore, he subscribed, in principle at least, to a physicalist thesis, according to which all science should be modelled upon the so-called exact sciences and all scientific knowledge should be reducible, ultimately, to statements made about the properties of the physical world. The reason for his pessimism concerning the prospects for the study of meaning was his feeling that it would be a long time before a complete scientific description of the situations in which utterances were produced and the responses they called forth in their hearers would be available. At the time that Bloomfield was writing, physicalism was more widely held than it is today, and it was perhaps reasonable for him to believe that linguistics should eschew mentalism and concentrate upon the directly observable. As a result, for some 30 years after the publication of Bloomfield's textbook, the study of meaning was almost wholly neglected by his followers; most American linguists who received their training during this period had no knowledge of, still less any interest in, the work being done elsewhere in semantics.

Result of Bloomfield's physicalist tendencies

Two groups of scholars may be seen to have constituted an exception to this generalization: anthropologically minded linguists and linguists concerned with Bible translation. Much of the description of the indigenous languages of America has been carried out since the days of Boas and his most notable pupil Sapir by scholars who were equally proficient both in anthropology and in descriptive linguistics; such scholars have frequently added to their grammatical analyses of languages some discussion of the meaning of the grammatical categories and of the correlations between the structure of the vocabularies and the cultures in which the languages operated. It has already been pointed out that Boas and Sapir and, following them, Whorf were attracted by Humboldt's view of the interdependence of language and culture and of language and thought. This view was quite widely held by American anthropological linguists (athough many of them would not go as far as Whorf in asserting the dependence of thought and conceptualization upon language).

Also of considerable importance in the description of the indigenous languages of America has been the work of linguists trained by the American Bible Society and the Summer Institute of Linguistics, a group of Protestant missionary linguists. Because their principal aim is to produce translations of the Bible, they have necessarily been concerned with meaning as well as with grammar and phonology. This has tempered the otherwise fairly orthodox Bloomfieldian approach characteristic of the group.

The two most important developments evident in recent work in semantics are, first, the application of the structural approach to the study of meaning and, second, a better appreciation of the relationship between grammar and semantics. The second of these developments will be treated in the following section on *Transformational–Generative Grammar*. The first, structural semantics, goes back to the period preceding World War II and is exemplified in a large number of publications, mainly by German scholars—Jost Trier, Leo Weisgerber, and their collaborators.

The structural approach to semantics is best explained by contrasting it with the more traditional "atomistic" approach, according to which the meaning of each word in the language is described, in principle, independently of the meaning of all other words. The structuralist takes the view that the meaning of a word is a function of the relationships it contracts with other words in a particular lexical field, or subsystem, and that it cannot be adequately described except in terms of these relationships. For example, the colour terms in particular languages constitute a lexical field, and the meaning of each term depends upon the place it occupies in the field. Although the denotation of each of the words "green," "blue," and "yellow" in English is somewhat imprecise at the boundaries, the position that each of them occupies relative to the other terms in the system is fixed: "green" is between "blue" and "yellow," so that the phrases "greenish yellow" or "yellowish green" and "bluish green" or "greenish blue" are used to refer to the boundary areas. Knowing the meaning of the word "green" implies knowing what cannot as well as what can be properly described as green (and knowing of the borderline cases that they are borderline cases). Languages differ considerably as to the number of basic colour terms that they recognize, and they draw boundaries within the psychophysical continuum of colour at different places. Blue, green, yellow, and so on do not exist as distinct colours in nature, waiting to be labelled differently, as it were, by different languages; they come into existence, for the speakers of particular languages, by virtue of the fact that those languages impose structure upon the continuum of colour and assign to three of the areas thus recognized the words "blue," "green," "yellow."

Colour terms in different languages

The language of any society is an integral part of the culture of that society, and the meanings recognized within the vocabulary of the language are learned by the child as part of the procers of acquiring the culture of the society in which he is brought up. Many of the structural differences found in the vocabularies of different languages are to be accounted for in terms of cultural differences. This is especially clear in the vocabulary of kinship (to which a considerable amount of attention has been given by anthropologists and linguists), but it holds true of many other semantic fields also. A consequence of the structural differences that exist between the vocabularies of different languages is that, in many instances, it is in principle impossible to translate a sentence "literally" from one language to another.

It is important, nevertheless, not to overemphasize the semantic incommensurability of languages. Presumably, there are many physiological and psychological constraints that, in part at least, determine one's perception and categorization of the world. It may be assumed that, when one is learning the denotation of the more basic words in the vocabulary of one's native language, attention is drawn first to what might be called the naturally salient features of the environment and that one is, to this degree at least, predisposed to identify and group objects in one way rather than another. It may also be that human beings are genetically endowed with rather more specific and linguistically relevant principles of categorization. It is possible that, although languages differ in the number of basic colour categories that they distinguish, there is a limited number of hierarchically ordered basic colour categories from which each language makes its selection and that what counts as a typical instance, or focus, of these universal colour categories is fixed and does not vary from one language to another. If this hypothesis is correct, then it is false to say, as many structural semanticists have said, that languages divide the continuum of colour in a quite arbitrary manner. But the general thesis of structuralism is unaffected, for it still remains true that each language has its own unique semantic structure even though the total structure is, in each case, built upon a substructure of universal distinctions.

TRANSFORMATIONAL–GENERATIVE GRAMMAR

A generative grammar, in the sense in which Noam Chomsky uses the term generative, is a rules system formalized with mathematical precision that generates, with-

Generation of grammatical sentences

out drawing upon any information that is not represented explicitly in the system, the grammatical sentences of the language that it describes, or characterizes, and assigns to each sentence a structural description, or grammatical analysis. All the concepts introduced in this definition of "generative" grammar will be explained and exemplified in the course of this section. Generative grammars fall into several types; this exposition is concerned mainly with the type known as transformational (or, more fully, transformational–generative). Transformational grammar was initiated by Zellig S. Harris in the course of work on what he called discourse analysis (the formal analysis of the structure of continuous text). It was further developed and given a somewhat different theoretical basis by Chomsky.

Harris's grammar. Harris distinguished within the total set of grammatical sentences in a particular language (for example, English) two complementary subsets: kernel sentences (the set of kernel sentences being described as the kernel of the grammar) and nonkernel sentences. The difference between these two subsets lies in nonkernel sentences being derived from kernel sentences by means of transformational rules. For example, "The workers rejected the ultimatum" is a kernel sentence that may be transformed into the nonkernel sentences "The ultimatum was rejected by the workers" or "Did the workers reject the ultimatum?" Each of these may be described as a transform of the kernel sentence from which it is derived. The transformational relationship between corresponding active and passive sentences (*e.g.*, "The workers rejected the ultimatum" and "The ultimatum was rejected by the workers") is conventionally symbolized by the rule $N_1V\ N_2 \rightarrow N_2$ be V+en by N_1, in which N stands for any noun or noun phrase, V for any transitive verb, en for the past participle morpheme, and the arrow (→) instructs one to rewrite the construction to its left as the construction to the right. (There has been some simplification of the rule as it was formulated by Harris.) This rule may be taken as typical of the whole class of transformational rules in Harris's system: it rearranges constituents (what was the first nominal, or noun, N,, in the kernel sentence is moved to the end of the transform, and what was the second nominal, N_2, in the kernel sentence is moved to initial position in the transform), and it adds various elements in specified positions (be, en, and by). Other operations carried out by transformational rules include the deletion of constituents; *e.g.*, the entire phrase "by the workers" is removed from the sentence "The ultimatum was rejected by the workers" by a rule symbolized as N_2 be V+en by $N_1 \rightarrow N_2$ be V+en. This transforms the construction on the left side of the arrow (which resulted from the passive transformation) by dropping the by-phrase, thus producing "The ultimatum was rejected."

Functions of Harris's rules

Chomsky's grammar. Chomsky's system of transformational grammar, though it was developed on the basis of his work with Harris, differs from Harris' in a number of respects. It is Chomsky's system that has attracted the most attention and has received the most extensive exemplification and further development. As outlined in ***Syntactic Structures*** (1957), it comprised three sections, or components: the phrase-structure component, the transformational component, and the morphophonemic component. Each of these components consisted of a set of rules operating upon a certain "input" to yield a certain "output." The notion of phrase structure may be dealt with independently of its incorporation in the larger system. In the following system of rules, S stands for Sentence, NP for Noun Phrase, VP for Verb Phrase, Det for Determiner, Aux for Auxiliary (verb), N for Noun, and V for Verb stem.

(1) S → NP + VP
(2) VP → Verb + NP
(3) NP → Det + N
(4) Verb → Aux + V
(5) Det → *the, a, . . .*
(6) N → *man, ball, . . .*
(7) Aux → *will, can, . . .*
(8) V → *hit, see, . . .*

This is a simple phrase-structure grammar. It generates and thereby defines as grammatical such sentences as "The man will hit the ball," and it assigns to each sentence that it generates a structural description. The kind of structural description assigned by a phrase-structure grammar is, in fact, a constituent structure analysis of the sentence.

In these rules, the arrow can he interpreted as an instruction to rewrite (this is to be taken as a technical term) whatever symbol appears to the left of the arrow as the symbol or string of symbols that appears to the right of the arrow. For example, rule (2) rewrites the symbol VP as the string of symbols Verb + NP, and it thereby defines Verb + NP to be a construction of the type VP. Or, alternatively and equivalently, it says that constructions of the type VP may have as their immediate constituents constructions of the type Verb and NP (combined in that order). Rule (2) can be thought of as creating or being associated with the tree structure in Figure 3.

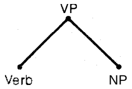

Figure 3: The constituent structure, or phrase structure, assigned by the rule VP→Verb + NP (see text).

Integrated system of rules

Rules (1)–(8) do not operate in isolation but constitute an integrated system. The symbol S (standing mnemonically for "sentence") is designated as the initial symbol. This information is not given in the rules (1)–(8), but it can be assumed either that it is given in a kind of protocol statement preceding the grammatical rules or that there is a universal convention according to which S is always the initial symbol. It is necessary to begin with a rule that has the initial symbol on the left. Thereafter any rule may he applied in any order until no further rule is applicable; in doing so, a derivation can be constructed of one of the sentences generated by the grammar. If the rules are applied in the following order: (1), (2), (3), (3), (4), (5), (5), (6), (6), (7), (8), then assuming that "the" is selected on both applications of (5), "man" on one application of (6), and "ball" on the other, "will" on the application of (7), and "hit" on the application of (8), the following derivation of the sentence "The man will hit the ball" will have been constructed:

(i)	*S*	
(ii)	NP + VP	by rule (1)
(iii)	NP + Verb + NP	by rule (2)
(iv)	Det + N + Verb + NP	by rule (3)
(v)	Det + N + Verb + Det + N	by rule (3)
(vi)	Det + N + Aux + V + Det + N	by rule (4)
(vii)	*the* + N + Aux + V + Det + N	by rule (5)
(viii)	*the* + N + Aux + V + *the* + *N*	by rule (5)
(ix)	*the* + *man* + Aux + V + *the* + N	by rule (6)
(x)	*the* + *man* + Aux + V + *the* + *ball*	by rule (6)
(xi)	*the* + *man* + *will* + V + *the* + *ball*	by rule (7)
(xii)	*the* + *man* + *will* + *hit* + *the* + *ball*	by rule (8)

Many other derivations of this sentence are possible, depending on the order in which the rules are applied. The important point is that all these different derivations are equivalent in that they can be reduced to the same tree diagram; namely, the one shown in Figure 4. If this is compared with the system of rules, it will be seen that each application of each rule creates or is associated with a portion (or subtree) of the tree. The tree diagram, or

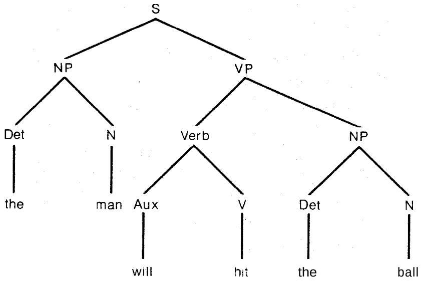

Figure 4: Structural description of the sentence "The man will hit the ball," assigned by the rules of a simple phrase-structure grammar (see text).

phrase marker, may now be considered as a structural description of the sentence "The man hit the ball." It is a description of the constituent structure, or phrase structure, of the sentence, and it is assigned by the rules that generate the sentence.

It is important to interpret the term generate in a static, rather than a dynamic, sense. The statement that the grammar generates a particular sentence means that the sentence is one of the totality of sentences that the grammar defines to be grammatical or well formed. All the sentences are generated, as it were, simultaneously. The notion of generation must be interpreted as would be a mathematical formula containing variables. For example, in evaluating the formula $y^2 + y$ for different values of y, one does not say that the formula itself generates these various resultant values (2, when $y = 1$; 5, when $y = 2$; etc.) one after another or at different times; one says that the formula generates them all simultaneously or, better still perhaps, timelessly. The situation is similar for a generative grammar. Although one sentence rather than another can be derived on some particular occasion by making one choice rather than another at particular places in the grammar, the grammar must be thought of as generating all sentences statically or timelessly.

Phrase-structure and transformational rules

It has been noted that, whereas a phrase-structure grammar is one that consists entirely of phrase-structure rules, a transformational grammar (as formalized by Chomsky) includes both phrase-structure and transformational rules (as well as morphophonemic rules). The transformational rules depend upon the prior application of the phrase-structure rules and have the effect of converting, or transforming, one phrase marker into another. What is meant by this statement may be clarified first with reference to a purely abstract and very simple transformational grammar, in which the letters stand for constituents of a sentence (and S stands for "sentence"):

PS rules
(1) $S \rightarrow A + B$
(2) $B \rightarrow C + D$
(3) $A \rightarrow a + b$
(4) $C \rightarrow c + e + f$
(5) $D \rightarrow d + g + h$
T rules
(6) $A + C + D \rightarrow D + A$

The first five rules are phrase-structure rules (PS rules); rule (6) is a transformational rule (T rule). The output of rules (1)–(5) is the terminal string $a + b + c + e + f + d + g + h$, which has associated with it the structural description indicated by the phrase marker shown in Figure 5 (left). Rule (6) applies to this terminal string of the PS rules and the associated phrase marker. It has the effect of deleting C (and the constituents of C) and permuting A and D (together with their constituents). The result is the string of symbols $d + g + h + a + b$, with the associated phrase marker shown in Figure 5 (right).

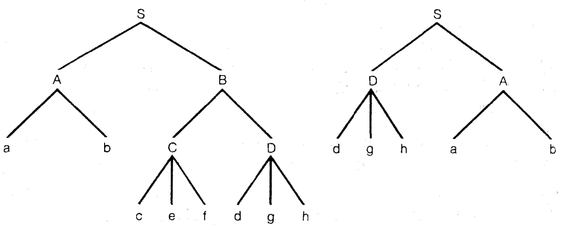

Figure 5: Phrase markers.
(Left) A phrase marker associated with the terminal string of a set of phrase-structure rules. (Right) The phrase marker resulting from the application to the phrase marker shown at left of the transformational rule $A + C + D \rightarrow D + A$ (see text).

The phrase marker shown in Figure 5 (left) may be described as underlying, and the phrase marker shown in Figure 5 (right) as derived with respect to rule (6). One of the principal characteristics of a transformational rule is its transformation of an underlying phrase marker into a derived phrase marker in this way. Transformational rules, in contrast with phrase-structure rules, are also formally more heterogeneous and may have more than one symbol on the left-hand side of the arrow. The linguistic importance of these abstract considerations may be explained with reference to the relationship that holds in English between active and passive sentences.

Chomsky's rule for relating active and passive sentences (as given in ***Syntactic Structures***) is very similar, at first sight, to Harris', discussed above. Chomsky's rule is:

$$\mathrm{NP,} - \mathbf{Aux} - \mathrm{V} - \mathbf{NP_2} \rightarrow \mathbf{NP_2} - \mathbf{Aux} + \mathrm{be} + \mathrm{en} - \mathrm{V} - \mathrm{by} + \mathrm{NP,}$$

Passive transformation

This rule, called the passive transformation, presupposes and depends upon the prior application of a set of phrase-structure rules. For simplicity, the passive transformation may first be considered in relation to the set of terminal strings generated by the phrase-structure rules (1)–(8) given earlier. The string "the + man + will + hit + the + ball" (with its associated phrase marker, as shown in Figure 4) can be treated not as an actual sentence but as the structure underlying both the active sentence "The man will hit the ball" and the corresponding passive "The ball will be hit by the man." The passive transformation is applicable under the condition that the underlying, or "input," string is analyzable in terms of its phrase structure as NP – Aux – V – NP (the use of subscript numerals to distinguish the two NPs in the formulation of the rule is an informal device for indicating the operation of permutation). In the phrase marker in Figure 4 "the" + "man" are constituents of NP, "will" is a constituent of Aux, "hit" is a constituent of V, and "the" + "ball" are constituents of NP. The whole string is therefore analyzable in the appropriate sense, and the passive transformation converts it into the string "the + ball + will + be + en + hit + by + the + man." A subsequent transformational rule will permute "en + hit" to yield "hit + en," and one of the morphophonemic rules will then convert "hit + en" to "hit" (as "ride + en" will be converted to "ridden"; "open + en" to "opened," and so on).

Every transformational rule has the effect of converting an underlying phrase marker into a derived phrase marker. The manner in which the transformational rules assign derived constituent structure to their input strings is one of the major theoretical problems in the formalization of transformational grammar. Here it can be assumed not only that "be + en" is attached to Aux and "by" to NP (as indicated by the plus signs in the rule as it has been formulated above) but also that the rest of the derived structure is as shown in Figure 6. The phrase marker in Figure 6 formalizes the fact, among others, that "the ball" is the subject of the passive sentence "The ball will be hit by the man," whereas "the man" is the subject of the corresponding active "The man will hit the ball" (cf. Figure 4).

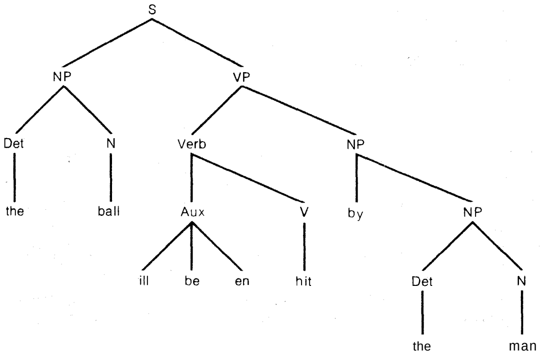

Figure 6: A possible derived phrase marker for a passive sentence (see text).

Although the example above is a very simple one, and only a single transformational rule has been considered independently of other transformational rules in the same system, the passive transformation must operate, not only upon simple noun phrases like "the man" or "the ball," but upon noun phrases that contain adjectives ("the old man"), modifying phrases ("the man in the corner"), relative clauses ("the man who checked in last night"), and so forth. The incorporation, or embedding, of these other structures within the noun phrase will be brought about by the prior application of other transformational rules. It should also be clear that the phrase-structure rules require extension to allow for the various forms of the verb ("is hitting," "hit," "was hitting," "has hit," "has been hitting," etc.) and for the distinction of singular and plural.

Operation of transformations on underlying structures

It is important to note that, unlike Harris', Chomsky's system of transformational grammar does not convert one sentence into another: the transformational rules operate upon the structures underlying sentences and not upon actual sentences. A further point is that even the simplest sentences (*i.e.*, kernel sentences) require the application of at least some transformational rules. Corresponding active and passive sentences, affirmative and negative sentences, declarative and interrogative sentences, and so on are formally related by deriving them from the same underlying terminal string of the phrase-structure component. The difference between kernel sentences and nonkernel sentences in Syntactic Structures (in Chomsky's later system the category of kernel sentences is not given formal recognition at all) resides in the fact that kernel sentences are generated without the application of any optional transformations. Nonkernel sentences require the application of both optional and obligatory transformations, and they differ one from another in that a different selection of optional transformations is made.

Modifications in Chomsky's grammar. Chomsky's system of transformational grammar was substantially modified in 1965. Perhaps the most important modification was the incorporation, within the system, of a semantic component, in addition to the syntactic component and phonological component. (The phonological component may be thought of as replacing the morphophonemic component of Syntactic Structures.) The rules of the syntactic component generate the sentences of the language and assign to each not one but two structural analyses: a deep structure analysis as represented by the underlying phrase marker, and a surface structure analysis, as represented by the final derived phrase marker. The underlying phrase marker is assigned by rules of the base (roughly equivalent to the PS [Phrase-Structure] rules of the earlier system); the derived phrase marker is assigned by the transformational rules. The interrelationship of the four sets of rules is shown diagrammatically in Figure 7. The meaning of the sentence is derived (mainly, if not wholly) from the deep structure by means of the rules of semantic interpretation; the phonetic realization of the sentence is derived from its surface structure by means of the rules of the phonological component. The grammar ("grammar" is now to be understood as covering semantics and phonology, as well as syntax) is thus an integrated system of rules for relating the pronunciation of a sentence to its meaning. The syntax, and more particularly the base, is at the "heart" of the system, as it were: it is the base component (as the arrows in the diagram indicate) that generates the infinite class of structures underlying the well-formed sentences of a language. These structures are then given a semantic and phonetic "interpretation" by the other components.

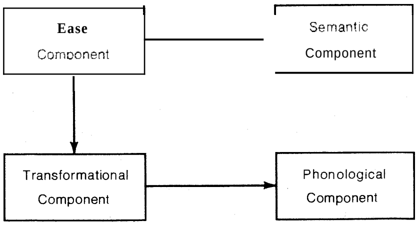

Figure 7: Diagrammatic representation of a transformational grammar (see text).

Base: categorial rules and a lexicon

The base consists of two parts: a set of categorial rules and a lexicon. Taken together, they fulfill a similar function to that fulfilled by the phrase-structure rules of the earlier system. But there are many differences of detail. Among the most important is that the lexicon (which may be thought of as a dictionary of the language cast in a particular form) lists, in principle, all the vocabulary words in the language and associates with each all the syntactic, semantic, and phonological information required for the correct operation of the rules. This information is represented in terms of what are called features. For example, the entry for "boy" might say that it has the syntactic features: [+ Noun], [+ Count], [+ Common], [+ Animate], and [+ Human]. The categorial rules generate a set of phrase markers that have in them, as it were, a number of "slots" to be filled with items from the lexicon. With each such "slot" there is associated a set of features that define the kind of item that can fill the "slot." If a phrase marker is generated with a "slot" for the head of a noun phrase specified as requiring an animate noun (*i.e.*, a noun having the feature [+ Animate]), the item "boy" would be recognized as being compatible with this specification and could be inserted in the "slot" by the rule of lexical substitution. Similarly, it could be inserted in "slots" specified as requiring a common noun, a human noun, or a countable noun, but it would be excluded from positions that require an abstract noun (*e.g.*, "sincerity") or an uncountable noun (*e.g.*, "water"). By drawing upon the syntactic information coded in feature notation in the lexicon, the categorial rules might permit such sentences as "The boy died," while excluding (and thereby defining as ungrammatical) such nonsentences as "The boy elapsed."

Generative semanticists

One further important aspect of generative phonology development of transformational grammar is the relationship between syntax and semantics. Scholars working in the field are now agreed that there is a considerable degree of interdependence between the two, and the problem is how to formalize this interdependence. One school of linguists, called generative semanticists, accept the general principles of transformational grammar but have challenged Chomsky's conception of deep structure as a separate and identifiable level of syntactic representation. In their opinion, the basic component of the grammar should consist of a set of rules for the generation of well-formed semantic representations. These would then be converted by a succession of transformational rules into strings of words with an assigned surface-structure syntactic analysis, there being no place in the passage from semantic representation to surface structure identifiable as Chomsky's deep structure. Chomsky himself has denied that there is any real difference between the two points of view and has maintained that the issue is purely one of notation. That this argument can be put forward by one party to the controversy and rejected by the other is perhaps a sufficient indication of the uncertainty of the evidence. Of greater importance than the overt issues, in so far as they are clear, is the fact that linguists are now studying much more intensively than they have in the past the complexities of the interdependence of syntax, on the one hand, and semantics and logic, on the other. Whether it will prove possible to handle all these complexities within a comprehensive generative grammar remains to be seen.

The role of the phonological component of a generative grammar of the type outlined by Chomsky is to assign a phonetic "interpretation" to the strings of words generated by the syntactic component. These strings of words are represented in a phonological notation (taken from the lexicon) and have been provided with a surface-structure analysis by the transformational rules (see Figure 7). The phonological elements out of which the word forms are composed are segments consisting of what are referred to technically as distinctive features (following the usage of the Prague school, see below). For example, the word form "man," represented phonologically, is composed of three segments: the first consists of the features [+ consonantal], [+ bilabial], [+ nasal], etc.; the second of the features [+ vocalic], [+ front], [+ open], etc.; and the third of the features [+ consonantal], [+ alveolar], [+ nasal], etc. (These features should be taken as purely illustrative; there is some doubt about the definitive list of distinctive features.) Although these segments may be referred to as the "phonemes" /m/, /a/, and /n/, they should not be identified theoretically with units of the kind discussed in the section on *Phonology* under *Structural linguistics.* They are closer to what many American structural linguists called "morphophonemes" or the Prague school linguists labelled "archiphonemes," being unspecified for any feature that is contextually redundant or predictable. For instance, the first segment of the phonological representation of "man" will not include the feature [+ voice]; because nasal consonants are always phonetically voiced in this position in English, the feature [+ voice] can be added to the phonetic specification by a rule of the phonological component.

Dependence of generative phonology on syntax

One further important aspect of generative phonology (*i.e.*, phonology carried out within the framework of an integrated generative grammar) should be mentioned: its dependence upon syntax. Most American structural phonologists made it a point of principle that the phonemic analysis of an utterance should be carried out without regard to its grammatical structure. This principle was controversial among American linguists and was not generally accepted outside America. Not only has the principle been rejected by the generative grammarians, but they have made the phonological description of a language much more dependent upon its syntactic analysis than has any other school of linguists. They have claimed, for example, that the phonological rules that assign different degrees of stress to the vowels in English words and phrases and alter the quality of the relatively unstressed vowel concomitantly must make reference to the derived constituent structure of sentences and not merely to the form class of the individual words or the places in which the word boundaries occur.

TAGMEMICS

The system of tagmemic analysis, as presented by Kenneth L. Pike, was developed for the analysis not only of language but of all of human behaviour that manifests the property of patterning. In the following treatment, only language will be discussed.

Modes of language. Every language is said to be trimodal—*i.e.*, structured in three modes: phonology, grammar, and lexicon. These modes are interrelated but have a considerable degree of independence and must be described in their own terms. Phonology and lexicon should not be seen as mere appendages to grammar, the former simply specifying which phonemes can combine to form morphemes (or morphs), and the latter simply listing the morphemes and other meaningful units with a description of their meaning. There are levels of structure in each of the modes, and the units of one level are not necessarily coterminous with those of another. Phonemes, for example, may combine to form syllables and syllables to form phonological words ("phonological word" is defined as the domain of some phonological process such as accentuation, assimilation, or dissimilation), but the morpheme (or morph) will not necessarily consist of an integral number of syllables, still less of a single syllable. Nor will the word as a grammatical unit necessarily coincide with the phonological word. Similarly, the units of lexical analysis, sometimes referred to as lexemes (in one sense of this term), are not necessarily identifiable as single grammatical units, whether as morphemes, words, or phrases. No priority, then, is ascribed to any one of the three modes.

Tagmeme defined

The originality of tagmemic analysis and the application of the term tagmeme is most clearly manifest in the domain of grammar. By a tagmeme is meant an element of a construction, the element in question being regarded as a composite unit, described in such terms as "slot-filler" or "function-class." For example, one of the tagmemes required for the analysis of English at the syntactic level might be noun-as-subject, in which "noun" refers to a class of substitutable, or paradigmatically related, morphemes or words capable of fulfilling a certain grammatical function, and "subject" refers to the function that may be fulfilled by one or more classes of elements. In the tagmeme noun-as-subject—which, using the customary tagmemic symbolism, may be represented as Subject:noun—the subject slot is filled by a noun. When a particular tagmeme is identified in the analysis of an actual utterance, it is said to be manifested by the particular member of the grammatical class that occurs in the appropriate slot in the utterance. For example, in the utterance "John is asleep," the subject tagmeme is manifested by the noun "John." Tagmemicists insist that tagmemes, despite their bipartite structure, are single units. In grammatical analysis, the distribution of tagmemes, not simply of classes, is stated throughout the sentences of the language. Subject:noun is a different tagmeme from Object:noun, as it is also a different tagmeme from Subject:pronoun.

Hierarchy of levels. Within the grammar of a language there is a hierarchy of levels, units of one level being composed of sequences of units of the level below. In many languages, five such levels are recognized, defined in terms of the following units: morpheme, word, phrase, clause, and sentence. (The term level is being used in a different sense from that in which it was used earlier to refer to phonology and grammar.) The difference between morphology and syntax is simply a difference between two of these five levels, no greater than the difference, for example, between the phrase level and the clause level. Normally, tagmemes at one level are manifested by units belonging to the level below: clause tagmemes by phrases, phrase tagmemes by words, and so on. Intermediate levels may, however, be skipped. For example, the subject tagmeme in a clause may be manifested by a single word in English (*e.g.*, "John," "water") and not necessarily by a phrase ("the young man").

It is also possible for there to be loop-backs in the grammatical hierarchy of a language. This means that a unit of higher level may be embedded within the structure of a unit of lower level; for example, a clause may fill a slot within a phrase (*e.g.*, "who arrived late," in "the man who arrived late").

Tagmemic notation

In regard to the notation of tagmemics, a construction is symbolized as a string of tagmemes (which commonly, though not necessarily, will be sequentially ordered according to the order in which elements manifesting the tagmemes occur in utterances). Each tagmeme is marked as obligatory or optional by having preposed to it a plus sign (+) or a plus-or-minus sign (±), respectively. For example, a formula representing the structure of a clause composed of an obligatory subject tagmeme, an obligatory predicate tagmeme, and an optional object tagmeme might be $\mathrm{Cl} = + \mathrm{S{:}n} + \mathrm{P{:}v} \pm \mathrm{O{:}n}$ (in which Cl stands for a clause of a certain type and n and v stand for the classes of nouns and verbs, respectively). This formula does not represent in any way the fact (if it is a fact) that the predicate tagmeme and object tagmeme together form a unit that is one of the two immediate constituents of the clause. It is one of the characteristic features of tagmemic grammar that it gives much less emphasis to the notion of constituent structure than other American approaches to grammatical analysis.

STRATIFICATIONAL GRAMMAR

Sememic, lexemic, morphemic, and phonemic strata

This system of analysis (whose principal advocate is Sydney M. Lamb, a U.S. linguist) is called stratificational because it is based upon the notion that every language comprises a restricted number of structural layers or strata, hierarchically related in such a way that units or combinations of units on one stratum realize units or combinations of units of the next higher stratum. The number of strata may vary from language to language. Four strata have been recognized for English, and it is probable that all languages may have at least these four: the sememic, the lexemic, the morphemic, and the phonemic strata. The sememic stratal system constitutes the semology of the language; the lexemic and morphemic stratal systems constitute the grammar (in the narrower sense of this term); and the phonemic system constitutes the phonology. In some later stratificational work, the term grammar covers the three higher stratal systems—the sememic, the lexemic, and the morphemic—and is opposed to "phonology." The deep structure of sentences is described on the sememic stratum and the surface structure on the morphemic. In the present account, "grammar" is used in the narrower sense and will be opposed to "semology" as well as "phonology."

The originality of stratificational grammar does not reside in the recognition of these three major components of a linguistic description, which are common to almost all schools of linguistics. The stratificational approach to linguistic description is distinguished from others in that it relates grammar to semology and phonology by means of the same notion of realization that it employs to relate the lexemic and the morphemic stratal systems within the grammatical component. Another distinguishing feature of stratificational grammar, in its later development at least, is its description of linguistic structure in terms of a network of relationships, rather than by means of a system of rules; linguistic units are said to be nothing more than points, or positions, in the relational network.

Technical terminology. Lamb has been very careful to make the terminology of stratificational grammar as consistent and perspicuous as possible; but, in fitting some of the more or less established terms into his own theoretical framework, he has reinterpreted them in a potentially confusing manner. Thus, the same terms have been used in different senses in different versions of the system. For example, "morpheme" in stratificational grammar corresponds neither to the unit to which Bloomfield applied the term (*i.e.*, to a word segment consisting of phonemes) nor to the more abstract grammatical unit that a Bloomfieldian morpheme might be described as representing (*e.g.*, the past-tense morpheme that might be variously represented by such allomorphs as /id/, /t/, /d/, etc.). Lamb describes the morpheme as a unit composed of morphons (roughly equivalent to what other linguists have called morphophonemes) that is related to a combination of one or more compositional units of the stratum above, lexons, by means of the relationship of realization. For example, the word form "hated" realizes (on the morphemic stratum) a combination of two lexons, one of which, the stem, realizes the lexeme HATE and the other, the suffix, realizes the PAST TENSE lexeme; each of these two lexons is realized on the stratum below by a morpheme. Another example brings out more clearly the difference between morphemes (the minimal grammatical elements) and lexemes (the minimal meaningful elements). The word form "understood" realizes a combination of three morphemes UNDER, STAND, and PAST. UNDER and STAND jointly realize the single lexeme UNDERSTAND (whose meaning cannot be described as a function of the meanings of UNDER and STAND), whereas the single PAST morpheme directly realizes the single lexeme PAST TENSE.

Morpheme defined in stratificational terms
